Optimizing Senior Living with Robots: A User Study on Social and Architectural Integration*

M. Sartorius, P. von Both, *Karlsruhe Institute of Technology*

***Abstract*— This research investigates the integration of Humanoid Assistance Robots into senior living environments to enhance independence and reduce the burden on caregivers. The user study of this paper was conducted to identify the housing needs of seniors and their openness to assistive technology, focusing on their technical competence and preferences for daily task assistance. The findings show a general openness towards technology that is intuitive and easily accessible. The participants strongly favored robotic assistance for physically demanding and repetitive chores but preferred human support for tasks requiring physical and emotional closeness. The results also highlight the need for ergonomic and accessible design. In the context of our Project JuBot at Karlsruhe Institute of Technology, the survey is relevant for the development of our humanoid robot ARMAR and a user-centered living typology. The project aims to enhance safety, independence, and autonomy by balancing technological assistance with human interaction.**

I. Introduction

Demographic changes and an aging population require modern solutions that enhance the quality of life in old age while also relieving the burden on caregivers and relatives. Extending independence in old age has been proven to affect aging positively [1] [2] and is one of the six main elements of the Active Aging Model [3]. It should also be supported "through suitable housing and infrastructure" [3]. However, some form of assistance is essential to make independent living as safe as possible despite physical limitations [4].

A. Motivation

Technical devices offer the option to compensate for physical limitations without depending on caregivers. Advancements in technology bring the vision of personal assistant robots closer to reality — robots capable of delivering breakfast, cleaning the kitchen, compensating for motor impairments, and handling heavy household items are already under development. To optimally integrate such assistance technology into future users' lives and living environments, it is essential to consider their attitudes, desires, and concerns.

Research questions to be asked are: Who can benefit most from such assistance? What requirements come from the users' side, and what reservations might they have?

The interdisciplinary project JuBot at the Karlsruhe Institute of Technology (KIT) investigates the integration of humanoid robots and assistive technologies for a senior-friendly living environment to maximize their independence and support caregivers without replacing interpersonal contact. The JuBot team brings together researchers "from robotics, artificial intelligence, human-machine interfaces, IT security, engineering and sports sciences, and architecture and technology assessment" [5]. Our work (at the Building Lifecycle Management professorship) concerns the architecture research area. As part of our work in JuBot, we conducted a user study with the following research questions: What residential needs do senior citizens have? Can they imagine using assistive technology (including assistive robotics) as a solution to maximize their independence? How competent do people over 50 currently consider themselves in technology? Which everyday tasks are mainly requested for assistance technology?

In this paper, we analyze and interpret the findings of this study and compare findings with the results of other studies. During the JuBot project, this information will be incorporated into further development of our humanoid assistant Robot ARMAR at the Institut für Anthropomatik und Robotik (IAR) [5] and, in addition, the optimization strategies for user-centered housing typologies.

The survey covered the following areas:

Part 1: Demographics and physical condition
Part 2: Technical affinity, openness, and everyday tasks
Part 3: Residential needs

The User Study was reviewed by the ethics committee and data protection officer of the KIT and has been conducted in accordance with their principles [6].

B. Methodology

The study was conducted in Germany. All participant quotes and survey content were originally in German and have been translated into English for this paper.

The Questions are aimed at the aging population. The option of reading and writing support allowed us to reach a group of participants with very different cognitive and physical abilities. In addition, the survey was divided into three parts to adapt the number of questions to the attention span of each individual. Participation in the study was voluntary and without monetary compensation. Each person was informed beforehand that they could withdraw at any time, even after receiving the questionnaire, without providing a reason or

* We would like to express our sincere recognition to the Carl-Zeiss-Stiftung, which generously supports the JuBot project and thus provides the basis for this research.

Marie P. Sartorius is with the Professorship of Building Lifecycle Management of Karlsruhe Institute of Technology, 76131 Karlsruhe, Germany (phone: 0049 – 151 556 429 14; e-mail: marie.sartorius@kit.edu).

Petra von Both is with the Professorship of Building Lifecycle Management of Karlsruhe Institute of Technology, 76131 Karlsruhe, Germany

facing any disadvantages. The results were anonymized to prevent any identification of our participants. In the questionnaire, we used Likert scales to ensure comparability. In addition, respondents were also given the option to express further thoughts in open-text fields for each question.

C. Demographics and physical condition

Part 1 of the study provides information on the demographic characteristics of the respondents. A total of 8 residents of the "Alte Mälzerei" nursing home in Karlsruhe, Germany and 13 individuals living independently participated in the study. The sample group consisted predominantly of persons over 50 without significant cognitive limitations. Most volunteers are from southern and western Germany. Twice as many women as men took part in the survey.

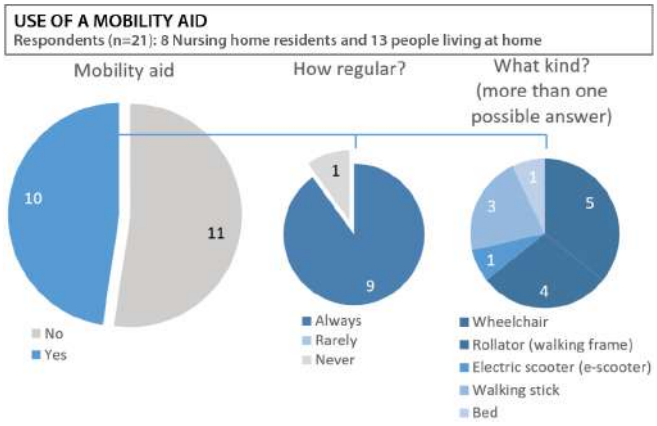

Figure 1. Use of mobility aid of interviewees

More than half of the respondents held a university entrance qualification or a master's degree as their highest level of education. The professional backgrounds were diverse. Slightly more than half of the respondents used a mobility aid. (Figure 1)

II. RESULTS: TECHNOLOGY

A. Technical affinity and openness to technology

While respondents generally viewed themselves as technically skilled and recognized the benefits of innovations, nearly half expressed reluctance to engage with new technologies if they can avoid it. A similar number reported that they do not enjoy exploring new technologies.

Contrary to previous statements, the majority of the 21 participants could still imagine getting help from a humanoid assistant robot for the following tasks:

- Reminders for meals, medication, and doctor's appointments (16 are positive, and two were unsure)
- Helping with directions in buildings (16 were positive, and three were unsure)
- Walking stabilization or pushing the wheelchair (13 are positive, and five were unsure)
- Transfer in and out of the wheelchair or use them as a stand-up aid (14 are positive, and two are not sure)

When asked, "Would you let a robot help you get up or transfer you out of bed, into a wheelchair and back?", most participants said they would be happy to accept such help. Only 4 out of the 21 surveyed did not want to use any technical assistance. These contrasting attitudes towards assistant technology suggest that technical devices are generally well-received as long as they are intuitive, easily accessible, and require minimal effort to learn how to operate them. Since robots are known for their easy access through speech recognition capabilities, this enhances acceptance even among individuals who don't enjoy learning to operate new technology.

B. Openness to Assistive Robotics

The responses to questions about opportunities and concerns regarding technical assistance in the home (Figure 2) were generally positive. Participants identified key opportunities in increased independence, enhanced safety (such as the ability to contact help in emergencies), reduced physical strain, and the potential to live at home longer.

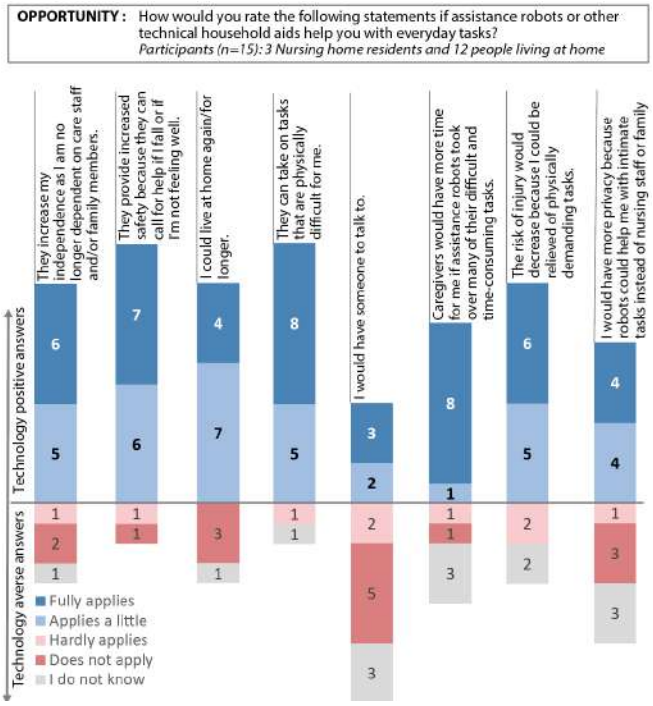

Figure 2. Opportunities towards technology

Notably, there was strong agreement that robots and assistive technologies should handle physically demanding tasks. One respondent emphasized this in the open comments, stating: "Assistance robots don't have a bad mood or get sick. - They are more reliable than humans".

The strong agreement that caregivers would gain more time for human interaction with robots highlights the value of human connection in old age. In line with this, most respondents disagreed with the statement, "I would have someone to talk to" (Figure 2), indicating that they do not perceive social benefits from social robotic interaction.

C. Concerns with Assistive Robotics

When asked about reservations, participants expressed concerns about dependence on technology, security risks, and potential privacy breaches. Despite providing primarily positive feedback, one respondent remarked, "Unless it gets

hacked". Addressing these issues will be essential to building and strengthening trust and encouraging the use of assistive devices in the daily lives of senior citizens. Possible approaches are discussed in Chapter III.

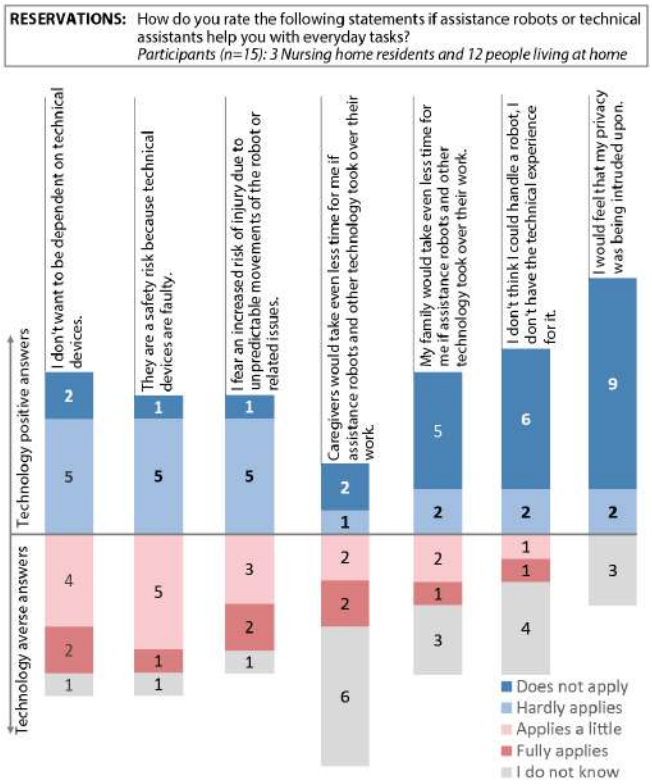

Figure 3. Reservations towards technology

D. *Preferences for Assistance Tasks*

The questions evaluating the acceptance of technical household aids for various daily tasks and activities are categorized into Household, Body care, Healthcare, and Leisure Activities.

The set of daily activities was already collected in an earlier project stage for a function-based analysis of user scenarios for assistive technology and can be found in [4]. The current user study now evaluates the potential distribution of stakeholders within the care setting.

Figure 4 presents the revised study results, with tasks arranged from left (high acceptance of technical support) to right (low acceptance of technical support). The answer option "equal" (indicating no preference) was interpreted as positive feedback towards technology, as the aim of this analysis is to identify growth potential for technical aids and pinpoint the task areas where caregivers and family members can be most effectively relieved.

The blue and purple areas of the graph indicate a preference for technical support. The upper boundary of the blue area reflects the combined responses for: "only technology," "rather technology," and "equal" preference. In contrast, the red line represents answers in favor of human support, comprising the responses: "only human" and "rather human".

The overall graphs show strong positive feedback for technical support in physically demanding and time-consuming tasks, such as carrying heavy objects, retrieving items, cleaning windows, refrigerators, and kitchens. Repetitive chores also benefit from technical assistance, especially when familiar technical aids are available. Key tasks in this category include remembering appointments, vacuuming, mopping floors, ironing clothes, and dusting.

In contrast, tasks involving emotional significance or physical contact are generally preferred to be handled by humans. These tasks include setting the table, washing dishes by hand, storing dishes, administering healthcare, or treating wounds. These findings align with the attitudes towards technology observed in earlier questions.

E. *Growth potential of Assistance Tasks*

The area where technology acceptance decreases and the preference for human support increases (the "narrowing gap of preferences") represents a key growth potential for technical solutions. Since there is no clear preference for human or technical support, the cautious openness can be further directed towards technology. Developing strategies that build trust and address the reservations highlighted in Chapter II, Sections B, and C are essential to increase acceptance and implementation areas. Since each use case combines its own set of benefits and concerns, the next chapter serves as an orientation to allocate those to design appropriate individual strategies for each use case.

III. Discussion: Empathising Technology Acceptance

The study results allowed us to allocate key factors that influence technology acceptance. The following topics are presented and compared with findings from other published studies. In our project, this information serves to weigh which tasks can be taken over by our assistant robot and find an appropriate implementation strategy. In addition, specific tasks can be identified that intentionally do not need to be further elaborated since the hurdles are too great, while the need for human contact in the care context cannot be surpassed in any case.

A. *Physical strain*

Due to motor limitations, physical straining tasks are often challenging or even painful for older adults. Previous studies have confirmed that physical relief benefits the acceptance of household technologies [7]. Additionally, as noted in earlier research, "seniors want to remain independent and not be a burden to anyone" [8] (German translation); another study reports that older adults strive for greater independence and autonomy to minimize their impact on family members [9].

B. *Familiarity with existing technical household aids*

Existing technical household aids, even those only seen through advertising, positively influence technology acceptance due to familiarity. In our study, this was strongly perceived in the context of appointment reminders (in the form of digital Calendars) and vacuuming. While most of the respondents themselves did not own a vacuum robot, they were very open to the idea. One respondent pointed out the positive feedback from friends as the reason.

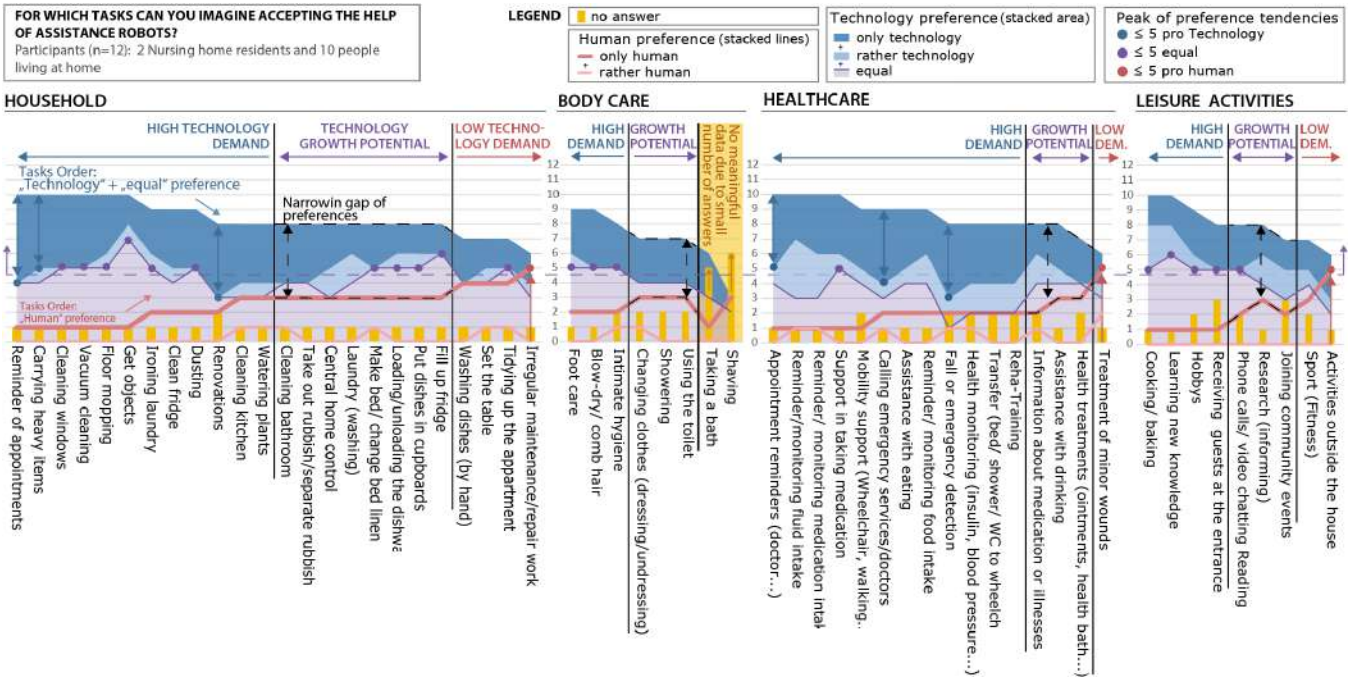

Figure. 4. Technology preference for everyday tasks

In addition to that, a study explores this topic, demonstrating that seniors' understanding and acceptance of technology increase after receiving training and using smartphones [10]. This suggests that technology acceptance is dynamic and can be positively influenced. As a consequence, future technology will always benefit from its predecessors due to already-learned functions. Therefore, the aging "digital natives" generation will continue to increase the acceptance of new technology, although according to a study, they also prefer easy-to-use interfaces [11].

C. *Emotional Significance*

Tasks with high emotional significance, such as setting the table, tidying up (organizing), or cooking and baking, reveal mixed preferences regarding technical support. While some respondents are open to technical assistance, others prefer human support. These tasks often carry social and emotional elements difficult for technical aids to replicate. The mixed responses indicate that a combination of human and technical support may be most appropriate for these activities. Studies also highlight the importance of emotional attachment and social interaction in accepting assistance [12].

D. *Physical Contact*

Most respondents expressed a clear human assistance preference for tasks requiring close physical proximity, such as intimate care, toileting, and showering, where trust, security, and empathy — qualities currently beyond the capabilities of robots — are crucial. One respondent commented, "I wouldn't allow an intimate wash, but I'd be fine with freshening up below (preparing panty liners would be okay)." Comments such as "If I were to fall in the process, I'd rather have a real person to help me up again" and "I'd like to see someone else do it first, to know how they handle patients and see how it works" show that the reasons for rejection are based on concerns around the physical proximity.

The study "Domestic Robots for Older Adults: Attitudes, Preferences, and Potential" [13] reflects a similar pattern, with an even stronger inclination toward human assistance in personal care. The tasks in this category include "shaving, washing/combing hair, bathing, eating/feeding, dressing, brushing teeth, and walking" [13].

There are hardly any studies that deal with specific strategies for increasing acceptance in this field. One study explored the "effective interaction method of robots in the functional intimate zone" [14] and came to the conclusion that intimate interactions via indirect "non-physical contact" will be more accepted [14].

E. *Complexity*

As tasks become more complex and motor-intensive, the preference for human versus technological assistance becomes less distinct in our study. Examples include making the bed, washing dishes by hand, putting dishes away, and performing repair work. These activities typically require a high degree of precision and skill, which respondents may associate with human assistance, or they may be uncertain about the capabilities of technical aids in handling such tasks. However, no additional evidence supports this hypothesis, and the study "Domestic Robots for Older Adults: Attitudes, Preferences, and Potential" [13] even contradicts this assumption.

F. *Data Security*

Security in the digital world is a sensitive topic that every technology must address. Although the majority of our respondents did not feel that their privacy was being invaded by assistance technology, there was the additional comment that this only applies if the assistance technology cannot be hacked.

This challenge is not new and already affects widespread technologies such as smartphones and their access to sensitive data (e.g. through banking apps), which can be protected by multi-factor authentication. Another solution is the integration

of blockchain technologies that are used successfully to secure data in other sensitive areas such as healthcare [15].

In order to strengthen user trust, it is necessary to develop secure data processing methods in addition to functional applications.

IV. RESULTS: ARCHITECTURAL NEEDS AND PREFERENCES

The survey's Architectural questions focus on senior citizens' housing needs. The results indicate that respondents place high importance on accessibility, ergonomic design, and privacy.

Participants were first asked which rooms they occasionally find challenging to navigate independently. The bathroom was mentioned most, followed by the kitchen, living room, and hallway. Common reasons included insufficient space (e.g., for wheelchairs), obstacles like door thresholds, and limitations related to medical conditions such as multiple sclerosis.

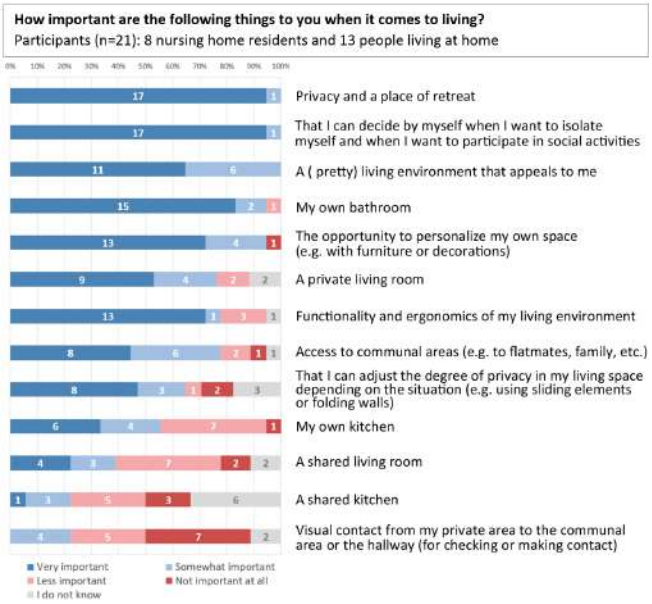

Figure 5. Living space preferences

In response to the question "Where would you prefer to live?" (with multiple answers allowed), 12 participants clearly preferred living in their own apartment or house. This was followed by the preference for multi-generational housing (with four votes) and living with family (with three votes). Retirement homes and private residential communities with other senior citizens were even less favored.

When asked about the importance of different aspects of living (Figure 5), 17 of the 21 participants rated privacy and the ability to retreat from shared spaces as "very important." The ability to choose between privacy and social interaction was also highly valued. Participants placed similar importance on having an aesthetically pleasing living environment, a private bathroom, and the freedom to personalize their space.

The survey also explored preferences for specific living area features. A floor-level shower with no steps or thresholds was considered "very important" (by 15 participants). Additionally, many respondents preferred natural lighting, direct outdoor views from the bedroom, access to outdoor spaces from both private and communal areas, ergonomic kitchen designs, and a seating option in the shower.

V. DISCUSSION: USER-ORIENTED LIVING

The results clearly show that even in old age, people are very attached to their private residence and that alternative forms of housing are generally only considered if circumstances leave no other choice. In addition, German care homes, for example, currently do not even have sufficient capacity for a quarter of all senior citizens [16]. This underlines the particularly high importance of a safe living environment and support with everyday tasks.

A diverse range of services is, therefore, the most promising approach to finding a suitable solution for each individual in old age. In addition to the various established living and care concepts, these services should increasingly include technical support options.

VI. CONCLUSION

The positive feedback regarding assistive technology opens up the possibility of rethinking the provision of care and expanding existing structures.

Applying the universal design strategy [17] [18], which emphasizes inclusivity across varying abilities, ages, needs, and social backgrounds, can expand this acceptance further. This philosophy posits that design "can be understood and used without additional technology or special adaptations" (German translation) [17]. According to [18] [19], these design principles can be extended beyond everyday objects to encompass architectural contexts as well.

At the same time, the architectural results underscore the desire for accessibility, privacy, and individual design options, which play just as important a role in the acceptance of assistive technologies. The study results show that the desire for privacy is not compromised by using a robot. Rather, the robot is perceived as a supportive element that strengthens independence and autonomy without interfering with personal space. Therefore, the combination of assistive robots with senior-friendly architecture offers a sustainable solution for age-appropriate living.

However, technical aids involving close physical contact will likely be accepted only under predominantly human control (such as orthoses). This underscores our aim not to replace care entirely with technology but to deploy it specifically for physically demanding and time-consuming tasks, while emotional and care-related activities should remain the preserve of human support.; our study confirms that technological support should not be seen as a substitute for social interaction but as a targeted supplement to create more time for personal care.

Our survey helps us to optimize our future studies in this context so that we can ask more targeted questions.

A. Outlook

Based on the Study findings, specific areas of application for the humanoid assistant robot ARMAR will be further developed and optimized during the JuBot project.

The most frequently requested areas of robot application will be an important basis for analyzing the robot's motion sequences (using navigation cost maps) in a residential context and for determining space requirements for the built environment. In collaboration with our project partner, the Anthropomatics and Robotics (IAR), this "navigation cost map" can be generated to ensure safe and reliable navigation, allowing the robot to maintain appropriate distances from obstacles [20].

The apartment modules developed from previous research, "Rule-Based Design for the Integration of Humanoid Assistance Robotics into the Living Environment of Senior Citizens" [4], can then be further enhanced to accommodate new robot tasks with requirements for increased space needs or specific furniture arrangements.

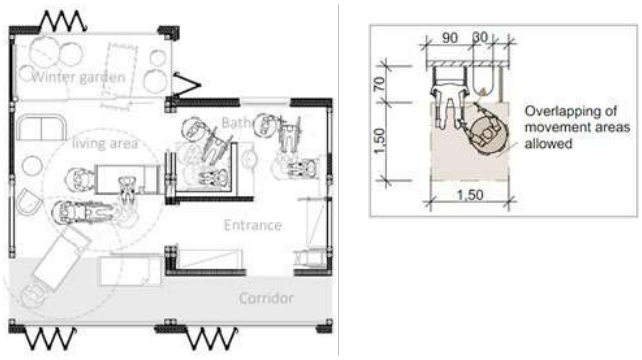

Figure 6. Development of an optimized senior apartment module

The long-term aim is to establish a closer link between Building Information Modeling (BIM) and robot simulation. Developing efficient technical interfaces, the integrated planning and construction process of buildings and robotics enhances the integrated planning process. This integration requires specific modeling standards for digital building models to provide all necessary information for robot navigation. Parametric mapping methods are ideal for modeling motion sequences like opening doors or drawers. Moreover, semantic information on furnishing properties, door types, and opening directions can be beneficial. As a result, the project will focus on creating a comprehensive model and interface concept to bridge BIM and robotics simulation. Initial investigations suggest that Industry Foundation Classes (IFC) are suitable for cross-platform data exchange.

Our Project partner will continue to focus on increasing the acceptance of assistance technologies through user-centered education strategies and accessible operating concepts in order to further enhance acceptance of Assistance Technology amongst seniors, relatives, and caregivers.

ACKNOWLEDGMENT

Special thanks go to the senior citizens of the nursing home "Alte Mälzerei" in Karlsruhe (Germany) for participating in the study and giving us an insight into their lives.

***Abstract*—Exoskeletons can make walking easier, but extensive training is needed to fully benefit from them, potentially hindering device adoption. Coaching new exoskeleton users to walk with energetically beneficial gait patterns might accelerate motor learning, but these target patterns have yet to be established. In this study, we characterized changes in gait biomechanics between healthy young adults' first exposure to ankle exoskeletons and after 7+ hours of training when they demonstrated full motor adaptation. We observed consistent markers of adaptation in ankle kinematics and spatial gait features; expert exoskeleton users exhibited greater ankle dorsiflexion before a powerful and concentrated push-off while walking with narrower and longer steps. Adaptations in muscle coordination patterns were more varied, but generally involved reducing co-contraction throughout the leg. By the end of training, non-propulsive exoskeleton-assisted gait features approached those of unassisted walking. Our results suggest that effective exoskeleton use involves selectively avoiding most disruptions to typical gait while accommodating energetically beneficial changes around push-off. All reported gait features can be monitored and targeted in real-time, facilitating the application of these results to reduce the time burden for novice users to maximally benefit from ankle exoskeletons.**

Keywords—exoskeletons, motor learning, gait, biomechanics

I. Introduction

Exoskeletons are promising tools to address losses in mobility, such as those arising from age, stroke, or neurodegenerative disorders. Exoskeletons can offload assisted muscle activity and augment biological joint power, reducing the energetic cost of walking [1–3]. Making walking easier for those who struggle with mobility could promote physical activity, increasing independence, social participation, and well-being [4]. Ankle exoskeletons have particular promise for real-world use, as they can be relatively lightweight, easy to don and doff, and have been shown experimentally to provide the largest reduction in energy cost of walking of any lower-limb joint [5].

This work was supported by the National Science Foundation (1828993 and DGE-1656518) and the Gabilan Stanford Graduate Fellowship.

The timescale of learning to effectively use exoskeletons is slow. Healthy young adults extract full metabolic benefit of ankle exoskeletons after approximately two hours of training [6], and they continue to explore varied motor control strategies for two additional hours before achieving steady-state gait [7]. This timescale is likely to be significantly longer as people age or experience neurologically-based gait changes, given slowed or impaired motor learning [8–11]. New training approaches should be explored to ensure that the time burden of learning how to comfortably and effectively use exoskeletons is not prohibitively high.

Coaching people to walk with efficient gait patterns might expedite exoskeleton training. Prompting low-cost gait patterns for even short periods of time can aid the nervous system in identifying relevant dimensions of energy optimization in a new motor context [12]. Neither natural gait variability nor open-ended prompts to explore new coordination strategies has reliably produced initiation of energy optimization within a comparable time scale [12]. While exploration is a critical component of motor learning [6,13], insufficient knowledge about the relevant dimensions to explore could unnecessarily slow the learning process. Identifying low-cost gait patterns, in order to strategically expose people to these behaviors, could be fruitful before deploying new assistive devices.

Existing characterizations of exoskeleton-assisted gait may be insufficient to accelerate exoskeleton mastery. Lower-limb biomechanics while walking with an ankle exoskeleton have primarily been characterized after 20-30 minute training sessions. These studies found reductions in both plantarflexor activity and co-contraction of antagonist muscles, while ankle kinematics, step width, and stride time remained unchanged due to training [14–17]. Notably, motor adaptation was not characterized in these studies, and may have been ongoing. Assessing biomechanical gait changes before and after complete motor adaptation would better indicate the most relevant gait dimensions for energy optimization.

Gait biomechanics of fully adapted exoskeleton users have only been characterized for a small number of gait features selected *a priori*. In one study of users who trained extensively with exoskeletons, expertise was demonstrated by an exponential decay of gait variability to steady-state values, corresponding to a final metabolic benefit triple that of initial

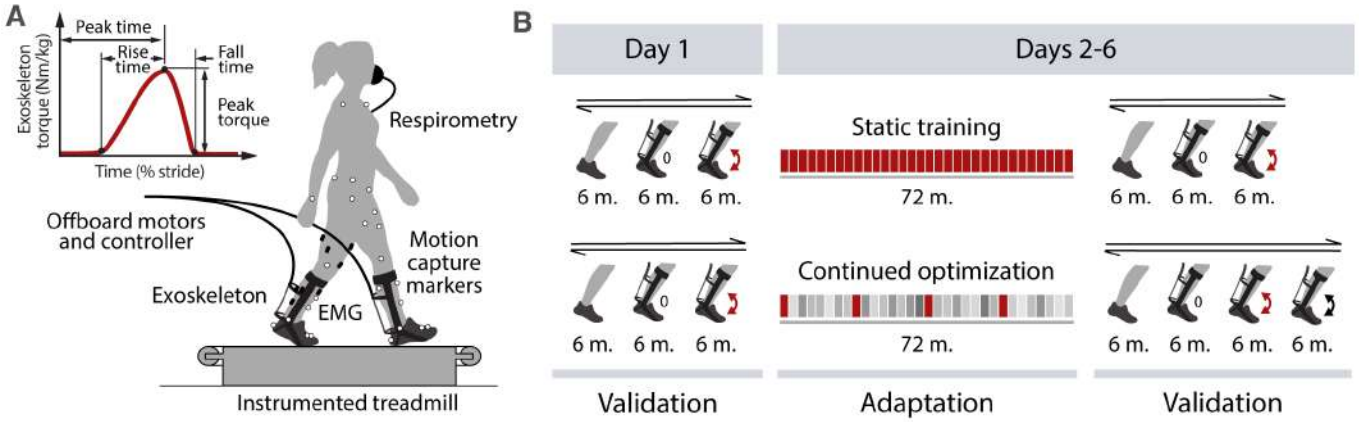

Fig. 1. (A) Schematic of the experimental setup. Respirometry, motion capture, electromyography, and ground reaction force data were recorded. Exoskeleton torque was applied by off-board motors and parameterized by the magnitude and timing of peak torque, rise time, and fall time. (B) Schematic of the experimental protocol. Validation trials were performed in a double-reversal order: wearing running shoes only, exoskeletons applying zero torque, and exoskeletons applying generic assistance. In adaptation trials, the static training group (n = 5) experienced generic assistance (red) and the continued optimization group (n = 5) underwent human-in-the-loop optimization, with generic assistance tested periodically. The continued optimization group also tested optimized assistance during validation.

exposure, and the largest benefit thus far reported for use of ankle exoskeletons [6,7]. Gait adaptations reported in this study included reduced step frequency, reduced ankle angle range over the gait cycle, and reduced total plantarflexor activity [6].

In this study, we performed a broader exploration of changes in gait biomechanics as the same participants—initially naïve to exoskeleton use—became expert at walking with plantarflexion assistance. We considered nine healthy young adults that trained with ankle exoskeletons over 7+ hours, and analyzed biomechanical gait data that can be monitored in real-time on a step-by-step basis: sagittal plane ankle kinematics, spatial gait features, and peak activity of lower-limb muscles. We compared changes between novices and experts, walking with and without plantarflexion assistance, to assess the relevant gait dimensions of energy optimization. We expect that this analysis can inform future work using biofeedback to guide first-time exoskeleton users toward beneficial gait patterns, expediting motor learning and improving perception of human-exoskeleton interaction.

II. Methods

A. Data Collection

Data for this study were taken from [7], with relevant details repeated here. The experimental protocol was approved by the Stanford Institutional Review Board (IRB-48749) and all participants provided written consent before participating. Healthy young adults naïve to exoskeleton use (N = 9; 3 females; age: 24 ± 3 years; body mass: 69.4 ± 10.6 kg; height: 1.73 ± 0.08 m) underwent a six-day protocol during which they walked with bilateral ankle exoskeletons at 1.25 m/s (Fig. 1). Each exoskeleton was controlled by an off-board motor, enabling the application of various high-magnitude plantarflexion torque profiles while remaining lightweight (0.88 kg). Torque profiles were parameterized by peak magnitude, peak time, rise time, and fall time (Fig. 1A).

In order to capture "novice" performance, participants first underwent six-minute pre-test trials of walking without exoskeletons, walking with exoskeletons tracking the ankle joint so as to apply negligible torque, and walking with exoskeletons applying an assistive plantarflexion torque once per step. This torque profile ("generic assistance") was set by parameters found to be widely beneficial in pilot testing: a peak magnitude of 0.54 times body weight at 52.9% stride with a rise time of 26.2% stride and a fall time of 9.8% stride. Each six-minute condition was then repeated in a double-reversal order (Fig. 1B).

Ten participants, comprising two experimental groups, were considered. Both groups experienced the same pre-test trials. The "static training" group (n = 5) then walked with generic assistance for 72 minutes in the remaining five experimental sessions. For the same duration, the "continued optimization" group (n = 5) underwent human-in-the-loop optimization [18], with a new torque profile tested every two minutes to minimize energy cost of walking. For this group, generic assistance was applied every 16 minutes to track learning (Fig. 1B). The six-minute double-reversal validation trials of no exoskeleton, unassisted, and generically-assisted walking were repeated at the end of each day for both groups. The continued optimization group also walked with optimized assistance in the end-of-day validation trials. Participants each accrued 7.4 to 8.4 hours of experience with assisted walking and 8.4 to 9.4 total hours of walking while wearing the exoskeletons. Throughout the study, data were collected from an indirect calorimetry device (Cosmed Quark CPET), motion capture system (Vicon), instrumented treadmill (Bertec), and eight electromyography electrodes per leg (Delsys). One participant from the continued optimization group was excluded from our analysis due to incomplete data recording on the first day of the study.

B. Data Analysis

The distinction between novice and expert exoskeleton use was made by comparing matched validation trials between the first and last experimental session. Expert status was conferred by participants tripling their initial metabolic benefit by the end of the study [7] and by gait variability

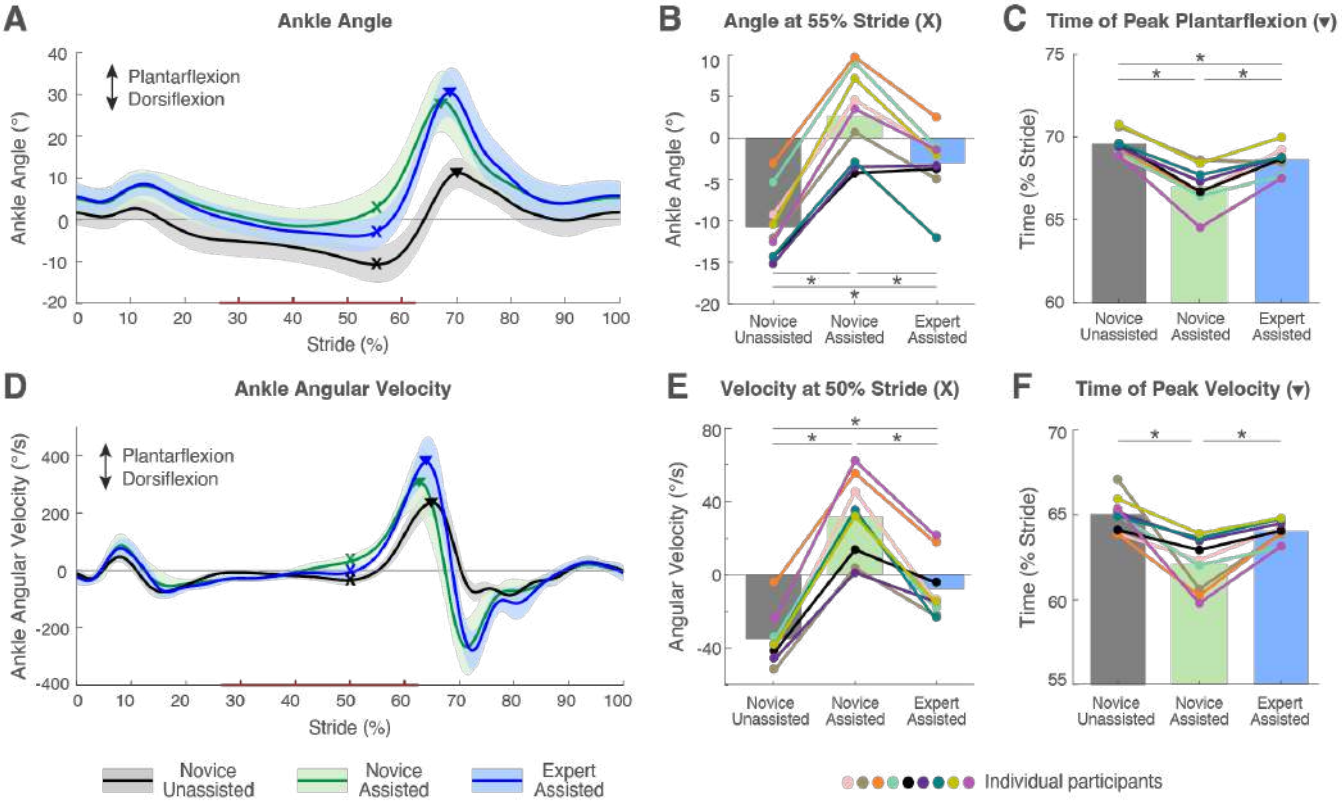

Fig. 2. Adaptations in ankle kinematics. Average (A) ankle angle and (D) ankle angular velocity profiles, measured from exoskeleton encoder. Key features of (B-C) ankle angle and (E-F) ankle angular velocity profiles across trial types. Shaded regions represent 95% confidence intervals. Red portion of axes denote when exoskeleton torque is non-zero. X denotes magitude at 50% or 55% stride and inverted triangle denotes peak magnitude. Individual participants are represented by distinct colored circles. Asterisk signifies $p < 0.05$.

exponentially regressing to that of walking without an exoskeleton, indicating acquisition of stable motor skill [6]. Both the static training and continued optimization groups were indistinguishable by these measures. Therefore, all strides from final validation sessions were treated as instances of expert behavior with no additional comparisons made between experimental groups. A significant difference between novice and expert gait outcomes was assessed using analysis of variance and post-hoc paired t-tests with the Bonferroni adjustment for multiple comparisons and an alpha value of 0.05.

Stride-by-stride trajectories of exoskeleton ankle angle and angular velocity were acquired through measurement from an on-board encoder. Step length and width were calculated from the position of the foot center of pressure at heel strike, measured from force plate data via the split-belt treadmill. Changes in stride duration were captured from analysis of changes in stride length given the fixed treadmill speed. Muscle activity was acquired from electromyography signals after high pass filtering at 30 Hz, rectifying, low pass filtering at 6 Hz, and normalizing to the peak activity calculated from no-exoskeleton trials in the same session. Trials with poor electromyography signal quality were excluded from analysis. Respirometry and motion capture data were not analyzed in this study, but were available for reference from this dataset.

All biomechanical profiles were normalized to percent stride, averaged across the final three minutes of each six-minute validation trial, and averaged across legs. We used visual inspection to identify features in kinematic profiles that consistently changed between novices and experts. If multiple features reflected the same gait behavior, we selected and reported one that appeared most robust to inter-subject and inter-session variability. To ensure a rigorous assessment of timing-related features, we report these analyses for biomechanical profiles both with and without normalization to stride duration.

Results

Ankle kinematics differed significantly between novice and expert exoskeleton users (Fig. 2). Experts dorsiflexed more mid-stride, evidenced by increased peak dorsiflexion, increased dorsiflexion at 50-55% stride, and decreased plantarflexion velocity at 50-55% stride. Natural variations in the curvature of ankle angle profiles made calculations based on peak dorsiflexion timing less consistent. Therefore, we focused our analysis on features at fixed points in the gait cycle.

Ankle angle at 55% stride was 5.7° more dorsiflexed by the end of training (Fig. 2A-B, Table 1, $p = 0.01$). With expertise, assisted ankle angle at this time approached that of unassisted walking (Fig. 2A-B). Novice users were 13.4° more plantarflexed when assisted than when unassisted ($p =$

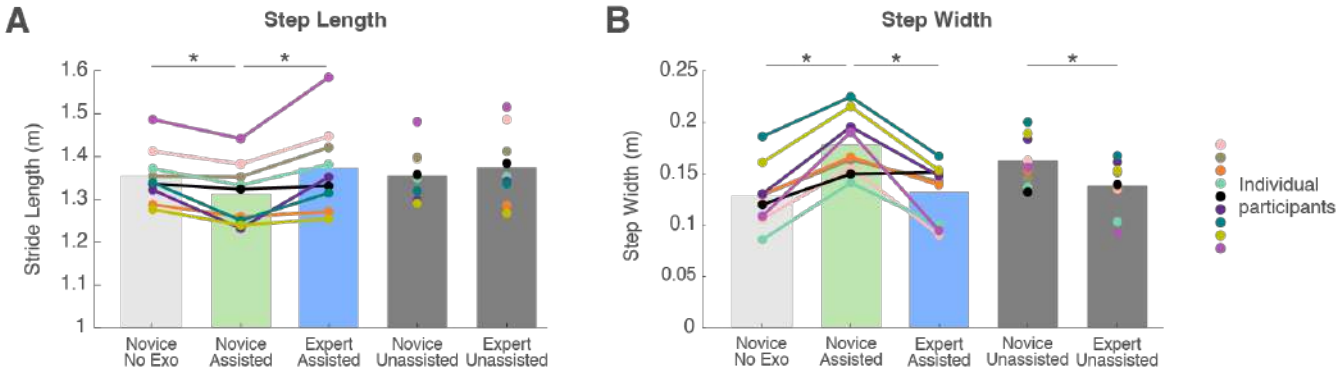

Fig. 3. Adaptations in spatial gait features. (A) Stride length and (B) step width for novice versus expert exoskeleton users across relevant trial types. Individual participants are represented by distinct colors. Asterisk signifies $p < 0.05$.

8e-7). Expert users were 7.7° more plantarflexed when assisted than when unassisted (p = 6e-4). In general, the application of plantarflexion torque from 26.7% to 62.7% stride resulted in greater ankle plantarflexion throughout the gait cycle (Fig. 2A). Unassisted ankle angle at 55% stride did not significantly change with expertise (p = 0.4).

All experts slowed their mid-stride ankle angular velocity (Fig. 2D-E). Expert walking with assistance corresponded to an angular velocity at 50% stride that was 39.2°/s slower than that of novices (p = 6e-4). With training, assisted angular velocity at 50% stride approached that of unassisted walking (Fig. 2D-E). Assistance resulted in a 66.2°/s speed increase during initial exposure (p = 2e-6) and 27.0°/s increase from baseline during final exposure (p = 2e-4). Expert ankle angular velocity without assistance was also 12.7°/s increased from baseline (p = 0.01).

Experts also shifted ankle kinematics to delay timing of toe-off. This shift was reflected in the later timing of peak plantarflexion and dorsiflexion angles, peak plantarflexion velocity, and transition times between plantarflexion and dorsiflexion for both angle and velocity profiles. In addition to the inconsistencies in peak dorsiflexion timing described previously, the transition from plantarflexion to dorsiflexion could not be reliably reported as differences in exoskeleton fitting across sessions caused artificial shifts in ankle angle at heel strike for some participants. Therefore, we focused analysis on the timing of peak plantarflexion angle and peak plantarflexion velocity.

Peak plantarflexion angle shifted later in stride as participants adapted to exoskeleton assistance (Fig. 2C, Table 1). Expertise corresponded to a peak plantarflexion angle 1.5% or 40 ms later in stride (p = 0.01 and p = 4e-4, respectively). Changes in peak plantarflexion timing approached participants' unassisted baseline with training (Fig. 2C): from 3.0% or 50 ms earlier on initial exposure (p = 0.003 and p = 3e-6, respectively) to 1.5% or 6 ms earlier on final exposure (p = 0.02 and p = 1, respectively). Peak plantarflexion timing during unassisted walking did not significantly change with expertise (p = 0.7 and p = 0.06 with and without stride normalization, respectively).

Peak ankle angular velocity also consistently shifted later in stride as people adapted to assistance, by an average of 1.2% stride or 46 ms (Fig. 2F, Table 1, p = 0.01 and p = 5e-4, respectively). As users adapted, their peak velocity timing during assisted gait approached their baseline timing during unassisted gait: from 2.0% or 53 ms earlier on initial exposure to 0.8% or 7 ms earlier on final exposure (Fig. 2F, p = 0.004, p = 4e-4, p = 0.3, p = 0.9, respectively). Peak velocity timing during unassisted walking did not significantly change with expertise (p = 0.1 and p = 0.09 with and without stride normalization, respectively).

All experts increased their stride length such that, on average, assisted strides were 6.0 cm longer after training (Table 1, Fig. 3A, p = 0.02). Compared to walking in normal shoes, assistance resulted in a 4.1 cm shortening of stride for novices and a 1.9 cm lengthening of stride for experts (Fig. 3A, p = 0.01, p = 0.9, respectively).

Step width decreased significantly with training. Expertise resulted in a 4.6 cm narrowing of step width when walking with assistance (Table 1, Fig. 3B, p = 0.005). Expertise also corresponded to a 2.4 cm narrowing of step width when walking without assistance (Fig. 3B, p = 0.04). After sufficient

TABLE I. BIOMECHANICAL GAIT FEATURES (MEAN ± STANDARD DEVIATION) DURING ASSISTED WALKING PRE- AND POST- ADAPTATION.

Gait Features	Novice	Expert	*p*
Ankle angle at 55% stride (°)	2.7 ± 5.4	-3.0 ± 4.0	0.01
Peak ankle angle time (% stride)	67.0 ± 1.3	68.7 ± 0.8	0.01

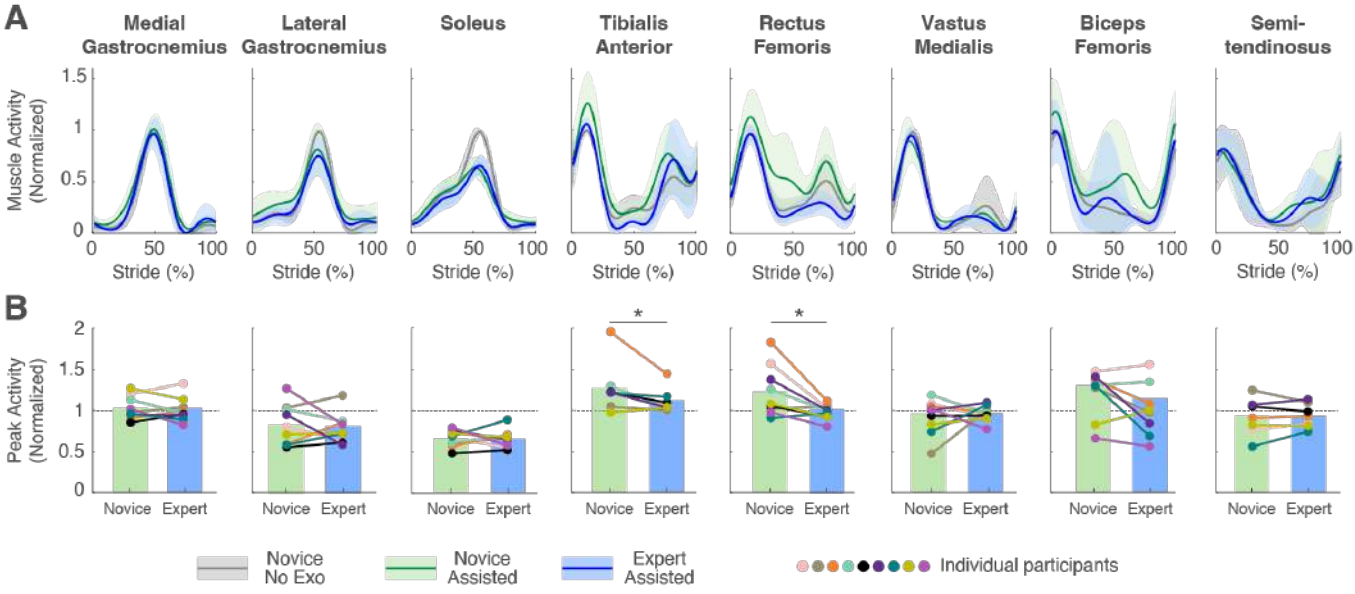

Fig. 4. Changes in muscle activity between novice and expert exoskeleton users. (A) Profiles of recorded muscle activity, averaged across subjects and between legs. All profiles are normalized to values from walking without exoskeletons. Green and blue graphs represent novice and expert exoskeleton-assisted trials, respectively. Gray curves represent novices walking with no exoskeleton. Shaded regions show 95% confidence interval. (B) Changes in peak magnitude of normalized muscle activity with expertise. Individual participants are represented by distinct colors.

training, assisted step width approached baseline values of walking in normal shoes. Initially, assisted steps were 5.0 cm wider than in no-exoskeleton gait ($p = 1e\text{-}4$) and, ultimately, only 0.3 cm wider ($p = 1$).

Some differences in muscle coordination patterns were observed between novice and expert exoskeleton users. The strategy to reduce energy consumption by offloading muscles assisted by the exoskeleton was not unique to experts, reflecting results from prior short duration studies [6,14–17]. In this dataset, peak muscle activity was similar between novices and experts for the medial gastrocnemius, lateral gastrocnemius, soleus, vastus medialis, and semitendinosus (Fig. 4, Table 1). Novices had relatively high activation in the tibialis anterior, rectus femoris, and biceps femoris compared to walking without an exoskeleton, indicating high stiffness throughout the leg. Experts generally reduced this stiffness via lowered activity of the rectus femoris (122.8% vs. 97.7%, $p = 0.02$) and tibialis anterior (127.4% vs. 110.6%, $p = 0.03$). Activity in the biceps femoris also decreased, though this effect was not statistically significant (130.3% vs. 112.4%, $p = 0.1$). Inter-subject variability of muscle coordination patterns was high overall, and trends of changing peak activity were not consistent across participants (Fig. 4B).

Discussion

We identified several biomechanical gait changes that occurred as novice exoskeleton users adapted to plantarflexion assistance. Changes in ankle kinematics and spatial gait features were highly consistent across participants. Changes in muscle coordination patterns were more variable, but the tendency for experts to decrease co-contraction throughout the leg appeared meaningful. Most reported changes emerged later in training than has previously been tested [14,16,17], indicating the importance of sufficient exposure to capture behaviors emerging over long or unknown timescales. The gait features we identified can be monitored and targeted in real time using wearable sensors and biofeedback, making them promising tools to elicit energetically efficient gait behaviors in new exoskeleton users.

Kinematic adaptations appeared to improve the efficiency of push-off. Novices generated positive plantarflexion velocity as exoskeleton torque was rising, causing plantarflexor muscles and tendons to shorten before significant power was needed for toe-off. In contrast, experts actively dorsiflexed, generating negative work, during this portion of stride (Fig. 2). Experts' lower metabolic cost is likely explained in part by eccentric muscle contractions generating force more efficiently than concentric contractions, and lengthening Achilles tendons enabling greater elastic energy storage and release [2,19].

Changes in step length and width throughout training could reflect task priorities shifting from maintaining balance to minimizing energy cost. Optimization of foot placement typically accounts for several objectives, including energy cost, stability, and maneuverability [20,21]; each objective may progress with a unique timescale [6,22]. For these participants, adaptations in step frequency variability—an indicator of dynamic balance [23]—occurred twice as quickly as adaptations in step frequency [6]. Participants may have initially responded to torque-induced perturbations of their typical gait by placing their feet further apart mediolaterally and closer to their base of support anteroposterially [21,24]. Once balance was more easily maintained, participants may have reduced step width to minimize the energetic cost of redirecting center of mass velocity during step-to-step transitions [21] and increased step length to mitigate the high energetic penalty of swing [25].

With experience, most gait features shifted toward participants' baseline values from unassisted or no-exoskeleton walking. Expert exoskeleton users reduced disruptions to gait where no energetic benefit was provided: increased plantarflexion throughout stride, wider stance, shorter steps, and greater co-contraction for stabilization. Simultaneously, experts preserved exoskeleton-induced gait changes that provided energetic benefits, namely offloading plantarflexor activity and stretching the plantarflexor muscle-tendon units before a powerful push-off. It should be further explored if this trend persists for groups other than healthy young adults, whose baseline gait patterns may be less energetically optimal.

Our findings suggest that short bouts of walking may be sufficient for individualization of desired exoskeleton-assisted gait behaviors. For each participant, step length and width generally returned to values observed during no-exoskeleton pre-test trials (Fig. 3). Experts' step lengths consistently exceeded baseline values by an average of 2 cm, likely due to the increased penalty of swing with the exoskeleton's added distal mass and medial envelope. Kinematic features did not revert to participants' initial values from unassisted walking, but did consistently progress toward the approximate average of unassisted and assisted baseline values (Fig. 2). Supplemental analysis showed that kinematic changes plateaued before the final experimental session, suggesting that these values would change minimally with additional training, and that the remaining offset is due to limits created by human-exoskeleton interaction. Given the high inter-subject variability of absolute gait outcomes and the consistency of trends across trial types (Fig. 2-3), we believe that prompting changes toward one's own unassisted or no-exoskeleton baseline will likely be more effective than trying to induce any absolute gait outcome.

A portion of the observed gait changes were attributed to learning to walk while wearing the exoskeletons alone. Gait compensations to the added medial envelope and mass of the device presented in both unassisted and assisted walking trials (Fig. 3). This suggests that training to adapt to wearing a new device is partially separable from training to adapt to assistance. Beginning with unassisted training might prove more tractable for novices learning to use exoskeletons that are particularly large, heavy, or restrictive of typical joint kinematics.

This study is limited by high inter-subject variability and a relatively small sample size. Findings may vary with additional or demographically distinct participants. We could not reliably calculate an ideal magnitude of change for each gait outcome, if such an absolute measure exists. However, the consistency of trends across participants strongly indicates that these are important dimensions for people to adapt along. Analyzing motion capture data could provide more detailed insights into adaptations occurring throughout the leg, and reveal more about the complex mechanisms underlying reduced metabolic cost of walking with exoskeletons.

Further research is needed to evaluate the generalizability of these findings. The observed trends reflect behavior from one lightweight, torque-controlled ankle exoskeleton assisting plantarflexion. Use of an ankle exoskeleton with a different mechanical design and control will likely affect the magnitude of changes between novices and experts. However, we expect the direction of the observed trends to remain consistent for other ankle exoskeletons given the similarity between early behavior in this study and outcomes of prior ankle exoskeleton research [6,14–17]. The spatial gait changes observed in this study were also consistent with the metabolic determinants of step length and width in simple walking models when accounting for the added penalty of distal mass and medial obstructions [21,25], suggesting that similar effects may occur during adaptation to other types of wearable robots.

Our future work will coach novice exoskeleton users to exhibit the expert gait biomechanics identified in this study. Kinematic, spatiotemporal, electromyographic, and metabolic changes co-occurred throughout the experimental protocol, but an immediate metabolic benefit from adopting the identified gait changes has not been demonstrated. Differences in timescales between neuromechanical and metabolic adaptations in this dataset [6,7] and others [22,26] suggest complex mechanisms of reducing whole-body metabolic cost. If it is shown that large energetic benefits can be extracted without extensive self-guided gait exploration, this could prove an effective technique for expediting required exoskeleton training times. Future work can additionally apply this approach to characterize biofeedback targets for expert use of a wide range of assistive devices.

Conclusions

There are consistent biomechanical differences in how people walk with ankle exoskeletons at the beginning and end of motor adaptation. Identified changes included dorsiflexing more preceding a later push-off, taking narrower and longer steps, and mitigating high levels of co-contraction throughout the leg. This study reveals that relatively subtle changes in human-exoskeleton interaction can correspond to large changes in energy cost of walking. However, these improvements take a long time for healthy young adults to discover when only subject to natural gait variability. Leveraging our results to coach new exoskeleton users toward the identified gait changes could reduce the time needed for people to extract maximum benefit from exoskeletons. Improving human-device interaction during training may increase user acceptance of exoskeletons for those who could benefit from them most.

Implementation and Validation of a Data-Driven Variable Impedance Controller on the Össur Power Knee

T. Kevin Best[1], C. Andrew Seelhoff[2], and Robert D. Gregg[1,2]

***Abstract*—While prototype prostheses and control algorithms have demonstrated compelling clinical benefits in research laboratories, studies with commercially-available robotic prostheses have often failed to demonstrate similar benefits for users, limiting their adoption into mainstream clinical practice. This work is a step towards addressing this shortcoming by presenting the implementation of a phase-based variable impedance controller on the commercially-available Össur Power Knee™ for walking and sit/stand tasks. We show that, through preliminary experiments with N=4 high-mobility above-knee prosthesis users, the Power Knee under our controller can produce clear clinical benefits compared to the users' prescribed prostheses. In sitting and standing, users demonstrated generally increased leg-loading symmetry and speed with the Power Knee, indicating easier motions with less over-use of the sound limb. In walking, users demonstrated improved gait with the Power Knee, including increases in toe clearance and early-stance knee flexion. These positive results are similar to our previous work on prototype hardware, demonstrating our controller's hardware generalization and its potential for generating clinical benefits with commercial prostheses. These results are a step towards a promising future in which commercially-available robotic prostheses provide users with concrete clinical benefits.**

I. Introduction

Robotic knee prostheses have been slow to gain widespread adoption in clinical practice, despite their many promised benefits [1], [2]. In research laboratories, prototype robotic knee-ankle prostheses have been shown to enable more normative joint biomechanics [3]–[5], improve inter-limb symmetry [3], [6]–[8], reduce energy expenditure [9], [10], and, in some cases, improve user endurance [11]. However, translating these technologies into clear clinical benefits with commercialized robotic knee prostheses, such as the Össur Power Knee™ (Reykjavík, Iceland), has historically been a challenge [12]–[14].

In addition to energy, weight, noise, and cost concerns, the limited adoption of robotic knees in clinical practice is likely due to challenges in designing their control systems. A commercial prosthesis must be extremely robust, predictable, and easy to use, often leading manufacturers to elect to use simple and conservative discrete control approaches, such as the seminal finite state machine (FSM) impedance controller [15]. An FSM impedance controller uses distinct impedance parameters in a sequence of discrete gait phases, which are uniquely defined for each discrete activity mode. While these types of controllers can be quite effective in their intended conditions, optimal performance often requires extensive tuning by trained experts [16]. This poses a problem for clinical deployment, as clinicians often lack both the time and technical expertise to optimally configure these controllers, potentially resulting in sub-optimal configurations and subsequent user outcomes. It is likely that, even with the same hardware, better user outcomes could be more consistently achievable either through automated parameter tuning [17], [18], or by using alternative control strategies with lesser tuning requirements. Additionally, better outcomes may be achievable with controllers that can automatically adapt to continuous variations in the user's activity (*e.g.,* walking speed or ground incline).

Our research group has worked towards addressing these challenges through the development of a continuous, data-driven control framework known as hybrid kinematic impedance control (HKIC). These controllers encode information from large biomechanics datasets of able-bodied (AB) individuals performing various activities of daily living (ADLs) [19]–[21], utilizing continuous gait phase and task estimates to synchronize with the user and to adapt prosthesis behavior to suit the current terrain. We have applied this control framework for walking at variable speeds and inclines [5], [22], stair ascent and descent at different step heights [23], [24], and transitioning to/from sitting with different chair heights [8]. When deployed on our high-torque, low-inertia prototype powered knee-ankle prosthesis [25], these controllers have been shown to produce clinical benefits such as biomimetic joint mechanics [5], [8], [23], improved symmetry [8], reduced toe stubbing [26], and improved endurance [11].

This data-driven control approach is attractive for use in clinical settings, as it would, in theory, allow users to realize these clinical benefits across a continuum of ambulation tasks without imposing a tuning burden on the clinician. It must be shown, however, that the controller's benefits persist when deployed on a clinically-ready robotic prosthesis rather than on our prototype prosthesis. The translation of benefits is not guaranteed, as commercially-available robotic prostheses have many more practical design constraints than research prototypes, such as cost, weight, reliability, manufacturability, and more. These opposing constraints often result in a device that is more difficult to control due to more limited sensing and more complicated drivetrain dynamics. Further, robotic knee prostheses are most often paired with passive ankle/foot prostheses. The lack of an actuated ankle joint likely affects the overall behavior of the prosthesis during some activities, potentially affecting the efficacy of our controller.

This material is based on work supported by the National Institute of Child Health & Human Development of the National Institutes of Health under Award R01HD094772 and by the National Science Foundation under the Graduate Research Fellowship DGE 1841052. Prosthetic hardware and initial financial support were provided by Össur hf (Reykjavík, Iceland).

Therefore in this work, we detail and validate the deployment of our phase-based data-driven HKIC controller on the latest generation Össur Power Knee (PKA01) for sit/stand and level-ground walking tasks. After reviewing the Power Knee hardware and our HKIC controller from [5], [8], [11], we describe the updates made to the controller that account for the Power Knee's lack of ankle actuation and its non-negligible actuator dynamics. We then describe a series of experiments with N=4 high-mobility above-knee prosthesis users that highlight the clinical benefits of our controller on Power Knee compared with the users' prescribed passive devices in a series of stand-walk-sit experiments. Our preliminary results show that, despite different hardware properties compared to our research prosthesis, many of our controller's benefits persist across devices. Specifically, we demonstrate an increase in sit/stand speed and loading symmetry, similar to [8]. We also show improved walking gaits with increased early stance knee flexion and toe clearance. However, we also highlight instances in which the lack of an actuated ankle adversely affects the controller's biomimicry, such as in sit/stand. Overall, our results indicate our controller's ability to generalize to commercially-viable prostheses while retaining most of its clinical benefits.

II. Related Work

Previous research has tested the clinical benefits of commercially-available robotic prostheses, including earlier generations of the Össur Power Knee. Highsmith et al. presented a case study investigating sitting, standing, and walking on the first generation Power Knee [12]. The authors found that, for their participant, the Power Knee increased hip moment symmetry while sitting down compared to a C-Leg. However, no substantial symmetry improvement was observed at the knee joint or at all during standing. Wolf et al. similarly investigated the biomechanical differences in sit/stand when using the second generation Power Knee and the C-Leg, but observed "few differences between components and no effect on the intact limb" [13].

Most recently, Hafner et al. compared clinical outcomes between mechanical, microprocessor (Össur Rheo Knee™ II), and powered (second generation Össur Power Knee) prosthetic knees in an extensive 14 month randomized crossover trial with 12 participants [14]. The authors found that the Rheo Knee significantly improved the participants' mobility compared to mechanical knees and all of the participants elected to keep their Rheo Knee after the study. With the Power Knee, however, users demonstrated worse performance in the laboratory-based outcomes and the authors noted "high attrition of subjects", suggesting that users were unhappy with the powered device.

These three studies were unable to demonstrate compelling clinical benefits with the early models of the Power Knee, perhaps due to limitations in the prosthetic hardware, control software, or both. New, lighter and more compact commercialized robotic knees are now available, which may enable stronger clinical benefits. In this work therefore, we aim to again investigate the potential clinical benefits of commercialized robotic knees, but this time with modern hardware and a fundamentally different control approach that has previously shown benefits on a prototype prosthesis.

III. Prosthesis and Control System

A. Hardware Overview

In this study, we utilize the latest generation Power Knee from Össur (model PKA01), which is a commercialized robotic knee prosthesis. The drivetrain of the Power Knee consists of a brushless DC motor, a harmonic drive transmission, and a compliant linkage that connects the transmission output to the knee joint. The torque-angle relationship of the compliant linkage is nonlinear, stiffening under increasing deflection. The knee assembly weighs 2.7 kg (including battery) and the joint has a 120 deg range of motion. The removable lithium ion battery powers the motor and the embedded control electronics. The sensing suite includes joint and motor position encoders, a shank-mounted inertial measurement unit, and an array of ground reaction force (GRF) hall-effect sensors [27].

Based on the manufacturer's recommendations, we paired the Power Knee with the Pro-Flex® carbon fiber ankle-foot prosthesis. We used the Low Profile (LP) variety for all participants in order to maximize compatibility with different user heights and limb geometries. The appropriate size and category foot was used for each participant based on the sizing guidelines in the Pro-Flex LP Catalog. For a representative participant with average height and weight, the entire prosthesis, including the Power Knee, pylon, foot, shoe, and other hardware components, weighed 3.9 kg.

B. HKIC Controller Overview

In place of the Power Knee's stock control software, we also deployed a simplified version of our multi-activity phase-based HKIC controller [11], [28] for sit/stand and walking on the Power Knee (Fig. 1). This controller integrates the sit/stand and walk controllers from our research group's prior work [5], [8], using continuous, data-driven models of joint impedance and kinematics to produce biomimetic joint behavior for various activities. Our controller comprises two high-level modes: $\mu \in \{\text{Sit/Stand, Walk}\}$, which are automatically selected via a Finite State Machine (FSM). Simple, explainable transition rules based on the user's thigh motion control the transitions between modes (see Fig. 1 in [8] for further detail). A time-based interpolation between modal torque commands is used to smooth transitions between control modes over 100 ms.

In addition to the discrete mode μ, the controller calculates a continuous task variable χ and a continuous phase variable ϕ to evaluate the kinematic and impedance models (Fig. 1). In this initial translation to the Power Knee, we only include walking speed in the task variable χ, though other variables such as ground incline could be included in future iterations [5]. The phase variable $\phi \in [0, 1]$ quantifies the user's progression through either a walking gait cycle [5] or sitting and standing motions [8]. We calculate ϕ based on algebraic mappings of the user's thigh angle θ_{th}, giving

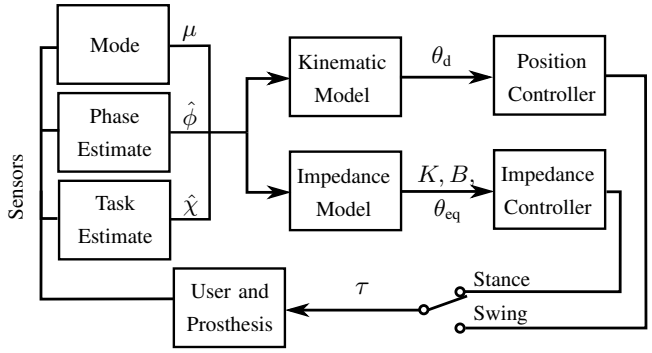

Fig. 1. A block diagram of the Hybrid Kinematic Impedance Controller used in this work. Real-time estimates of gait phase $\hat{\phi}$, task variation $\hat{\chi}$ (*i.e.* walking speed), and control mode μ (*i.e.* Walk vs. Sit/Stand) define desired joint impedance parameters K, B, θ_{eq} and joint angles θ_d using data-driven models. The torque commands τ are calculated using an impedance controller during stance or a position controller during swing.

them indirect volitional control over the prosthesis's behavior. The parameters used to calculate the phase variables adjust to the current task, allowing ϕ to appropriately parameterize the motion regardless of the varying thigh kinematics associated with different speeds and chair heights [19], [20].

While the user is in stance (which includes the entirety of Sit/Stand mode), the knee torque set point τ is calculated based on the joint angle θ_j and velocity $\dot{\theta}_j$ using impedance control:

$$\tau = K(\phi, \chi, \mu)\,[\theta_{eq}(\phi, \chi, \mu) - \theta_j] - B(\phi, \chi, \mu)\dot{\theta}_j, \quad (1)$$

where the stiffness K, damping B, and equilibrium angle θ_{eq} are functions of the phase variable ϕ, task variable χ, and mode μ. These parametric functions are fit offline to able-bodied training datasets [19], [21] such that (1) produces biomimetic joint torques when subjected to biomimetic joint kinematics. Details on the impedance model can be found in [5], [8].

Similarly, we use position control during the swing phase, where the desired joint angle θ_d and velocity $\dot{\theta}_d$ are modeled as functions of ϕ, χ, and μ. This kinematic model is likewise generated based on able-bodied kinematic data via convex optimization, with details in [29]. The knee torque is calculated through a proportional-derivative position controller as

$$\tau = k_p[\theta_d(\phi, \chi, \mu) - \theta_j] + k_d[\dot{\theta}_d(\phi, \chi, \mu) - \dot{\theta}_j], \quad (2)$$

where k_p and k_d are proportional and derivative gains, respectively. These gains are held constant across users.

C. HKIC Modifications for the Power Knee

In our previous work, our controllers have been mainly developed and evaluated using a prototype quasi-direct drive knee-ankle prosthesis [25]. While the Power Knee is distinct from this prototype prosthesis in many ways, there are two differences that are most relevant for control: 1) the Power Knee's drivetrain dynamics are more complex, and 2) the Power Knee does not have an actuated ankle joint. These differences impact how the knee joint should be controlled. We detail the modifications we made to our HKIC controller in response to each of these distinctions in turn below.

1) Low-Level Drivetrain Dynamics Compensation: Historically, the simple drivetrain dynamics of our original prototype prosthesis have allowed us to accurately control the joint impedance by assuming a proportional relationship between motor current and joint torque via the gear ratio and the motor's torque constant [25]. These assumptions are invalid on the Power Knee, as the design's high gear ratio and nonlinear series elasticity add substantial complexity to the drivetrain dynamics. For similar devices with these complex dynamics, such as the second generation Open-Source Leg [30], it has been shown that the motor inertia, series elasticity, and friction effects can introduce errors in the rendered joint impedance and ultimately errors in the produced joint torque [31], [32]. Further, it is well known in control theory that series elasticity can introduce stability problems when attempting to directly control joint position via non-collocated joint feedback [33]. Therefore, modifications to our original implementation are necessary in order to ensure accurate and stable impedance control on the Power Knee.

We utilize the approach presented in [32] to calculate optimal motor feedback gains that account for the drivetrain dynamics and minimize the rendered impedance error. Instead of calculating a motor torque setpoint using (1) and (2) directly, we use a collocated motor-space controller of the form

$$\tau = K_1(\theta_{eq,m} + \theta^* - \theta_m) - B_1\dot{\theta}_m, \quad (3)$$

where K_1 and B_1 are feedback gains that depend on the desired impedance K and B, the system parameters (inertia, viscous damping, etc.), and the transmission stiffness at the current transmission deflection. The motor states θ_m and $\dot{\theta}_m$ are decoupled from the joint states θ_j and $\dot{\theta}_j$ via the transmission elasticity. An offset angle θ^* is included to account for the transmission's nonlinear torque-angle relationship. Details on the calculation of K_1, B_1 and θ^* can be found in [32].

2) Unactuated Ankle Joint: Our previous work was performed using a prosthesis with an actuated ankle joint, allowing the ankle to behave biomimetically during all tasks. In contrast, the Pro-Flex foot used in conjunction with the Power Knee has fixed elastic properties that relate its ankle kinematics to ankle torques, constraining the space of producible behaviors. For level-ground walking, this added biomechanical constraint has comparatively little effect, as the Pro-Flex LP prosthesis is designed to primarily emulate level-ground walking biomechanics. For other activities however, normative ankle biomechanics deviate from this constraint curve in the torque-angle space, making it impossible for the passive prosthetic foot to replicate them.

One such activity in which the ankle biomechanics deviate substantially from the constraint curve is sit/stand. Average able-bodied seated data shows a moderately dorsiflexed ankle joint with zero ankle torque [21] (Fig. 2a). With a passive foot prosthesis and an unarticulated ankle joint however, the user cannot reach this low-torque, dorsiflexed configuration. They must instead choose between either a flat foot configuration with a vertical shank (Fig. 2b) or a non-flat foot configuration with an inclined shank (Fig. 2c).

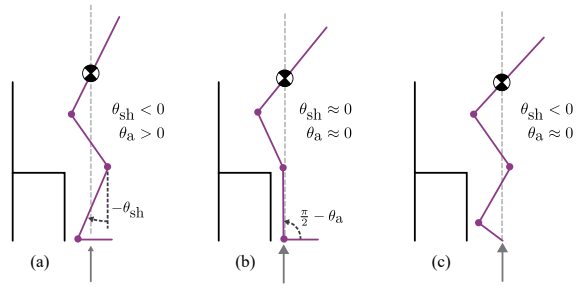

Fig. 2. A planar model of a person's foot, shank, thigh, and torso during the sit-to-stand motion in three possible configurations. The ground reaction force (gray arrow) is applied at the CoP, coinciding with the user's center of mass based on a quasi-static assumption. Tile (a) shows the nominal joint configurations used by able-bodied individuals, with $\theta_{sh} < 0, \theta_a > 0$, and the CoP located posterior to the knee joint center. Tiles (b) and (c) show the possible sit-to-stand configurations for a person using an above-knee prosthesis with a passive foot ($\theta_a \approx 0$), with either (b) a vertical shank ($\theta_{sh} \approx 0$) or (c) a non-flat foot ($\theta_{sh} < 0$).

Of the three configurations, the dorsiflexed configuration (Fig. 2a) is the most advantageous, as it allows the user to locate their center of pressure (CoP) posterior to the knee joint center. Assuming minimal anterior/posterior forces, it can be shown that the posterior separation of the CoP relative to the knee joint center prevents the foot/ankle complex from rotating off the ground (*i.e.* pivoting about the heel of the foot) when substantial knee torques are applied. The dorsiflexed configuration also helps prevent foot slipping, as the knee moment is opposed primarily by normal ground reaction forces rather than only by friction.

Of the two configurations available with a passive ankle, the inclined shank configuration (Fig. 2c) is most advantageous, as it does allow the CoP to be posterior to the knee joint, though only briefly. However, it requires the user to balance on the toe of the prosthesis during the motion, which may feel unstable. In our experience, most participants habitually use the configuration in Fig. 2b with their prescribed prostheses.

With a powered knee prosthesis, there is a risk of the applied knee extension torque producing negative consequences when the user elects to use the vertical shank configuration (Fig. 2b). If the CoP is too far anterior, the foot will rotate about the heel, sending the knee center backwards and potentially making the user lose their balance. Additionally, insufficient ground reaction force in this configuration may cause the knee torque to produce foot slipping rather than body weight support.

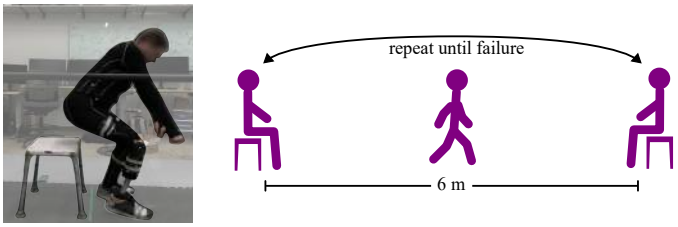
In response to this limitation caused by the unarticulated ankle joint, we modified our original sit/stand controller to prevent applying knee torques when the user elects to sit with a vertical shank (Fig. 2b). We scale the sit/stand knee stiffness and damping references with a unit logistic function of the user's shank angle θ_{sh}. The logistic mapping is defined as

$$\xi(\theta_{sh}) = \frac{1}{1 + e^{1.5(\theta_{sh}+2)}}, \tag{4}$$

where the angle constants have units of degrees. To prevent closed-loop oscillations that can occur from the interaction between the torque command and θ_{sh}, we low-pass filter θ_{sh} prior to (4). Since users typically adjust their posture slowly before standing, a 1 Hz cutoff frequency is sufficient to filter the signal without causing noticeable delays or response lag. As θ_{sh} increases above 0, the stiffness and damping asymptotically scale to 0, resulting in no knee joint torque. Conversely, as θ_{sh} decreases beyond 0, the logistic function approaches 1 and the stiffness and damping commands remain unchanged.

IV. Experimental Validation

To validate our controller's implementation on the Power Knee and to test for its clinical benefits, we recruited four participants with unilateral above-knee amputations (Table 1) to participate in our study. All participants were strong community ambulators (K4) and did not require mobility aids. The experimental protocol was approved by the University of Michigan Institutional Review Board (HUM00230065) and each participant provided informed consent.



A. Methods

We tested two conditions in this experiment over three sessions, with the participants using either 1) their prescribed prostheses (PRES), or 2) the Power Knee running our HKIC controller (PKNE). Each condition was tested on a separate day to mitigate fatigue effects, and the testing order was randomized to prevent procedural bias. Prior to the experiments, an acclimation day was provided during which the Power Knee prosthesis was fit and aligned to the participant by a certified prosthetist. The appropriate Pro-Flex LP foot was used for each participant based on their weight, activity level, and shoe size. The participant was taught how to use the Power Knee with the novel controller, and provided ample time to practice sitting, standing, and walking. The research team also provided coaching on how to best leverage the device's capabilities. This acclimation session lasted up to four hours.

The remaining two visits were identical aside from the prosthesis used (either PRES or PKNE). First, the participants were allowed to practice sitting, standing, and walking to warm up and re-familiarize themselves with the prosthesis.

TABLE 1
Enrolled Participant Details

Participant	Sex	Age (yrs)	Mass (kg)	Prescribed Prosthesis (Knee/Ankle)	Etiology	Amputation Type	Time Since Amputation (yrs)
TF01	M	23	79	Genium/Triton	Dysvascular Disease	Above Knee	10
TF02	M	25	84	Rheo/Proflex XC	Congenital	Knee Disartic.	24
TF03	M	20	75	Quattro/Shockwave	Cancer	Above Knee	2
TF04	F	42	66	X3/Triton LP	Trauma	Knee Disartic.	6

(a) (b)

Fig. 3. (a) A photo of participant TF01 standing from the first stool during the PKNE condition. (b) A graphical depiction of the incremental shuttle walk test protocol, depicting the participants walking between two stools approximately 6 m apart. Participants repeated walking between the stools until they could no longer keep up with the slowly increasing cued pace.

Visual feedback during sit-stand was provided to allow the participants to practice symmetric limb loading, similar to [8]. This feedback was removed after the warm up period.

Next, the participants completed the main experiment, which involved completing repeated laps of an ambulation circuit consisting of two stools (45 cm tall) located approximately 6 m apart (Fig. 3). The protocol was inspired by the incremental shuttle walk test used to assess fitness in other domains [34], [35]. Handrails were provided along the walkway for safety, but their use was discouraged unless required to prevent a fall. Upon an auditory cue, participants stood up from a stool, walked to the opposite stool, turned around, and sat down to wait until the next cue. The cues were automated and followed this schedule: four cues at 65-second intervals, six at 43.3-second intervals, and eight at 32.5-second intervals, and so on, gradually increasing the minimum average walking pace from 0.1 m/s to 0.15 m/s and 0.2 m/s, respectively. The number of repetitions was chosen such that the total time at each pace was 260 s. Participants were allowed to choose their walking speed, but needed to reach the opposite stool before the next cue. The test ended if a participant failed to reach the stool on time for two consecutive laps.

During the experiments, motion capture and ground reaction force data were recorded (Vicon, Oxford, UK). These data were processed in OpenSim 4.5 (Stanford, CA, USA) using the model from Rajagopal et. al [36] with appropriate modifications made to the prosthetic side inertial properties, similar to [37]. Forceplates were located at each stool, allowing individual measurements of each leg's ground reaction force and inverse dynamics calculations. The walkway was not instrumented, and thus no walking joint kinetics were calculated.

In this work, we are only concerned with the non-rushed portions of the experiment (before the time between cues decreased substantially), as these are most similar to how our controller was previously tested on our prototype hardware. Therefore, we limit our analysis to the first 70 laps of the experiment. These early laps correspond to minimum average walking paces of ≤ 0.4 m/s and thus allow for "leisurely" activity completions without time pressure. Future work will analyze the latter portions of the experiment to investigate how performance changed under time pressure and with fatigue.

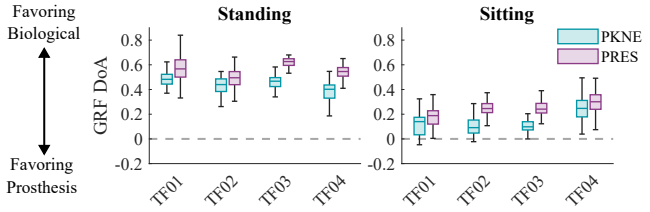


Fig. 4. Boxplots of the mean vertical GRF degree of asymmetry during sitting (left) and standing (right) for each participant. Values closer to zero indicate better GRF symmetry, whereas ± 1 indicate complete asymmetry.

We segmented the experiment data from the first 70 laps into sitting, standing, transitioning, walking, and resting periods based on kinematic and force thresholds. We further divided the walking data into individual gait cycles based on the marker positions using methods from [38]. To examine whether the prosthesis condition had a statistically significant effect on the biomechanical measures of interest, we utilized linear mixed-effects models (LMMs). LMMs were chosen for their ability to include both fixed and random effects, allowing us to account for inter-participant variability. We treated the prosthesis condition (PRES or PKNE) as a fixed effect and the participant as a random intercept. Our null hypothesis posited that there would be no significant difference in these biomechanical measures between the prosthesis conditions, and our significance threshold was set to $\alpha = 0.05$.

B. Results

All participants were able to complete over 100 laps of the circuit with both their prescribed prostheses and the Power Knee, demonstrating the baseline functionality of our HKIC controller. The following subsections present results for the sitting/standing and walking portions of the circuit. For clarity in the presented boxplots, we excluded data points that are considered outliers, specifically those below Q1-1.5×IQR and above Q3+1.5×IQR.

1) Sitting and Standing: On the prototype hardware, our controller previously produced improved ground reaction force (GRF) symmetry [8]. We define the GFR degree of asymmetry DoA as

$$DoA = (F_\mathrm{b} - F_\mathrm{p})/(F_\mathrm{b} + F_\mathrm{p}), \tag{5}$$

where F_b and F_p are the vertical GRFs on the biological and prosthetic limbs, respectively. $DoA = 0$ indicates perfect GRF symmetry, whereas $DoA = 1$ and $DoA = -1$ indicate all force on the biological and prosthetic limbs, respectively. Similar to what was observed with the prototype hardware in [8], the mean GRF loading symmetry was improved in the PKNE condition compared to PRES condition for all participants (Fig. 4). The fit LMM showed an average DoA improvement of 11.6% for standing ($p < 0.001$) and 9.5% in sitting ($p < 0.001$) by the PKNE condition. Both conditions showed better sitting symmetry than standing symmetry.

We also calculated the time the participants took to perform the standing and sitting motions in each lap (Fig. 5). These timings only include the duration of the actual motions, excluding

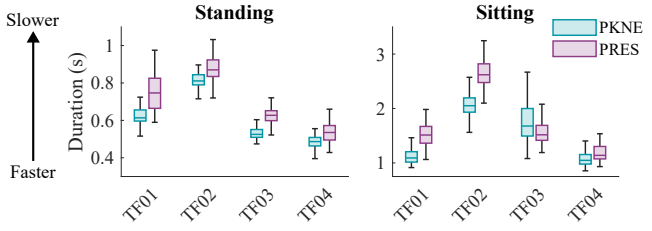

Fig. 5. Boxplots of the average duration of the sitting and standing motions during the experiment for each participant. The PKNE condition was significantly faster on average than the PRES condition.

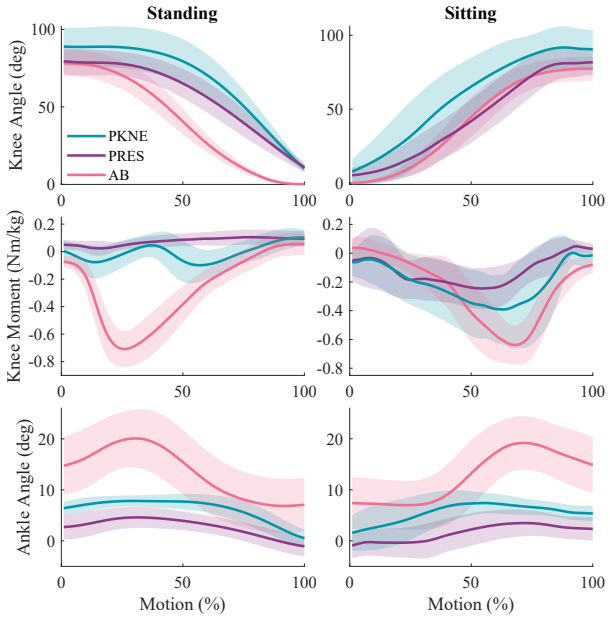

Fig. 6. Inter-participant average prosthetic-side joint kinematics and kinetics while sitting (left) and standing (right). Normative trajectories (AB) from [21] are shown as well for context. Ankle moments are excluded for brevity. Shaded regions represent ± 1 standard deviation.

transitions. On average, the PKNE condition produced faster motions than the PRES condition, with 11.9% ($p < 0.001$) and 13.0% ($p < 0.001$) reductions in standing and sitting times, respectively. Larger variance was observed in sitting, with some participants showing similar speed in both conditions.

We then compared the mean prosthetic knee and ankle kinematics and kinetics during sit/stand with normative able-bodied trajectories (Fig. 6). We did not plot the ankle moments, as they were small and their shape can be inferred from the kinematics due to the elastic nature of the prosthetic foot. Both conditions produced knee kinematics that are similar to able-bodied, with the PRES condition being the most similar in sitting. However, the ankle kinematics produced by either condition's passive feet differ substantially from the normative trajectories, likely impacting the knee's behavior. The knee moments in sitting are more similar to able-bodied for the PKNE condition than for the PRES condition. While the standing knee moments for PKNE are also closer to able-bodied than the PRES condition, they are still not as biomimetic as what was observed in [8], likely due to the

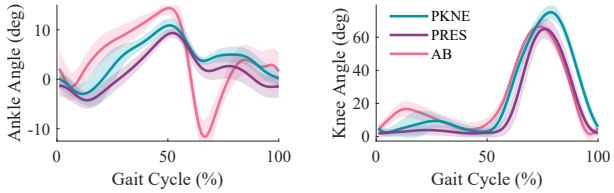

Fig. 7. Inter-participant average kinematic trajectories of the prosthetic joints during the overground walking portions of the experiment. Mean able-bodied trajectories (AB) of 1.0 m/s walking from [19] are also plotted for reference. Shaded regions represent ± 1 standard deviation.

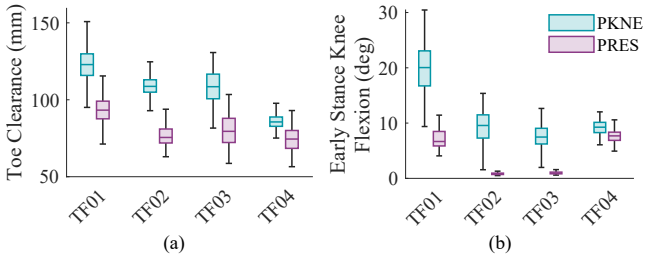

Fig. 8. Boxplots of the average kinematic features during the overground walking portions of the experiments. Tile (a) shows the minimum toe clearance during swing and tile (b) shows the peak early stance knee flexion.

configuration mismatch caused by the passive ankle and our control modification to taper knee torque as $\theta_{sh} \to 0$.

2) Overground Walking: Like in sit/stand, we compared the mean prosthetic knee and ankle kinematics with normative able-bodied trajectories (Fig. 7), as previous experiments with the prototype hardware demonstrated improved biomimicry [5]. Qualitatively, the kinematics at both joints were reasonably similar to able-bodied for both conditions, with a few notable differences in key kinematic features. The PKNE condition showed slightly larger peak ankle dorsiflexion angles, suggesting more energy storage in the prosthetic foot available for push off. The PKNE condition also showed increased peak swing knee flexion angles (mean $\approx$ 76 deg). The peak knee flexion angle in the HKIC controller's kinematic model is $\approx$ 68 deg, indicating that the observed extra flexion was caused by natural swing dynamics rather than explicit control effort. Though less biomimetic, the increased knee flexion was likely beneficial in increasing the toe clearance during swing (Fig. 8a). We calculated this toe clearance based on the minimum position of the 1st and 5th metatarsal markers during mid-swing. On average, the PKNE condition produced 25.5 mm (31.4%) more toe clearance than the PRES condition ($p < 0.001$). An increase in early stance knee flexion was also observed in the PKNE condition (Fig. 8b), with one participant approaching the average able-bodied amount of 16.5 deg. On average, the PKNE condition produced 7.4 deg (172.8%) more early stance knee flexion than the PRES condition ($p < 0.001$).

Finally, we calculated the step length symmetry index for each stride and condition, defined as ratio between the prosthetic and the subsequent biological leg step lengths. A step length symmetry index of 1 corresponds to perfectly symmetric step lengths, while values greater than 1 indicate

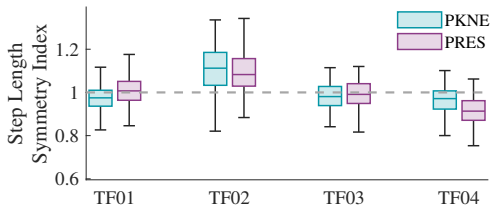

Fig. 9. Mean step length symmetry index for each participant and condition during the overground walking portions of the experiment. Perfectly equal step lengths would result in a symmetry index of 1, whereas values greater than 1 indicate longer steps with the prosthesis.

longer steps with the prosthesis. Shown in Fig. 9, no significant relationship between the prosthesis condition and step length symmetry was observed ($p = 0.54$).

V. Discussion

Many, but not all, of the clinical benefits observed on the prototype hardware in [5], [8] transferred with the HKIC to the Power Knee. The improved GRF symmetry during sit/stand observed in the PKNE condition is an important clinical result, as the better sharing of the GRF between limbs will likely reduce overuse injuries over time. Further, while the speed increase is not directly clinically relevant, it is likely indicative of the sit/stand motions being easier to perform with the PKNE condition than the PRES condition.

However, these effects are not as large as they were previously in [8], likely due to configuration mismatches caused by the passive ankle (Fig. 2). In particular, the standing knee moments produced by the PKNE condition were not as biomimetic as they had been previously (Fig. 6). We hypothesize that this is due, in part, to the difficulty of maintaining the Fig. 2c configuration. Participants often reverted to the vertical shank configuration, in which our controller does not apply knee torque in order to avoid slipping. Systematically characterizing the effects of a non-articulated ankle in sit/stand is an interesting avenue for future work.

In the overground walking portions of the experiment, we observed improvements in key kinematic gait features. The increased toe clearance in the PKNE condition (Fig. 8a), which likely resulted from the increased peak swing knee flexion (Fig. 7), is beneficial for real-world use, as mid-swing trips are a common source of falls [39]. Importantly, the participants did not note any disadvantages of the increased toe clearance or swing knee flexion. The PKNE condition also created more early stance knee flexion than the PRES condition, though not quite to the extent of normative able-bodied gait. Early stance knee flexion is desirable, as it can absorb heelstrike impacts and allow individuals to better maintain forward momentum [40]. Although the prescribed MPKs used by the participants all support early stance knee flexion, the participants did not appear to leverage this feature in the PRES condition.

Though promising, this initial study is not without limitations. First, our study cohort represents only a limited segment of the population, which restricts the generalizability of our findings. The participants were all high-activity (K4) ambulators, and it is possible that our results are unique to this demographic. For instance, related work in robotic ankle prostheses found that higher mobility groups benefited more from the robotic assistance compared to those with lower mobility [41]. Future work is required to understand the PKNE condition's effects across broader populations.

Furthermore, our experiments did not capture all aspects of everyday prosthesis use. For example, we tested only a portion of the activities that occur in real-world ambulation, neglecting activities such as stair traversal. Experiments testing the generalization of our stairs controller [23] should be performed as well. Additionally, we provided limited training and acclimation to the novel device, whereas the participants were extremely acclimated to their PRES prostheses. In real-world use, the acclimation levels across conditions would be more balanced. As our controller matures and becomes appropriate for take-home use, a more comprehensive experiment with longer acclimation and testing horizons should be performed, similar to [14].

Finally, the extent to which the HKIC control methodology independently influenced the observed outcomes was not tested in our experiments. Future work should compare results between the Power Knee under HKIC control to those created with its default control behavior to isolate these effects.

VI. Conclusion

In this article, we presented the first implementation of a phase-variable impedance controller on the Össur Power Knee, utilizing data-driven impedance and kinematic models in place of FSM control. In preliminary experiments involving walking and sit/stand, we showed that many of the clinical benefits that we observed with the same control approach on prototype hardware generalized to the Power Knee. By demonstrating compelling evidence of clinical benefits on commercially-viable prosthesis hardware such as the Power Knee, we aim to help accelerate the adoption of robotic knee-ankle prostheses into mainstream clinical practice.

Acknowledgments

The authors would like to thank Jeffrey Wensman, CPO for providing clinical support, Atli Örn Sverrisson and David Langlois for assistance with the Power Knee hardware, Dr. Ryan Posh for providing valuable feedback on the manuscript, and our dedicated participants for making this work possible.

Conflict of Interest Disclosure

TKB and RDG have applied for patents related to the HKIC control method.

This research received initial funding from Össur ehf (Reykjavík, Iceland), which may have a financial interest in the outcomes of this study. The authors independently conducted the research and analysis, and the results and conclusions presented in this paper are those of the authors alone. These findings do not necessarily reflect the views or positions of Össur ehf, the National Science Foundation, or the National Institutes of Health.

Real-time Prediction of Leg Joint Kinematics during Steady-State Walking and Task Transitions*

Louis Devillez[1,3] and Renaud Ronsse[1,2]

***Abstract*— Amputations and other impairments heavily impact human locomotion. To compensate for these disabilities, advanced devices such as active orthoses and prostheses are being developed with the aim of restoring locomotor function. To achieve this goal, the control of such technologies has been identified as a key research challenge. A reference kinematic profile for the affected or missing joints is often useful for device control. This paper introduces a novel method for estimating reference kinematics of leg joints from kinematic signals of the contralateral leg. This method leverages fusion of two different estimators – i.e. Complementary Limb Motion Estimation and Adaptive Oscillators – which are combined through the use of a logistic function. The method is then applied to estimate the kinematics of a hip joint, and the performance is compared with that of each individual estimator during walking. The correlation between the estimated signal and the ground truth is assessed on a cycle-by-cycle basis. During transitions, our new method behaves similarly to Complementary Limb Motion Estimation. After a few cycles, the method shifts towards Adaptive Oscillators to achieve a better correlation during quasi-steady-state locomotion.**

I. Introduction

There are many neuromusculoskeletal disorders impacting lower limb functions. Examples include Parkinson's disease, stroke, or amputation, and each of them leads to serious locomotion disabilities. Advanced technologies have been developed to alleviate the effects of these disorders, such as powered orthoses [1], [2] or prostheses [3], [4]. A key challenge that remains to be solved is the control of such technologies. A particularly emerging approach consists in governing the device behavior through bio-inspired control principles, mainly through descending activation patterns, feedback-driven reflexes, and/or motor primitives [5]. Implementation of such control can be divided into two key steps. First, reference kinematics of affected joints need to be generated. Then, the device behavior is regulated as a function of these reference kinematics, either through a stiff PID controller [6], or by computing assist-as-needed force profiles in an impedance-based controller [7]. Finite-state machines can be used to sequence the controller behavior into a series of distinct phases synchronized with events — such as heel strike — to modulate gains or combine different control modes [8], [9].

In this paper, the focus is on the first step, i.e. generation of relevant reference kinematics. Since the corresponding joint is missing or no longer functional, its reference kinematics need to be estimated, for instance by measuring signals on the contralateral leg. Ideally, this reference kinematics should also adapt as a function of the executed task: leg joints do not follow the same pattern during overground walking and stair ascending/descending, and even during walking at two different speeds. These statements are particularly relevant for proximal joints, since they govern the whole leg rhythmicity [10]. For example, in the case of hip disarticulation, i.e. amputation of a whole leg, the reference kinematics of the hip prosthesis module could only be estimated from signals measured on the rest of the body [11].

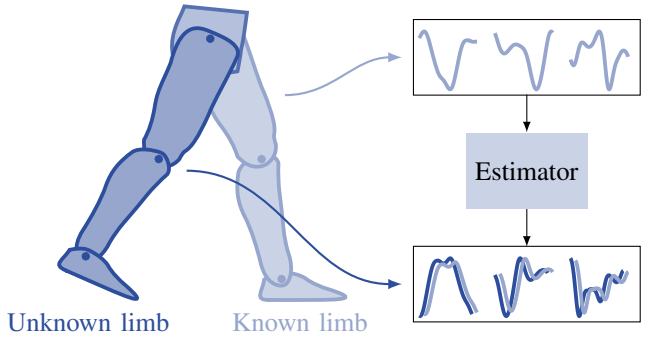

Fig. 1. Schematic representation of the problem statement. By measuring the kinematic signals of one leg, we aim at predicting the kinematics of at least one joint of the contralateral leg.

Human locomotion is a combination of rhythmic and discrete movements [12]. Walking and ascending stairs are examples of rhythmic movements — at least during their steady-state segments — while the transition from standing to walking or sitting are discrete movements. A large proportion of controllers for assistive locomotion devices rely on phase-based methods, i.e., real-time estimation of a continuously evolving gait phase between 0 % and 100 % [13] to generate reference kinematics. This implies that they only work during (quasi-)rhythmic tasks. For example, [14] used precomputed signals as reference kinematics, that varied with respect to the estimated gait phase. In echo control, the kinematic profile of one joint is recorded and replayed with some time delay to serve as a reference for the contralateral joint [15]. Adaptive Oscillators (AO) are dynamical systems capable of synchronizing with a quasi-periodic input by learning its features in state variables [16]. Since these methods require rhythmicity, they are not well adapted to discrete transitions. Other methods, such as Complementary Limb Motion Estimation (CLME), do not leverage the intrinsic

[3]louis.devillez@uclouvain.be

rhythmicity of locomotion in their working principle. CLME infers the intended motion of the affected joints from the motion of the residual joints [17]. This method can handle transitions but requires specific parameter tuning for each task and potentially even for each user.

The methodology presented in this paper combines two methods, i.e. AO and CLME, in order to leverage their respective benefits. We strive to develop an estimator adapted to both discrete and rhythmic segments of walking, i.e. giving precedence to AO during rhythmic segments, and to CLME during discrete transitions. Additionally, this method can reduce the need for gain tuning. The article is structured as follows: Section II presents the problem statement. Section III overviews the algorithms of CLME and AO in detail. The mechanism to combine both methods is described in Section IV. Section V applies this combined estimator to our target application, i.e. estimating the kinematics of a missing hip joint. Results are compared and analyzed in Section VI. The paper ends with a discussion and a conclusion.

II. Problem statement

The problem addressed in the present paper consists in estimating in real-time the joint kinematics of one leg from measurements of kinematic signals taken from the other leg. A schematic representation is depicted in Fig. 1. Let $\boldsymbol{q}$ be a time-dependent vector with $3M$ components containing kinematic signals of M leg joints, such that for each joint i:

- $q_{3(i-1)+1}$ is the joint position
- $q_{3(i-1)+2}$ is the joint velocity
- $q_{3(i-1)+3}$ is the joint acceleration

The problem can thus be expressed as finding a function f such that:

$$\boldsymbol{q}_U[t] = f(\boldsymbol{q}_K[t]) \tag{1}$$

The subscripts K and U are used to denote the known limb and the unknown one.

III. Related work

In this section, we overview two existing methodologies providing a particular implementation of the function f. First, CLME augmented with a Kalman filter is presented; then AO are introduced.

A. Complementary limb motion estimation

CLME was developed by Vallery and colleagues in [17]–[20]. The principle behind this method is to leverage interjoint coordination [21] and, consequently, to find the best linear combination of known joint kinematic variables (position, velocity, and/or acceleration) to estimate similar variables of another joint.

To construct a CLME, data from both known and unknown joints are required. Moreover, this framework does not require to specify which kinematic variables are used to compose vectors $\boldsymbol{q}_U$ and $\boldsymbol{q}_K$ since it can be implemented with any combination of position, velocity, and acceleration signals.

The first step consists in normalizing the variables, i.e. computing normalized vectors $\boldsymbol{x}$ as:

$$\boldsymbol{S}_i = \text{diag}\left(\text{var}(\boldsymbol{q}_i)\right) \tag{2}$$

$$\boldsymbol{x}_i = \boldsymbol{S}_i^{-1}\left(\boldsymbol{q}_i - \bar{\boldsymbol{q}}_i\right) \tag{3}$$

with $\text{var}(\boldsymbol{q}_i)$ being the variance and $\bar{\boldsymbol{q}}_i$ the mean of $\boldsymbol{q}_i$, and the subscript i denoting both U and K. The best estimator is defined as the matrix $\boldsymbol{C}$ such that the expected error between the normalized vector of the unknown joint and the estimation is minimized, i.e.:

$$\text{argmin}\left(\sum(||\boldsymbol{x}_U - \boldsymbol{C}\boldsymbol{x}_K||)\right) \tag{4}$$

Importantly, since this problem is linear, it has an exact solution, that can be computed as:

$$\boldsymbol{C}_{\text{opt}} = \left(\text{cov}^{-1}(\boldsymbol{x}_K, \boldsymbol{x}_K) * \text{cov}(\boldsymbol{x}_K, \boldsymbol{x}_U)\right)^T \tag{5}$$

with $\text{cov}(\cdot,\cdot)$ denoting the covariance function. An estimator of the unknown joint kinematics can then be constructed as:

$$\boldsymbol{q}_U^{\text{CLME}} = \boldsymbol{A}\boldsymbol{q}_K + \boldsymbol{b} \tag{6}$$

$$\boldsymbol{A} = \boldsymbol{S}_U\boldsymbol{C}\boldsymbol{S}_K^{-1} \tag{7}$$

$$\boldsymbol{b} = \boldsymbol{A}\bar{\boldsymbol{q}}_K + \bar{\boldsymbol{q}}_U \tag{8}$$

This approach computes estimates of the kinematic variables independently of each other, i.e. without accounting for the fact that one might be the derivative of another. In other words, following the problem statement, it does not guarantee that the derivative of $q_{3(i-1)+1}$ is equal to $q_{3(i-1)+2}$ and that the derivative of $q_{3(i-1)+2}$ is equal to $q_{3(i-1)+3}$.

However, there are many reasons why satisfying these constraints between position, velocity, and/or acceleration is essential. For instance, if the position estimate is used as a reference signal for a controller, its dynamics can benefit greatly from having an estimate of the reference velocity, as long as it is the actual derivative of the position [22].

To solve this problem, this correlation-based CLME measurement can be coupled with a model-based prediction that takes into account the derivative relationship between variables. This can be achieved by coupling a Kalman filter [17], thus combining a predictor based on an internal model with a series of integrators, to the CLME-based estimation [23]. Therefore, we define the following variables:

- $\boldsymbol{q}_U^*$: the prediction from the internal model of the filter
- $\boldsymbol{q}_U^{\text{KF}}$: the output from the Kalman filter, combining the model-based prediction and CLME-based estimation
- $\boldsymbol{K}$: the Kalman gain matrix

The internal model estimate is expressed as a chain of Euler-explicit integrators, i.e.:

$$\boldsymbol{q}_U^*[t+1] = \begin{bmatrix} \boldsymbol{F} & & \\ & \ddots & \\ & & \boldsymbol{F} \end{bmatrix} \boldsymbol{q}_U^{\text{KF}}[t] \tag{9}$$

where

$$\boldsymbol{F} = \begin{bmatrix} 1 & \Delta t & 0 \\ 0 & 1 & \Delta t \\ 0 & 0 & 1 \end{bmatrix} \tag{10}$$

The output of the whole filter is then obtained as:

$$\boldsymbol{q}_U^{\text{KF}}[t+1] = \boldsymbol{q}_U^*[t+1] + \boldsymbol{K}\left(\boldsymbol{q}_U^{\text{CLME}}[t] - \boldsymbol{q}_U^*[t]\right) \quad (11)$$

The principle of a Kalman filter is to find the best gain matrix $\boldsymbol{K}$ that minimizes the error of the combined estimates. Several references explain how to compute $\boldsymbol{K}$, as a function of the covariance of the process noise (here the variance of the acceleration, i.e. var $\left(q_{U,3(i-1)+3}\right)$) and the observation noise (here, the variance of the measurement error, i.e. var $\left(q^{\text{CLME}}_{U,3(i-1)+1} - q_{U,3(i-1)+1}\right)$) [24].

B. Adaptive oscillators

Any periodic signal can be decomposed into an infinite sum of sinusoidal signals, as captured by Fourier's theorem. An estimate of this signal can be constructed by truncating this sum to its first N terms. Such an estimation can be applied to the position of the known leg and is thus expressed as:

$$q^{\text{AO}}_{K,3(i-1)+1}(t) = \alpha_0 + \sum_{j=1}^{N} \alpha_j \sin\left(\phi_j(t)\right) \quad (12)$$

$$\dot{\phi}_j(t) = j\omega \quad (13)$$

with the following parameters: α_0 the offset, α_j the amplitude of the j-th harmonic, ω the frequency of the fundamental harmonic, and ϕ_j the phase of the j-th harmonic.

AO are a mathematical tool specifically developed in order to estimate these parameters [25]. The estimation error, ϵ is computed as the difference between the periodic signal to be estimated and its estimation. Here we assume the signal to be estimated is the measured joint angular position of the known leg, i.e.:

$$\epsilon(t) = q_{K,3(i-1)+1}(t) - q^{\text{AO}}_{K,3(i-1)+1}(t) \quad (14)$$

The dynamics governing the learning of the estimation state variables are given as follows:

$$\dot{\alpha}_0(t) = \epsilon(t)\ \eta \quad (15)$$

$$\dot{\alpha}_j(t) = \epsilon(t)\ \eta \sin\left(\phi_j(t)\right) \quad (16)$$

$$\dot{\omega}(t) = \epsilon(t)\ \nu_\omega \frac{\cos\left(\phi_1(t)\right)}{\sum_{j=1}^{N} \alpha_j(t)} \quad (17)$$

$$\dot{\phi}_j(t) = \epsilon(t)\ \nu_\phi \frac{\cos\left(\phi_j(t)\right)}{\sum_{j=1}^{N} \alpha_j(t)} + j\omega(t) \quad (18)$$

with η, ν_ω and ν_ϕ being the learning gains for, respectively, the amplitude, frequency and phase. Note that the state equations (15)-(18) should be discretized in order to be solved in real-time. This can be done through classical explicit integration schemes like Euler or Runge-Kutta. In [16], a method to tune the learning gains gave the following rules:

$$\eta = \frac{2}{\tau_\alpha} \qquad \nu_\omega = \frac{20}{\tau_\omega^2} \qquad \nu_\phi = \frac{22}{\tau_\omega} \quad (19)$$

with τ_α and τ_ω being the time constants of the amplitude and frequency dynamics, respectively.

Assuming that both legs are in antiphase during walking, the estimation of the unknown leg can be built based on the state variables learned from the known leg, yet with an extra phase shift of $j\pi$. The estimation of the unknown angular position can then be expressed as:

$$q^{\text{AO}}_{U,3(i-1)+1}(t) = \alpha_0(t) + \sum_{j=1}^{N} \alpha_j(t) \sin\left(\phi_j(t) + j\pi\right) \quad (20)$$

The velocity and acceleration can be obtained by analytically differentiating (20), i.e.:

$$q^{\text{AO}}_{U,3(i-1)+2}(t) = \sum_{j=1}^{N} \alpha_j(t) j\omega(t) \cos\left(\phi_j(t) + j\pi\right) \quad (21)$$

$$q^{\text{AO}}_{U,3(i-1)+3}(t) = -\sum_{j=1}^{N} \alpha_j(t) j^2 \omega(t)^2 \sin\left(\phi_j(t) + j\pi\right) \quad (22)$$

Since AO build a kind of real-time Fourier series, it only works during (quasi-)rhythmic movements, i.e. steady-state walking. During transients, its performance degenerates to that of a low-pass filter.

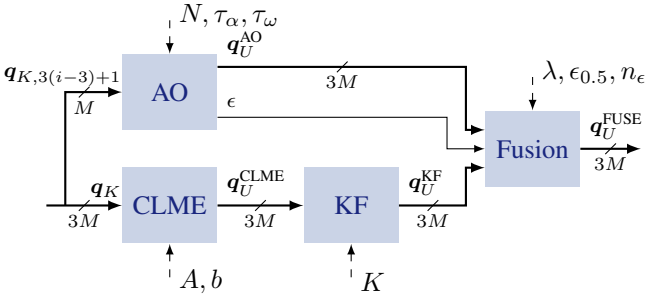

Fig. 2. Block diagram of the various components of the fused estimator. Each block has its own parameters, represented by the vertical arrows. The input of both CLME and AO are kinematics signals. The CLME output is filtered with a Kalman filter (KF). Fusion of both estimators is governed by the AO error ϵ.

IV. Fusing the estimators

In the previous section, we introduced CLME and AO, two methods to estimate the unknown leg kinematics from the known one. In this section, both estimators are fused together to obtain a more robust estimation of the unknown side. Fig. 2 illustrates the relationship between the different blocks.

Both methods have their advantages and disadvantages. CLME is time-invariant and provides a time-independent optimal estimation, in the least-squares sense. However, the quality of this estimation depends on the dataset on which the gains have been optimized and does not exactly satisfy relationships between position, velocity, and acceleration signals. AO can provide an estimation that is exactly in antiphase with respect to the known leg and that satisfies relationships between kinematic derivatives. However, it is governed by its intrinsic dynamics and thus needs time to reach a new (quasi) steady-state after each transition. As a consequence, it is preferable to use the estimation from CLME during transient phases, and to give more weight to

the estimation provided by AO once steady-state locomotion has been reached.

A fixed weighted average between both estimators would not take into account the temporal dynamics of the AO-based estimation. Yet, the quality of this AO-based estimation is directly provided by the error signal ϵ. For large ϵ, when the estimation does not match the measurement, state variables evolve rapidly (15-18), indicating that AO have not converged. In contrast, small ϵ indicates a slow evolution of state variables, capturing that AO have converged.

In order to hide high-frequency variations in both the measured signal and its estimate, we chose to use the moving average of ϵ, denoted, ϵ_{MA}, as the convergence metric of AO. Its window size is denoted by n_ϵ. The weight that should be given to the estimation provided by AO is then defined by the following logistic function, bounded between 0 and 1:

$$W(\bar{\epsilon}) = 1 - \frac{1}{1 + \exp\left(\lambda\left(\epsilon_{0.5} - \epsilon_{\text{MA}}\right)\right)} \tag{23}$$

with $\epsilon_{0.5}$ being a parameter equal to the value of ϵ_{MA} corresponding to a weight of 0.5, and λ being another parameter capturing the function steepness. The nonlinear profile of (23) allows a rapid shift between CLME and AO. The output of the fused estimator is eventually computed as:

$$\boldsymbol{q}_U^{\text{FUSE}} = W(\epsilon_{\text{MA}}) \cdot \boldsymbol{q}_U^{\text{AO}} + (1 - W(\epsilon_{\text{MA}})) \cdot \boldsymbol{q}_U^{\text{CLME}} \tag{24}$$

V. Application for an Active Hip Prosthesis

The previous section showed how to fuse CLME- and AO-based estimations into a single estimate, giving more weight to AO when it has converged, i.e. during steady-state locomotion. In this section, this algorithm is applied to estimate the position and velocity of a hip joint. These estimates could be used directly to control a hip prosthesis, like the one we developed in [11]. In the remainder of this section, the position of the unknown hip will be denoted θ and its velocity $\dot{\theta}$.

A. Dataset

Two pre-existing datasets were used to train, test and evaluate the estimators. The position and velocity of both legs were extracted as well as their decomposition into gait cycles. The first dataset is taken from [26] and contains data from 12 subjects performing different cyclic or non-cyclic locomotion-related tasks. Only walking trials with speeds ranging from $0.6\,\text{m}\,\text{s}^{-1}$ to $1.8\,\text{m}\,\text{s}^{-1}$ were kept for analysis. The second dataset is taken from [27] and contains data from 22 subjects who also performing different locomotion tasks. Only the level-ground and treadmill trials were kept for all subjects, with walking speeds ranging from $0.5\,\text{m}\,\text{s}^{-1}$ to $1.85\,\text{m}\,\text{s}^{-1}$. Trials with fewer than 5 cycles were excluded. This resulted in a total of 329 trials and 1,974 cycles. We arbitrarily chose the right leg as the known leg and the left leg as the unknown leg for each trial.

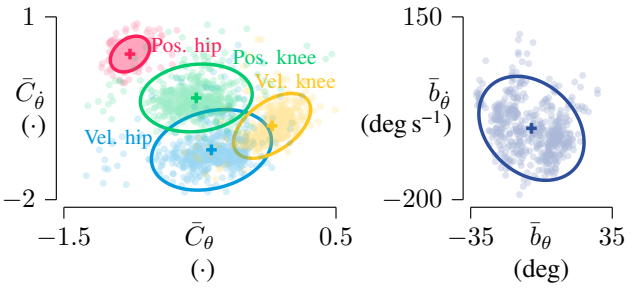

Fig. 3. Normalized gains of CLME trained on all available trials. Left: $\boldsymbol{C}$ matrix; right: $\boldsymbol{b}$ vector. The color represents the different input signals of CLME and each axis captures its magnitude for estimating both the position and velocity of the hip. Ellispses capture the normalized distribution of these points.

B. Generic CLME implementation

The CLME implementation is very similar to that of [17], where the authors showed that using acceleration signals to estimate position and velocity was of little interest. Therefore, we also decided to use only the position and velocity signals of the known leg to build the estimate. Furthermore, only hip and knee signals are used and not ankle ones, with the aim of keeping requirements for body instrumentation as low as possible, given our target application.

Data from both the known and unknown joints are required to compute the gains of CLME. Using data from the same user for both learning and estimation leads to an individualized CLME, i.e. with user-dependent gains $\boldsymbol{A}$ and $\boldsymbol{b}$. This yields the optimal CLME that can be designed for a given individual and task. However it is not always possible to have access to these data for each and every user. For instance, no data exist for the unknown joint kinematics of an individual with an amputation.

On the other hand, it is possible to use generic gains for CLME, providing a kind of "one-size-fits-all" estimator. This degrades individual estimations but removes the need for learning data for each user. To compute these generic gains, matrix $\boldsymbol{A}$ (7) and $\boldsymbol{b}$ (8) are averaged over all available trials. A representation of the distribution of the best individual gains, along with their mean value, is shown in Fig. 3. Note that the $\boldsymbol{C}$ matrix is displayed in Fig. 3 instead of the $\boldsymbol{A}$ matrix, as it captures normalized gains. As pictured in Fig. 3, each indiviual gain is distributed in signal-dependent dense clusters. This suggests that averaging may be a valid approach, at least when it is not possible to compute individualized gains.

For the used datasets, numerical values for $\bar{\boldsymbol{A}}$ and $\bar{\boldsymbol{b}}$ are the following:

$$\bar{\boldsymbol{A}} = \begin{pmatrix} -0.987 & -0.063\,\text{s} & -0.439 & 0.003\,\text{s} \\ 2.47\,\text{s}^{-1} & -1.15 & -1.79\,\text{s}^{-1} & -0.473 \end{pmatrix} \tag{25}$$

$$\bar{\boldsymbol{b}} = \begin{pmatrix} -4.95\,\text{deg} \\ -63.3\,\text{deg}\,\text{s}^{-1} \end{pmatrix} \tag{26}$$

The Kalman gain matrix is also averaged over all trials, and

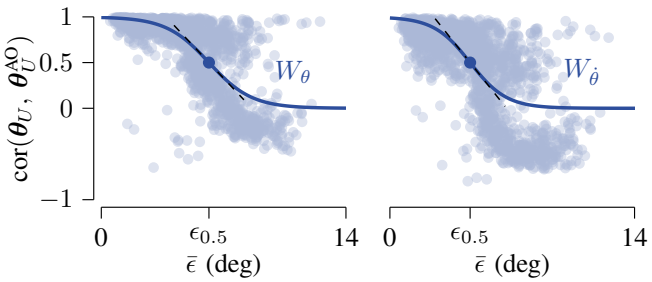

Fig. 4. Correlation between the AO-based estimation and ground-truth signals from the dataset, as a function of the time-averaged AO error $\bar\epsilon$, for the position (left) and velocity (right) signals. Each dot represents one walking cycle for the datasets. The solid lines represent the best possible fit of the weighting function (23), eventually used as weight given to the AO-based estimation. The dashed line captures the slope of the logistic function at $(\epsilon_{0.5}, 0.5)$.

we obtained the following optimal gains:

$$\bar{\boldsymbol{K}} = \begin{pmatrix} 0.049 & 0.004\,\mathrm{s} \\ 0.179\,\mathrm{s}^{-1} & 0.446 \end{pmatrix} \tag{27}$$

C. AO implementation

AO parameters were selected as follows: $N = 3$, $\tau_\alpha = \tau_\omega = 3\,\mathrm{s}$. At the beginning of each trial, the initial parameters of AO were set to the following values: $\alpha_0 = \alpha_i = 1\,\mathrm{deg}$, $\omega = 5\,\mathrm{rad\,s^{-1}}$ and $\phi_i = 0\,\mathrm{rad}$.

A useful pragmatic addition to the generic AO is to prevent the learned frequency ω to go below a certain threshold. This facilitates convergence during steady-state locomotion. Here, we set a threshold to 0.3 Hz, i.e. well below a typical walking frequency.

D. Merging function

In the fused estimator, a window size n_ϵ = 100 was used, which corresponds to a time frame of 0.5 s, given the signal sampling rate. The parameters of the logistic function (23), i.e. λ and $\epsilon_{0.5}$, were fitted using values from the whole datasets. For each cycle of each trial, the correlation between the AO-based estimation and the actual signal was computed as a function of the time-averaged AO error $\bar\epsilon$. The logistic function was then fitted to this data cloud using a least-squares method (Fig. 4).

Note that the value of the correlation may be negative (when the AO-based estimate is poor), but not the logistic function. This forces the logistic function to remain close to 0 for negative correlations. This behavior is desired when the correlation is close to 0 or negative, CLME should be preferred over AO. The values for the best-fit parameters are: $\lambda = 0.82$ and $\epsilon_{0.5} = 6.2\,\mathrm{deg}$ for the position estimate, and $\lambda = 0.96$ and $\epsilon_{0.5} = 4.6\,\mathrm{deg}$ for the velocity estimate. Note that the transition from CLME to AO is steeper for velocity estimation and occurs for a smaller value of ϵ_{MA}.

VI. Kinematic estimation results

Fig. 5 provides a typical estimation result obtained with CLME, using both individualized and generic gains. The individualized CLME produces a good estimation for the

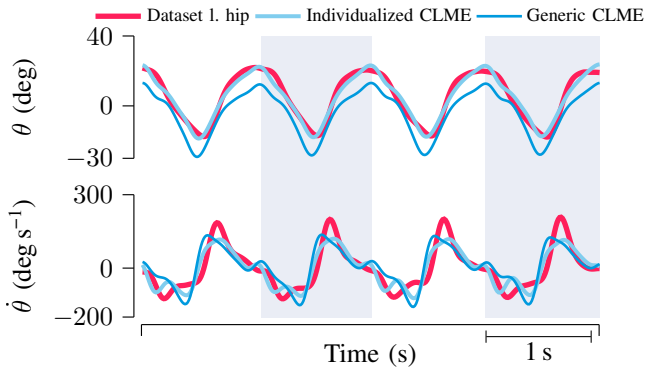

Fig. 5. Time evolution of the left hip angular position (top) and velocity (bottom) from subject 08 walking at $1.2\,\mathrm{m\,s^{-1}}$ (first four cycles). Red lines are taken from [26], light blue lines are the estimates from the individualized CLME and dark blue lines from the generic CLME. Different shades of grey in the background separate successive cycles.

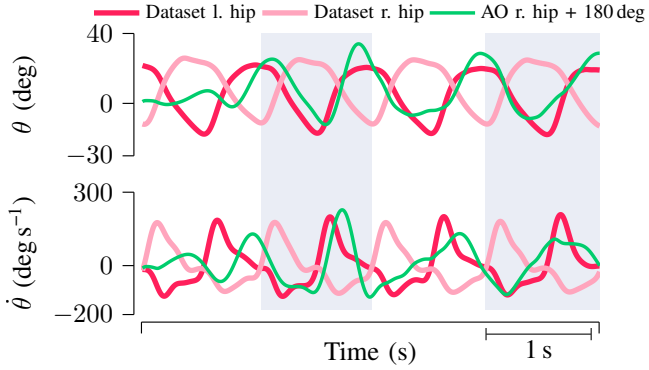

Fig. 6. Time evolution of both hips angular position (top) and velocity (bottom) from subject 08 walking at $1.2\,\mathrm{m\,s^{-1}}$ (first four cycles). Red lines are taken from [26], green lines are estimations from AO. Different shades of grey in the background separate successive cycles.

position. It is less performant for velocity as it cannot capture all signal variations. The generic CLME performs similarly well, but with a significant offset in its position estimation.

The same trial is used as a typical trial for AO (Fig. 6). It clearly shows that AO need time to converge to their best estimate, since their quality improves over time. In fact, AO cannot estimate the left leg position well in the first cycle. During the following cycles, the shape and amplitude of the signal converge to those of the actual signals. The estimation convergence is similar for position and velocity.

An example of the fused estimator is depicted in Fig. 7. It is compared to the CLME- and AO-based estiamtors for the same trial as above. Initially, the fused estimator follows the CLME estimation. As ϵ_{MA} decreases, the weight given to AO, W, increases. The AO contributions are not the same for position and velocity, with velocity using more of the CLME estimation. Importantly, the error of the fused estimator is never larger than the largest error of either the CLME- or AO-only estimates. This highlights the interest of the proposed fusion technique, which exploits both approaches during their most favorable epochs.

Finally, we performed a global analysis of all trials com-

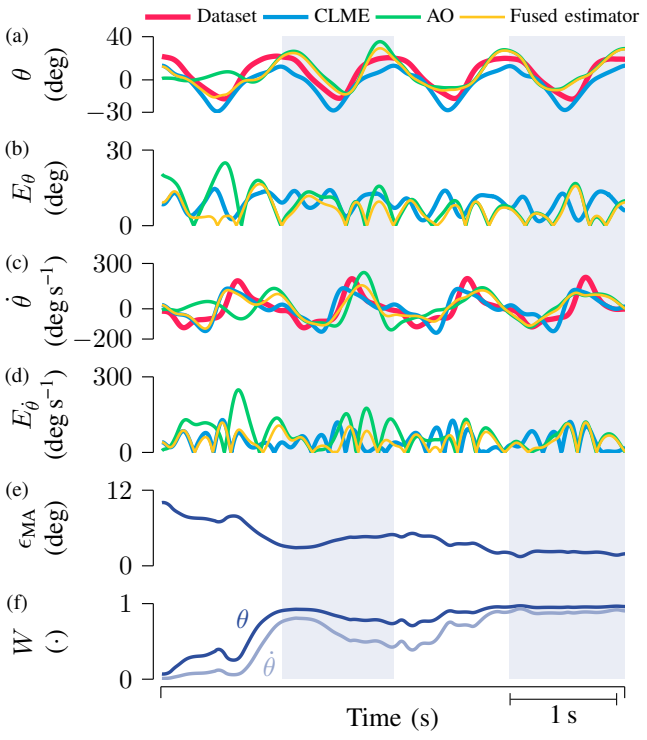

Fig. 7. Time evolution of left hip angular position (a) and velocity (c) from subject 08 walking at 1.2 m s^{-1} (first four cycles). The different lines represent actual data from [26] (red), estimation from CLME after Kalman filter (blue), estimation from AO (green), and estimation from fused estimator (yellow). The position and velocity errors are given in panels (b) and (d), respectively. The evolution of the window-averaged mean error of the AO is given in panel (e), and the corresponding weights of AO in panel (f). Different shades of grey in the background separate successive cycles.

paring the correlation between each of the three estimators (CLME only, AO only, fused) over each cycle and the actual kinematic signals from the whole dataset (Fig. 8). We decided to focus on the first five cycles of each trial, as this is the epoch where the transition between both estimators is most valuable. As expected, CLME provides consistent estimates across cycles for both position and velocity, given that it is time-invariant. Also, the position correlation is higher than the velocity correlation, i.e. about 0.81 for position as compared to 0.14 for velocity. AO obey a dynamic learning trend: their performance is poor during the first cycle, and improves together with their convergence (correlation of about 0.30 in position, and even negative in velocity). They eventually reach a correlation of 0.96 in position and 0.86 in velocity, indicating that they provide a high quality estimate after convergence. As captured by the inter-trial standard deviation, the variability of the AO-based estimate also decreases over time. This variability is equal to 0.28 for the first cycle, and decreases to 0.03 for the fifth one. The fused estimator starts with a performance close to the CLME estimator, and then shifts towards the AO. This holds for both mean and standard deviation.

VII. Conclusion and Discussion

This paper presents a novel method to predict the kinematics of missing leg joint(s) based on corresponding kinematic

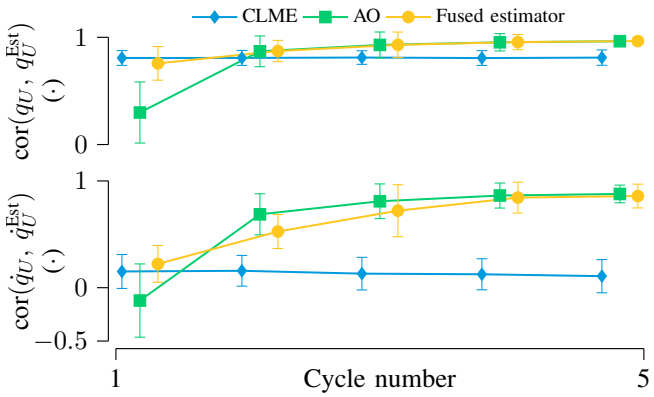

Fig. 8. Correlation between the ground-truth kinematic signals from the datasets and the corresponding estimation provided by the three estimators: CLME only, AO only, and fused one. Values are given for the first five cycles of each trials. Error bars capture the inter-trials standard deviation.

signals measured on the other leg. The method is designed for both steady-state walking and task transitions, and is based on two estimators of kinematic signals: CLME, a correlation-based approach that works during both transients and steady-state locomotion, and AO, which exploits the rhythmicity of the task and therefore works only during steady-state epochs. First, both methods were presented, and then the fusion approach was explained. We applied the fused estimator to estimate hip kinematic signals from two different datasets. The parameters of the different estimators were computed in a way that they could be used for a generalized population, although this brought some issues for the CLME-based estimation, especially with respect to the position offset. As expected, our new method takes the best of both individual approaches, favoring CLME when AO have not yet converged, and AO otherwise.

We observed that CLME is not robust to position offset. This is expected since its gains are computed on normalized data. Note that this does not degrade the performance metric shown in Fig. 8, i.e. correlation, since it is not sensitive to offset. However, poor offset estimation would be critical in an actual application, such as controlling an orthosis or prosthesis. In our future work, we will investigate the possibility of using the offset estimated by AO, i.e. the state variable α_0, to mitigate this error in the CLME-based estimator, even when AO have not yet converged. Indeed, preliminary results suggest that α_0 converges faster than the other AO state variables.

In the present paper, the performance of our estimator is evaluated only during steady-state walking. However, our method is also designed to handle sharp transients as well. During transitions, e.g. between standing still and walking, we would expect CLME to quickly supersede AO, since the AO error would increase rapidly. Other datasets include such transitions (e.g. [28]) and could be used to assess our method. Preliminary results indicate a good correlation between the CLME-based estimation and the hip signal during such transitions, as well as for other transitions, such as from

walking to standing and between different walking speeds. The correlation analysis showed that the contribution of the CLME to our fused estimator is larger in the first cycle, where the convergence of the AO is low. Effective control of powered devices requires accurate estimation for each cycle, including the very first one, thus highlighting the necessary contribution of CLME in our method, even if limited to few cycles. Moreover, we expect that locomotion in an ecological environment – i.e. out of the treadmill – would contain much more walking speed variations and transitions between tasks, thus providing a larger role to the CLME.

Our newly developed method is well suited for real-time applications, since neither CLME nor AO require large computational power. Instead, both rely on a minimal amount of code. Furthermore, input signals can be acquired in real-time, for example using IMUs.

Our future work will focus in implementing the proposed estimator for the control of our designed hip prosthesis [11] and evaluating its performance in generating reference signals for this device.

PLEXUS Hand: Lightweight Four-Motor Prosthetic Hand Enabling Precision–Lateral Dexterous Manipulation

Yuki Kuroda[1], Tomoya Takahashi[1], Cristian C. Beltran-Hernandez[1], Masashi Hamaya[1] and Kazutoshi Tanaka[1]

***Abstract*— Electric prosthetic hands should be lightweight to decrease the burden on the user, shaped like human hands for cosmetic purposes, and have motors inside to protect them from damage and dirt. In addition to the ability to perform daily activities, these features are essential for everyday use of the hand. In-hand manipulation is necessary to perform daily activities such as transitioning between different postures, particularly through rotational movements, such as reorienting cards before slot insertion and operating tools such as screwdrivers. However, currently used electric prosthetic hands only achieve static grasp postures, and existing manipulation approaches require either many motors, which makes the prosthesis heavy for daily use in the hand, or complex mechanisms that demand a large internal space and force external motor placement, complicating attachment and exposing the components to damage. Alternatively, we combine a single-axis thumb and optimized thumb positioning to achieve basic posture and in-hand manipulation, that is, the reorientation between precision and lateral grasps, using only four motors in a lightweight (311 g) prosthetic hand. Experimental validation using primitive objects of various widths (5–30 mm) and shapes (cylinders and prisms) resulted in success rates of 90–100% for reorientation tasks. The hand performed seal stamping and USB device insertion, as well as rotation to operate a screwdriver.**

I. INTRODUCTION

Electric prosthetic hands are used by people who cannot perform hand functions because of congenital conditions or acquired causes such as accidents. These prostheses should be shaped similar to a biological human hand for cosmetic purposes, be lightweight (maximum acceptable weight is around 500 g [1]) to decrease the burden on the user, have motors inside the hand due to protect them from damage and dirt, and be capable of performing activities of daily living (ADLs) [2], [3], [4]. ADLs include fundamental tasks necessary for daily self-care, including housework and communication, which involve grasping and manipulating various objects such as tableware, writing implements, cash, and tools. As currently used prosthetic hands can only provide grasping functions [5], [6], [7], we focus on incorporating in-hand manipulation capabilities to move objects between different grasping postures.

As the complex movements for in-hand manipulation require multiple motors, maintaining a lightweight design for daily use is challenging. A modular prosthetic limb is a sophisticated prosthetic hand that can perform in-hand manipulation [8]. Although its 10 motors afford this capability, its weight of 1315 g makes it too heavy for daily use.

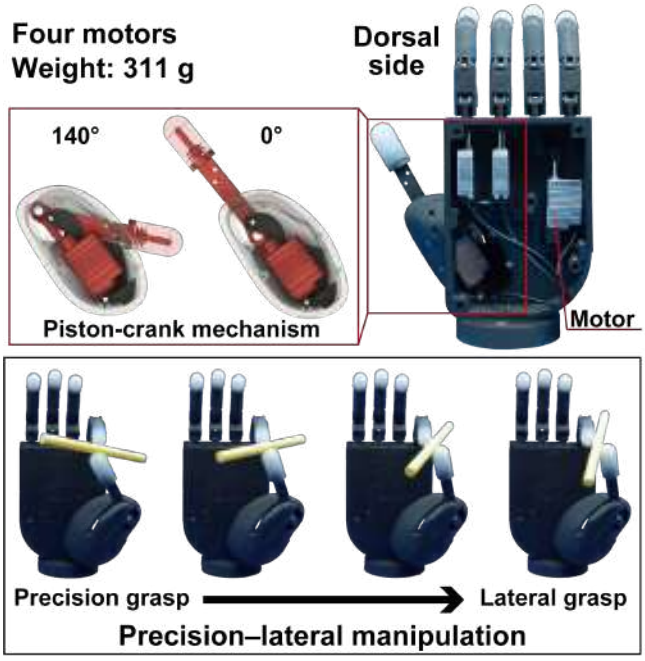

Fig. 1: Configuration of PLEXUS hand and images of precision–lateral manipulation.

In this study, we develop an electric prosthetic hand that can perform in-hand manipulation and basic hand postures with a minimal number of motors (NoM) for a lightweight design. Our approach enables rotational movements between different grasp types. To this end, we focus on the transition between precision and lateral grasps, which we refer to as precision–lateral manipulation, as illustrated in Fig. 1. This rotational capability enables performing essential daily tasks (e.g., reorienting objects such as cards before slot insertion and operating screwdrivers and other tools that require rotational manipulation) while minimizing compensatory movements.

We combined a single-axis thumb design at the carpometacarpal (CM) joint with optimized positioning. Liu et al. [9] reported that, although the human thumb is anatomically capable of movement along more than five axes, it primarily rotates around a single axis at the CM joint during daily grasping tasks, particularly during distal grasping, such as when using fingertips. Inspired by these findings, we propose a prosthetic hand design that enables in-hand manipulation in addition to basic hand postures by optimizing the position of the CM joint rotation axis in the thumb. This optimization maximizes the range of object widths for precision–lateral manipulation while ensuring the

capability of basic hand postures.

We evaluated the performance of the prosthetic hand by testing the rotation of cylinders and square prisms with widths ranging from 5 to 30 mm and other objects in daily life. The results indicated high success rates for rotating cylinders, prisms, cards, personal seals, spoons, and screwdrivers. Practical applications included using personal seals, inserting USB devices, and turning screws using a screwdriver, suggesting the high potential effectiveness of the proposed prosthetic hand in ADLs.

The main contribution of this study is the development of a lightweight (311 g) prosthetic hand that enables both basic hand postures and precision–lateral manipulation using only four motors.

II. RELATED WORK

Two categories of hands, that is, practical electric prosthetic hands and anthropomorphic robotic hands capable of in-hand manipulation, are discussed. Table I summarizes related work. We analyze the characteristics of available solutions based on existing studies and demonstrations focusing on total NoM, NoM in the thumb, weight, motor placement, capabilities in five basic hand postures (i.e., power, precision, tripod, and lateral grasps, as well as index pointing) [22], [23] and manipulation. Table I defines slight rolling and repositioning as minimal in-hand manipulations that do not enable transitions between static grasp postures.

A. Anthropomorphic Robotic Hands with the Capability of Daily Life In-Hand Manipulation

In-hand manipulation can be achieved through two approaches: high-NoM designs (e.g., 13 motors [18], 16 motors [19], and 20 motors [17]) and mechanical solutions with fewer motors. Notable examples of the latter include EthoHand (seven motors) [20], which employs a tendon-driven ball joint for the thumb to reproduce human-like movements, and the design by Kontoudis et al., which achieves thumb abduction, adduction, and flexion using a tendon-driven differential mechanism with only two motors [21]. Although these mechanical solutions achieve in-hand manipulation with fewer actuators, their mechanisms occupy space on the palm, impeding internal motor placement, which is crucial to ensure durability and space efficiency when attached to the residual limb of the user [3]. Consequently, existing solutions either became too heavy (exceeding 1500 g) because of the large NoM or required palm space for their mechanisms. Our prosthetic hand addresses these limitations with a four-motor design weighing 311 g, which can perform five basic postures and in-hand manipulation while maintaining all mechanisms inside the hand.

B. Lightweight Prosthetic Hand with Low NoM

A modular prosthetic limb (10 motors) was developed as a prosthetic hand and can perform object rotation. However, its large NoM makes it too heavy (1315 g) for typical prosthesis users [8]. To date, several practical electrical prosthetic hands have been proposed. Among them, the two widely adopted electric prosthetic hands in clinical use are bebionic (five motors) [6] and i-Limb (six motors) [7]. Most practical hands weigh approximately 500 g, which is the minimum weight of prosthetic hands mentioned in previous studies [1]. However, further weight reduction is necessary to minimize the burden on the users.

Recently, electric prosthetic hands that incorporate adaptive grasp mechanisms (e.g., differential mechanisms) have been developed for achieving a lighter weight while enabling diverse grasping motions with a low NoM. The TUAT/Karlsruhe humanoid hand, which combines compound four-bar linkages with differential mechanisms, achieves four basic hand postures and all 14 types of Kamakura's grasp taxonomy with only one motor [12]. Several other studies have achieved coordinated finger movements using differential mechanisms, enabling various hand postures with minimal actuation [13]–[16].

Although the abovementioned developments represent a significant progress in static grasping, technical challenges

TABLE II: Parameters of PLEXUS Hand.

Grasp range requirements	
Radius for precision grasp [R_{Gmin}, R_{Gmax}]	[0, 60] mm
Radius for lateral grasp [R_{Gmin}, R_{Gmax}]	[0, 30] mm
Radius for tripod grasp [R_{Tmin}, R_{Tmax}]	[10, 80] mm
Width for in-hand manipulation [W_{min}, W_{max}]	[0, 30] mm
Common geometric parameters	
δ_m (maximum fingertip deformation)	4.87 mm
θ_{min} (minimum grasp angle)	110°
α_{perm} (permitted contact angle)	30°

related to in-hand manipulation persist because the mechanically linked adaptive mechanism that connects all finger movements is incompatible with the independent finger control required for object manipulation [24]. Existing advanced anthropomorphic hands require from two to four motors [20], [21] for thumb rotation and two motors [17], [18], [19] for each non-thumb finger for translational operations, thereby making implementation challenging in prosthetic hands that must be lightweight and have internal actuators. In contrast, our hand achieves in-hand manipulation with a single motor for the thumb by combining a single-axis thumb design at the CM joint with optimized positioning.

III. HAND DESIGN OPTIMIZATION

A. Design Requirements

1) Grasping Requirements: Cipriani et al. claimed that a hand should be able to perform five basic postures: power, precision, tripod, and lateral grasps, as well as index pointing [22], [23]. The range of graspable object widths is based on the inter-fingertip distance, and only fingertip-based grasping postures (i.e., precision, tripod, and lateral grasps) are considered because palm-based grasping (i.e., power grasp) has uncertain contact positions, hindering range definition. Unlike human-enveloping grasps, prosthetic hands achieve a power grasp by adding palm contact to fingertip-based grasping. Therefore, satisfying the geometric requirements for precision grasping ensures power grasping. Based on daily object grasping analysis [25] and considering contact position uncertainty, we set the grasp range to approximately three times the average grasping width, as indicated in Table II.

2) In-Hand Manipulation Requirements: The hand must handle flat and curved surfaces to accommodate the manipulation of objects with different geometries. Based on daily object-grasping analysis studies [25], the average object width for lateral and precision grasps is approximately 20 mm. We set the requirement to 30 mm for providing a margin above this average to perform in-hand manipulation.

3) Implementation Requirements: Actuators should be placed inside the hand for durability and space limitations [3]. In addition, actuation must enable independent control of the thumb, index, and middle fingers for basic postures, with a synergistic ring–little finger actuation for achieving a power grasp using a minimal NoM. The selected prosthetic hand dimensions are based on the 50th percentile of the Japanese anthropometric data [26]. Moreover, the prosthesis employs actuators equivalent to those in clinically validated hands [10], [11] to ensure sufficient grasping force, and they should achieve a significantly lower weight (under 350 g, excluding electronics) than common electric prostheses [6], [7].

Algorithm 1 Optimize thumb configuration for grasping and manipulation

Require: Four-finger configuration, search ranges, grasp constraints, manipulation parameters
Ensure: Optimal thumb configuration ω_{opt} (x, y, z, roll, pitch, yaw)
function FINDOPTIMALTHUMBCONFIGURATION
  $\Omega_{valid} \leftarrow \emptyset$ ▷ Valid configurations
  for each thumb configuration ω in search space **do**
    if ISVALIDGRASP(ω) **then**
      $\Omega_{valid} \leftarrow \Omega_{valid} \cup \{\omega\}$
    end if
  end for
  $\omega_{opt} \leftarrow$ null, $w_{max} \leftarrow 0$ ▷ Best configuration and its range
  for each $\omega \in \Omega_{valid}$ **do**
    $W(\omega) \leftarrow$ CALCULATEMANIPULATIONRANGE(ω)
    if $|W(\omega)| > w_{max}$ **then**
      $\omega_{opt} \leftarrow \omega$, $w_{max} \leftarrow |W(\omega)|$
    end if
  end for
  return ω_{opt}
end function

B. Optimization Method

We aim to maximize the range of precision–lateral manipulation through optimal thumb positioning to achieve better manipulation capabilities for common objects while satisfying the requirements described in Sec. III-A. A manual search is impractical because even small position errors can lead to manipulation failures. This challenge explains why conventional prosthetic hands, in which thumb positioning is predominantly based on anatomical structures [27], struggle with precision–lateral manipulation. Hence, we employ optimization to determine the position using the parameters defined in Table II.

We propose a two-stage optimization process to find the optimal thumb axis configuration, ω_{opt} (x, y, z, roll, pitch, and yaw). First, we identify configurations that satisfy all grasp requirements to reduce the search space and then select the configuration that enables the largest range of object widths for precision–lateral manipulation.

For simplicity, we model the fingertips and grasped objects as spheres. The grasped object is assumed to be sufficiently light such that its mass can be neglected. Let $\boldsymbol{c}_{\text{T}}$, $\boldsymbol{c}_{\text{I}}$, and $\boldsymbol{c}_{\text{M}}$ represent the position vectors of the thumb, index, and middle fingers, respectively, and $\boldsymbol{c}_{\text{O}}$ represent the position of the grasped object. Their radii are r_{T}, r_{I}, r_{M}, and R.

The following sections describe the grasp requirements and manipulation range calculations implemented in ISVALIDGRASP and CALCULATEMANIPULATIONRANGE. The complete optimization process is summarized in Algorithm 1.

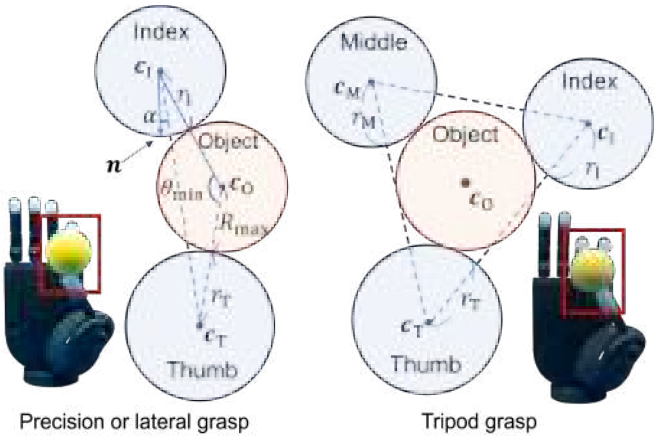

Fig. 2: Geometric definitions of fingers and object to calculate grasp requirements. In precision and lateral grasps, the orientation of reference vector $\boldsymbol{n}$ differs. This vector defines the grasping direction of the object.

1) Grasp Validation: Function IsValidGrasp in Algorithm 1 evaluates whether a given thumb configuration satisfies the requirements for precision, lateral, and tripod grasps. For thumb configuration ω to be valid, all three grasp types must be achievable within their respective object size ranges.

For precision and lateral grasps, we consider the relative positions between thumb position $\boldsymbol{c}_{\mathrm{T}}(\omega)$ determined by configuration parameters ω and index finger position $\boldsymbol{c}_{\mathrm{I}}$. A configuration is considered valid if it satisfies the following geometric range requirements:

- The maximum graspable distance, R_{max}, calculated as shown in Fig. 2, must satisfy $R_{\mathrm{max}} \geq R_{\mathrm{Gmax}}$. This limit is determined by θ_{min} (illustrated in Fig. 2), which represents the minimum angle between vectors $\boldsymbol{c}_{\mathrm{T}}(\omega) - \boldsymbol{c}_{\mathrm{O}}$ and $\boldsymbol{c}_{\mathrm{I}} - \boldsymbol{c}_{\mathrm{O}}$ required for stable grasping considering friction.
- The minimum distance between fingertips, R_{min}, occurs when $\boldsymbol{c}_{\mathrm{T}}(\omega)$, $\boldsymbol{c}_{\mathrm{I}}$, and $\boldsymbol{c}_{\mathrm{O}}$ are colinear, and it must satisfy $R_{\mathrm{min}} \leq R_{\mathrm{Gmin}}$.

Grasping is established when the following conditions are satisfied:

- As illustrated in Fig. 2, angle α between reference vector $\boldsymbol{n}$ (normal to the optimal contact surface of the index finger) and the grasp direction must satisfy $-\alpha_{\mathrm{perm}} \leq \alpha \leq \alpha_{\mathrm{perm}}$, where α_{perm} is empirically determined due to the lack of standardized angular definitions for grasp types.
- The force-applying digit (i.e., index finger for precision grasp and thumb for lateral grasp) must maintain its motion direction at an angle less than 45° relative to vector $\boldsymbol{c}_{\mathrm{T}}(\omega) - \boldsymbol{c}_{\mathrm{I}}$ and $\boldsymbol{c}_{\mathrm{I}} - \boldsymbol{c}_{\mathrm{T}}(\omega)$, respectively, to maintain the appropriate force direction.

For the tripod grasp, we evaluate the triangle formed by the thumb ($\boldsymbol{c}_{\mathrm{T}}(\omega)$), index finger ($\boldsymbol{c}_{\mathrm{I}}$), and middle finger ($\boldsymbol{c}_{\mathrm{M}}$). The object center, $\boldsymbol{c}_{\mathrm{O}}$, must lie within this triangle, and the achievable grasp radii, $[R_{\mathrm{min}}, R_{\mathrm{max}}]$, must encompass the specified range ($R_{\mathrm{min}} \leq R_{\mathrm{Tmin}}$ and $R_{\mathrm{max}} \geq R_{\mathrm{Tmax}}$).

2) Manipulation Range Analysis: Function CalculateManipulationRange analyzes the precision–lateral transition path where the thumb moves from the lateral to the precision grasp position to determine the range of object sizes that can be manipulated. Let $i \in I$ and $j \in J$ be discretized steps along the motion ranges of the index finger and thumb, respectively. For each index finger position $\boldsymbol{c}_{\mathrm{I}}(i)$ and corresponding thumb position $\boldsymbol{c}_{\mathrm{T}}(\omega, j)$ determined by configuration ω, we identify two critical points: $j_{i,\mathrm{L}} \in J$ (i.e., the last position allowing lateral grasp, Sec. III-B.1) and $j_{i,\mathrm{P}} \in J$ (i.e., the first position permitting precision grasp, Sec. III-B.1). The manipulation interval is $J_m = \{j \in J \mid j_{i,\mathrm{L}} \leq j \leq j_{i,\mathrm{P}}\}$.

For each index position i, the maximum and minimum distances during the transition are calculated as $d_{\mathrm{max}}(\omega, i) = \max_{j \in J_m} |\boldsymbol{c}_{\mathrm{I}}(i) - \boldsymbol{c}_{\mathrm{T}}(\omega, j)|$ and $d_{\mathrm{min}}(\omega, i) = \min_{j \in J_m} |\boldsymbol{c}_{\mathrm{I}}(i) - \boldsymbol{c}_{\mathrm{T}}(\omega, j)|$.

The range of manipulatable object widths $W_i(\omega)$ at each index position i for thumb configuration ω is defined as

$$W_i(\omega) = [d_{\mathrm{max}}(\omega, i) - (r_{\mathrm{T}} + r_{\mathrm{I}}), d_{\mathrm{min}}(\omega, i) - (r_{\mathrm{T}} + r_{\mathrm{I}}) + 2\delta_m], \tag{1}$$

where δ_m represents the allowable deformation of the flexible fingertip, calculated as $\delta_m = \sqrt{F/(\pi E)}$ [28] with an assumed pinch force $F = 10$ N based on a prosthetic hand using equivalent actuators [10], and Young's modulus E given in Table III. The lower bound is determined by subtracting the fingertip radii from the maximum distance, whereas the upper bound considers the additional grasp range enabled by fingertip deformation.

The overall manipulation range, $W(\omega)$, for the configuration is calculated as the intersection of the ranges across the set of all index finger positions I.

$$W(\omega) = \bigcap_{i \in I} W_i(\omega) \tag{2}$$

This ensures that objects within range $W(\omega)$ can be stably manipulated throughout the precision–lateral transition.

Among all valid thumb configurations Ω_{valid} found by IsValidGrasp, we select optimal configuration ω_{opt} that maximizes the manipulation range.

$$\omega_{\mathrm{opt}} = \arg\max_{\omega \in \Omega_{\mathrm{valid}}} |W(\omega)| \tag{3}$$

IV. PLEXUS Hand

Based on the optimization described in Sec. III, we engineered a prototype of the PLEXUS hand (Precision–Lateral dEXteroUS manipulation hand), incorporating the optimal thumb axis position as determined by our optimization algorithms. The PLEXUS hand achieves both precision–lateral manipulation and the basic hand postures required for prosthetic applications (Fig. 3) while maintaining a simple design with only four motors, including a single motor for the thumb. Table III lists the specifications of the PLEXUS hand and optimization conditions.

The PLEXUS hand features distinct actuation mechanisms for different digit groups. All digits are driven by linear actuators to simplify the control system integration.

Fig. 3: Execution of basic postures using PLEXUS hand. Index pointing was omitted because the index finger can clearly move independently.

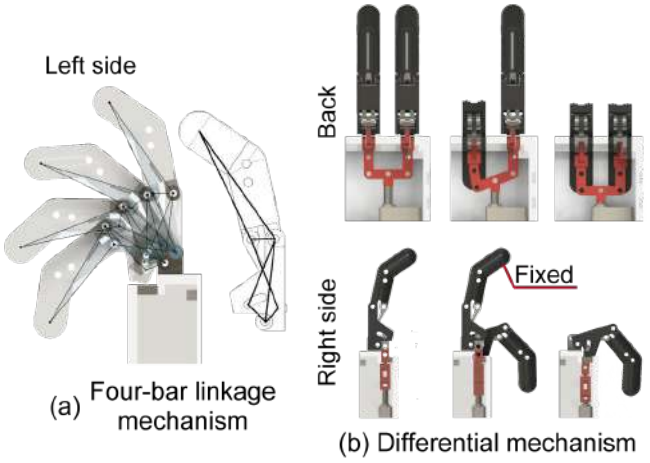

Fig. 4: (a) Actuation and structure of four-bar linkage mechanism. (b) Differential mechanism that distributes motion between the fingers. When one finger is constrained, the displacement is redirected entirely to the unconstrained finger. Without constraints, motion is distributed to both fingers equally.

i) Thumb: Driven by a LAS16-023D linear motor (Beijing Inspire Robots Technology, China) and utilizing a piston–crank mechanism [10] as the simplest solution for linear-to-rotary motion conversion, as shown in Fig. 1.

ii) Index and middle fingers: Actuated via four-bar linkage mechanisms [10], as shown in Fig. 4(a). Each mechanism transforms the linear motion of LAS10-023D actuators (Beijing Inspire Robots Technology) into natural curling movements, enabling multiple contact points with objects for stable grasping.

iii) Ring and little fingers: Sharing a single LAS10-023D actuator through a differential mechanism [13], as shown in Fig. 4(b). The differential mechanism automatically distributes the displacement of the actuator between both fingers. When one finger encounters an object, the other can continue to move, enabling adaptive grasping while reducing the number of actuators needed.

TABLE III: Specifications of PLEXUS hand.

Physical specifications	
Dimensions (W × D × H)	130 × 30 × 210 mm
Weight	311 g
NoM (thumb)	4 (1)
Main material	Nylon (3D printed)
Fingertip silicone	
Type	TSG-E10 (TANAC, Japan)
Young's modulus	134.3 kPa [29]
Optimization	
Optimization method	Grid search
Number of axis positions explored	19,200,000

V. EXPERIMENT AND RESULTS

We conducted a quantitative evaluation using primitive and common objects to verify the capability of the proposed prosthetic hand to perform precision–lateral manipulation across a range of object sizes and shapes and a preliminary demonstration of practical applications for validating the effectiveness of the hand in real-world scenarios.

A. Experiment 1: Quantitative Evaluation with Primitive and Common Objects

1) Objects Used: The following two object categories were used for Experiment 1:

- **Primitive objects:** Square prisms and cylinders with height of 120 mm. Both types varied in width/diameter from 5–30 mm in 5 mm increments, totaling six variations per object. These objects allowed us to evaluate performance on flat and curved surfaces.
- **Common objects of daily living:** Business card, light pen, heavy pen, seal stamp, spoon, and precision screwdriver [30]. These objects were chosen as representative examples of objects requiring precision–lateral manipulation in everyday situations.

2) Experimental Procedure: Sec. III-B.2 determines the optimization target range between the thumb positions corresponding to trajectory elements $j_{i,\mathrm{P}}$ and $j_{i,\mathrm{L}}$ for object manipulation. We implemented the following setup to experimentally validate the manipulation capability in this range. Considering mechanical errors and calibration constraints,

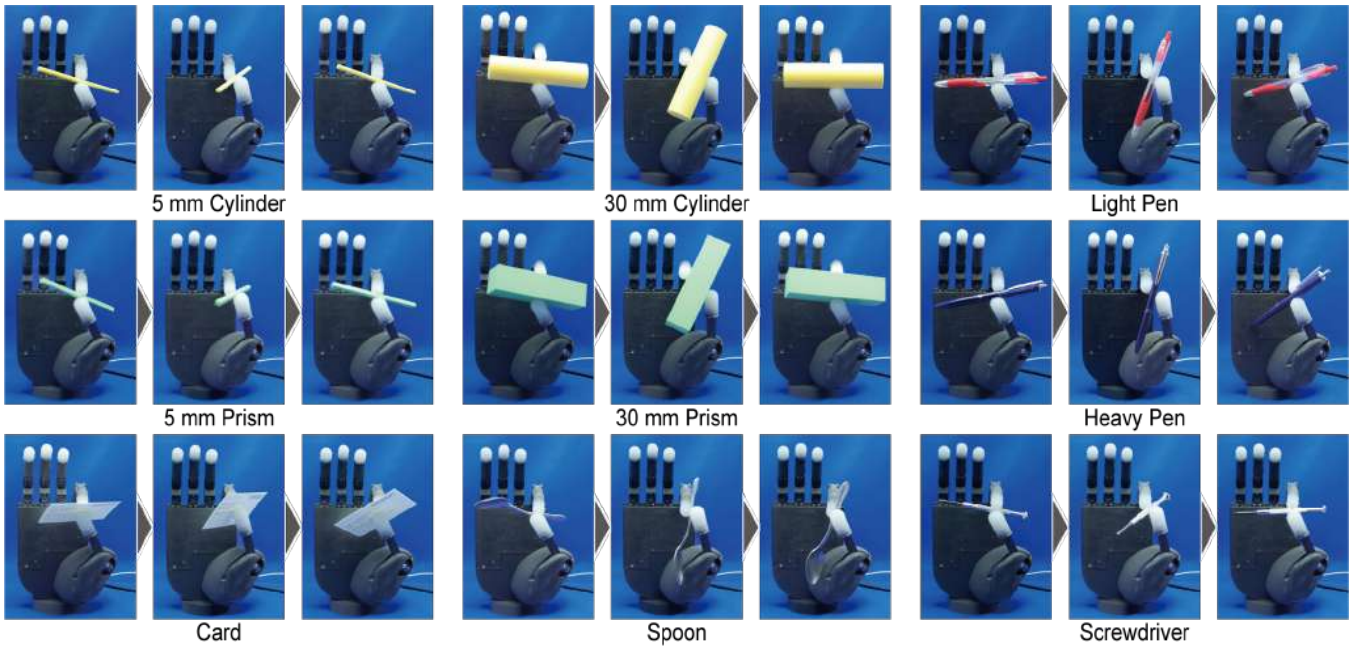

Fig. 5: Precision–lateral manipulation experiments for each object.

we prioritized achieving the target position for lateral grasp (corresponding to $j_{i,\mathrm{L}}$) because precise positioning is crucial owing to its dependence on geometric constraints. For precision grasping, we adopted an initial position with the thumb directly below the index finger. The index finger position was adjusted for each object to enable secure holding in a precision grasp and remained fixed throughout manipulation, while only the thumb moved. This setup resulted in a validation over an extended range, including the position corresponding to $j_{i,\mathrm{P}}$.

For each object, we performed the following steps 10 times:

i) The object was grasped near its center using a precision grasp, and its stability was manually confirmed by slightly moving the object.
ii) The manipulation from precision to lateral grasp was executed over 2.5 s, with the thumb moving to the position corresponding to $j_{i,\mathrm{L}}$ optimized for each object width.
iii) The grasp was maintained at the lateral position for 2 s to confirm stability.
iv) The manipulation from lateral back to precision grasp was executed over 2.5 s.

Manipulation was considered successful if the object was grasped during both transitions.

3) Results: The success rates for precision–lateral manipulation are listed in Table IV. Images of the experiment are shown in Fig. 5.

B. Experiment 2: Demonstration of Practical Applications

1) Experimental Setup: Although comprehensive testing with users wearing a prosthetic hand remains a key objective for future work, we conducted preliminary demonstrations in three practical scenarios to illustrate the potential real-world applications of our approach and developed prosthesis.

TABLE IV: Success rates for precision–lateral manipulation.

Width (mm)	Primitive type	Weight (g)	Success rate (%)
5	Cylinder	2.79	100
	Square prism	2.49	100
10	Cylinder	5.04	90
	Square prism	6.20	100
15	Cylinder	9.90	100
	Square prism	11.59	100
20	Cylinder	14.58	100
	Square prism	18.03	100
25	Cylinder	20.80	100
	Square prism	24.65	100
30	Cylinder	28.34	100
	Square prism	34.34	100
0.3	Card	1.16	100
10.3	Heavy pen	23.45	60
10.2	Light pen	9.75	50
9.9	Seal	4.68	100
1.7	Spoon	15.48	100
6.2	Screwdriver	21.22	80

i) **Precision screwdriver operation:** This task demonstrated turning screws with a precision screwdriver. The PLEXUS hand lacked the flexibility afforded by a human hand with a flexible palm for stabilization. This hindered steady handling of the screwdriver. Therefore, guides were used to maintain the position of the screwdriver. Developing a flexible palm for better object manipulation will be part of future work.
ii) **Seal (hanko) usage:** We also demonstrated the ability to pick up, manipulate, and apply a seal to a document. This task addressed a common need in Japan, particularly for package receipt confirmation.
iii) **USB device insertion:** Finally, we demonstrated the capability of the prosthetic hand to pick up, manipu-

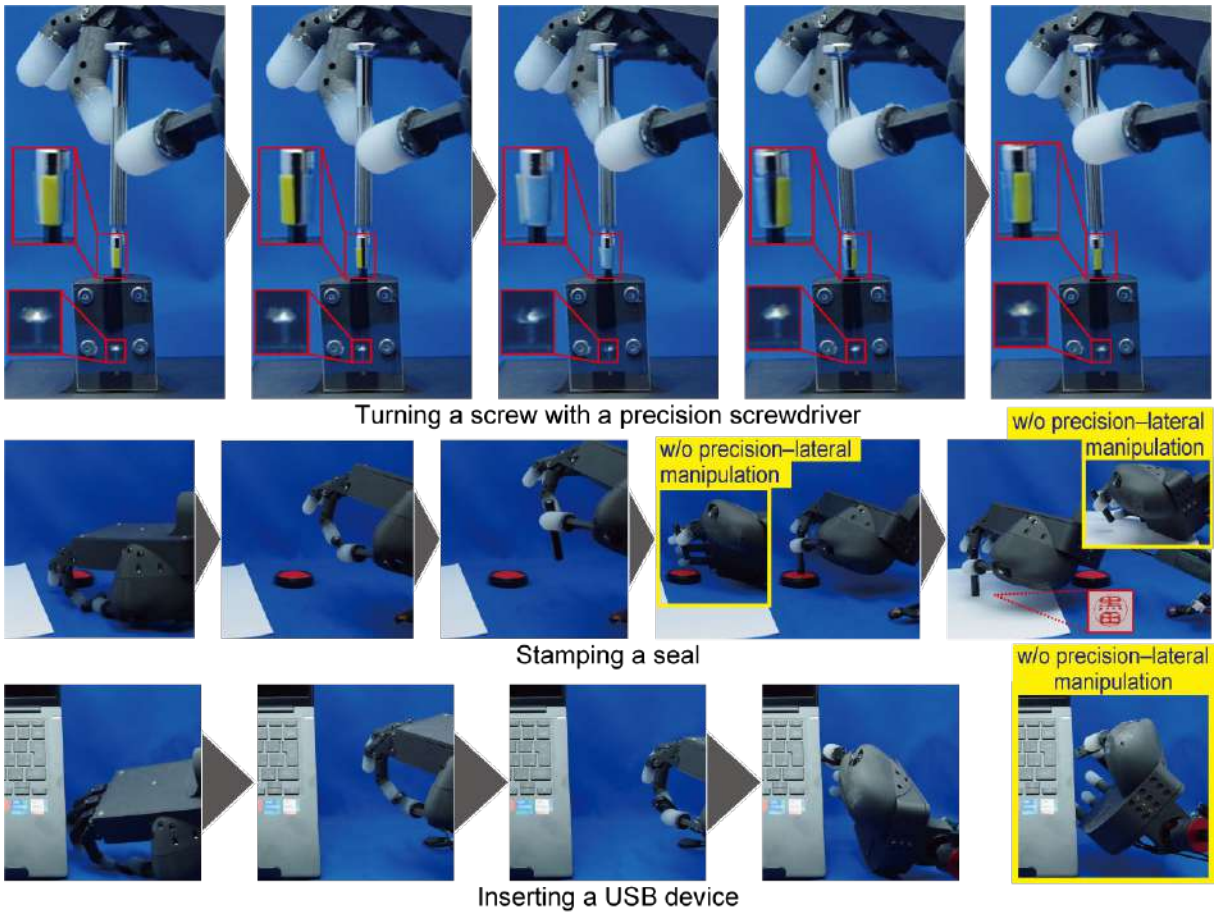

Fig. 6: Precision–lateral manipulation and its applications. Without precision–lateral manipulation (yellow frame), the palm blocks the movement.

late, and insert a USB device into a laptop port.

2) Results: Images of the practical demonstrations are shown in Fig. 6. The "w/o precision–lateral manipulation" condition refers to cases without precision–lateral manipulation, where palmar interference prevented successful task execution.

VI. DISCUSSION

A. Experimental Results

1) Primitive Objects: Experiments with primitive objects generally achieved high success rates. However, narrower objects with smaller contact areas tended to be less stable, particularly cylinders. This instability resulted from the reduced elastic force and friction caused by a low compression of the flexible tissue of the fingertip on small cross-sectional areas.

2) Common Objects of Daily Living: Experiments with common objects of daily living revealed instability when handling heavy items relative to their width and cylindrical shape, such as a pen or screwdriver, making it difficult to secure an adequate contact area. The primary challenge was the insufficient pinch force to manipulate or hold heavy objects. This limitation stemmed from our fixed-finger control approach. Although precision grasps achieved a proper force direction where the thumb trajectory intersected the motion path of the index finger, lateral grasps were limited because the fixed index finger could not be positioned along the motion path of the thumb. Future improvements should involve repositioning the index finger during manipulation, which may require advanced control systems with touch sensors for adaptive adjustments. Furthermore, a spherical finger shape decreased the contact area with cylindrical objects, making finger shape optimization another challenge for future work.

B. Practical Use

Conventional practical prosthetic hands cannot be used to perform rotational movements essential for tasks such as turning screws. Furthermore, they often require non-disabled hands to reposition objects or force users to adopt physically demanding postures [31], [32], [33]. Our developed prosthetic hand may increase the number of achievable ADLs while reducing the burden on the user by enabling in-hand manipulation using only the prosthetic hand.

VII. CONCLUSIONS

We present a novel approach to design a four-motor lightweight electric prosthetic hand that can perform five basic hand postures and precision–lateral manipulation. Our

PLEXUS hand demonstrates the ability to manipulate objects of various widths and common objects of daily living with high success rates. Our study and findings provide insights into improving the performance of electric prosthetic hands, potentially enhancing the quality of life of people with upper limb deficiencies.

Optimization of an exosuit design for elbow and shoulder joints considering comfort and safety

Pierre Garnault[1] Yannick Aoustin[1] Vigen Arakelian[2]

***Abstract*—To ensure comfort and safety in the design of wearable robots, a multi-objective optimization method is defined for shoulder and elbow assistance. This optimization method is evaluated with a simulation platform implemented on Matlab integrating biomechanical features from the software OpenSim. Thus, the interaction forces between skin and cuffs and the metabolic cost could be estimated during design phase. Finally a drinking task trajectory is carried out to validate the efficiency of wearing an exosuit reducing the fatigue by 32%.**

I. Introduction

For assistance and rehabilitation a new type of wearable device called "exosuit" is developed since a decade [1]. These devices are lightweight, with compliant materials and soft actuators like cables or pneumatic actuators. As the motors are no longer located directly at the joints, unlike exoskeletons, this reduces the mass and inertia of the limbs. Another advantage is that there are no rigid links to constrain the movement of the joints [2]. Elbow flexion is not a pure rotation and the revolute joint axis undergoes a slight translation. But a cable driven exosuit raises new issues, in particular how to place these cables and define a suitable path for them. Indeed, the actuators must assist the user during the movement effectively, while complying with safety and comfort objectives, particularly at skin-cuff contact [3]. In literature design optimization algorithms are synthetized considering force distribution, following or ensuring human workspace [2]. Then, energy saving is estimated after prototyping. All these approaches are mechanical without taking into account human with muscles and its contribution during an assisted movement. From this point of view, developing a simulation platform that couples a musculoskeletal model and its exosuit is of great potential. First, Thelen et al, 2003 [4] proposed steps to implement computed muscle control algorithm and simulate human movement. Recently Sambhav et al, 2022 [5] presented a framework to integrate simulation with ©OpenSim and ©Matlab on a very simple model for elbow flexion. In this paper, a simulation platform is set with a full upper limb model using OpenSim biomechanical model and Matlab simulation environment. This platform will be used for two purposes: optimize the cable routing for an active upper limb exosuit considering safety and comfort and estimate metabolic savings offered by the new design. The method is described as follows. A musculoskeletal model is built and an exosuit design is added. A platform, including the model, simulates a daily life task (drinking task), the computed trajectory and the energy gain. Then a multi-objective optimization based on NSGA-II [6] and safety objectives lead to design of cable path. Three cable paths are optimized following three clinical motions: shoulder abduction, shoulder flexion, and elbow flexion.

II. Human in the loop simulation platform

The simulation is implemented in Matlab using OpenSim features. OpenSim [7] is a software developed by Stanford University and commonly used in biomechanical modeling and movement analysis.

A. Musculoskeletal model

The chosen model is 'MoBL-ARMS.osim' updated [8] from Holzbaur et al, 2005 [9]. It is a full upper limb model with seven degrees of freedom (DoF), 50 muscles, ligaments and model of the scapula sliding along the thorax (passive DoF).

To measure the effort, a metabolic probe (*'Umberger2010MuscleMetabolicsProbe'*) derivating from Umberger et al, 2003 [10] is added. Metabolic cost is based on thermodynamic principle where it is the sum of the heat and mechanical work delivered by muscles during contractions:

$$\dot{E} = \dot{B} + \dot{A} + \dot{M} + \dot{S} + \dot{W} \tag{1}$$

Where $\dot{E}$ is the effort, $\dot{B}$ is basal rate to satisfy essential physiological needs (breathing, functioning of vital organs), $\dot{A}$ is the heat produced to activate the muscle, $\dot{M}$ is the heat resulting from maintaining position which appears during tetanic efforts, $\dot{S}$ depends on the speed of contraction $\dot{W}$ is mechanical work rate. These six physical variables involved in (1) are defined in Watt as functions of intern parameters of muscle (mass, density, fiber length...) but also from the twitch fibers ratio. Indeed, there are two types of fibers: fast twitch fibers (FTF) and slow twitch fibers (STF). FTF are recruited for short but intense contractions more energy-consuming than STF used during endurance efforts. By default the ratio is 50/50, but to be consistent in our modeling the ratio is determined for each muscle according to biomechanical literature ([11], [12], [13], [14], [15], [16], [17], and [18]). From these papers, STF or FTF ratio is extracted for all 50 muscles described in our musculoskeletal model. When

a muscle is depicted in several papers, the ratio is the mean of values weighted by the number of samples. These papers do not provide ratio estimations for supinator and brachialis. However estimated values about these missing ratios can be found in [19] on a monkey species *Macaca mulatta*.

Then rigid bodies are added to model user and exosuit. First, there are a skull and a spine for aesthetic reasons and next three cuffs to match the design of commercialised orthoses : a shoulder cuff, an arm cuff and a forearm cuff. Shoulder cuff dimensions are $r_1 = 0.058\,\mathrm{m}$; $r_2 = 0.073\,\mathrm{m}$; $h = 0.120\,\mathrm{m}$ (Figure 1). Arm and forearm cuffs are both cylinder with dimensions: $r_{arm} = r_{forearm} = 0.041\,\mathrm{m}$; $l_{arm} = l_{forearm} = 0.120\,\mathrm{m}$. Because the wearable device is lightweight, we assume them massless.

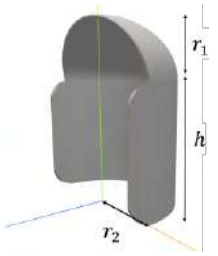

Fig. 1. Shoulder cuff dimensions.

Finally, *'wrap'* objects are added to avoid collision between cables and bone meshes and make an organic cable routing. Three *'wrap'* have been added to the existing ones: a sphere and a cylinder for the shoulder cuff and an ellipse for the scapula (Figure 2).

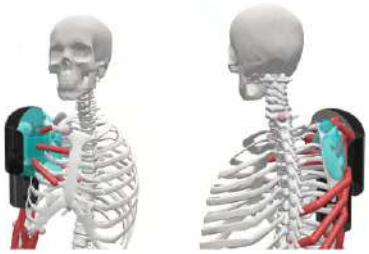

Fig. 2. Biomechanical model with key components highlighted cuffs (black), new *'wrap'* objects (cyan), muscles (red).

B. Simulation platform

The OpenSim API can be used on MATLAB to work with our biomechanical model, solvers and functions integrated into OpenSim. The aim is to run a simulation with a closed control loop (Figure 3). The input is a reference trajectory, i.e. the position, velocity, and angular acceleration of each joint, and the outputs are the simulated trajectory, the metabolic cost and the forces in the cable. The simulator is made up of four blocks.

1) Inverse Dynamics: Generalized forces τ_h are determined knowing angular position q, angular velocity $\dot{q}$ and angular acceleration $\ddot{q}$ with dynamic model :

$$\tau_h = M\ddot{q} + C(q,\dot{q}) + G(q) + \Upsilon \tag{2}$$

Where M is the positive definite inertia matrix of the system, C is the vector of centrifugal and Corriolis forces, G is the gravity vector and Υ is the vector of external forces applied to the system. In the OpenSim API, the function *InverseDynamicsSolver* is used to solve this equation. According to Thelen et al, 2003 [4], $\ddot{q}$ is the sum of $\ddot{q}_{des}$ and the corrected errors in velocity and position such that:

$$\ddot{q} = \ddot{q}_{des} + k_v(\dot{q}_{des} - \dot{q}) + k_p(q_{des} - q) \tag{3}$$

The gains k_p and k_v are chosen so that the error $e = q_{des} - q$ asymptotically converges to zero without overshoot and oscillation, i.e., it is governed by the equation $\ddot{e} + k_v\dot{e} + k_p e = 0$ with $k_v = 2\sqrt{k_p}$ for a given k_p.

2) Static Optimization: Optimizing muscular activity is necessary to determine the strength and contribution of each muscle. The contribution J of muscular activation a must be optimized and minimized because it is directly linked to energy expenditure. This means that only the muscles useful for the movement will be activated. A static optimization problem, i.e., independent of time, can be defined as follows for m muscles:

$$\begin{cases} \arg\min_{a_i} J = \sum_{i=1}^{m} a_i^2 \\ \\ 0 \leq a_i \leq 1 \end{cases} \tag{4}$$

Such as the torque τ_j applied by a muscle i in joint j is equal to

$$\tau_j = \sum_{i=1}^{m} d_{i,j} F_i \tag{5}$$

Here $d_{i,j}$ is the moment arm of muscle i with respect to joint j, a_i the activation of muscle i and F_i is the muscle force. For a muscle its force F is calculated using the activation a and biomechanical parameters according to the Hill model [20]:

$$F = \left(a\tilde{f}_a(l^m)\tilde{f}_v(\dot{l}^m) + \tilde{f}_p(l^m)\right) f_{iso}\cos\alpha \tag{6}$$

Here l^m is the length of the muscle, $\dot{l}^m$ is the speed of the muscle elongation, $\tilde{f}_a$ is the active force normalized in relation to the maximum isometric force (f_{iso}), $\tilde{f}_p$ is the normalized passive force, $\tilde{f}_v$ a coefficient derived from the force-velocity relationship. All these parameters can be obtained using the API with the functions *getMaxIsometricForce*, *getActiveForceLengthMultiplier*, *getForceVelocityMultiplier*, *getPassiveForceMultiplier*, *getCosPennationAngle* and the moment arms are determined using *computeMomentArm*. This static optimization problem is solved using the *fmincon* function in the MATLAB toolbox *Optimization Toolbox*.

3) Gravity Compensation Controller: The control law is defined to compensate the weight of arm, forearm or hand. It is possible to add a known external load in the hand.

$$\tau_{exo} = m_{limb} g l \sin(q_{joint}) + m_{load} g L \sin(q_{joint}) \tag{7}$$

With m_{limb} the mass of limb, l the length between joint and center of mass of the limb, m_{load} the mass of external load, g is the gravity constant and L the length between joint and

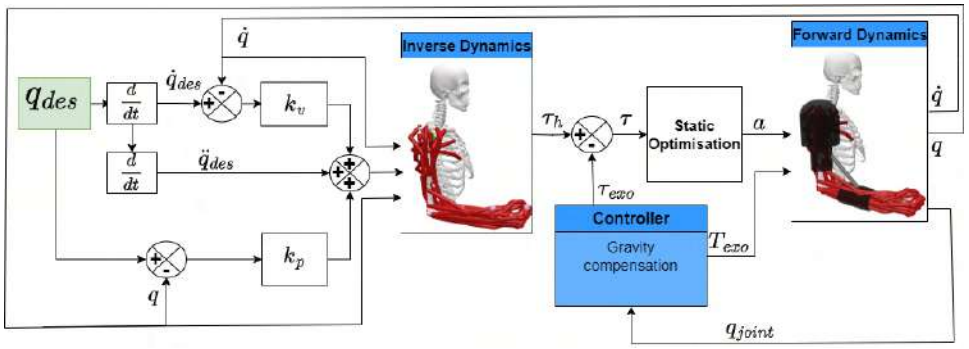

Fig. 3. Block diagram of the simulation platform.

center of mass of the load. Then knowing d_{cable} the moment arm, the tension is:

$$T_{exo} = \frac{\tau_{exo}}{d_{cable}} \tag{8}$$

4) Forward Dynamics: A group of actuators is created with muscles and cables and the function *PrescribedController* is used to activate actuators. The activation a follows a dynamic transformation into excitations according to Thelen et al, 2003 [21]:

$$\frac{\mathrm{d}a}{\mathrm{d}t} = \frac{u-a}{\delta_a(a,u)} \tag{9}$$

Where u is the excitation, δ_a is a time constant depending on activation level:

$$\delta_a(a,u) = \begin{cases} \delta_{act}(0.5+1.5a); u > a \\ \delta_{deact}/(0.5+1.5a); u \leq a \end{cases} \tag{10}$$

With $\delta_{deact} \approx 40$ms and $\delta_{act} \approx 10$ms.

With Runge-Kutta algorithm the following inverse model is solved to get $\dot{q}$ and q :

$$\ddot{q} = M^{-1}(\tau + \tau_{exo} - C(q,\dot{q}) - G(q) - \Upsilon) \tag{11}$$

C. Drinking task trajectory

To illustrate and validate our method, a daily life task is computed. The chosen task is a drinking task during four seconds which involves all of the DoF of the arm at the same time. The arm and hand are along the body, then the hand reaches the mouth in one second and the arm and hand return along the body in one second. The musculoskeletal model shoulder joints are defined following ISB recommendations [22]. For elbow, it is a flexion/extension from 0° to 130° and for the shoulder there are an elevation plane rotation from 0° to 53°, a shoulder elevation from from 0° to 75° and an internal/external rotation from from 0° to 34°. These DoF are different from the clinical description: abduction, flexion and rotation. It is because clinical movements are described in planes, and composing a movement with these definitions would make the arm position dependent on the angular sequence (Paradox of Codman). Flexion or abduction are both movement of elevation, only the plane in which the elevation takes place changes. This is why an elevation plane is constructed. When the angle of the plane of elevation is 0° (respectively 90°), it coincides with the coronal plane (respectively sagittal plane). According to Figures 4 and 5, the simulated angular trajectory is consistent with the reference. The RMSE is calculated in Table I and supports the accuracy of the simulation. At 0.2s, the shoulder rotation briefly deviates but stabilises, without significantly affecting the task.

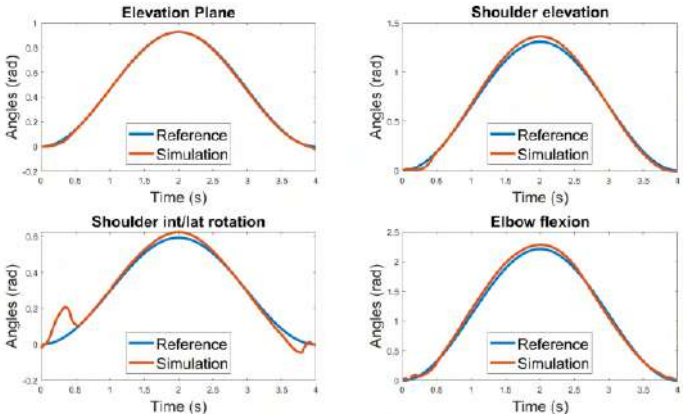

Fig. 4. Angular trajectory at each joint for a drinking task. The reference is in blue and the simulation results in red.

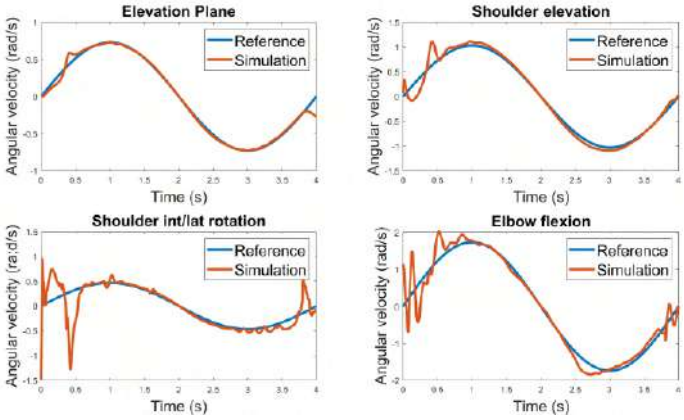

Fig. 5. Angular velocity at each joint for a drinking task. The reference is in blue and the simulation results in red.

TABLE I
RMSE BETWEEN THE REFERENCE AND THE COMPUTED TRAJECTORY

RMSE	Angle (rad)	Angular velocity (rad/s)
Elevation plane	0.007	0.044
Shoulder elevation	0.032	0.106
Int/Lat. rotation	0.043	0.261
Elbow flexion	0.057	0.258

III. Design Optimization

A. Interaction force constraints

Comfort and safety are expressed through force constraints based on pain tolerance thresholds.

1) No pain condition: According to algometry research, humans experience discomfort and pain at circumferential compression levels around 25 kPa [23]. Given that the cable is limited to pulling forces, the pressure is concentrated on the side of the cuffs opposite the pulling direction. Maximal peak of normal force $||\vec{F}_N||$ is constrained such as:

$$||\vec{F}_N|| \leq P_{pain}(\pi r_{cuff} l_{cuff}) \tag{12}$$

2) No slipping condition: When a cuff applies continuous pressure on human body, the threshold pressure is at 30mmHg i.e. 4kPa [3]. 3.5kPa is a comfortable compression level. Assuming well-distributed forces, the tangential force must satisfy Coulomb's friction criterion to prevent slipping on the skin.

$$\begin{cases} ||\vec{F}_T|| \leq ||\vec{F}_{cuff}||\mu \\ \\ \quad \text{with } ||\vec{F}_{cuff}|| = P_{lim}(2\pi r_{cuff} l_{cuff}) \end{cases} \tag{13}$$

$||\vec{F}_{cuff}||$ is the force required to hold the cuff and μ is the coefficient of friction between skin and cuff, equal to 0.6 [24].

B. Geometric constraints

Cables are defined by via points and anchors points. Each point is localized in a frame of parent body. Some geometric constraints are set to limit exosuit volume, avoid collision between cables and the user and to guarantee that the final anchor points are on the cuffs.

1) elbow flexion: The cable is straight with an anchor point on each cuff.

- P_1: Point on arm cuff. Should stay at the surface of the cuff on the anterior side
- P_2: Point on forearm cuff. Should stay at the surface of the cuff on the anterior side.

2) shoulder flexion: Five points are considered to avoid collision with bones and keep consistent the cable path during a movement from 0° to 90° in one second.

- P_1: Fixed point along the spine.
- P_2: Point located at the back of the shoulder between the scapula and the glenohumeral joint. Its frame is the thorax, so it is immobile during shoulder movement.
- P_3: Point located around the spherical part of the cuff, around the glenohumeral joint with maximal height of 5 cm above the cuff.
- P_4: Point along anterior side of the cuff with maximal height of 5 cm above the cuff.
- P_5: Point along anterior side, on the cuff's surface.

3) shoulder abduction: For the same reason as shoulder flexion, four points are built according to abduction from 0° to 120° in one second.

- P_1: Fixed point along the spine.
- P_2: Point located around the spherical part of the cuff, around the glenohumeral joint with maximal height of 5 cm above the cuff.
- P_3: Point along sagittal side of the cuff with maximal height of 5 cm above the cuff.
- P_4: Point along sagittal side, on the cuff's surface.

C. Multi-Objective Optimization: NSGA-II

In a previous work [25], we showed that cable placement influences force distribution more than metabolic cost. The results indicate that energy consumption, used in cost function, depends more on the level of assistance than on cable routing. Since assistance is determined by joint torque and thus cable path, we optimise using normal and tangential forces to ensure safety and comfort, then evaluate energy consumption separately. For multi-objective optimization, NSGA-II [6] is set up on Matlab. The optimization will be done cable by cable according to the actuated DoF with all the range of motion of the movement as described section III-B.

1) Cost function: The cost functions are defined in function of the mean norm of normal forces ($\vec{F}_N$) and shear forces ($\vec{F}_T$).

$$\begin{cases} f_{1,T} = \frac{1}{n}\sum_{i=1}^{n} \left\|\vec{F}_{T,i}\right\| \\ \\ f_{2,N} = \frac{1}{n}\sum_{i=1}^{n} \left\|\vec{F}_{N,i}\right\| \end{cases} \tag{14}$$

2) Algorithm parameters: The population is composed of 50 individuals and each individual has three coordinates for each point as parameters. The genes are evaluated with simulation platform, the best 10 solutions are selected, made 7 children, 10 genes are from mutations of this population and 23 are from new random genes. During mutation or random phases, the gene parameters have to respect geometric constraints defined section III-B and after evaluation if a solution does not respect force constraints defined section III-A, it is penalized. The optimization is performed over 100 generations.

IV. Results

A. Pareto front

For shoulder movements, the placement of the cables can lead to a completely normal or completely tangent force distribution. The most limiting constraint for comfort relates to shear forces, however, taking a solution that has no shear would be unrealistic as forces will be exerted by the anchor point supports. Since constraints are set on the forces and solutions that don't respect them are eliminated, all Pareto-front solutions are viable. To make a trade-off for each cable,

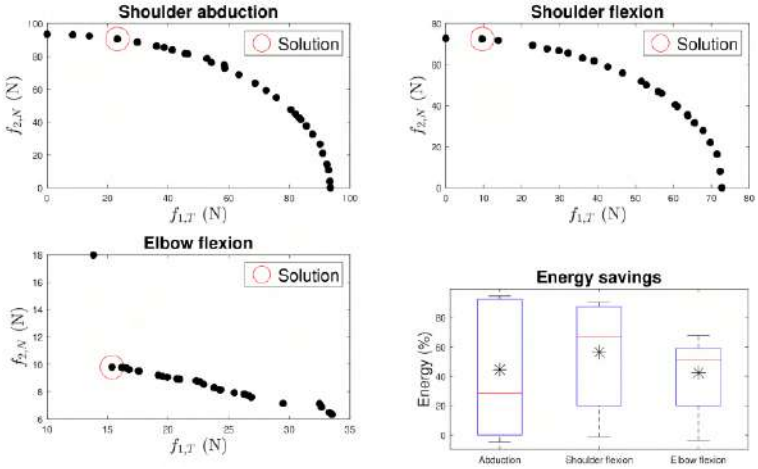

Fig. 6. Pareto front of each cable optimization and metabolic savings due to exosuit during clinical movements. * is the mean.

the selected solution (circled on Figure 6), is the solution with minimal norm tension where normal effort is than higher tangent effort. In terms of metabolic cost, the gain is calculated by taking into account the metabolic rate of muscles expending the most energy. For example, for abduction, it is the intermediate part of the deltoid muscle, which is recruited, and it consumes a lot of energy. The cable compensates for this effort by almost 45% on average, and even more than 90% in few phases of the movement. For shoulder flexion, it is the anterior part of the deltoid which is activated and for the elbow there are three flexors: the biceps, the brachialis, and the brachioradialis. As depicted on Figure 6, there is no saving at some points. It happens when the arm is along the body, with gravity compensation law there is no tension in cable at this phase.

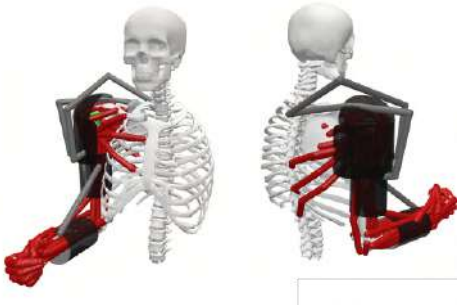

Fig. 7. Biomechanical model with fully optimized exosuit design.

The proposed solution (Figure 7) found by the genetic algorithm follows a simple principle: position the attachment points to maximize the moment arm and stay in the plane of the movement. It is particularly visible on the cable for elbow flexion. Then, to reduce frictional forces, the cable should be connected to the cuff as normal as possible.

B. Drinking task trajectory

To illustrate the efficiency of wearing an exosuit, the drinking task is simulated with and without the device. According to the results (Figure 8), the exosuit reduces fatigue in the movement to reach the mouth by 32%. As explained above,

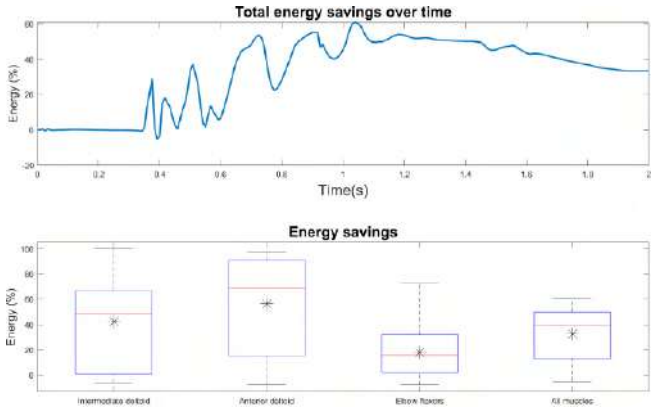

Fig. 8. Comparison of metabolic expenditure with and without exosuit. (1) total energy savings (%) over time, (2) distribution of saved energy across muscle groups (mean shown *).

in the first phase the exosuit provides very small assistance to the user, but as the movement progresses, the user is increasingly assisted. On a movement with several DoF, the average saving is no longer around 50%. Actually, in this task, there is non assistive internal rotation, so bi-articular muscles are recruited in at least two DoF. Furthermore, the combination of movements leads to the combination and synchronization of activations between several muscles.

V. Discussion & Perspectives

In this work, a platform is implemented following guidelines to simulate a user and its musculoskeletal model with a cable driven exosuit. Designed to follow a reference movement, the outputs are the simulated trajectory, energy expenditure and cable tensions. With this new tool, the cable routing of an

exosuit for shoulder and elbow assistance is optimized considering the force distribution to ensure safety and comfort. These requirements are guaranteed by limits on shear and normal forces and multi-objective problem is solved by NSGA-II. The results show a maximization of the moment arm and an energy saving of more than 32% when wearing the exosuit. The advantage is that the simulation method can be reused for other limbs and other musculoskeletal models, weight can easily be put on to simulate load lifting and new control laws can be tested. In addition, different exosuit designs can be evaluated, and passive elements can be added to the design to help the prototyping phase. However, the cable placement appears straight, lacking a organic flow because we do not develop a detailed design to propose a simplified one. The results presented in this study depend on the geometry of the cuffs, the number of points, models, the control laws, the joints and motions. These parameters can be customized in OpenSim or in the simulation platform as well as in the definition of the population and constraints within the genetic algorithm. A future project would be to propose a real prototype based on these results, perhaps incorporating more attachment points and technical solutions for routing cables (pulleys, sheaths, etc). Another point is that OpenSim does not have a finite element calculation tool to estimate exactly the pressure applied to the skin and its distribution. Our assumptions are that the force is homogeneously distributed and that the tension in the cable is ideal (no friction, no backlash). In addition, the model is a closed chain and cannot interact with an external environment to perform more complex simulations.

***Abstract*—The analysis of human movements has highlighted the presence of stereotyped coordination patterns among the different joints of the human body. These patterns are commonly referred to as kinematic synergies. Synergies have been used to both elucidate the underlying neuromotor control strategies adopted by humans during coordinated motion and inform the design and control of assistive and rehabilitative devices such as prostheses and exoskeletons. A particularly thorny problem in the analysis of synergies is the comparison of the synergy postures i.e., the hyper-dimensional vectors containing the contribution of each analyzed feature (e.g., joint angles) to the considered synergies. Often, synergy postures are compared using cosine similarity, which is sensitive to the dimensionality of the input data and does not offer an intuitive understanding of the synergies' similarities and differences. In this study, we introduce a new geometric method, Geometric Configuration Similarity (GCS), specifically designed to compare kinematic synergy postures, with a particular emphasis on hand kinematic synergies. GCS provides a more intuitive geometric understanding of how these postures relate to one another. We demonstrate its advantages over cosine similarity through experimental and numerical results, offering the human motor control and rehabilitation robotics communities a new tool for analyzing kinematic hand synergies and improving the design and control of assistive systems.**

***Index Terms*—synergies, kinematics, hand, manipulation, dexterity, similarity**

I. Introduction

The fine and dexterous control of the hand requires the coordination of a large number of joint degrees of freedom (20+) (i.e., hand joints), and more than double that number of intrinsic and extrinsic muscles of the hand [1], [2]. Given this complexity, the question arises: how do humans seamlessly control their hands without incurring the control limitations associated with the curse of dimensionality [3]? One of the leading theories assumes that humans might take advantage of lower-dimensional and sufficiently stereotyped commands to simplify the motor control problem. Such commands are often referred to as motor synergies, and depending on the considered physiological nature of the signals, they are usually classified as neural [4], [5], muscular [6] or kinematic synergies [7]–[10].

The seminal work by Santello et al. [4], [7] showed that a few kinematic synergies - typically extracted by means of dimensionality reduction techniques such as principal component analysis (PCA) [11] or singular value decomposition (SVD) [12] - accounted for most of the variance in the data of healthy humans performing a variety of reaching and grasping movements. Subsequent work has found similar results in tasks that involve object manipulation [8], [13], [14] the American sign language [6], and even piano playing [10], [15]. For review see [16]. Moreover, some research has highlighted how such synergies are both the results of biomechanical constraints (e.g., tendons and ligaments), as well as descending neural commands [8], [17]. Additionally, research indicates that the reduction of the operational degrees of freedom of the hand may facilitate more straightforward control [18]–[22]. Prior work by the authors showed how humans need to recruit a growing number of synergies in order to perform more advanced dexterous manipulation tasks such as wire-harnessing or playing a musical instrument [10]. A recent theoretical framework highlighted how the number of synergies that humans can employ to perform a given motor task may exceed the number of controlled features, such as joint angles or muscle contractions [23]. Moreover, substantial efforts have been made to refine mathematical methods for extracting synergies [9], [24], [25] through various dimensionality reduction techniques [11], [12], [26].

However, a particularly thorny problem is represented by the difficulty of comparing the synergy vectors resulting from these reduction techniques. The synergy vectors or hyper-points are often high dimensional - with dozens if not hundreds of elements - which limits our capability to visualize and, consequently, get a profound insight on their relation to each other. A common approach to compare synergy vectors, specifically termed 'synergy postures' for kinematic synergies, is to compute the cosine similarity between them. The most widely used formulation computes the positive angle between two vectors, returning 0 if the vectors are orthogonal and 1 if the vectors are collinear.

Recent work by Tessari and Hogan highlighted how the cosine similarity metric is sensitive to the number of dimensions [27]. Specifically, for increasing dimensions the cosine similarity between any 2 random vectors will tend to converge to a value of about 0.75, with decreasing variance. This represents a substantial limitation to the use and interpretability of such a metric. An alternative approach would be to use a dimension-insensitive metric, such as the dimension insensitve Euclidian

metric (DIEM) [27]. This metric is unaffected by the number of dimensions, enabling robust statistical analysis and hypothesis testing—areas where cosine similarity falls short. However, DIEM relies on comparing synergy vectors that are not of unit length. This can be the case for muscular synergies extracted through Non-Negative Matrix Factorization [26], [28], [29], but not for kinematic synergies obtained through PCA or SVD. Moreover, most distance metrics still do not provide an intuitive way to visualize and internalize the similarity between kinematic synergies. To address the limitations of cosine similarity and DIEM, we propose a new geometric approach to compare kinematic hand synergies, called "Geometric Configuration Similarity". This method, which maps kinematic synergies to task-space motion, enables users to quantitatively compare and visualize pairs of kinematic hand synergy postures. In the following sections, we demonstrate the shortcomings of cosine similarity while contrasting it with our proposed approach. Additionally, we provide a library for future researchers to implement the Geometric Configuration Similarity in their work.

II. Materials and Methods

A. Synergy Extraction through SVD

Consider a matrix $X \in \mathbb{R}^{n \times m}$ containing the kinematic data of the joint trajectories recorded across n observations (e.g., the time evolution of each degree of freedom) and m number of features (e.g., the number of analyzed degrees of freedom, DoF) for a given set (one or more) of experiments.

According to West et al. [9], prior to synergy extraction the data should be centered i.e., the mean value of each column - which represents the average angular value for that DoF - needs to removed. This is done to prevent the first synergy from incorrectly 'aiming' toward the center of the offset data distribution.

$$X^* = X - mean(X) \tag{1}$$

Then, synergies can be extracted using SVD — the most adopted algorithm for kinematic synergy extraction [7], [8] — on the mean-removed data set:

$$X^* = U \cdot S \cdot V^T \tag{2}$$

where $U \in \mathbb{R}^{n \times n}$ is an orthonormal matrix whose columns denote the temporal evolution of a given synergy, $S \in \mathbb{R}^{n \times m}$ is diagonal matrix of singular values which give an estimate of the Variance-Accounted-For (VAF) in a given synergy, and $V \in \mathbb{R}^{m \times m}$ is an orthonormal matrix whose columns represent the synergy vectors $V = [\mathbf{v_1}, \mathbf{v_2}, ..., \mathbf{v_m}]$. The elements of each synergy vector represent the contribution of each DoF to that synergy $\mathbf{v_i} = [\theta_1, \theta_2, ..., \theta_m]^T$. The synergy vectors $\mathbf{v_i}$ are of unitary length. For a geometrical interpretation of this, see [9]. In the specific case of hand joint kinematic synergies, the elements of $\mathbf{v_i}$ represent the proportion by which each joint of the hand contributes to that synergy.

B. Limitations of Cosine Similarity

Comparing a pair of synergy vectors $\mathbf{v_i}, \mathbf{v_j}$ fundamentally requires establishing a distance metric between these two hyper-dimensional quantities. As briefly mentioned in the Introduction, this is often done by computing the cosine similarity between them:

$$cos(\phi) = \frac{|\mathbf{v_i}^T \cdot \mathbf{v_j}|}{||\mathbf{v_i}|| \cdot ||\mathbf{v_j}||} \tag{3}$$

However, Tessari et al. showed that this metric is **sensitive to the number of dimensions** and, thus, is not able to provide statistically reliable comparisons [27]. Specifically, as the number of dimensions grows the cosine similarity of two randomly generated vectors tends toward 0.75. Moreover, the resulting computation does **not provide an intuitive geometrical understanding** of how the posture of the hand differs between the two synergy vectors.

C. Geometric Configuration Similarity

To address the limitations of the cosine similarity metric—namely (i) dimension-sensitivity, and (ii) geometric interpretability—the authors propose a new approach coined 'Geometric Configuration Similarity' (GCS), to compute the degree of similarity or difference between any two pairs of kinematic synergy vectors $\mathbf{v_i}$, and $\mathbf{v_j}$. The approach is showcased for hand kinematic synergies, but its application extends to any form of kinematic synergies at every level of the human body.

The core idea of the GCS is to map the synergy vectors from the joint-space to the task-space. This mapping is biomechanically informed through direct kinematics. Given a specific geometry of the hand (i.e., link lengths and joint types) the mapping of any point $\mathbf{p}$ on the hand with respect to a set of joint coordinates—assumed here to be the relative angles between successive links—is unique and well defined as:

$$\mathbf{p} = \mathcal{L}(\Theta) = \mathcal{L}(\theta_1, ..., \theta_m) \tag{4}$$

where $\mathcal{L}$ describes the forward kinematics.

To map a synergy vector $\mathbf{v_i}$ to a hand task-space configuration, we need to (i) multiply it by an activation coefficient u—which could also be a function, $u(t)$, if the intention is to reconstruct the entire motion—and (ii) add back the previously subtracted average posture of the original dataset $\mathbf{\Theta}_{avg} = mean(X)$:

$$\mathbf{\Theta_i} = u \cdot \mathbf{v_i} + \mathbf{\Theta}_{avg} \tag{5}$$

Together, Equations 4 and 5, allow for the mapping of a synergy vector to any point of the considered geometry (e.g., the hand).

In the proposed case (i.e., hand kinematic synergies), we considered a 20 DoFs hand model characterized by 4 DoFs per finger. For the index, middle, ring and little fingers, we included flexion-extension of the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal

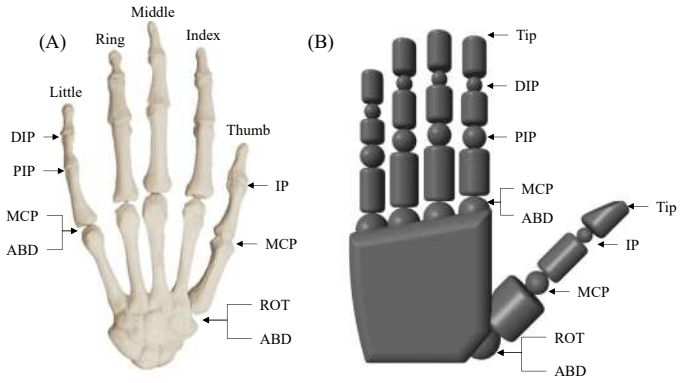

Fig. 1. Adopted hand model. Panel (A) shows the considered human anatomical joints. Panel (B) presents the reconstructed rigid link model.

(DIP) joints, and abduction-adduction (ABD) of the metacarpophalangeal joint. For the thumb, we included rotation (ROT) and abduction-adduction (ABD) at the carpometacarpal and flexion-extension at the metacarpophalangeal (MCP), and interphalangeal (IP) joints. Figure 1A provides a schematic representation of the considered anatomical hand joint.

A rigid-link model (Figure 1B), based on the aforementioned 20 DoFs, was developed considering the following two assumptions. First, the PIP and DIP joints of the index, middle, ring, and little fingers, along with the MCP and IP joints of the thumb, were modeled as perfect rotational joints. Second, the MCP and ABD joints of the index, middle, ring, and little fingers, as well as the ROT and ABD joints of the thumb, were modeled as universal joints (U-joints or Cardan joints).

The link lengths were sized considering the 50th percentile male hand size [30]. However, we want to emphasize that the proposed metric is not influenced by the size of the considered hand. Additional details are provided in the Discussion.

Considering the presented hand model and the mapping from joint-space to task-space using Equations 4 and 5, the 'Geometric Configuration Similarity' fundamentally computes the Euclidean distance between a pair of hand configurations from two synergy vectors $\mathbf{v_i}, \mathbf{v_j}$. The Euclidian distance is computed at 3 different key-points for each finger. Specifically, for the index, middle, ring and little fingers the Cartesian coordinates of the PIP joint, DIP joint and tip of the finger are considered; for the thumb, the MCP joint, IP joint and tip of the thumb are considered. These distances are normalized by the maximum distance that each key-point can assume considering the biomechanical range of motion (ROM) limits of each joint of the hand. The ROM for each joint were extracted from the works of: Bain et al. for the index, middle, ring and little MCP, DIP, and PIP joints [31], Gracia-Ibanez et al. for the ROT, MCP, and IP joints of the thumb [32], and from available online data sheets for the ABD joints [33].

This normalization provides two advantages: (i) it ensures that the size of the hand will not influence the proposed metric, (ii) it guarantees a finite range for the metric, namely 0 to 100.

Mathematically, the Geometric Configuration Similarity between two task-space mapped synergy vectors Θ_i, Θ_j is formulated as:

$$GCS(f) = \frac{1}{3}\sum_{k=1}^{3} 100 \cdot \left(1 - \frac{||\mathbf{p_k}(\mathbf{\Theta_i}) - \mathbf{p_k}(\mathbf{\Theta_j})||_2^2}{max(d(k,f))}\right) \quad (6)$$
$$with\ f = 1, ..., 5$$

Where f represents the finger index, and k is the key-point index. $\mathbf{p_k}(\mathbf{\Theta_i})$, and $\mathbf{p_k}(\mathbf{\Theta_j})$ are, respectively, the task-space Cartesian positions of the k-th key-point for the synergy vector $\mathbf{v_i}$ and $\mathbf{v_j}$. $max(d(k,f))$ is the maximum Euclidean distance that the k-th key-point of the f-th finger can assume considering the human physiological ROM [31]–[33]. Note, GCS produces a similarity measure for each of the five fingers.

Intuitively, for a given finger f, if the two synergy vectors map to the exact same position, their distance will be $||\mathbf{p_k}(\mathbf{\Theta_i}) - \mathbf{p_k}(\mathbf{\Theta_j})||_2^2 = 0\,\forall k$, and therefore the Geometric Configuration Similarity will be 100. Alternatively, if the two synergy vectors map to the maximum possible biomechanical distance $||\mathbf{p_k}(\mathbf{\Theta_i}) - \mathbf{p_k}(\mathbf{\Theta_j})||_2^2 = max(d(k,f))\,\forall k$, then the Geometric Configuration Similarity will be 0.

To provide a unique scalar macroscopic description of the similarity between two synergy vectors, we can use the arithmetic mean of the Geometric Configuration Similarities of the five fingers:

$$mean(GCS) = \frac{1}{5}\sum_{f=1}^{5} GCS(f) \quad (7)$$

D. The Selection of the Activation Coefficients

Particular attention must be given to the selection of the activation coefficient u. As presented in Equation 5, the activation coefficient is necessary to map the synergy vector to a given joint configuration or trajectory. In fact, without an activation coefficient, the synergy vectors just inform us of the proportionality ratio between features but not the extent to which such synergies are employed. Several options for the selection of u are possible. However, for the sake of comparing synergies, two main approaches are considered here.

The first approach consists in using the maximum and minimum activation coefficients found in the columns of the matrix product $U \cdot S = T$, found in Equation 2. The resulting matrix $T = [\mathbf{t_1}, \mathbf{t_2}, ..., \mathbf{t_m}]$ will have as columns the temporal evolutions of each synergy vector based on the input data X^*. Consequently, the $min(\mathbf{t})$ and $max(\mathbf{t})$ values of each temporal evolution represent the maximum and minimum values that a given synergy assumed based on the input data.

This approach is data-driven and, therefore, eliminates the risk of over-activating a synergy vector with respect to another one. Moreover, it will always generate physiologically reasonable movements - assuming no errors during data acquisition.

However, one should remember that by using PCA or SVD, the synergies are extracted in decreasing order of variance-accounted-for. Therefore, higher order synergies will have smaller activation coefficients, and this will influence the comparability of synergy vectors with different orders.

Moreover, if interested in reconstructing the entire motion, you can use these activation coefficients to craft a personalized temporal evolution. In the provided software package, a 4^{th} order polynomial (sine-wave like) starting at 0 and stopping at 0 and passing through $max(\mathbf{t})$ and $min(\mathbf{t})$ was adopted.

The second approach is instead driven by biomechanics. Instead of using the activation coefficients extracted through PCA/SVD, these can be modeled so that a synergy vector spans the maximum range of motion of a certain feature. A reasonable choice is to select the largest element of a synergy vector i.e., the largest contributing joint DoF in the hand case, and scale it such that its value will reach the minimum and maximum ROM of that hand joint. In this case, the activation functions for higher order synergies will not be limited by the lower variance-accounted-for synergies. However, it is not guaranteed that the resulting hand posture will represent a physiological configuration.

The authors think the selection of the appropriate activation function is context dependent. In the case of comparison with experimental data, the first approach i.e., using the columns of T, seems more appropriate, and that is what is used in the Results of this work. In the case of using synergies for design or control purposes, the second approach i.e., extending the synergy to the ROM limits, might be the right choice.

E. The three Geometric Configuration Similarities

Considering two synergy vectors $\mathbf{v_i}$, and $\mathbf{v_j}$ extracted from dataset having average postures $\mathbf{\Theta_{i_{avg}}}$, and $\mathbf{\Theta_{j_{avg}}}$, and with minimum and maximum activation coefficients u_{max_i}, u_{max_j}, u_{min_i}, and u_{min_j}, three different, Geometric Configuration Similarities are computed. These represent the average posture, maximum posture and minimum posture conditions:

$$GCS(f)_{avg}|\mathbf{\Theta_i} = \mathbf{\Theta}_{i_{avg}} \wedge \mathbf{\Theta_j} = \mathbf{\Theta}_{j_{avg}} \tag{8}$$

$$GCS(f)_{max}|\mathbf{\Theta_i} = u_{max_i} \cdot \mathbf{v_i} + \mathbf{\Theta}_{i_{avg}} \wedge \quad \mathbf{\Theta_j} = u_{max_j} \cdot \mathbf{v_j} + \mathbf{\Theta}_{j_{avg}} \tag{9}$$

$$GCS(f)_{min}|\mathbf{\Theta_i} = u_{min_i} \cdot \mathbf{v_i} + \mathbf{\Theta}_{i_{avg}} \wedge \quad \mathbf{\Theta_j} = u_{min_j} \cdot \mathbf{v_j} + \mathbf{\Theta}_{j_{avg}} \tag{10}$$

The $GCS(f)_{avg}$ provides information on how much the average postures of the considered datasets are similar to each other. This parameter is independent of the considered synergy vectors and it is always equal to 100 when the comparison is performed between synergies extracted from the same dataset i.e., $\mathbf{\Theta_i} = \mathbf{\Theta_j}$. $GCS(f)_{max}$ and $GCS(f)_{min}$ quantify the geometric difference between the maximum or minimum postures between the considered synergy vectors.

Two different applications of the Geometric Configuration Similarity are reported in the following. The first presents a numerical example involving two biomechanically relevant, artificially synthesized hand postures that yield a GCS close to the minimum. This example highlights a disparity between GCS and cosine similarity. The second provides an experimental example, consisting of two case studies, and applies the GCS to the kinematic hand synergies extracted from the authors' previously reported work on piano playing [10].

A software package to run GCS and reproduce the experimental results presented in this work can be found at the following GitHub repository: https://github.com/ftessari23/GCS.

III. Results

The hand model was calibrated on the 50th percentile male hand, and the resulting maximum distances $max(d(k,f))$ for each key-point (PIP,DIP,Tip) and each finger are reported in Table III.

$max(d(k,f))$ $[m]$	Joints		
	Tip	**DIP (IP)**	**PIP (MCP)**
Thumb	0.195 ± 0.003	$0.159 \pm < 0.001$	$0.083 \pm < 0.001$
Index	0.176 ± 0.003	0.126 ± 0.002	$0.071 \pm < 0.001$
Middle	0.193 ± 0.003	0.144 ± 0.003	$0.085 \pm < 0.001$
Ring	0.194 ± 0.002	0.149 ± 0.002	$0.086 \pm < 0.001$
Little	0.170 ± 0.003	0.126 ± 0.002	$0.076 \pm < 0.001$

TABLE I

Maximum Euclidean distance plus-minus the numerical measurement tolerance at each key-point (PIP, DIP, Tip) in each finger. In brackets you can find the name of the thumb joints.

A. Numerical Example: Joints Limit Hand Configurations

In this first example, we aimed to compare the most biologically distinct hand postures. Thus, we chose two hand configurations in which the first has all the joints at the maximum ROM and, the second has all the joints at the minimum ROM:

$$\mathbf{\Theta_1} = [\theta_{1_{max}}, ..., \theta_{20_{max}}] \tag{11}$$

$$\mathbf{\Theta_2} = [\theta_{1_{min}}, ..., \theta_{20_{min}}] \tag{12}$$

The cosine similarity between these biomechanically distinct hand postures is 0.71, which corresponds to an angular difference of about $44.6°$. This suggests a non-negligible similarity between the vectors.

However, when the vectors are mapped to the task-space and the GCS is computed, we observe (Figure 2) that the 2 postures have very poor similarity - as expected - with an average GCS of 8.7% across the five fingers. It is worth emphasizing that, despite the very small value, the GCS did not converge completely to 0%. This is expected, since the maximum and minimum ROM do not always represent the condition of maximum Euclidean distance for each of the different finger key-points.

B. Experimental Example: Piano Playing

Next, we compare kinematic synergies extracted on a group of healthy individuals while performing a series of piano pieces. All subjects were right-handed, received a comprehensive briefing on the experimental procedures, and signed a consent form approved by MIT's Institutional Review Board. We invite readers to refer to the work by West et al. for details on the experimental data acquisition and processing [10]. Here, two case studies are considered to highlight the benefits of the Geometric Configuration Similarity.

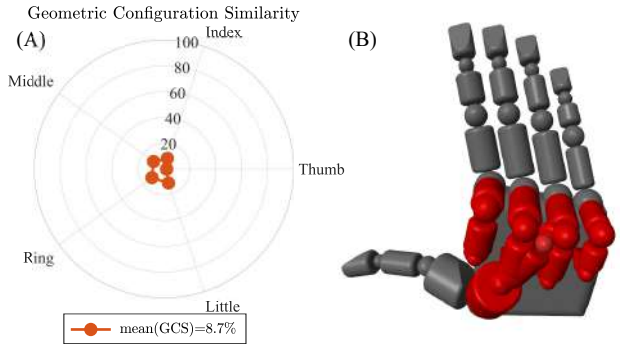

Fig. 2. Geometric Configuration Similarity between two synthetic synergy vectors $\mathbf{v_1}$ and $\mathbf{v_2}$ obtained by having the hand joints at their maximum and minimum ROM, respectively. In panel (A), the orange, dotted polygon represents the comparison between the two hand configuration postures $GCS(f)$. In panel (B), the maximum hand postures $\mathbf{\Theta_{1_{max}}(v_1)}$ and $\mathbf{\Theta_{2_{max}}(v_2)}$ are reported in the 3D hand model in gray and red, respectively.

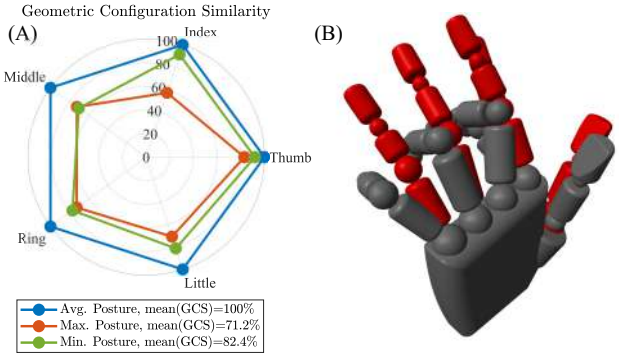

Fig. 3. Geometric Configuration Similarity between the first two synergy vectors, $\mathbf{v_1}$ and $\mathbf{v_2}$, of a representative subject playing the piano piece Bach Prelude in C Major. In panel (A), the blue, dotted polygon represents the comparison between average postures $GCS(f)_{avg}$, the orange, dotted polygon is the comparison between maximum postures $GCS(f)_{max}$, and the green, dotted polygon is the comparison between minimum postures $GCS(f)_{min}$. In panel (B), the maximum hand postures $\mathbf{\Theta_{1_{max}}(v_1)}$ and $\mathbf{\Theta_{2_{max}}(v_2)}$ are reported in the 3D hand model in gray and red, respectively.

1) Within-Subject - Different Order Synergies: In the first case study, we present a comparison of the first 2 kinematic synergies of a representative subject (nr. 2) performing the Bach Prelude in C Major by J.S. Bach. The synergies were extracted using the approach presented in Section II.A; they represent the first 2 columns of matrix V (i.e., $\mathbf{v_1}$ and $\mathbf{v_2}$). They account, respectively, for 44% and 25% of the Variance-Accounted-For (VAF). By computing the cosine similarity of these two synergies, we observe that such synergies are perfectly orthogonal:

$$cos(\theta) = \frac{|\mathbf{v_1}^T \cdot \mathbf{v_2}|}{||\mathbf{v_1}|| \cdot ||\mathbf{v_2}||} = 0 \tag{13}$$

This follows directly from SVD, as the columns of V are orthonormal, meaning they are mutually orthogonal.

However, when using the Geometric Configuration Similarity, we observe (Figure 3) that the two synergies - despite their orthogonality - present substantial similarities. Specifically, the maximum and minimum postures of the first 2 synergies show an average Geometric Configuration Similarity across the five fingers of 71.2% and 82.4%, respectively. The average posture $\mathbf{\Theta_{avg}}$ presents, instead, a GCS of 100%. This is a natural consequence of the fact that both synergies were extracted from the same dataset, thus they must have the same average posture.

2) Between-Subjects - Same Order Synergies: In the second case study, we compare the first synergies of two different subjects (nr. 2 and nr. 5) performing the same piano piece (i.e., Bach Prelude in C Major). These two synergies account, respectively, for 44% and 42% of the Variance-Accounted-For. Their cosine similarity is equal to 0.19, which represents an angular difference of about $79°$. Once more, the synergies appear close to orthogonality, and thus would typically be considered very *different postures*.

However, when the synergies are compared with the Geometric Configuration Similarity, we observe (Figure 4) that the average postures present an average GCS of 89.4% indicating that the two subjects had a similar - but not identical - average hand configuration while playing the same piano piece. Moreover, the maximum and minimum hand postures - dictated by each subjects' first synergy - show an average GCS of 64.5% and 78%, respectively. These values provide a geometrically intuitive understanding of how *similar* the two synergies between the subjects are. Moreover, this tool enables us to observe that the index and little fingers are actually the ones that were used most differently between the subjects (see Figure 4).

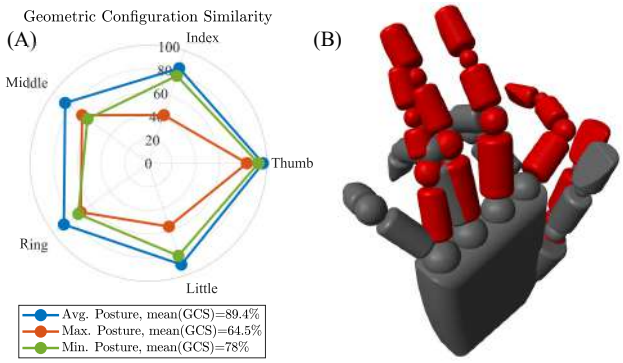

Fig. 4. Geometric Configuration Similarity between the first synergy vectors $\mathbf{v_{1_{s2}}}$ and $\mathbf{v_{1_{s5}}}$ of two representative subjects (nr.2 and nr. 5) performing the same piano playing task i.e., Bach Prelude in C Major. In panel (A), the blue, dotted polygon represents the comparison between average postures $GCS(f)_{avg}$, the orange, dotted polygon is the comparison between maximum postures $GCS(f)_{max}$, and the green, dotted polygon is the comparison between minimum postures $GCS(f)_{min}$. In panel (B), the maximum hand postures $\mathbf{\Theta_{1_{max}}(v_{1_{s2}})}$ and $\mathbf{\Theta_{1_{max}}(v_{1_{s5}})}$ are reported in the 3D hand model respectively in gray and red, respectively.

IV. Discussion

In this paper, we addressed the limitations of cosine similarity by proposing a novel geometric approach for comparing kinematic hand synergies, termed Geometric Configuration Similarity (GCS). GCS utilizes MATLAB's multibody simulation, Simscape, and forward kinematics to map joint space

synergies to a task-space hand configuration. This mapping enables both visual and analytical comparison of kinematic synergies. Through numerical and experimental comparisons, we demonstrate that GCS provides valuable insights overlooked by cosine similarity. Looking ahead, we believe that the publicly available GCS framework will assist researchers in conducting more thorough analyses of hand kinematics.

A. Geometric Interpretability

1) Numerical Example: In our numerical example, we compared two biologically distinct hand configurations: one with all joints at their maximum range of motion (ROM) and another with all joints at their minimum ROM. The Geometric Configuration Similarity (GCS) metric revealed a stark contrast between these two postures, yielding a low similarity score of 8.7% across the five fingers (Fig. 2). This finding highlights the significant differences in hand kinematics that are present, despite the similarity suggested by the cosine similarity score of 0.71. Such a high cosine similarity value implies significant similarity, which is misleading given that the two configurations are functionally and anatomically disparate.

This discrepancy underscores the limitations of relying solely on cosine similarity for evaluating hand postures. While cosine similarity may indicate a non-negligible relationship between the two synergy vectors, it fails to capture the true geometric differences that GCS effectively elucidates. By mapping the synergy vectors to task-space configurations, GCS provides a more intuitive representation of the distinct hand postures, thereby enhancing our understanding of the complex mechanics involved in hand manipulation.

It is important to note that in this numerical example, the GCS did not reach a minimum value of zero; instead, it was 8.7% (Fig. 2). While it may be theoretically possible to achieve a lower GCS, attaining a value of zero is unlikely. As outlined in Eq. 6, the Cartesian distance between each pair of keypoints is normalized by its theoretical maximum, which considers the biomechanical range of motion. For the GCS to equal zero, all keypoints would need to be positioned at points of maximum distance simultaneously. However, due to the interconnected nature of finger joints in our multibody model, the position of each keypoint is influenced by the configuration of the distal joints. Consequently, a configuration that maximizes the distance between the PIP and DIP joints may not necessarily maximize the distance at the TIP. This issue becomes even more pronounced when considering movements such as abduction and adduction. Nevertheless, Fig. 2 provides a useful reference for understanding the range of GCS values achievable under different configurations.

2) Experimental Example: In our first experimental example (*Within-Subject - Different Order Synergies*), we examined the kinematic synergies of a subject performing the Bach Prelude in C Major, focusing on the first two synergy vectors extracted via Singular Value Decomposition. While cosine similarity indicates that these two vectors are orthogonal, signifying that they span completely different hyperspaces—a result of the SVD design—Geometric Configuration Similarity reveals significant kinematic similarities in the configuration space. This distinction is crucial, and it, again, underscores the limitations of relying solely on cosine similarity to evaluate hand postures. Moreover, GCS allows for a more intuitive interpretation of the data, enabling us to easily identify which fingers exhibit higher or lower similarity between the synergies. For example, in Fig. 3 we can see that the largest discrepancy lies in the motion of the index finger, whose maximum posture GCS is 57%, while there is high similarity in the thumb whose minimum and maximum posture GCS are 92% and 83%, respectively. Such insights are vital when discussing the functional roles of each synergy in hand movements. Consequently, one could argue that GCS serves as a valuable proxy measure for assessing the similarity of kinematic synergies as they relate to function, providing a deeper understanding of the intricacies of hand manipulation.

In our second experimental example (*Between-Subjects - Same Order Synergies*), we compared the first synergy vectors of two different subjects performing the same piano piece, the Bach Prelude in C Major. Notably, the cosine similarity for these vectors was measured at 0.19, indicating a relatively higher degree of similarity compared to the first example, where cosine similarity was 0 for within-subject comparisons of different order synergies. However, the Geometric Configuration Similarity tells a different story. In this case, the GCS for the maximum posture scenario decreased from 71.2% in the within-subject example to 64.5% when comparing between subjects, and similarly dropped from 82.4% to 78% in the minimum posture scenario. This juxtaposition highlights the limitations of cosine similarity and shows that GCS provides a more nuanced understanding of the functional similarities and differences in hand configurations. Moreover, GCS intuitively highlights that index and little finger motion might be the root of this cause; their maximum posture GCS reduced from 57%, index, and 71%, little, (Fig. 3) to 43% and 56% (Fig. 4), respectively. Such insights are critical for assessing how different individuals may employ similar synergies in varied ways during complex motor tasks.

B. Methodological Considerations

We want to highlight that the choice to utilize three key points per finger in measuring configuration was intentional and is crucial for eliminating discrepancies that may arise from redundancy in joint movements. For instance, if we were to measure only the distance at the Tip of each finger, that position could be achieved through multiple joint configurations. Specifically, the fingertip is described by three Cartesian degrees of freedom (DOF), while the finger possesses 4 (three flexion + 1 ab/addcution) DOFs, resulting in a one-dimensional null space. This means that different combinations of joint angles could yield the same TIP position, leading to ambiguity in interpreting movement. By selecting three key points—namely the PIP, DIP, and TIP, we increase the number of task-space DOFs relative to joint-space DOFs. This approach effectively eliminates the potential for errors due to

redundancy, and enhances the reliability of the GCS metric in capturing the complexities of hand movements.

The current version of the GCS is implemented in Matlab 2023b by using the multibody library available in Simulink/Simscape. However, alternatives exist. The first is to use Exp[licit], a recently released robotic control library, which has demonstrated better computational efficiency compared to standard robotic control toolboxes [34]. A second alternative is represented by advanced physics simulators such as Mujoco [35]. It is worth emphasizing that GCS is independent of the adopted software framework and is only a function of the considered hand geometry.

C. Limitations

One limitation of this study lies in the geometric assumptions regarding the hand model used for analyzing kinematic synergies. The model was based on a rigid-link representation of a 20-degree-of-freedom hand, incorporating four degrees of freedom per finger. However, more detailed mechanical models could be used to include the hand's remaining degrees of freedom [36]. Additionally, the current model may not adequately account for individual anatomical variations among subjects (e.g., larger or smaller hands, as well as different proportions between the phalanges), which could influence the accuracy of the Geometric Configuration Similarity (GCS) measurements. To help mitigate these limitations, we have open-sourced the GCS framework, allowing future researchers to utilize the metric and customize the hand model to better fit the specific anatomical characteristics of their study populations. Moreover, we are planning to parameterize the GCS model so that users will be able to input the hand percentile and automatically scale the GCS to the size of interest.

Another limitation of this study is the inability of GCS to provide statistical measures. In this regard, cosine similarity also falls short. As noted in our previous study [27], cosine similarity tends to converge toward 0.75, as the number of dimensions increases. DIEM addresses this issue [27], but requires non-unitary length vectors. Therefore, DIEM can be applied to either the reconstructed joint configurations (Equation 5) or the task-space positions (Equation 4). Future work should investigate the statistical properties of GCS and DIEM to enhance reliability and interpretability.

D. Impact

The discrepancies observed between cosine similarity and Geometric Configuration Similarity (GCS) can be attributed to the inherent differences in what each metric measures. Cosine similarity evaluates the angle between vectors, providing insight into their orientation rather than their geometric relationship in configuration space. This can lead - as shown in this paper - to misleading interpretations that fail to capture the intricate functional differences that exist between hand configurations, potentially obscuring the understanding of how specific movements contribute to overall hand function.

In contrast, GCS is inherently linked to the function of hand movements, as it assesses geometric distances between mapped configurations in task space. This metric provides insights into how individual joint positions relate to functional outcomes in hand manipulation. By focusing on spatial configurations, GCS reveals critical kinematic similarities and differences essential for understanding motor control. For instance, it allows researchers to identify which fingers demonstrate higher or lower similarity in their movements, thus connecting the analysis of synergies to their functional roles.

This relationship highlights the utility of GCS in rehabilitation and motor control research, offering a more meaningful understanding of how hand movements serve specific functional objectives. For example, the GCS could be used as an input for the design of exoskeletal or prosthetic devices [37], [38] that aim to reconstruct specific hand motions e.g., piano playing or tool-use. Often times synergy orthogonality (observed through cosine similarity) is used to introduce a new DOF in assistive or rehabilitative devices. GCS offers a much more direct intuition of the geometric consequences of adding a new synergy to a certain hand configuration, thus enabling more adequate design choices. Additionally, GCS could be used as a metric to assess the recovery of hand motor function when computed between healthy and impaired individuals.

Finally, it is important to underline that the Geometric Configuration Similarity approach can be extended beyond hand kinematics to other parts of the human body such as upper-limb or lower-limb kinematic synergies.

Comparing GCS and cosine similarity offers an interesting parallel to a classic question in motor control: do humans plan and execute motion using intrinsic or extrinsic coordinates [39]–[41]? Cosine similarity, by comparing synergy vectors based on joint configurations, inherently reflects comparisons in intrinsic coordinates. This perspective has been used to discuss how humans may simplify the highly redundant motor control problem when planning an action. On the other hand, GCS compares synergies after projecting them into task-space, which corresponds to the end-effector positions and represents the extrinsic coordinates in which actions are typically executed. A substantial body of evidence suggests that humans often plan motion in extrinsic coordinates [39]–[41], where the focus is on achieving goals in the environment rather than coordinating individual joints. Therefore, future work using GCS could provide valuable insights into how humans simplify path planning in extrinsic coordinates, shedding light on how synergies are organized for task-level control.

V. Conclusions

The human hand, with its high degrees of freedom and ability to perform a vast array of complex tasks, poses significant challenges for studying its kinematics and motor control [36]. To simplify this analysis and enhance understanding, researchers have turned to the concept of synergies [16]. Cosine similarity has traditionally been the go-to method for comparing these synergies. However, as highlighted in this paper, cosine similarity has notable limitations, particularly when it comes to its interpretability and capturing the true

geometric relationships between hand configurations. To address these shortcomings, we introduced the Geometric Configuration Similarity (GCS) metric, a tool designed to provide researchers with a more intuitive and meaningful way to compare kinematic synergies. GCS can help researchers gain a deeper understanding of hand function, ultimately advancing the study of hand motor control in both healthy and impaired populations.

***Abstract*—Recent developments have created differentiable physics simulators designed for machine learning pipelines that can be accelerated on a GPU. While these can simulate biomechanical models, these opportunities have not been exploited for biomechanics research or markerless motion capture. We show that these simulators can be used to fit inverse kinematics to markerless motion capture data, including scaling the model to fit the anthropomorphic measurements of an individual. This is performed end-to-end with an implicit representation of the movement trajectory, which is propagated through the forward kinematic model to minimize the error from the 3D markers reprojected into the images. The differential optimizer yields other opportunities, such as adding bundle adjustment during trajectory optimization to refine the extrinsic camera parameters or meta-optimization to improve the base model jointly over trajectories from multiple participants. This approach improves the reprojection error from markerless motion capture over prior methods and produces accurate spatial step parameters compared to an instrumented walkway for control and clinical populations.**

I. Introduction

Markerless motion capture (MMC), using multiple synchronized cameras to capture and reconstruct movement using computer vision, can greatly expand access to movement analysis in rehabilitation and movement science research and clinical practice. In recent years several open and proprietary systems have emerged and been validated for this purpose [1]–[4]. However, existing approaches are limited by the lack of biomechanical body models designed for integration into machine learning pipelines. OpenSim is a widely used open-source biomechanical modeling framework [5], [6], for which there are many models including for the whole body and focused models of the arm [7]–[9]. However, simulation in this environment is slow and not easily integrated into GPU-accelerated frameworks. Although the NimblePhysics biomechanical simulator is faster it still cannot be parallelized and or accelerated on a GPU [10].

Mujoco [11] is another simulator that supports biomechanical models, including muscle-actuated models. Recently, GPU acceleration was integrated into Mujoco as Mujoco-MJX, based on the physics simulator from Brax [12]. Mujoco has enabled the development of multiple biomechanically oriented frameworks designed integration with machine learning and reinforcement learning, including MyoSuite [13], [14], which includes a tool for converting OpenSim models into Mujoco, and LocoMujoco [15], a locomotion imitation benchmark suite.

In addition to performance, a benefit of simulators like Brax and Mujoco-MJX is that they are differentiable, which opens up the opportunities that we explore in this work. We previously showed that implicit representations for movement trajectories, where a function is learned that maps for time to a coordinate space, $f_\theta : t \rightarrow \mathbf{x}$, recover smoother and more anatomically consistent trajectories from markerless motion capture while having better convergence properties [16]. We then perform inverse kinematic fits of a biomechanical to these marker trajectories to recover joint angles [17]. This was done using a bilevel optimization approach that jointly estimates the skeleton scaling and the inverse kinematics across multiple trajectories [18]. We were forced into this two-stage approach because we could not propagate gradients from the reprojected marker location errors through the kinematic model and into the learned implicit representation, which is straightforward to do with differentiable, GPU-accelerated simulators.

However, a barrier to this is that, to the best of our knowledge, scaling the models to fit the anthropomorphic measurements of an individual is not supported with current platforms using Mujoco. Furthermore, there are many different human pose estimation (HPE) algorithms for detecting keypoints from images, that are trained on a diversity of datasets, each having different idiosyncracies. To obtain accurate fits, the model must have marker locations that are optimized for the keypoint set used. Differentiable biomechanical models allow the marker locations on the base model to be optimized end-to-end with the reconstructions from a population of individuals with a range of anthropomorphic measurements. Differentiability also allows marker offsets and skeleton scaling for each individual to integrate naturally into the optimization process. In this work, we selected the MOVI keypoints outputs from the MetrABs-ACAE algorithm [19], which our prior work found are some of the most accurate and anatomically consistent when varying viewpoints. Full differentiability also means that we can perform bundle adjustment [20] by computing the derivatives with respect to the extrinsic camera parameters. Thus the biomechanically constrained observations of the movement can even improve the calibration.

In short, our contributions are:

- We enable personalized model scaling and inverse kinematic fitting with bilevel optimization using a GPU-accelerated, fully differentiable biomechanical model using Mujoco.
- Implement this using an end-to-end differentiable bilevel optimization with an implicit representation of pose trajectories propagated through the forward kinematic biomechanical model to minimize the error from the 3D markers reprojected into the images.
- Perform bundle adjustment to refine the extrinsic camera parameters during this optimization.
- Implement a trilevel optimization process that meta-optimizes the base biomechanical model marker locations over a dataset of trajectories from multiple participants.

II. Methods

A. Participants

This study was approved by the Northwestern University Institutional Review Board. Participants performed several activities, with the majority performing multiple walking trials, often at different speeds or using different assistive devices. These were performed while participants walked along an instrumented walkway that recorded foot contact and toe-off timing and locations [21], [22]. Some participants performed additional tasks like the timed-up-and-go and the four-square-step-test [23]. Our dataset contains a mixed population with able-bodied controls and participants with a history of neurologic conditions, predominantly stroke but some traumatic brain injury, spinal cord injury, peripheral neuropathy, as well as lower limb prosthesis users. There are also several participants with a history of knee osteoarthritis and pediatric participants. For quantifying and comparing performance, we focus on the set of trials that were fit using our previously described biomechanical pipeline [16], [17].

B. Markerless Motion Capture

Multicamera data was collected with a custom system we developed using 8 to 12 FLIR BlackFly S GigE cameras with F1.4/6mm lens [16], [17]. This system acquires 2048 $\times$ 1536 images at 30 fps that are synchronized using the IEEE1558. Extrinsic and intrinsic calibration was performed using the anipose library [24] using a checkerboard. These fitted parameters produce a function for each camera i that projects points in the 3D space of the acquisition volume onto the 2D image plane of each camera:

$$\Pi_i : \mathbf{x} \rightarrow y,\ \mathbf{x} \in \mathbb{R}^3,\ y \in \mathbb{R}^2 \tag{1}$$

We used the previously described user interface to select the person of interest from an initial scene reconstruction, which is used to compute the bounding box for that individual across all of the cameras and frames. Keypoints were estimated independently for each frame using an algorithm trained on numerous 3D datasets that outputs the superset of all these formats (MeTRAbs-ACAE) [19]. We used a subset from this output that are the 87 keypoints from the MOVI dataset [25], which correspond to those often used in biomechanical analysis and that we used in our prior reconstruction methods [16], [17]. MeTRAbs-ACAE also directly outputs 3D joint locations from each camera, but we only use the 2D outputs. In our prior work, we have found the keypoints from this algorithm are more geometrically consistent when varying perspectives than other algorithms [17], likely due to the unique training on extensive 3D datasets. It does not provide confidence intervals for each keypoints, so we approximated them by measuring the standard deviation of each 3D joint location estimated from 10 different augmented versions of each video frame. This was converted to a confidence estimate using a sigmoid function with a half maximum at 30mm and a width of 10mm. This is different than the value we previously used (200 and 50 respectively) [16], as we discovered these prior values provided more of a binary "detected" signal than a continuous score.

C. Implicit representation

When reconstructing biomechanics from multiple synchronized cameras, we previously found an implicit representation that uses a function to map from time to virtual marker positions, $f_\phi(t) \rightarrow \mathbf{x}$ with $\mathbf{x} \in J \times 3$, outperforms optimizing an explicit trajectory for $\mathbf{x}(t)$ or using a robust triangulation [16]. This learnable function is instantiated as a multi-layer perceptron (MLP) and time is input using sinusoidal positional encoding after scaling the time inputs from 0 to π to prevent aliasing in the encoding [26]. In this work, we modified the implicit representation from directly outputting 3D joint locations to outputting pose parameters that are input to a forward kinematics model implemented in Mujoco. The pose parameters corresponding to joint angles were constrained to the joint range limits through a `tanh` nonlinearity.

D. Mujoco model

We used a biomechanically grounded, forward kinematic implemented in Mujoco [11]. We based our model on LocoMujoco [15], which in turn is based on the OpenSim model Hamner, Seth, and Delp [8]. We modified the LocoMujoco model by removing collisions other than on the feet, which significantly accelerated the forward kinematics, and we also added a neck joint with 3 degrees of freedom. In our prior work, we optimized marker locations compatible with the MOVI keypoints on a similar biomechanical model in the OpenSim format using the nimblephysics simulator [10]. We ported these marker locations to the model used in this work using the site Mujoco element, which corresponds to a virtual marker rigidly attached to a component of the model.

To the best of our knowledge, model scaling, and marker offset calculation have not been implemented using Mujoco and MJX. LocoMujoco implements a similar process by modifying the model specification in the XML before instantiating it, but this does not allow these parameters to be changed dynamically in the GPU or to compute the derivatives or trajectories with respect to scaling and offsets. We implemented a wrapper for the forward kinematics that allows passing in scaling parameters as well as marker offsets in

addition to the joint angles. The base model is then modified in memory before computing the forward kinematics. The scaling was implemented using a matrix that maps from a set of scale parameters to scaling individual body segments isotropically. We included 8 scale parameters: an overall size, the pelvis, left thigh, left leg and foot, right thigh, right leg and foot, the left arm, and the left leg. This could be naturally extended to allow separate scales on more body segments or anisotropic scaling, but we did not explore that in this work. Following notation used by the popular skinned multi-person linear model (SMPL)[27], we can thus represent our GPU-accelerated, biomechanical forward kinematic equation as:

$$\mathbf{x} = \mathcal{M}(\theta, \beta) \tag{2}$$

Where $\theta \in \mathbb{R}^{40}$ are the inputs to the skeleton model, $\beta \in \mathbb{R}^{8+87*3}$ are the set of 8 scaling parameters are the offsets for each of the marker locations, and $\S \in \mathbb{R}^{87\times 3}$ are the predicted marker locations. The forward kinematic model also can provide the location and orientation of each of the 21 body components along the kinematic tree as well as the mesh geometry locations and orientations, neither of which we use in this work. Finally, the model includes dynamics, with each component having linear and rotational velocities that respond to torques from the joints, which we also do not use in this work.

E. MyoSkeleton model

We were also kindly granted early access to a new model being developed for MyoSuite [13], [14], called the MyoSkeleton. This has many more degrees of freedom (152), such as all the degrees of freedom in the spine at many vertebral levels, a fully articulated hand, and even an articulated patella. These additional degrees of freedom are governed by 66 equality constraints corresponding to typical movement, such as how the flexion at L4-5 should be related to the flexion at L3-4. MJX allows computing an error function for how much these constraints are violated [11], $\boldsymbol{\epsilon} = \mathrm{err}(\boldsymbol{\theta})$. When fitting the MyoSkeleton model, in addition to having the implicit function output 152 degrees of freedom, we included an additional loss term that penalized the violation of these constraints,$\mathcal{L}_\epsilon = \lambda_\epsilon \frac{1}{66}\sum_i \epsilon_i^2$. We used $\lambda_\epsilon = 0.01$ based on initial experiments showing this drove the constraint violations to very low levels, and leave further optimization of this to future work. Otherwise, fitting the MyoSkeleton used identical code and settings to the LocoMujoco model.

F. Bilevel optimization

We followed the bilevel optimization approach of Werling, Raitor, Stingel, *et al.* [18], jointly solving for the skeleton scaling, marker offsets, and joint angle trajectories over multiple movement sequences. This approach was developed for precomputed 3D marker trajectories, either from traditional optical marker-based motion capture and then adopted in our recent work to virtual 3D marker trajectories from markerless motion capture [17]. In this work, we make two critical modifications: 1) we represent the pose trajectory over time, θ_t, with an implicit representation instead of using this function to predict virtual marker locations, $\mathbf{x}_t$, and 2) we minimize the error between the detected joint locations in the image plane and the marker locations in 3D space after reprojecting the coordinates through the calibrated camera function, Π_i, for camera i. Thus, this approach directly optimizes the joint angles that control the biomechanical model to produce marker locations consistent with keypoints detected in the image plane. This is possible because our entire model is end-to-end differentiable and accelerated on the GPU.

More formally, we have a set of N recordings, each of which has keypoints detected for each joint, j, per timestep, t, and per camera, c: $\left\{y^{(n)}_{t,j,c}\right\}_{n=1...N}$. The modeled 3D virtual marker locations are produced from the learned implicit function learned separately for each trajectory, which is then passed through the forward kinematic model using a common β parameter for all trajectories:

$$\mathbf{x}^{(n)}_t = \mathcal{M}(f_{\phi_n}(t), \beta) \tag{3}$$

The parameters for the set of trajectories, $\{\phi_0, ..., \phi_N, \beta\}$, are jointly optimized by minimizing the reprojection loss between the detected 2D keypoints and the reprojected 3D marker locations:

$$\mathcal{L}_\Pi = \frac{1}{T \cdot J \cdot C} \sum_{T,J,c\in C} w_{c,t,j}\, g\left(||\Pi_c \mathbf{x}_{t,j} - y_{t,j,c}||\right) \tag{4}$$

Where $g(\cdot)$ is the Huber loss and $w_{c,t,j}$ is the confidence of the detected keypoint. We also include an L2 regularization on the components of β corresponding to the site markers to prevent them from shifting too far from the default location:

$$\mathcal{L}_\beta = \frac{1}{87\times 3} \sum_{i=8...8+87*3} \beta_i^2 \tag{5}$$

The total loss is then:

$$\mathcal{L} = \mathcal{L}_\Pi + \lambda_\beta \mathcal{L}_\beta + \lambda_\epsilon \mathcal{L}_\epsilon \tag{6}$$

We did not find any additional regularization for temporal smoothness was necessary, although this could be an opportunity for future improvements. We only included the constraint violation loss, $\mathcal{L}_\epsilon$, when fitting the MyoSkeleton model.

1) Bundle adjustment: Because the entire system, including the camera parameters, is end-to-end differentiable, we can also perform bundle adjustment to further refine the calibration parameters. Specifically, we allowed the translation and rotation parameters of Π_c from (4) to be learnable parameters, while performing the optimization. We used a learning rate schedule that only allowed these parameters to start adjusting later during the optimization process.

2) Implementation and Optimization details: Our implicit representations were implemented in Jax using the Equinox framework [28]. We used an MLP with layer sizes of 128, 256, 512, 1024, 2048, 2048, 4096. Time was scaled to not exceed π and was positionally encoded, using an encoding dimension

of 29. We performed optimization with the AdamW optimizer from Optax [29], [30], using $\beta_1 = 0.8$ and weight decay of $1e-5$. The learning rate used included an exponential decay from an initial value of $1e-4$ to an end value of $1e-7$. We used 40k optimization steps with bundle adjustment enabled at the 30k step using a separate Adam optimizer with a learning rate of $1e-5$. We typically performed this on an A6000 and found it could perform more than 500 iterations a second for a single trajectory of 10 seconds. For typical sessions with 10 trials, this optimization took several minutes. Because Jax operates more efficiently on fixed array sizes (new array sizes trigger tracing and recompiling the code), when training on multiple trajectories with different lengths we would randomly sample a set of 300 time points from each trajectory per iteration.

G. Trilevel optimization

One challenge is placing all of the markers on the biomechanical model in a location that is consistent with the marker locations produced by the model. When developing our prior method using nimblephysics, we iteratively optimized many separate runs and then applied the mean marker offsets to the original unscaled model. Several rounds of this process did improve our results [17]. However, this process required repeatedly correcting some of the marker locations that shifted too far and did not necessarily produce the optimal locations.

We took advantage of the fact that our framework is fully differentiable and runs extremely quickly to jointly optimize the default marker locations by fitting the model to 31 different individuals from our dataset with 2 trials per individual, which we found could be performed on a single 80GB A100. This optimization included multiple of the 31 independent models similar to the one described under bilevel optimization. However, the marker offset for the base model was also made learnable, with the models from the 31 individuals each being independently scaled $\mathcal{L}_\beta$ applied to their independent site offsets. To prevent the markers from shrinking inward, which we had initially observed, we froze the position of the bilateral heel markers on the base model. We performed this process once at the beginning of this work and then used this optimized base model to fit all of the trajectories for each individual using a bilevel optimization approach, which then scaled the model and learned individualized marker offsets with regularization from (5) to prevent the markers moving much beyond this.

H. Baseline biomechanics

We compare the biomechanics results against our prior methodology, which decomposes this into two steps equivalent to a typical biomechanics pipeline [16], [17]. Specifically, it uses an implicit representation to reconstruct the 3D marker trajectories over time, which we found produced better results than optimizing explicit marker trajectories directly or robust triangulation. It then uses the nimblephysics library for bilevel optimization, which fits the model scaling and marker offsets while performing inverse kinematics for each trial. However, in contrast to the approach proposed in this paper, this prior approach is not end-to-end differentiable so the nimblephysics model results are optimized against the reconstructed marker trajectories instead of the raw image observations. We hypothesized this decomposition would limit performance.

I. Performance metrics

1) Geometric Consistency: We measured the geometric consistency between the model-based marker trajectories and the detected keypoints, based on the distance between the reprojected model-based markers and the detected keypoints. To quantify this, we computed the fraction of the points below a threshold number of pixels, conditioned on being greater than a specified confidence interval.

$$\delta_{t,j,c} = ||\Pi_c \mathbf{x}_{t,j} - y_{t,j,c}|| \tag{7}$$

$$q(d, \lambda) = \frac{\sum(\delta_{t,j,c} < d)(w_{t,j,c} > \lambda)}{\sum w_{t,j,c} > \lambda} \tag{8}$$

Below, we report $GC_d = q(d, 0.5)$ with $d = 5$ pixels.

2) GaitRite comparison: We compared the heel marker position from the forward kinematics to those measured by the GaitRite to measure the error of each step length, stride length, and step width. We report the width of the error distribution as normalized IQR, $\sigma_{IQR} = 0.7413 \cdot IQR(x)$. We use this in place of the standard deviation because it is more robust to the few outliers we observe, and we also show the histogram of errors in the results.

III. Results

A. Visualizations

We first visually confirmed the quality of the reconstructions by creating videos comparing the reprojected model-based markers reprojected into each of the image planes to the 2D keypoint detections. Figure 1 shows an example frame from 10 cameras acquired simultaneously, showing close alignment between the reconstructed and detected keypoints.

We also used the Mujoco renderer videos of the walking trajectories, which replicated the movements seen in the videos. Figure 2 shows example frames from a walking trial, reconstructed with both skeletons. Note that the fully articulated MyoSkeleton hand is not properly constrained by the 87 keypoints used.

B. Samples waveforms

Figure 3 shows sample waveforms from a single trial from a control participant reflecting a stable, symmetric, periodic gait pattern. Figure 4 shows a sample waveform from a participant with a history of stroke which captures the spatiotemporal asymmetry and greater step-width variability.

C. Reprojection loss

We also compared the error in the camera reprojections between our prior approach and the new approach, measured by the fraction of sites that reproject within a specific number of pixels, GC_x. We found that the end-to-end optimization approach with differentiable biomechanics had a better GC_5 for almost every trial. When comparing the GC_5 for trials

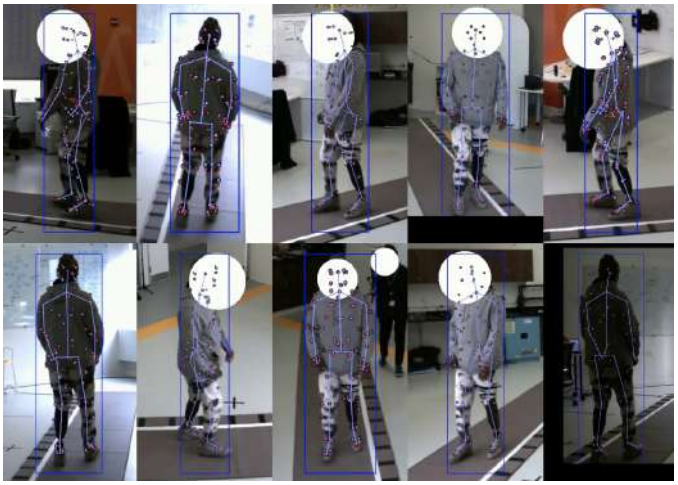

Fig. 1. Visualization of reprojection errors. Each panel is a zoomed in crop from the image around the detected bounding box from a different view. The red dots are the 87 detected keypoints in each frame and the blue dots are the reprojected model-based markers, with the drawn skeleton connecting a subset of these keypoints.

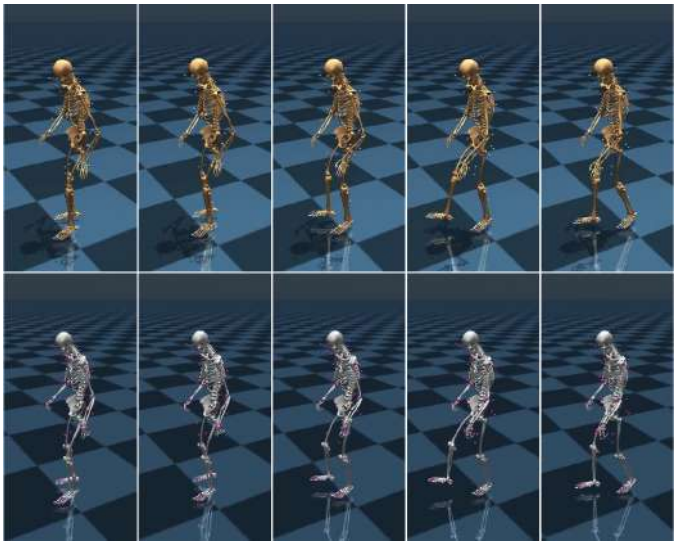

Fig. 2. Sample rendered frames from a walking trial fit from an individual with a history of stroke using a cane on the left side. The top row is the modified LocoMujoco skeleton and the bottom row is the MyoSkeleton.

using differentiable biomechanics without and with bundle adjustment enabled, we also saw a performance improvement. The average GC_x curve for differentiable biomechanics with calibration exceeded the other approach for all x values (Figure 5).

We quantified this difference by performing an ANOVA with method as the main factor and GC_5 as the dependent variable. This was highly significant ($p < 1{\times}10^{-5}$, $F = 4418$) and a post-hoc Tukey test showed a significant difference between all conditions. This included the small 1.9% increase in GC_5 when enabling bundle adjustment. Note, that this analysis only included 851 of the trials in our dataset, as we do not routinely run reconstruction with Nimblephysics anymore.

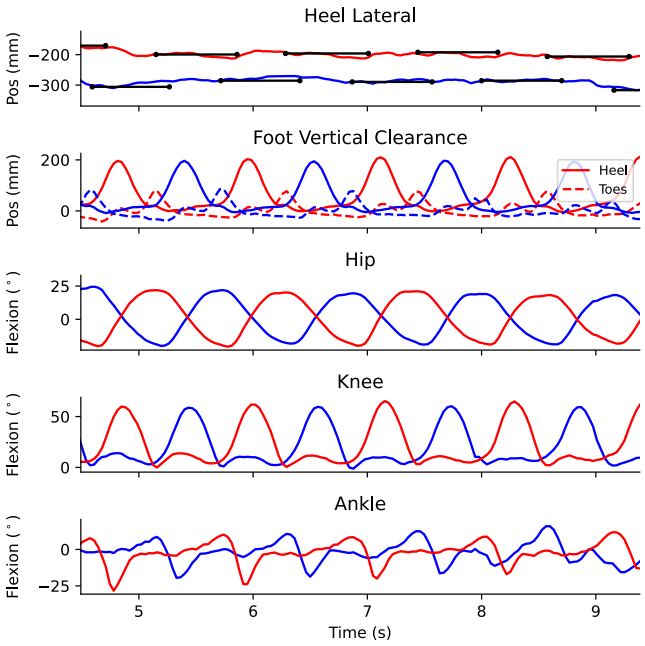

Fig. 3. Sample waveforms from a control participant. The left leg is shown in blue and the right leg is shown in red. The top row shows the lateral position of the heel with the positions detected from the instrumented walkway shown in black. The next row shows the vertical clearance from the heel and toes. The last three rows show the flexion angles for the hip, knee, and ankle, respectively.

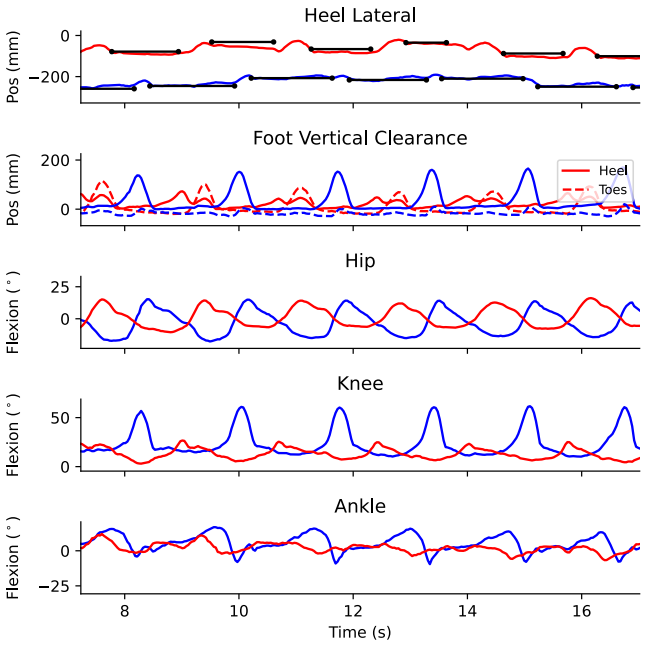

Fig. 4. Sample waveforms from a participant with a history of stroke, corresponding to the visualization from Figure 2. This captures the reduced range of motion on the right hemiparetic side, particularly with reduced knee flexion.

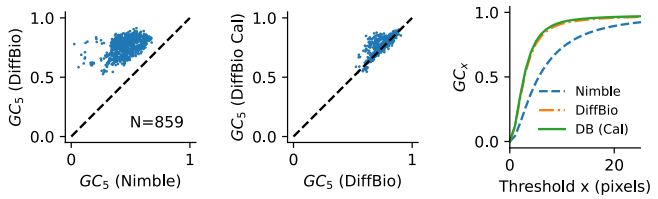

Fig. 5. Reprojection losses for reconstruction with two-stage approach using implicit representation followed by nimblephysics versus end-to-end approach with implicit representation and forward kinematic biomechanical model in mujoco. The left panel compares the GC_5 between our prior two-stage approach using nimble physics (horizontal axis) with differentiable biomechanics (vertical axis) for a number of trials. The middle panel compares trials with and without bundle adjustment to refine calibration. The right panel shows the average GC_x as a function of the pixel threshold for those trials.

D. Step parameter errors

We also compare the errors in the spatial step parameters computed between the GaitRite and the heel marker from the fitted model. The process of aligning the reference frame spatially and temporally between the two systems was the same as our prior work [16], with an affine transformation and temporal offset computed to minimize the error over a set of trials. Note this marker location does not precisely correspond to the same anatomic location as the center of pressure from the heel measured by the instrumented walkway, but provides a rough estimate of accuracy. Figure 6 shows the distribution of errors for each of these parameters.

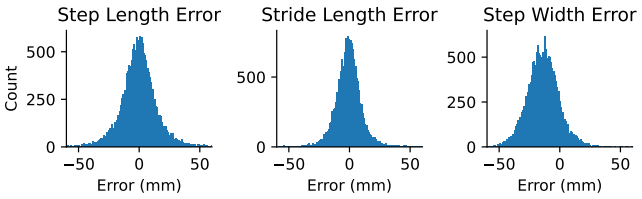

Fig. 6. Histogram of step length, stride length, and step width errors comparing the GaitRite and biomechanical reconstruction.

Table I shows the σ_{IQR} for each of these parameters broken down by several clinical populations. We see for control participants, the error is about 8-10 mm across the parameters but is slightly higher for some of the clinical populations. In particular, for some of the clinical populations, the step length error increases more than the stride length error. We hypothesize this may arise due to asymmetries in weight loading that are measured differently from the instrumented walkway than from the location of heel markers. This may also be due to reduced keypoint detection accuracy of HPE algorithms in some clinical populations, which we have shown for lower limb prosthesis users (LLPUs), particularly those with more proximal or bilateral amputations [31]. Finally, the error may also arise from keypoints detected on physical therapists who are often walking closely to the participant for safety, which are then misattributed to the participant, although our Huber loss is generally robust to this [16].

TABLE I
σ_{NIQR} FOR GAIT METRICS BROKEN DOWN BY CLINICAL POPULATION, AS WELL AS THE NUMBER OF SUBJECTS AND TRIALS IN EACH CATEGORY.

Population	Step Width	Stride Length	Step Length	Subjects	Trials
Controls	10.6	8.1	7.9	29	622
LLPU	10.6	9.0	15.1	46	431
Neurologic	12.4	10.2	19.1	37	333
Orthopedic	15.3	8.5	7.9	5	37
Pediatric	16.2	13.1	15.1	5	34

TABLE II
GAIT METRICS OVER ALL TRIALS FOR DIFFERENT MODELS AND OPTIMIZATION APPROACHES.

Model	Bund Adj	Step Width	Stride Length	Step Length	GC_5
LocoMujoco	False	12.31	9.97	13.00	0.70
LocoMujoco	True	12.19	9.05	12.57	0.72
MyoSkeleton	False	12.33	9.91	13.17	0.69
MyoSkeleton	True	12.18	9.07	12.73	0.72

We also computed this for the LocoMujoco model and the MyoSkeleton model, both with and without bundle adjustment. We found that both models perform well, despite the MyoSkeleton having higher degrees of freedom. Errors in the spatial gait parameters were similar to our prior work, although here we computed on a large sample [17].

IV. DISCUSSION

Having a fully differentiable biomechanical model that can be accelerated on a GPU is an extremely powerful tool for rehabilitation and movement science research. Here, we showed we can drive this forward kinematic with implicit representation for movement trajectories and optimize them to get accurate movement reconstructions. The trajectories from multiple trials can be jointly optimized with the skeleton scaling and marker offsets in a consistent end-to-end framework, providing a straightforward implementation of bilevel optimization [18].

Our model also allows trilevel optimization, where multiple individuals' trajectories and skeleton scaling are fit simultaneously while also optimizing the base model marker offsets. This is a powerful tool for integrating biomechanics into different computer-vision pipelines, as in our experience, inconsistencies between marker conventions are a source of error. Now, these markers can be roughly initialized and attached to the right body component and then fine-tuned on an entire dataset. This will be convenient for creating new models for new HPE algorithms, such as detailed hand tracking or other commonly used markersets. We did note some limitations from our trilevel approach. The first limitation was that only 31 individuals with 2 trials each were used due to limitations in GPU memory, and this many people might not be sufficiently representative. This limitation arose as all trials were processed for each iteration. In the future, we will implement mini-batching over subsets to allow jointly optimizing parameters over many participants. We are also experimenting with manually setting and anchoring additional

markers that are anatomically well-defined in addition to the heel, as we saw that the elbow site location was displaced more anterior than we believe it should be. Thus, the current model risks introducing a biased offset in the joint angles compared to ground truth.

Our results show that end-to-end optimization produces fits that are more geometrically consistent with the detected keypoints than a two-stage optimization approach, as measured through the GC_x of the reprojected fit results. This is fairly unsurprising, as decomposing the problem does not allow the initial trajectories to be directly constrained by the biomechanical model. Our prior work with the implicit representation included explicit regularization to keep the bone lengths consistent over the trajectory for certain keypoints [16], but for many keypoints, such as those in the foot or the middle of a limb, it was less clear how to structure those constraints. In our fully differentiable implicit reconstruction approach, these constraints and others, such as joint limits, arise naturally from the biomechanical model fit for each individual over multiple trials. In the case of the MyoSkeleton, this also extended to the joint equality constraints to allow fitting the many degrees of freedom over the spine with anatomically valid values.

We exploited differentiability through the camera model to incorporate bundle adjustment into the later iterations of optimization, to refine extrinsic camera parameters. This step made a small but significant improvement in the reprojection errors and the step parameter errors. This is despite us already performing a rigorous calibration with anipose before each experiment [24]. While we are not ready to skip the calibration step yet, removing this need is another useful step to making MMC even easier to use. This also suggests a path to optimizing other differentiable meta-parameters for a session, such as how we account for the keypoint confidence scores.

Optimizing how we account for keypoint uncertainty is another opportunity to improve the reconstructions we have not yet explored. Our current approach does not produce confidence bounds on the joint angles, which will vary across a trial based on the number of cameras viewing certain markers and their relative geometry. Reliable confidence estimates are critical for wider usage, particularly in clinical settings, as knowing when you can trust the data is essential. In the context of lifting from 2D to 3D keypoints, we have shown that fitting probabilistic models and optimizing the negative log-likelihood (NLL) instead of minimizing a point estimate of error can produce these calibrated uncertainty estimates [32]. Our recent work demonstrates that we can expand the implicit representations over joint angles to a probability distribution and optimize it using variational inference to accomplish this aim [33].

Computing confidence over joint angles will also benefit approaches where obtaining ground truth information is hard. This includes large-scale data collection on representative clinical populations, as in our current work. This also includes tracking the hand, where placing markers on individual joints is impractical and alters the visual appearance and function of the hand. The MyoSkeleton [13], [14] includes a fully articulated hand, and we have also ported the MoBL-ARMS biomechanical model [34] to MuJoCo. The end-to-end optimization approach we demonstrate here can be extended to full hand tracking with only a few millimeters of error [35]. We have also validated our end-to-end approach for multiview video reconstructions against marker-based motion capture of arm kinematics during a drinking task and find agreement within a few degrees [36].

It is reassuring that our model produces high-quality fits for a range of clinical populations, including lower-limb prosthesis users, those with neurologic conditions, pediatric patients, and people with musculoskeletal conditions. The step parameters do increase in some populations, with the noise in the step length increasing to as high as 2cm for individuals with neurologic conditions often walk with an accompanying therapist, where keypoints from the wrong individual may be mis-associated. This suggests opportunities for improving the geometric scene understanding and using multi-person tracking to improve the results further. Stride length remains 1cm in this condition, which may also suggest this relates to systematic differences between measuring weight pressure locations versus computer vision.

While multiview markerless motion capture is a powerful tool that produces accurate results, it has limitations. This includes substantial amounts of processing power and time to analyze the results. Furthermore, our optimization approach is fit to the full trajectory, precluding any attempt to make it run in realtime. Another limitation is the requirement of multiple cameras. Thus, we are excited about our recent results demonstrating this technique can be extended to smartphone video, showing a close correspondence to results from multiview video [37].

GPU-accelerated biomechanical models offer additional opportunities. We are currently extending the implicit representation to include actions, allowing optimization of dynamic rollouts with ground reaction forces and joint torques. We also recently showed that using reinforcement learning (RL) to train an imitation learning policy driven by monocular computer vision improves gait analysis from single camera views [38], which can be further improved by using the more accurate biomechanical models in MuJoCo. Finally, MyoSuite is building a community and set of tools around neuromuscular and biomechanical modeling using Mujoco, and the work we described here will enable the creation of large-scale datasets of movements from real people compatible with their tools [13]. This hybridizes well with recent advances such as the SKEL and OSSO model [39], [40], which map biomechanical models to the body models more typically used in computer vision research, such as SMPL [27].

V. Conclusion

Fully differentiable biomechanical models that can be accelerated on a GPU are a promising tool for rehabilitation and movement science. Here, we demonstrate an end-to-end bilevel optimization algorithm to scale biomechanical models, compute inverse kinematics over multiple trials, and even

perform bundle adjustment of the camera calibration. This end-to-end optimization approach can both improve the accuracy of biomechanics from multiview markerless motion capture and open up new avenues.

***Abstract*— Effective rehabilitation is critical for individuals with motor deficits, such as following a stroke or brain injury. Although high doses of intensive motor rehabilitation can provide maximal benefit, several barriers can prevent attaining necessary therapy levels, including cost, physical access, clinical resource availability, and patient disengagement. Virtual Reality (VR) offers a potential solution to overcome these challenges and enable home-based, self-directed therapy. Here we present custom software that runs on the low-cost Meta Quest 2 headset to deliver immersive rehabilitation exercises. The system uses movement amplification to virtually reduce motor deficits, enabling successful task completion even in individuals with severe disabilities. This approach leverages reinforcement learning to maintain patient engagement during rehabilitation. The system capitalizes on recent advances in VR technology, including inside-out hand tracking, voice recognition, and a responsive virtual coach, to create a more accessible environment for users with no prior VR experience. We present the custom virtual rehabilitation implementation and test whether motor amplification leads to an increase in visually induced motion sickness experienced by individuals without disabilities. We find that motor amplification does not elevate reported motion sickness levels, suggesting that low-cost VR systems may enable increased access to individualized and guided motor rehabilitation.**

Keywords—motor rehabilitation, virtual reality, assistive technology, accessible healthcare

I. Introduction

Emerging medical treatments have improved survival rates for many conditions, including stroke [1] and neurodevelopmental disabilities [2], with the consequence of increased disability rates. For example, over the past 30 years, stroke has led to a steady increase in disability-adjusted life-years lost, especially in lower and lower-middle-income countries [1]. Motor, sensory, and cognitive deficits associated with stroke, traumatic brain injuries and neurodegenerative disorders contribute to a loss of function that makes daily life challenging, often requiring intensive and expensive assistive care. Motor disabilities often lead to a reinforcing cycle – the more difficult it is to use an affected limb, the less it will be used, and the more quickly remaining function will be lost. Overcoming this process of learned non-use, such as in the approximately 70% of stroke patients with upper limb motor deficits [3], is a key focus of efforts to improve access to motor rehabilitation.

Higher doses of therapy following an acute loss of function – including physical therapy, occupational therapy, and speech and language therapy – lead to better recovery outcomes [4], [5], [6]. For example, using and moving a limb affected by a stroke is critical to leveraging the brain's natural neuroplasticity in regaining lost motor and sensory function, and ultimately improving daily life functionality. Many effective treatments capitalize on this principle including constraint-induced movement therapy [7] and emerging robot-assisted systems [8].

There are numerous impediments to providing high volumes of motor rehabilitation therapy, which means patients often receive less care than they should [9]. Access to treatment can be limited by cost. For example, a best practice stroke rehabilitation protocol, constraint-induced movement therapy, spans 10 to 15 days with up to 6 hours of therapy per day [10], costing thousands of dollars [11]. Other emerging rehabilitation technologies such as robot-assisted therapy also require high costs and significant clinician oversight [8].

Physical access to rehabilitation services is another barrier patients face. Long distances to clinics in areas with limited transportation options can be difficult to overcome, especially for patients that often suffer from limited mobility. Barriers to travel to seek rehabilitation services are exacerbated in rural areas [12].

Some of these barriers to accessing treatment can be reduced by prescribing home exercises which have been shown effective in reducing disability, improving quality of life, and increasing patient self-efficacy [13]. However, at-home therapies face their own barriers to maximal

This work was supported by ResearchNS under the New Health Investigator Grant program.

effectiveness. Rates of exercise completion are low with about 60% of patients not fully adhering to at-home physiotherapy programs [13], [14], and even compliant patients incorrectly executing 10-20% of exercises after clinician instruction [13], [15]. Patients often struggle to incorporate exercises into their daily lives [14]. Memory issues, especially in older adults, contribute to noncompliance [16]. Increased clinician-patient interaction improves compliance with home exercise programs [17] yet resource constraints and access barriers limit this option.

Virtual Reality (VR) solutions have the potential to expand patient access to therapy and ultimately improve rehabilitation outcomes. Immersive VR rehabilitation has shown significant benefit compared to conventional rehabilitation, particularly with improvements in activities of daily living and gross motor function [18], [19]. For example, stroke patients receiving VR rehabilitation therapy as a supplement [20] or instead of [21] conventional rehabilitation therapy have shown significant improvements on the Box & Block Test and Fugl-Meyer Upper Extremity Scale, respectively.

Several recent efforts [22], [23] have implemented gamified rehabilitation exercises on the Meta Quest 2, an affordable commercially-available system that supports controller-free hand tracking. Gamified exercises have consistently been shown to boost motivation and engagement [24], [25].

One approach to boost engagement is to artificially reduce motor deficits in the virtual environment, leading to more consistent task completion that leverages positive reinforcement to encourage ongoing system use. When a stroke-affected limb's real-world movements are amplified in the virtual space, stroke patients are more likely to use their motor deficient limb, suggesting a way to counteract learned non-use [26]. On the Meta Quest 2, others have attempted to diversify the range of grasps in VR for those with motor deficits [27] or to use relocation algorithms to adapt the virtual world to a user's range of motion [28].

One key concern with virtual reality-based rehabilitation systems is the potential for induced motion sickness [29]. In previous work, VR users have demonstrated sometimes debilitating motion sickness, an effect more pronounced in women [30]. The expectation is that emerging VR technologies may reduce visually-induced motion sickness (e.g. [31]), but this has not been systematically tested with the latest technology. A key step in determining the initial feasibility of a low-cost VR rehabilitation system is to assess levels of motion sickness in its users, particularly when motor amplification is applied.

Here we describe a novel virtual reality rehabilitation system that addresses some of the systemic and individual patient barriers to treatment, namely limited location flexibility, high costs, and the need for constant clinician oversight. For an initial assessment, younger adults without disability tested our novel rehabilitation program to determine if motor amplification leads to increased visually-induced motion sickness in users.

II. Technology development

We developed a software program in which participants could engage in 12 gamified tasks, three of which were tested in this work. Tasks were designed to either emulate activities of daily living, such as pouring water into a glass, or serve as immersive games in which the hand becomes a controller in a classic game like Pong or Snake. Each task focused on one category of movement: 1) Gross reaching; 2) Reach and grasp; or 3) Precision Grasping. In this study, all tasks involved Gross reaching as this has been shown to be a motor skill most sensitive to immersive VR rehabilitation [19].

A. Virtual reality system

The VR setup used a Meta Quest 2 Head Mounted Display (HMD) connected to a Windows PC via a USB tether cable. The software used to develop this program was Unity3D with the use of the Oculus Integration Kit for VR interactions, including simulating the user's position in the virtual environment and capturing their inputs to drive actions like picking up an object. The headset can be used as a wireless standalone system to support eventual at home use.

B. Hand tracking and user input

The Meta Quest 2 HMD utilizes four infrared (IR) cameras built into the headset to facilitate positional tracking of the user in their environment, as well as to track hand positions for interactions in the program. This standalone headset enables the potential for future at home use with minimal setup, unlike typical VR headsets that require external IR cameras to be physically mounted in the environment around the user. Users can interact with the system by touching virtual buttons, manipulating objects, and using voice commands detected with an onboard microphone.

C. Physics interactions

The virtual environment presented to participants simulates the physics of gravity and normal forces in the real-world using engines built into the Unity environment. Due to the lack of touch feedback with hand tracking, interactions with virtual objects rely on visual changes in VR. When the hand hovers over an object that it can interact with, the hand changes color from gray to yellow. When the first finger and thumb are pinched together while overlapping the object, the hand turns blue indicating that the object is being grasped. Now the object will move as the hand moves and can be moved to a different part of the virtual world. Users are given a demonstrative tutorial at the beginning of their VR experience to learn the nuances of interacting with a virtual environment.

D. Motor amplification

For users with limited range of motion, physical movements can be amplified in the virtual space, increasing their functional range of motion in VR [26]. The motor amplification algorithm works similarly to how a computer mouse's sensitivity can be adjusted on a desktop computer. A "rest" or center position is determined during calibration, and the position of the amplified hand relative to that center point is multiplied by an amplification factor. For example, a user sitting with their arm on a chair's armrest would have their rest position at that point in the world. Lifting the arm up 20cm from that point, with an amplification factor of 2, would mean

that the virtual hand appears in VR to be 40cm above the starting rest position. We accomplish this by taking the amplification factor and multiplying it by the position vector (the *x,y,z* value) of the amplification target. In the Unity3D environment, the *x* is the horizontal axis relative to the subject, the *y* is the vertical axis, and *z* is the depth (or the axis that extends directly out in front of the user).

The amplification factor is determined through a software-guided calibration process which measures the range of motion for both upper limbs and for hand grasp apertures. At the start of each session, participants complete a Calibration Task in which they are guided to reach to four targets in the virtual space: 1) straight ahead with full arm extension (arms parallel to table), 2) 45 degrees laterally left, 3) 45 degrees laterally right, and 4) 45 degrees above the horizon and straight ahead. Hand location (*x, y, z* position), rotation (*x, y, z*) and grip aperture (*fingerCurl* parameter in Unity) are continuously tracked throughout the Calibration Task. For positional amplification, the range of movement (maximum minus minimum position away from the body) in each of the three environmental axes is computed for both hands. The hand with lower movement extent in at least two axes is automatically selected to be amplified and is used as the target hand during virtual rehabilitation exercises. The proportional difference between the hand with greater range of motion and the hand with lesser range of motion is averaged across all three axes and that value is used to multiply the positions when motor amplification is applied.

Since the tasks tested in this study involved only gross reaching, wrist rotation and grip aperture amplification were not enabled. Nevertheless, the respective amplification factors are computed similarly to that of positional amplification.

E. Motor smoothing

Noise in the IR camera tracking system due to factors like lighting condition and the system's confidence in localizing hand positions can cause jitter in a visually displayed hand. In typical unamplified movements, this is not an issue as the positional noise is nearly imperceptible, but when amplified, it becomes apparent. To resolve this issue, the program uses a spring-damper function to adjust the hand's position proportional to the amount of amplification applied (i.e., the more a hand is amplified, the stronger the smoothing function becomes). This approach could theoretically introduce some lag in the graphics display, which is part of the reason why assessing visually induced motion sickness is important. However, it is unlikely for the delay to have a noticeable impact; amplification of at least 150% is necessary for the delay to equal the framerate of the headset, and there is a delay maximum of 300ms which would occur with amplification factors over 800%.

III. Assessment of Visually-induced motion Sickness

After the initial development of the VR software, we tested a sample VR rehabilitation session in younger adults without disability. All study protocols were conducted with the approval and oversight of the Acadia University Research Ethics Board (File #22-07). Sixty participants were recruited from the Acadia University student population using an online study recruitment platform. Students were enrolled in psychology courses and received course credit for their participation. Demographic information was collected from each participant including gender identity [M/F/other], handedness [L/R/other], and age.

A. Study setup

A Meta Quest 2 HMD connected to a desktop computer, as described in Section II.A., was used to implement the VR exercises (Fig. 1(a)). The experimenter could watch the participant's view of the virtual environment on a separate screen and provide assistance when needed. Including the Calibration Task and coach-guided instructions, the VR exercises lasted approximately 10-15 minutes. This was enough time to observe motion sickness as VR-induced nausea often occurs quickly, with mean onset times of 62 seconds reported for a VR rollercoaster experience [32]. Immediately following the VR session, participants completed a motion sickness survey. Other data were collected to generate a normative motor performance dataset and are not reported here. Half of the participants were randomly assigned to receive motor amplification of hand position; the other half served as a baseline control with no amplification.

B. VR tasks

All participants first completed a Calibration Task (see Section II.D.), after which amplification was enabled for the experimental group, and then all participants played the Bubble Pop game (Fig. 1(b)) (see below for detailed descriptions of each task). The Bubble Pop game was always played first as it was the simplest game, enabling users to engage most easily, and this provided consistency in the initial experience for participants. Participants then completed two more tasks, a Pong Paddle game (Fig. 1(c)) and an Animal Feeding game (Fig. 1(d)). The order of the last two tasks was counterbalanced: half of the participants within each group completed the Pong Paddle game first, while the other half completed the Animal Feeding task first. Here is a description of each task in the VR session:

Calibration Task: During this task, participants reach towards different locations in the room indicated by colored cubes. The software logs the minimum and maximum extent of points reached by the left and right hands to calculate the range of motion for each. In the Amplification group, the hand with the smaller movement extent is selected to be amplified by the proportional difference between the sides. The range of motion is also used to set the boundary area for object interaction in the tasks that follow. See Section II.D. for more details about the Calibration Task.

Bubble Pop Task: The user pops as many bubbles as possible within one minute. Bubbles appear one at a time and only appear within the participant's field of view within the headset. During this period the user's hand positions are recorded every 20ms to map their movements in the space.

Pong Paddle Game: While seated at a table, the user controls a paddle by moving their hand forward or backward. The hand with the lower range of motion is assigned to control the paddle, with this hand amplified in the Amplification condition. A small ball bounces across the board which is oriented from left to right. On the side opposite the user's

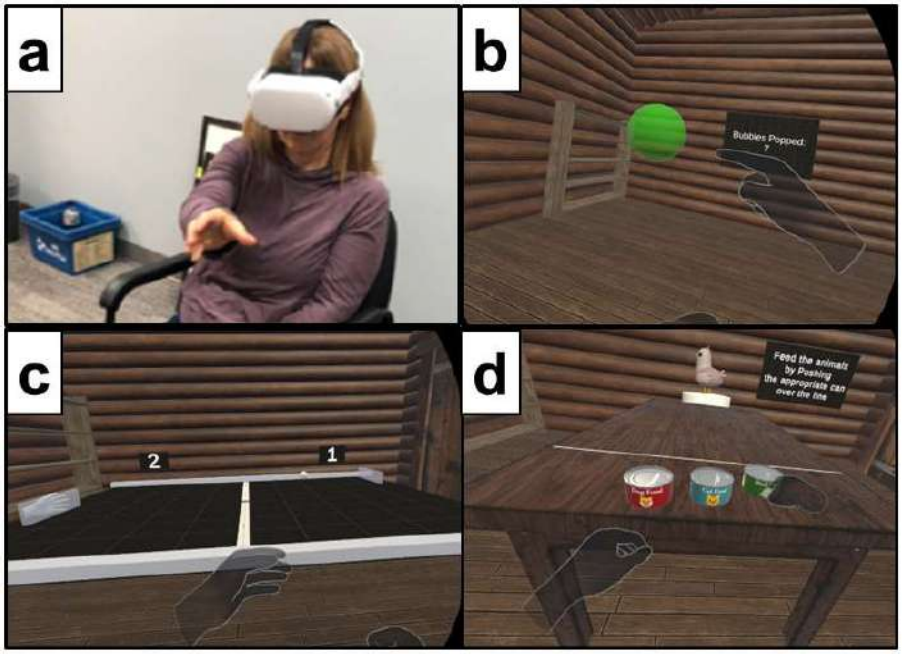

Fig. 1. Low-cost VR system overview. (a) User operating the system. (b) Screenshot of the Bubble Pop game. (c) Screenshot of the Pong Paddle game. (d) Screenshot of the Animal Feeding game.

paddle is a paddle controlled by the computer. A point is earned if the ball passes by the paddle of the opposing player. Participants practice the task for one minute and then complete a two-minute game.

Animal Feeding Game: The participant is seated at the end of a long table with an animal visualized at the far end of the table. The participant pushes forward one of three cans sitting on the table until it crosses a white line to "feed" the animal, with the line's distance calibrated to the user's range of motion. Each can is labeled as a food for one of three animals (a dog, cat, and bird) and users must push the can that matches the visualized animal. Once the can has crossed the line, the animal will change its appearance into one of the other available options and play a sound clip (a bark for a dog, a meow for a cat, and a tweet for a bird). Participants practice the task for one minute and then complete a two-minute game.

C. *Visually induced motion sickness survey*

Following the VR exercises, an abbreviated motion sickness symptom assessment was administered consisting of 5 of 9 items from the Virtual Reality Sickness Questionnaire (VRSQ) [33]: General Discomfort, Fatigue, Eyestrain, Difficulty Focusing, Headache. The mean score across the five items was used to indicate visually induced motion sickness immediately following the VR experience.

D. *Analysis plan*

To determine if motion sickness levels exceeded minimal levels following the VR experience, a Wilcoxon signed rank test was conducted (on the medians) with the alternative hypothesis that the true location is greater than 1 (median > 1). Wilcoxon rank sum tests were run for comparisons between groups for reported motion sickness levels. Medians (and thus the nonparametric Wilcoxon tests) were selected due to non-normally distributed zero-inflated data. Analysis scripts in the R programming language, along with all data, are available at OSF [https://osf.io/45kad/].

IV. Results

Sixty younger adults without disability completed VR rehabilitation exercises, with or without motor amplification. 47 participants identified as women, 10 as men, and 3 as non-binary. Participants ranged in age from 18 to 39 years old (mean age = 19.7 years, SD = 3.22 years). Three self-reported as left-handed.

Across all participants in both conditions there was a mean motion sickness score of 0.57 immediately following the VR experience (Fig. 2) (SD = 0.44, median = 0.4). Note that three participants did not complete all of the questions on the motion sickness survey and their data have been omitted from these results. As a motion sickness score below 1 indicates less than a mild response on the VRSQ [34], a Wilcoxon signed rank test with continuity correction rejected the alternative hypothesis that $u > 1$ ($V = 95.5$, $p = 1$).

Amplified group participants, with an average of 4.4% amplification applied, showed slightly higher motion sickness scores (mean = 0.64, median = 0.6) compared to control participants (mean = 0.50, median = 0.4), but a Wilcoxon rank sum test with continuity correction indicated that this was not a statistically significant difference ($W = 326$, $p = .20$) (Fig. 3).

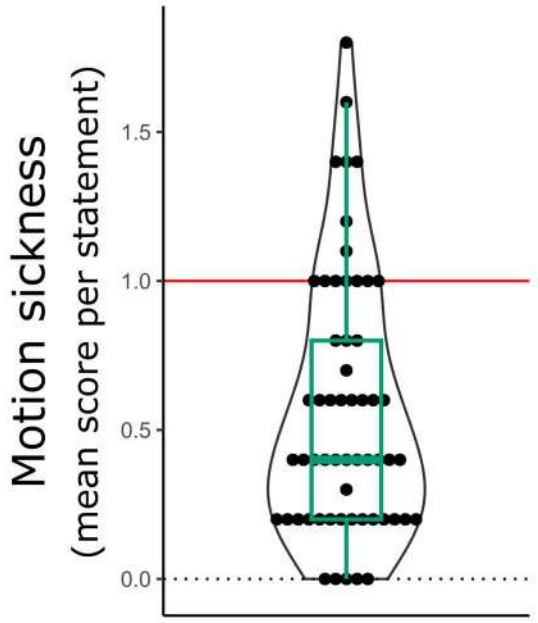

Fig. 2. Average motion sickness scores for all participants following the VR session. Dots represent individual participant mean scores, the box plot indicates the group median.

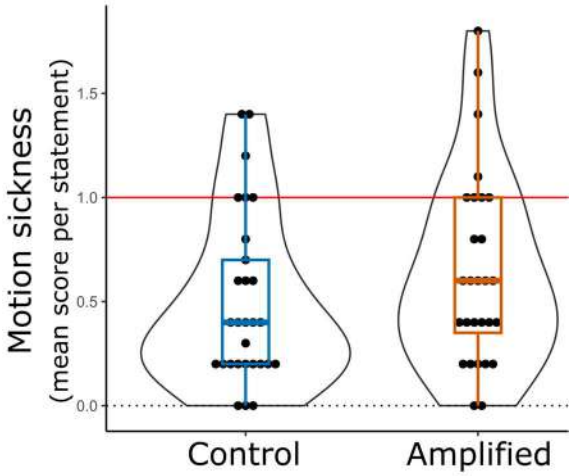

Fig. 3. Average motion sickness scores by amplification status during the VR session. Dots represent individual participant mean scores, the box plots indicate the group medians.

V. Discussion

We developed a virtual reality motor rehabilitation platform using a low-cost commercially available headset, the Meta Quest 2. In younger adults without disability tested in this work, we observed low levels of reported motion sickness, though slightly higher motion sickness levels were observed in the motor amplification group. Although this was not a statistically significant difference, it could indicate potential issues with the greater amplification factors required in clinical populations. Careful study with participants with reduced ROM requiring increased amplification is necessary to further investigate this.

Seven out of 60 participants did present average motion sickness scores above 1, suggesting that there is room for improvement in the VR system. However, no baseline motion sickness data were collected, so it is possible that other factors could have contributed to the feelings of motion sickness data reported. Nevertheless, more recently released low-cost headsets with improved graphics and hand tracking, like the Meta Quest 3, may organically reduce experienced motion sickness. Lessons learned from this study have led to subsequent software improvements, including a more standardized testing environment, improved virtual coach instructions and demonstrations, and more stringent task constraints to reduce head movements.

One key benefit of the system presented is its accessibility, which increases its potential for widespread implementation. By using a commercially available low-cost HMD, costs are reduced, thus increasing its availability to potential users. The calibration process enabling motor amplification allows for use by patients with a wide range of motor deficits. As this process is automated, unlike with other currently available software solutions [35], the need for clinician oversight is reduced. A virtual coach guiding participants through the exercises further supports standalone use at home. User-friendly interaction options make the technology more approachable for novice users, including hand tracking (i.e. the patients do not hold anything) and multiple interaction options (e.g. an option to speak commands to the virtual coach). Ultimately, the assistive motor amplification in gamified tasks demonstrated in this work enables more consistent task completion and more positive task engagement, supporting those with severe motor deficits.

The low level of reported motion sickness we observed indicates the potential for the use of low-cost off-the-shelf HMDs to deliver rehabilitation therapies. We are currently testing the system in older adults without disability and stroke survivors of all ages. With these additional results, we will continue exploring the platform's potential to deliver widespread access to evidence-based rehabilitation interventions, supporting motor recovery following brain damage.

Balance Assistance without Mechanical Support using a Virtual Cane with Haptic Feedback

Sindhu Reddy Alluri, Sambad Regmi, Fazlur Rashid, Devin Burns, Yun Seong Song, *Member, IEEE*

***Abstract*—Light Touch (LT) has been known to improve standing balance without mechanical support by providing sensory information about the movement of the body. Inspired by this, this work developed a Virtual Cane (VC) which gives no physical support but provides other sensory information that a physical cane would. The VC is developed with a distance sensor and vibration actuators to provide cane tip-to-ground distance information to the user. The extent to which this haptic feedback improves standing balance was assessed in a human experiment. 10 healthy young participants underwent a standing balance experiment with tandem stance and eyes closed, using VC with No Feedback (NF) as the baseline, VC with feedback, and with physical cane (PC). Center-of-Pressure (CoP) metrics as well as Sway-density metrics were analyzed to study the effect of these conditions on standing balance. It was found that the CoP metrics in VC were significantly improved compared to baseline (NF) and approaching the benefit of a full physical cane (PC). Sway-density metrics showed no difference between the conditions. This shows that simple, binary feedback from VC on the position of the body and cane was sufficient to positively affect standing balance without significantly altering the biomechanical strategy of standing balance. This is also a demonstration of an assistive device with a complete absence of mechanical support that can provide substantial benefit to balance.**

I. Introduction

Falls are the second leading cause of accidental or unintentional injury deaths worldwide, where each year an estimated 684,000 individuals die from falls globally according to the World Health Organization (WHO) [1]. In particular, falls are one of the major causes of life-threatening injuries in older adults [2, 3]. Passive assistive devices such as canes, crutches, or walkers, can help improve balance and reduce the risk of falls, especially for populations who require substantial physical assistance [4].

Light interaction forces, or light touch (LT), may help improve balance while allowing users to use their functional muscles. Without relying on substantial physical support, it was shown by Jeka [5] that light contact of the fingertip on a rigid surface was enough to reduce the Center-of-Pressure (CoP) sway of healthy individuals during quiet standing. That is, a simple application of a small force onto one of the most distal parts of the human body (fingertip) was sufficient for the human participant to outperform his/her own best effort to stand as still as possible. Such improvement was observed in a wide range of populations, including healthy young adults [5, 6], healthy older adults [9], stroke patients [8, 9], peripheral neuropathy patients [10], Parkinson's Disease patients [11] and anterior cruciate ligament (ACL) injury patients [12]. LT was also shown to affect balance during treadmill walking [13]. Interestingly, this improvement in the balance due to LT is not due to mechanical support. Indeed, the LT magnitude is too small (often below 1 N) to provide any meaningful physical assistance [4, 5, 14, 15]. Instead, it is suggested that the additional sensory information about the body movement with respect to a fixed reference, which is provided through LT, helps improve balance [5, 14, 16]. This was demonstrated in [16] using virtual LT, where the information about the position of one's body provided through vibrations could improve standing balance. However, the device in [16] required an indoor motion capture system which cannot be deployed in everyday outdoor activities.

Inspired by the balance improvement from LT, our goal is to understand the effect of providing sensory information about body movement on standing balance and to investigate the potential of a new type of balance assistive device that does not provide mechanical support, which also shows potential for practical use. For this, we investigated the balance assistance by one of the most widely used items, a cane. While the physical contact between a typical cane handle and the hand of the user may not be considered an LT, the contact of the cane to the ground and the subsequent sensory information through the hands could resemble the information provided by LT, thereby improving balance. In this work, an instrumented cane (hereon called the Virtual Cane, or VC), is developed that can provide information about the hand position with respect to the ground surface. This VC, however, does not make any contact with the ground and therefore does not provide mechanical support that physical canes do. We hypothesized that, if the hand position information can be provided to the user of VC without making physical contact with the ground, then balance improvement would be observed. We further hypothesized that this improvement would be less than the total benefit provided by a physical cane that makes contact with the ground and provides mechanical support in addition to sensory information.

II. METHODS

A. Apparatus

The VC was designed to allow the testing of the above-mentioned hypothesis such that it is capable of delivering information through the hand and assisting in improving human body balance. In this view, the VC should feel like a physical cane in its weight and inertia, except for the inevitable difference in the sensation of contact with the ground. To ensure as similar a mechanical feel as possible, we developed VC apparatus - a foldable cane with a sensor that measures the distance between the cane and the ground, and a glove that provides this information to the user in the form of vibration. The trifold physical cane (Figure 1) is height adjustable (83 cm ~ 93 cm). At 21 centimeters from the bottom of the shaft of the physical cane, an Ultrasonic sensor (HC-SR04; measurement range of 2 ~ 500 cm, resolution of 0.3 cm) is mounted. This is used to measure the distance between the bottom tip of the folded cane and the ground. This information is monitored by an Arduino Uno microcontroller which modulates the vibration actuators on the instrumented glove (Figure 1). If the distance measured is 21±2.5 cm, there is no vibration. If the change in distance is more than 2.5 cm from the nominal distance of 21 cm, the vibration actuators are turned on to inform the user of this deviation. The vibration "dead zone" of 5 cm was selected to be more than 10 times the sensor resolution, but less than 10% of the length of the cane. The glove consists of three bend sensors/ short flex sensors (ID:1070, Adafruit.com) and four vibration actuators (ID:1201, Adafruit.com). Bend sensors are placed along the top sides of the thumb, middle finger, and little finger of the glove, and are used to detect if the hand is making a grip while holding the cane. This was to prevent the vibration actuators from unnecessarily turning on during experiment trials. Vibration actuators were attached to the outer side of the glove at the fingertips.

B. Experiment Procedure

Ten healthy young participants were recruited for standing balance experiments (5 males, 19-30 years of age). All the participants were physically active and healthy with no self-reported history of neurological disorders or musculoskeletal injuries. The protocol was approved by the Missouri S&T Institutional Review Board (IRB). All participants provided written consent.

The participant was asked to stand on the force plate (Optima OPT400600HF, Advanced Material Technology Inc., sampling frequency of 1 kHz) without shoes with the tandem stance (right foot forward [17]) with their eyes closed, as depicted in Figure 2. This provided challenges to standing balance which would otherwise be trivial for the study population. To ensure the same foot position in all the trials for all participants, the anterior-posterior axis was marked on the center of the force plate using adhesive tape. The participants were given two minutes to get accustomed to the pose. Their right hand with the instrumented glove held the handle of the cane to a comfortable height while their left hand rested freely on the side. This pose was maintained throughout the trials. After the 2-minute accustomation. The participant was instructed to stand as still as possible during trials with one of the three conditions:

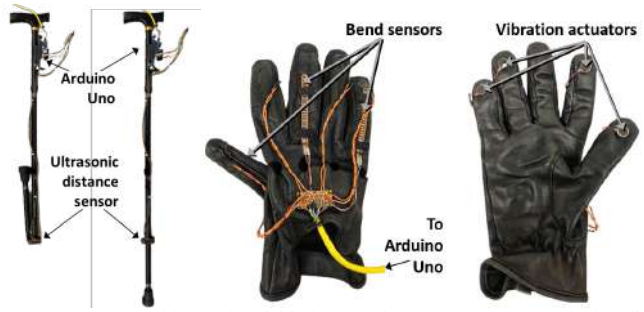

Figure 1. (Left) Folded and unfolded VC with an Arduino Uno at the handle and an ultrasonic sensor at the bottom fold of the cane's shaft. (Right) Instrumented glove. The outer side has the bend sensors on the thumb, middle, and little fingers. The inner side of the glove shows the vibration actuators.

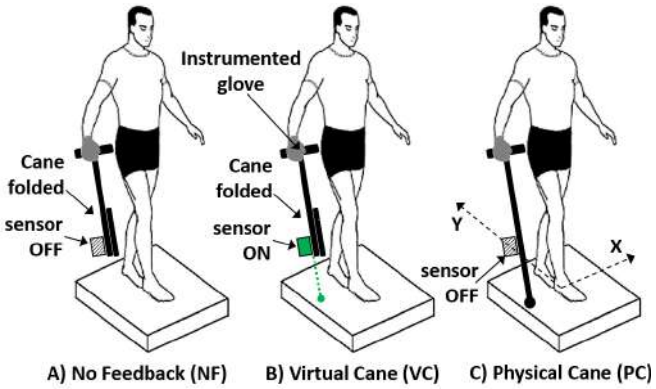

Figure 2. A participant standing on the force plate in tandem stance, with eyes closed, right foot in front of the left in three control conditions. A) No Feedback, B) Virtual Cane, and C) Physical Cane.

i. No Feedback (NF) – In this control condition, the participant held the physical cane whose bottom quarter of the shaft was folded, and the instrumented glove with the vibration actuators was turned off for the entire length of the trial. They held the cane to a height that an unfolded cane would have touched the ground. This condition preserved the sense of mechanical grip on the handle as well as the sense of the inertia of the physical cane (weight and rotational inertia) but did not provide mechanical support or the sense of the cane touching the ground.

ii. Virtual Cane (VC) – In this condition, the cane remained folded, but the instrumented glove was powered on. The ultrasonic sensor on the cane pointed to the surface of the force plate (note that the participants were able to maintain the VC to point on a surface on the force plate). The distance between the sensor and the ground (force plate surface) was constantly measured. Whenever this distance deviated from the expected distance of 21 cm by more than a 2.5 cm threshold in either direction (providing a 5 cm thickness of no vibration zone), feedback was provided to the participant's fingertips by turning on the vibration actuators. The amplitude of the vibration was constant and did not depend on the distance measured by the sensor. This condition provided no physical assistance from the cane but provided information to the user on the distance between the sensor and the ground, similar to what a normal cane would provide.

iii. Physical Cane (PC) – In this condition, the glove was powered off and the participant was given physical support

by resting the end of the unfolded cane shaft on the surface of the force plate. The participants were free to exhibit their desired amount of force through the cane as they would with any ordinary cane.

Each participant performed three blocks of 12 trials (36 trials total), with four of each condition whose order is randomized in each block. The duration of each trial was 20 seconds. A 5-minute break was given to the participant after each block. In each trial, the force plate measured the ground reaction forces and torques.

C. Analysis

Data from blocks 1 & 2 were not analyzed to help mitigate learning effects. The third blocks of all 10 participants were analyzed using MATLAB (MathWorks) to derive the center of pressure (CoP) during the trials. This data was then smoothed with a moving average filter with a 100 ms window. The standing balance was analyzed in terms of the variability metrics of the static (CoP) and dynamic (velocity of CoP) aspects commonly used in standing balance studies that involves haptics and/or LT [14, 18, 19]. From the CoP of each trial, the mediolateral (CoPx) and the anterior-posterior (CoPy) CoP, as well as their time derivatives (vCoPx, vCoPy) were obtained. The standard deviations of these values, SD-CoPx, SD-CoPy, SD-vCoPx, and SD-vCoPy, were then obtained for each trial. As the distributions were reasonably normal (Figures 3 and 4), each metric of balance was then analyzed with 2-way ANOVA using SPSS (IBM, version 23) with participants and conditions (NF, VC, or PC) as fixed effects. Tukey HSD was used to test the significance at $p < 0.05$.

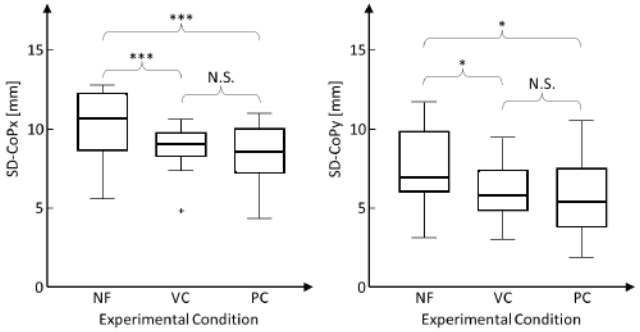

Figure 3. Box plots of SD-CoPx and SD-CoPy of all participants by experimental condition. *denotes $p < 0.05$, ***denotes $p<0.001$, N.S. denotes not significant ($p > 0.05$).

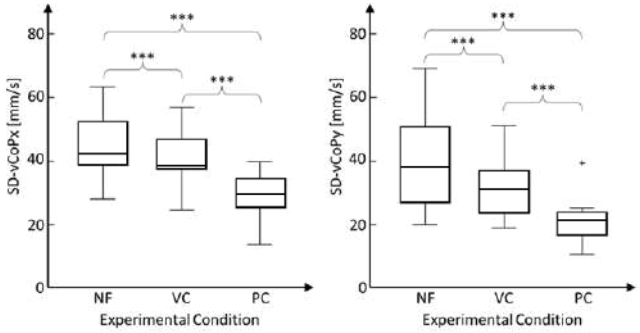

Figure 4. Box plots of SD-vCoPx and SD-vCoPy of all subjects by experimental condition. ***denotes $p<0.001$.

TABLE I. SWAY-DENSITY METRICS

	MeanP	MeanT	MeanD
Condition	$p = 0.733$	$p = 0.711$	$p = 0.642$
Participant	$p = 0.008$**	$p = 0.0004$***	$p = 0.094$
Condition x Participant	$p = 0.785$	$p = 0.223$	$p = 0.646$

** denotes p<0.01, *** denotes p<0.001

In addition to the CoP-derived balance metrics, sway density was calculated to analyze possible modifications in the postural stabilization process between experimental conditions [20]. From the 2-dimensional CoP trajectories of each trial, the mean value of the peaks (meanP), the mean value of the time interval between successive peaks (meanT), and the mean value of the distance between successive peaks (meanD) were calculated. These three metrics were then analyzed with ANOVA using R (R Foundation) with participants and conditions (NF, VC, or PC) as fixed effects.

III. RESULTS

Comparisons between conditions are provided in Figures 3 and 4 (all F-tests resulted in $p < 0.001$). As expected, CoP metrics were always significantly lower with PC than with NF. Both SD-CoPx and SD-CoPy were significantly lower with VC than NF ($p < 0.001$ and $p = 0.038$, respectively). These metrics were not significantly different between VC and PC ($p > 0.05$). Also, both SD-vCoPx and SD-vCoPy were significantly lower with VC than NF ($p < 0.001$). These metrics were also significantly lower with PC than VC ($p < 0.001$).

The statistical analysis results for the sway-density metrics are shown in Table I. While there were individual differences between participants, there were no statistical differences in all three metrics (meanP, meanT, meanD) between experimental conditions. There was also no significant interaction between participants and experimental conditions.

IV. DISCUSSION

The only other device that the authors are aware of, that provides balance assistance with LT without mechanical support, is in [16]. There are functional as well as practical differences between this work and [16]. In [16], the users must lift their arm and constantly 'tap' the finger attached to the biofeedback actuator to 'feel' the virtual boundary (or virtual wall) around the participant. This virtual boundary is implemented using the indoor precision motion capture system that constantly acquires the finger position on the global coordinate. This makes the system in [16] difficult to deploy in practical scenarios where precise and continuous monitoring of finger locations is nearly impossible. On the other hand, the VC in this works very similar to a physical cane in that no continuous movement of the hand/finger nor a sophisticated portable measurement unit is required. The VC is fully portable, lightweight, and cost-effective to develop.

The four CoP-based balance metrics used in this study all show significantly lower values in PC than in NF, implying that the lower these metrics, the better performance in standing balance the participants showed. In this view, participants were better in standing balance with the Virtual

Cane as compared to the no-cane condition (NF). Since the only difference between VC from NF was the existence of the vibration feedback, it can be inferred that the distance feedback provided by VC was key to balance improvement - supporting our first hypothesis. Nonetheless, the level of balance improvement with VC was not as good as with physical cane (PC) in the SD-vCoP metrics. This supports our second hypothesis that the distance feedback alone cannot account for the total improvement in balance due to PC. This was expected since the mechanical support in PC was absent with VC.

The CoP position metrics (SD-CoPx and SD-CoPy) were not significantly different between VC and PC, whereas the velocity metrics (SD-vCoPx and SD-vCoPy) were significantly different between the two conditions. This may be interpreted as the position-dependent feedback provided by VC acting to more effectively reduce position-based balance metrics. This interpretation is comparable to the work in [19] where velocity-dependent feedback provided by the robot arm acted to more effectively reduce velocity-based balance metrics. While this work did not specifically investigate the relationship between the nature of feedback and the corresponding CoP-based metric improvements, this work and [19] together suggest that specific aspects of balance (sway or velocity of sway) could be targeted by biofeedback devices for patient-specific balance assistance.

Analysis of Sway Density Curves (SDC) is often used to study the postural stabilization mechanism [20]. Changes in the parameters in meanP, meanT, and/or meanD indicated modifications of motor control strategy in quiet standing in various populations, including patients with low back pain [21], obese children [22], obese adults [23], and in older adults [24]. In this regard, there being no significant differences in these metrics in this study between all three conditions implies that using VC did not compel participants to modify their balancing strategy. This may be viewed as normal since there were no physiological changes such as body weight [22, 23] within any participant during the experiment. Nonetheless, this result shows that, at least to the healthy young participants in this study, using VC did not require a substantially different strategy than using PC or even NF.

This work provides notable observations regarding the mechanism underlying balance improvement from LT experiments. While it is widely accepted that LT provides sensory feedback and not mechanical support [5, 14], this idea was not explicitly tested in the pure absence of mechanical support and in comparable experimental settings. Since light 'touch' assumed humans make physical contact with an external reference, mechanical support, although very small, could not be completely removed in previous LT experiments. In this regard, this work provided an experimental setup (using VC) that removes mechanical support entirely but still provides feedback similar to that by LT. And because of this unique setup, this work was able to provide an experimental verification of pure sensory feedback through hands providing balance improvements.

Another notable observation in relation to LT is that, according to our results, very low-bit information such as the binary feedback in this study is sufficient to improve balance. Without providing more high-fidelity feedback (e.g. modulating the intensity of vibration according to the distance error), a simple on-off scheme with as much as 5 cm dead zone led to balance improvements. Because the dead zone was not small, some participants did not feel the vibration in certain trials and wondered if the device was working properly. Furthermore, our vibration feedback scheme simply informed the participant whether or not the 'virtual tip' left the dead zone, but did not inform if the dead zone was crossed at the upper or lower boundary. These observations suggest that even small information can be used by the human body for significant modulation of balance and that a low-cost, simple-design assistive device like VC may be more useful than it first appears.

The haptic feedback in this work was provided at the hand in the form of vibration. This choice was made because the study aimed to mimic the haptic information that the user would receive when using a physical cane. Nonetheless, if the design was to harness the benefit of sensory feedback while not necessarily constrained to mimic a physical cane, opportunities may exist where the feedback can be provided in a different way. For example, it can be provided visually or through audio, or through a vibration actuator attached further away from the hand, to free the hand from having to hold the cane.

In this specific setup of VC, we provide not only the lower boundary but the upper boundary of no-vibration zone. This choice was made for the VC to provide haptic feedback that represents the 'correct distance' between the hand and the ground, similar to PC. That is, when using PC, the distance between the hand and the ground is maintained constant. Anything less (cane piercing the ground) or more (cane being off the ground) is deemed undesirable in standing balance with a PC. Hence, the vibration actuators would turn on to signal these scenarios to the user. If there was only a lower bound to the no-vibration zone, then a substantial increase in the distance between the tip of the cane to the ground would not be communicated to the user.

This work aimed at studying whether haptic information could provide balance assistance in the complete absence of mechanical support. That is, the goal of this work was not to train the users to have better balance through VC – but rather a cross-sectional behavioral study to analyze the effect of haptic feedback in standing balance. This led us to omit blocks 1 and 2 and analyze only the last block (block 3) of the experiment. However, if the study goal was to analyze the learning effect and retention of such effect using VC, a longitudinal study is recommended in the future.

While walkers, canes, or crutches help with balance, they may provide more-than-needed assistance by providing extensive mechanical support. This could cause reduced usage of weak yet functional muscles and may prevent recovery and accelerate dependence on these assistive devices. In this regard, LT-motivated balance assistive devices such as the VC in this work can provide an alternative solution which allows usage of functional muscles while providing subtle yet effective balance assistance.

V. Conclusion

The benefit in standing balance provided by the proposed Virtual Cane highlights the potential for using LT-inspired

assistive devices. This is especially promising given the simplistic nature of the feedback provided by Virtual Cane. This allows the development of portable and affordable balance assistive devices, specifically for population whose balance can be assisted without a strict mechanical support.

Can Learning from Demonstration Approaches Encode and Generalise Human Movements for Neurorehabilitation?

Jia Quan Loh, Vincent Crocher, Denny Oetomo, Ying Tan

***Abstract*—The use of robotic systems in Upper-Limb (UL) neurorehabilitation typically involves semi-standardised, simple movement exercises controlled by the robot. However, alternative approaches aim to support more complex movements that align with Activities of Daily Living (ADLs) and offer greater customisation of interactions tailored to individual patients by clinicians. These approaches, however, require increased therapist involvement, which underscores the need for methods that allow clinicians to teach a set of exercises to the robot. This has led to the development of various Learning by Demonstration (LfD) algorithms. These algorithms require the ability to encode the movements demonstrated by the clinician and generalise them across various task variations. Towards this goal, this study compares two existing LfD algorithms, Task-Parameterised Gaussian mixture models (TPGMM) and Dynamic Movement Primitives (DMP), in their capacity to generalise UL movements required for ADLs. The study then extends the best performing algorithm — TPGMM — to encode movements from both healthy and post-stroke participants performing a drinking task. TPGMM shows better performance in generalising healthy human movements for tasks and environments of increasing complexity when compared to a model-based approach and DMPs. TPGMM further shows that it better encodes movements of individuals post-stroke compared to ones of healthy individuals.**

***Index Terms*—Neurorehabilitation, Upper-Limb, Learning from Demonstration, Generalisation, Movement Quality.**

I. Introduction

Although rehabilitation robotic approaches in Upper-Limb (UL) therapy often aim for a high-level of automation and standardisation of therapy [1], another approach consists of enabling the clinician to customise rehabilitation exercises and possibly orient patients towards more functional practice. In this later approach, as attempted by Johnson or Timmermans with the Haptic Master [2], [3] or by the authors [4], the robotic device is used as an adjunct for clinicians to provide high intensity and consistent feedback to the patient. Thus, the presence of the therapist is required at all times to redemonstrate movement when task variations are introduced, which in turn leads to decreased robot autonomy and limits the possible cost and intensity benefit of robots.

In this scenario, it is thus desirable to allow a clinician to demonstrate examples of a (potentially complex) rehabilitation exercise, customised to a given patient, and allow the robot to guide the patient through this exercise and associated variations in the next therapy episode. It is expected that the robot can capture the "essence" of the exercise demonstrated — and the associated therapist action — and that the robot can then autonomously guide the patient through the exercise and its variations.

The *encoding*, *reproduction* and *generalisation* of an action — or a set of actions — demonstrated by a user to a robot is the objective of Learning from Demonstration (LfD) approaches encountered in classic robotic applications including pick-and-place or complex object manipulation [5], [6].

In a neurorehabilitation scenario, we assume that the patient's movements are more important than the robot's, shifting the focus towards learning actual human movement. This requires LfD algorithms to be applied in a larger dimensional space representing UL joints compared to the 3-DoF wrist position or robot joints classically used in LfD. The learning can then be extended towards human-on-human demonstration during therapy rather than relying on the rehabilitation robot's parameters during kinaesthetic teaching.

Reviewing existing literature on LfD in neurorehabilitation, Najafi et al. [7], Luciani et al. [8] and Lauretti et al. [9] employed Gaussian Mixture Models (GMM), Hidden Markov Models and Dynamic Movement Primitives (DMP) respectively to encode the joint kinematics of rehabilitation robots.

Noticeably, most LfD approaches constrain their learning space within the robot parameters, though one could argue that [8], [9] provides an UL approximation using their exoskeleton. Only Liu et al. [10] attempted to encode actual UL joints of humans using Kernel Movement Primitives. Furthermore, only [9] thoroughly evaluated the generalisability of deterministic LfD algorithms to tasks variations (*i.e.* new task points), which is essential to quantify the level of autonomy a rehabilitation robot can achieve. More importantly, to date, only [11] proposed a formal comparison of human movement quality preserved from each algorithm's reconstruction.

In this work, we extend Luciani's work [11] by investigating how well existing LfD algorithms generalise UL movement for unimanual daily activities (*e.g.* pick-place and drinking tasks) used in rehabilitation sessions. Specifically, this work proposes implementations of Task-Parameterised Gaussian Mixture Models (TPGMM) and DMP applied to UL joint trajectories (see Section II) and compares their performances on experimental data to a purely model-based representation of UL kinematics (using minimum jerk trajectories and inverse kinematics). The comparison is specifically evaluated on

The authors are with the Human Robotics Laboratory, Department of Mechanical Engineering and the Graeme Clark Institute, The University of Melbourne.
Correspondence: jqloh@student.unimelb.edu.au

kinematic metrics relevant to human movement analysis and rehabilitation (see Section III). In addition, we tested whether the best performing algorithm is able to capture the specificity of the movements of stroke patients compared to those of people without impairment for a classic drinking task from an existing datatset [12].

II. Objective and LfD algorithms evaluated

A. Upper-limb kinematics modelling and encoding objective

In this work, we propose to compare how well existing LfD algorithms are able to encode UL joint trajectories for common ADLs and generalise these trajectories to task variations (*i.e.* different starting, final or intermediate — via — points). Due to the importance of varying task points, we chose algorithms that explicitly address varying task points within their mathematical formulation to ensure convergence towards specified points.

The UL is modelled as a two links serial manipulator, connected with four DoFs: three coaxial revolute joints representing the gleno-humeral joint and a revolute joint for the elbow flexion-extension. This model references the MVN Biomechanical model for ease of comparison with datasets captured using XSENS (Xsens Technologies, Enschede, Netherlands).

B. LfD algorithms evaluated

The objective of the LfD algorithms is to encode a demonstrated kinematic trajectory $\Xi \in \mathcal{R}^{T\times 5}$, made of T vectors $\boldsymbol{\xi}_t = [\sigma_t, q_{1,t}, q_{2,t}, q_{3,t}, q_{4,t}]$ with $q_{1-4,t}$ the UL joint angles and σ_t the sampled time at each timestep $t \in [1, \dots, T]$.

Both TPGMM and DMP algorithms are adapted as follows to encode UL joint movements rather than the conventional task space movement.

1) Task-Parameterised Gaussian Mixture Model and Regression (TPGMM + GMR): In contrast to stochastic policies (*e.g.* ProMPs, HMM) that generalise distributions in a single reference frame (*e.g.* inertial frame or the trajectory starting point or end point), TPGMM adapts the distribution to multiple different start, final or via-points by superposing different reference frames relevant for a task [13].

For each task demonstration, the joint trajectory Ξ is observed from P reference frames, each assigned to the start, via and final points of the demonstration. Each p^{th} reference frame is characterised by a rotation matrix $A_p \in \mathcal{R}^{N\times N}$ and a displacement vector $\boldsymbol{b}_p \in \mathcal{R}^{1\times 5}$, referenced from an inertial frame. The kinematic profile at time step t in the p^{th} reference frame, denoted as $\boldsymbol{\xi}_t^{(p)}$, can be expressed as

$$\boldsymbol{\xi}_t^{(p)} = A_p^{-1}(\boldsymbol{\xi}_t - \boldsymbol{b}_p), \quad p = 1, ..., P, \tag{1}$$

where $\boldsymbol{\xi}_t$ is the t^{th} row vector of Ξ. Adapting this to joint space, A_p is set to the identity matrix and $\boldsymbol{b}_p$ is the joint displacement from the origin pose when the UL is at the p^{th} reference frame. Here, the displacement $\boldsymbol{b}_p$ represents the full transformation from one reference UL posture to another.

M demonstrations of P trajectories with T time steps each are concatenated demonstration by demonstration.

From these observations, K Gaussian kernels are identified, with each k^{th} kernel parameterised to P multivariate Gaussian distributions $\mathcal{N}(\boldsymbol{\mu}_k^{(p)}, \Sigma_k^{(p)})$ and their associated weight π_k. $\boldsymbol{\mu}_k^{(p)}$ and $\Sigma_k^{(p)}$ are respectively the mean vector and covariance matrix of the k^{th} Gaussian kernel in the p^{th} reference frame.

The number of Gaussian kernels K required to represent the task is optimised using the Bayesian Information Criterion test [14]. The $\boldsymbol{\mu}_k^{(p)}$ and $\Sigma_k^{(p)}$ of each Gaussian distribution are identified by an Expectation-Maximisation algorithm which maximises the likelihood of the demonstrated trajectories to lie within the identified Gaussian distributions [13].

To reconstruct a movement for new start, via and final UL postures, a new GMM and its corresponding Gaussian kernels $\mathcal{N}(\hat{\boldsymbol{\mu}}_k, \hat{\Sigma}_k)$ is obtained by conditioning the learned $\mathcal{N}(\boldsymbol{\mu}_k^{(p)}, \Sigma_k^{(p)})$ to the new reference frames defined by $\boldsymbol{b}_p$ (*i.e.* the joint configurations required at the new task points):

$$\hat{\boldsymbol{\mu}}_k = \Sigma_k \sum_{p=1}^{P} {\Sigma_k^{(p)}}^{-1} \hat{\boldsymbol{\mu}}_k^{(p)}, \quad \hat{\Sigma}_k = \left(\sum_{p=1}^{P} {\Sigma_k^{(p)}}^{-1} \right)^{-1} with \tag{2}$$

$$\hat{\boldsymbol{\mu}}_k^{(p)} = \boldsymbol{\mu}_k^{(p)} + \boldsymbol{b}_p. \tag{3}$$

The conditioned GMM is then used to generate a new motion plan with the sampled time, σ_t as the input, via Gaussian Mixture Regression, which calculates the conditional probability and expectation of the output for this given input.

Note: The conditioning of the new GMM (Eq. 2 and 3) is simplified compared to the common $\mathcal{R}^3$ case given the absence of rotation A_p in the joint configuration space.

2) Dynamic Movement Primitives: Dynamic Movement Primitives formulate a movement as a dynamical model (*e.g.* a spring-damper system) that modulates its non-linear forcing term after a desired attractor behaviour, usually an ideal demonstrated trajectory [15]. For each DoF of the UL model, the equation of the point attractor system is given by:

$$\tau \ddot{q}_n(t) = \alpha_n(\beta_n(g_n - q_n(t)) - \dot{q}_n(t)) + f_n(x), \tag{4}$$

where $q_n(t)$, $\dot{q}_n(t)$ and $\ddot{q}_n(t)$ are the n^{th}-DoF trajectory and its time derivatives, τ is the duration of the demonstrated movement and $g_n = q_n(t = \tau)$ is the corresponding joint angle of the final UL posture. α_n and β_n are positive constants selected such that the system is critically damped (*e.g.* $\beta_n = \alpha_n/4$). $f_n(x)$ is the forcing term expressed as:

$$f_n(x) = \frac{\sum_{k=1}^{K} \Psi_k(x_n)\omega_k}{\sum_{k=1}^{K} \Psi_k(x_n)} x_n(g_n - s_n), \tag{5}$$

where K is the chosen number of Gaussian kernels, $s_n = q_n(t = 0)$ is the starting posture of the trajectory, and ω_k are the DMP weights that will be learned from the demonstration(s) [15]. $\Psi_k(x_n)$ are Gaussian kernels expressed as:

$$\Psi_k(x_n) = \exp\left(-\frac{1}{2\sigma_k^2}(x_n - \mu_k)^2 \right), \tag{6}$$

where σ_k and μ_k are the selected widths and centers of the Gaussian kernels.

(5) and (6) are dependent on state variable x_n, expressed as a decaying canonical system to inhibit time dependence of the system:

$$\tau \dot{x}_n = -\gamma_n x_n, \tag{7}$$

where γ_n is set as a positive constant. Recommended values for α_n, μ_k, σ_k and γ_n were obtained from [16]. As there are no formal optimisation process for the exact number of K, a linear search up to 250 kernels was performed, with K kernels providing lowest RMSE when reconstructing the training dataset.

DMP weights ω_k are learned through the Locally Weighted Regression algorithm [17]. Given a demonstration of T time steps indexed by $t \in [1, ..., T]$, the recorded DoF and their derivatives, $q_n(t)$, $\dot{q}_n(t)$ and $\ddot{q}_n(t)$, are inserted into (4) to obtain T forcing terms f_n at each timestep:

$$f_n(t) = \tau \ddot{q}_n(t) - \alpha_n(\beta_n(g_n - q_n(t)) - \dot{q}_n(t)). \tag{8}$$

To learn ω_k, the locally weighted quadratic error is minimised for each Gaussian kernel using the following cost function, J_k:

$$J_k = \sum_{t=1}^{T} \Psi_k(x)(f_n(t) - \omega_k \epsilon(x))^2 \quad with \tag{9}$$

$$\epsilon(x) = x_n(t)(g_n - s_n). \tag{10}$$

An independent DMP is learned for each DoF of the UL model. As proposed by Lauretti et al. [9] to overcome the potential limitation of encoding a complex task with a single set of DMPs, a task is divided into sub-movements (each corresponding to a part of the movement stopping at a via-point and with a zero-velocity crossing) for which the above DMP approach is applied, effectively creating a dictionary of DMPs for different sub-movements. To reconstruct each new sub-movement, the start and final posture, s_n and g_n are adjusted to the desired postures and inserted into (4) and (5) of the corresponding DMP for said sub-movement. The q_n trajectory is obtained via forward integration.

Given the DMP approach does not explicitly learn from multiple demonstrations; when required, the ideal learning trajectory is taken from the average of multiple demonstrations aligned in time.

3) Model-based comparison: In addition to the two LfD algorithms above, a purely model-based approach is used as a comparison point in this work. Namely, the hand trajectory for each sub-movement is represented by a point-to-point minimum jerk function [18].

A numerical inverse kinematics using the Moore-Penrose inverse and Gauss-Newton algorithm is then applied onto each sampling point to define the corresponding UL posture. For the first point of each sub-movement the actual UL posture is used as the initial guess of the optimisation.

The joint space trajectories obtained with this model-based methods are then evaluated the same way as the trajectories obtained from the LfD algorithms.

III. Experimental evaluations

Two distinct experimental evaluations of these LfD algorithms were performed to evaluate if these methods could be used in neurorehabilitation: one to assess the ability of LfD algorithms to generalise healthy human movements to new task variations; and a second one to evaluate if the best of these algorithms can encode the specificity of participants with UL impairment after stroke. Both experiments rely on the evaluation of reconstructed movements (by LfD algorithms and model) against the original human movements. This comparison is here performed thanks to dedicated kinematic metrics.

A. Evaluation metrics and analysis

The set of metrics selected aims to cover the human likeness aspect of movements both at the end-effector and joints level and their temporal and spatial aspects:

1) *Joints Trajectory Dynamic Time Warping (Joints DTW)*: DTW aligns two signals by optimizing the distance value between points of the signals at current and previous time steps [19]. Its associated alignment cost is used as a temporal similarity measure for human action recognition [20]. DTW is used to evaluate the temporal similarity of the UL joints trajectories.
2) *Swivel Angle Trajectory DTW (Swivel DTW)*: Considering a 4-DoF UL model, a reaching movement contains a redundant DoF which can be parameterised by the swivel angle [21]. The swivel angle is defined as the angle between the the arm-plane and the vertical direction, with 0° when the arm-plane is parallel to the sagittal plane and 90° when parallel to the transverse plane. DTW is applied separately to the swivel angle trajectory to evaluate similarity of the encoded movement's redundancy.
3) *Mean Absolute Relative Phase Difference ($\Delta MARP$)*: Continuous Relative Phase (CRP) quantifies inter-joint coordination. It extracts phase angles between joint position and velocity, then compares it between different joints. A joint trajectory, $q(t)$ is decomposed into a complex signal, $\zeta(t)$ using the Hilbert Transform, $H(q(t))$ as described in [22]:

$$\zeta(t) = H(q(t)) = q(t) + iH(t). \tag{11}$$

The phase trajectory $\phi(t)$ is calculated by

$$\phi(t) = \arctan\left(\frac{H(t)}{q(t)}\right). \tag{12}$$

The CRP trajectory, $CRP(t)$ between two joints $q_1(t)$ and $q_2(t)$ is obtained by subtracting the phase angles

$$CRP(t) = \phi_1(t) - \phi_2(t). \tag{13}$$

where $\phi_1(t)$ and $\phi_2(t)$ is the phase angles of the two joints respectively.
Since CRP is a time series, the mean absolute value over the trajectory called Mean Absolute Relative Phase (MARP) is used to quantify the average phase of a movement [23]. To capture the extent of how the LfD algorithms encode joints coordination, the maximum difference in MARP between movements is reported in this study (*i.e.* the worst change among the six inter-joint pairs).

4) *Hand Trajectory Hausdorff Distance (Hand HD)*: The minimum Hausdorff Distance is the minimum value of the greatest of all the distances from a point in one trajectory to the closest point in the other trajectory [24]. HD is used to evaluate spatial similarity between hand movements, independently of time.
5) *Smoothness Difference (ΔSAL)*: Spectral Arc Length (SAL) defines movement smoothness as introduced in [25]. SAL is always negative with a value closer to zero corresponding to a smoother movement. The difference ΔSAL between the SAL of recorded and reconstructed sub-movements is calculated.
6) *Time-to-Peak-Speed Difference (ΔTTP)*: The speed profile of each sub-movement is calculated on the hand trajectory using a first-order Euler approximation. The peak speed and time-to-peak-speed refer to the largest value in the profile and corresponding time stamp relative to the start of the sub-movement. For each sub-movement, TTP is normalised to the sub-movement duration [26] and the difference ΔTTP between these normalised TTP is calculated. The average ΔTTP across all sub-movements is reported.

For all these metrics, a smaller value corresponds to a better, more faithful, movement reconstruction.

B. Experiment 1 - Standardised ADLs generalisation

In the first experiment, participants without movement impairment were recruited to perform ADLs tasks. The study was approved by the University of Melbourne HREC ($\#2024-31144-60078-3$).

1) Setup: Participant's joint angles were recorded using Vive Inertial Trackers (HTC, Taiwan) providing 6-DoF position and orientation measurements at the shoulder, the end of the humerus, and the wrist as shown on Fig. 1-a and recording at 90Hz. The trackers are interfaced with a custom C# program and a Unity UI (Unity Technologies, USA).

2) Task protocol: Participants were asked to sit at a table in front of a custom setup (see Fig. 1-b) and to perform a series of physical tasks while wearing the Vive Trackers.

Four tasks of increasing complexity associated with ADLs were selected: T1-Planar Pick-Place, T2-Elevated Pick-Place, T3-Obstructed Planar Pick-Place and T4-Pick-Drink. For each task, six configurations corresponding to a different picking or placing locations were recorded (see Fig. 2 and Table I). The placement of the task points were normalised based on the participant's forearm length, shoulder width and furthest diagonal reach.

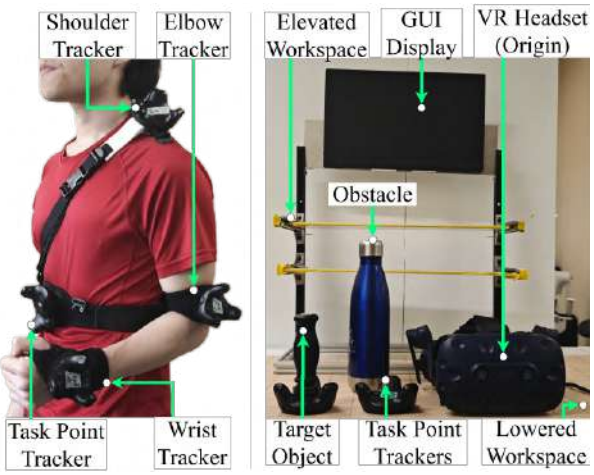

Fig. 1. Motion capture sensors (a) and experimental bench (b) and used for standardised ADLs movements recording. Note that the VR headset is only used here as a reference frame and not worn by the participants.

TABLE I
TASK DESCRIPTION

Task	Sub-task	Description
1	1-1	Move wrist from home position to TP1.
	1-2	Move object from TP1 to TP2 on a low level.
	1-3	Release object on TP2 and return to home position.
2	2-1	Move wrist from home position to TP1.
	2-2	Move object from TP1 to TP2 on an elevated level.
	2-3	Release object on TP2 and return to home position.
3	3-1	Move wrist from home position to TP1.
	3-2	Move object from TP1 to TP2 on a low level avoiding the obstacle in the middle.
	3-3	Release object on TP2 and return to home position.
4	4-1	Move wrist from home position to TP1.
	4-2	Move object from TP1 to mouth.
	4-3	Return to home position.

For each task, participants were asked to perform three demonstrations for each configuration using their dominant hand. They were then given a ten-minute rest, before repeating the experiment with their non-dominant hand. The overall session consisted in a total of 144 tasks repetitions.

3) Data post-processing and analysis: A fourth-order, low-pass Butter-worth filter with a cut-off frequency of 5Hz [27] was applied on joint angle signals. The filtered signal is then down-sampled to 50Hz to reduce model computation. To align multiple demonstrations in time, each joint trajectory was then normalised to unit time.

For each Task and each Participant, two non contiguous configurations were randomly selected for generalisation evaluation whereas the remaining four configurations were used for LfD training. The reconstructed trajectories from the generalisation set were compared to their corresponding recorded movements using the six kinematic metrics.

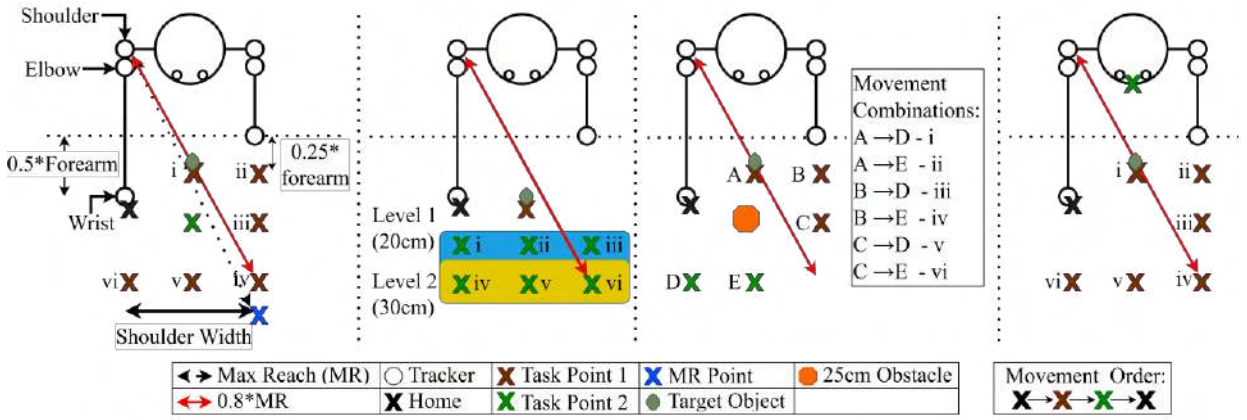

Fig. 2. Schematic of setup and Tasks configurations i / vi. Overall motion consists of moving from the home position (black cross) to grasp the object at TP1 (red cross), transporting it to TP2 (green cross) and returning to the home position. From left to right: 1) Lowered Pick-Place, 2) Elevated Pick-Place, 3) Obstructed Pick-Place, 4) Pick-Drink.

Distribution of each metric outcome for each LfD Algorithm and each Task were tested for normality (Shapiro–Wilk test, $p < 0.05$), followed by a repeated ANOVA / Friedman test and corresponding post-hoc paired t-test / Wilcoxon signed-rank test to evaluate differences between the three reconstructions.

C. Experiment 2 - Impaired movements encoding

To further evaluate the capability of LfD algorithms to encode movements for a rehabilitation context, the best performing algorithm was further applied to encode movements of five participants with stroke (51 to 74 years, FMA-UE: 21 to 61) and five control healthy participants (42 to 78 years) performing a drinking task. Movements were selected from the UL-ADL dataset by Schwarz et al. [12]. Only participants with a right-dominant-impaired side were selected for better comparison with the group of non-impaired individuals (all right handed). TPGMM as described in Section II was used to encode each task for each participant (using three repetitions).

Movement reconstructions were then compared to the three recorded repetitions using the same set of kinematic metrics. The distribution of the metrics difference for each group are reported for comparison.

This analysis specifically aims to test if the encoding of movements preserve the specificity of movements with participants with stroke compared to the encoding of individuals without neurological injury (*i.e.* are movements of individuals with stroke reconstructed as well or worse as those of healthy individuals).

IV. Results

A. Experiment 1 - Standardised ADLs generalisation

Five naive, healthy participants (28.4 ± 3.36 years old) were recruited. According to the Edinburgh Handedness Inventory [28], three participants were predominantly right-handed, 1 ambidextrous, and 1 predominantly left-handed.

Fig. 3 shows an example of an Obstructed Pick-place task (Task 3) and corresponding reconstruction by the LfD algorithms.

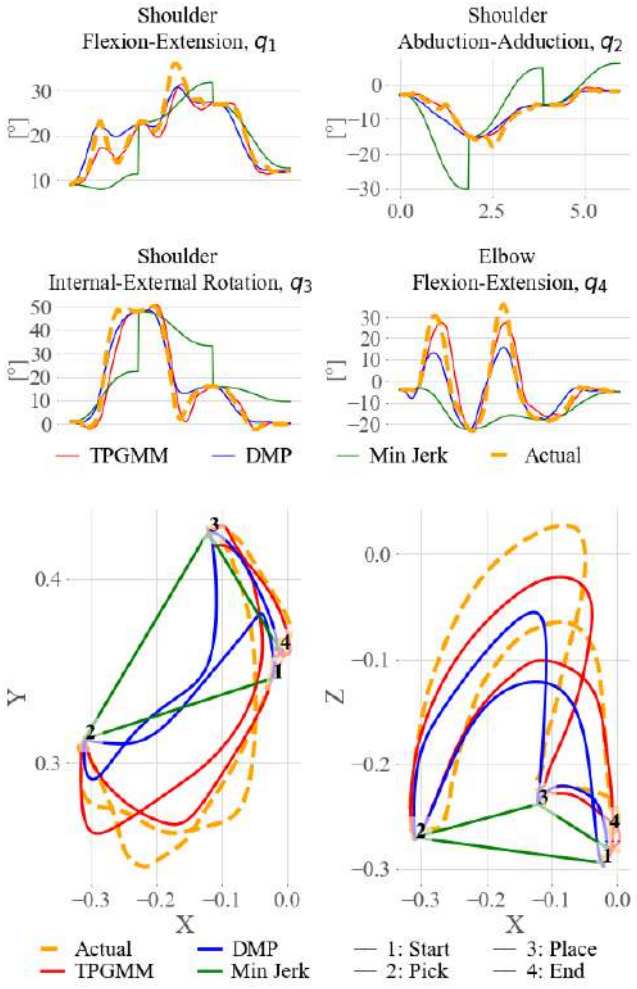

Fig. 3. Example of actual and reconstructed UL joint trajectories (a) and hand trajectories (b) (left: Top View, Right: Front View) between actual and reconstructed joints for Task 3 - Obstructed pick-place task.

Table II presents the mean difference (and post-hoc significance level) between the different approaches for each metric for each task. Metrics for which methods are not statistically different are omitted.

TABLE II
METRIC COMPARISON BETWEEN LFD ALGORITHMS AND MINIMUM JERK

B. Experiment 2 - Impaired movements encoding

Fig. 4 compares the distribution of the metrics obtained from TPGMM reproductions between healthy and post-stroke participants.

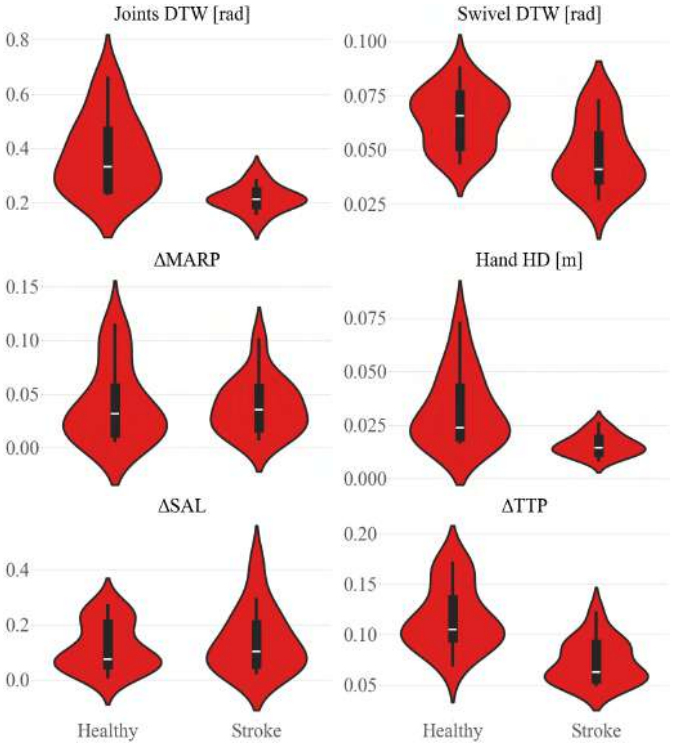

Fig. 4. Violin plots showing the metric distribution of TPGMM reconstruction for healthy and stroke participants.

V. DISCUSSION

A. Generalisation over increasing task complexity

The purely model-based approach is able to generate simple planar point-to-point movements of the hand equally well to the LfD policies but already failed to capture as good a representation in joints space. As task complexity increases and divert from a simple point-to-point reaching, the LfD algorithms perform significantly better than the simple model, even in reproducing the hand trajectory.

Although DMPs and TPGMM did not show significant difference in maintaining human likeness for its generalisation during T1, T2 and T4; of which a similar behaviour was observed in [11]'s work for reproducing pick-place and pick-drink joint movement; TPGMM significantly better generalises to new task parameters than DMPs when both task and environment becomes more complex, demonstrated by the addition of obstacles in T3. While not visible for all metrics, this is clear for both hand space (as shown by the Hand HD) and joints space (as shown by the Joints DTW and Swivel angle DTW) for T3 as presented on Table II. This better generalisation of complex tasks might be due to TPGMM's formulation that explicitly observes the joints distribution from multiple coordinate frames.

Importantly, the advantage of TPGMM is clearly visible in joint space (Joints and Swivel DTW). This is an important point for neuro-rehabilitation given the specificity of joint synergies and compensatory behaviour observed post-stroke which are desirable to capture.

In addition, the complexity (*i.e.* number of kernels) of LfD techniques can significantly influence their performance and, despite using optimisations approaches in this work, the choice made may have influenced the results. Still, it is to note that TPGMM outperforms DMPs in the current work while requiring a lower number of kernels with 118 on average compared to 280 for DMPs.

B. Encoding of movements specificity of participants with stroke

It is well documented that following a stroke, UL movements are impaired and the execution of classic tasks differs in

multiple way from one of healthy individuals. Thus, evaluating how TPGMM, which shows the best ability in more complex tasks, can capture this specificity does provide an indication on how well it could encode rehabilitation movements (*i.e.* assuming that those movements lie somewhere in between those of healthy individuals and natural ones of the stroke patient). Interestingly, the evaluation performed on a drinking task reveals that TPGMM produces a more faithful and consistent encoding of stroke participants' movements compared to ones of healthy individuals. This is the case for all metrics except for ΔSAL (see Fig. 4). This encoding performance comes at the expense of an increased modelling complexity: healthy participants movements required between 20 and 63 kernels, whereas stroke participants movements required between 38 and 92 kernels.

C. Limitations and future work

It is to note that the UL model used is limited to only four DoFs and does not include any scapula or trunk motion. This is an important limitation for rehabilitation applications where patients tend to compensate for limited elbow and shoulder flexion/extension using trunk and scapula motions [29]. Such motions should thus ideally be encoded and reconstructed by the LfD policies.

While this first analysis provides insights on the two LfD algorithms to encode human movements that could be used in neurorehabilitation, the two experiments presented do not truly represent actual rehabilitation exercise prescribed by therapists. While the results indicate that TPGMM is the best candidate for such scenario, a formal evaluation in real conditions should still be conducted.

ACKNOWLEDGEMENT

***Abstract*—This study introduces a novel approach to home rehabilitation exercise instructions, utilizing a 3D-printed robotic hand that can mimic the patient's hand movements and follow pre-programmed instructions. This robotic hand, made from inexpensive 3D printed components and hobbyist equipment, is controlled by open source computer vision tracking.**

Two within-subject crossover studies were conducted with 30 healthy participants. The first study assessed the participants' sense of embodiment, while the second compared their ability to remember movement exercises when instructed by the robotic hand versus video clips.

The results showed that the participants experienced a higher sense of embodiment with the robotic hand in its active mode. Furthermore, they demonstrated significantly better short-term memory retention of medium and difficult finger movement sequences when instructed by the robotic hand compared to video instruction ($F_{1,56}$ = 4.047, p $<$ .05) and ($F_{1,56}$ = 19.463, p $<$ .05). These findings suggest that this innovative method could improve remote therapy and strengthen bodily ownership, which is essential in stroke rehabilitation.

***Index Terms*—Body Ownership Illusion, Embodiment, Human-Robot Interaction, Rubber Hand Illusion, Stroke Rehabilitation**

I. Introduction

Rehabilitating finger and grip movements at home is relevant for several patient groups, for example, stroke survivors. Stroke can cause paralysis or reduced muscle control in the hand, which requires rehabilitation to regain strength and coordination. According to the World Health Organization, approximately 15 million people suffer strokes annually worldwide [1]. A significant proportion of stroke survivors experience hand weakness or motor deficits, indicating a substantial number of patients who need hand rehabilitation services. Furthermore, stroke is one of the leading causes of long-term severe disabilities, underscoring the need for effective rehabilitation strategies. Despite the availability of therapeutic interventions that can ameliorate post-stroke disabilities, a significant proportion of survivors continue to face chronic physical or cognitive impairments. For example, approximately 65% of the survivors struggle to reintegrate their affected hand into daily activities after completing conventional therapy [2]. This scenario is set against a backdrop of increasing costs, with stroke-related expenses in the European Union expected to grow significantly from an estimated 45 billion euros in 2017 [3].

In addition, hand rehabilitation is commonly needed after surgeries. Patients recovering from hand injuries, such as fractures, dislocations, or severe sprains, require rehabilitation to regain strength and dexterity. As the aging population increases, so does the prevalence of age-related hand problems. Conditions such as osteoarthritis and rheumatoid arthritis, both known to impact hand movement, are relatively common; consequently, a significant number of older adults are likely to seek hand rehabilitation services. Parkinson's disease can also affect hand function, necessitating ongoing rehabilitation. Finally, age-related weakness and loss of dexterity in the hands are common among the elderly, making exercises crucial to maintaining joint mobility and reducing pain.

The primary objective of this paper is to support the rehabilitation of late-stage stroke, carried out within the home environment. This phase lacks a clear end point and may last for years, relying heavily on the motivation, effort, and set goals of the survivor [4]. We relate to mirror therapy, since our robotic hand acts as a direct alternative to mirror therapy with the added benefit of being able to personalize the rehabilitation of the patient by having them interact with their therapist remotely.

The rubber hand illusion (RHI) [5] is an important method in investigating body ownership and agency and plays a crucial role in the effectiveness of mirror therapy. In this experiment, we successfully elicited the RHI using a robotic hand, demonstrating a key component to leverage mirror therapy techniques.

Rehabilitation robotics offers promising prospects for improving therapeutic interventions and addressing the challenges of teletherapy. By allowing therapists to remotely interact with patients through the robotic hand, our goal is to improve the personalization and effectiveness of home rehabilitation. The development of a 3D robotic hand instructor that is controlled by stroke patients and accessible remotely to therapists exemplifies this approach, aiming to surpass the limitations of conventional therapy [12] [13].

Our study investigates the potential for a 3D printed robotic hand to induce a sense of embodiment in participants, similar to the illusion of a rubber hand [5], and explores its effects

Fig. 1. The Robotic Hand connected to an Arduino Uno, alongside an Intel RealSense D435 Stereovision Camera.

on performance in memorizing task instructions. In this way, we focus on developing user-friendly teletherapy support systems that provide clear instructions, ensuring accessibility for individuals with limited digital literacy.

II. Related work

The rubber hand illusion demonstrates how sensory information can manipulate the feeling of body ownership, where participants come to accept a rubber hand as part of their own body through a combination of visual, tactile, and proprioceptive stimuli. This illusion is induced by simultaneously stroking both the participant's hidden real hand and a visible rubber hand, leading to an altered perception of self-ownership over the artificial limb. Investigating the limits of self-perception via the rubber hand illusion and body ownership illusions allows researchers to uncover significant insights into the brain's adaptable representation of self. Research has extended the RHI to virtual bodies [6] and explored the use of robotic hands to induce similar illusions [7] [8]. The relationship between ownership and agency in these illusions has been investigated [9], with findings suggesting that these are distinct but interacting cognitive processes. Furthermore, the embodiment of robotic or virtual hands has been explored in the field of psychology and robotics [10] [11]. These studies highlight the potential for technology to manipulate body perception and create novel rehabilitation strategies.

Mirror therapy is a therapeutic technique used to alleviate sensory and motor deficits, particularly in the affected limb, by employing the principle of visual illusion. A mirror is strategically placed to reflect the image of the unaffected limb, creating the illusion that the affected limb is moving without difficulty [14]. Mirror therapy capitalizes on neuroplasticity in the brain, promoting the re-wiring of neural pathways associated with motor function and sensory perception [15]. By visualizing the affected limb in a normal state, the brain is encouraged to restore connections and improve motor control, which has shown promise in improving motor function of the limb, reducing pain perception, and improving overall recovery of the upper limb [16] [17]. However, therapy success depends on the patient's ability to perform exercises correctly, which, in some cases, requires guidance and practice under the supervision of a skilled healthcare professional [18]. This required guidance ensures that patients engage in mirror therapy with precision, optimizing its potential benefits, while mitigating the risk of incorrect execution. Furthermore, the applicability of mirror therapy may vary from person to person. Some people do not respond as well as others to mirror therapy [19]. Consequently, the utility and generalizability of mirror therapy in the context of hand stroke rehabilitation remain subject to review and ongoing investigation [20].

Teletherapy serves as a powerful conduit to transcend geographical barriers that have historically restricted access to expert stroke rehabilitation services [21]. The ability to receive therapy remotely ensures that people residing in remote or underserved areas, often far away from specialized rehabilitation centers, can access the specialized care they require. This geographical inclusivity addresses a disparity in healthcare access, promoting equity and ensuring that stroke survivors from various locations can benefit from the latest advances in upper limb stroke rehabilitation [22]. In addition, teletherapy offers the flexibility of scheduling sessions at times convenient to the patient, further enhancing adherence and overall therapeutic results. Despite its considerable advantages, teletherapy faces a series of challenges in the context of upper limb stroke rehabilitation, the most notable being the limited physical interaction it provides. The absence of physical interaction in teletherapy poses a fundamental limitation, particularly in cases where personalized tactile interventions are crucial to rehabilitation success [23].

The effectiveness of teletherapy is intricately intertwined with technological prerequisites. Patients must have access to suitable equipment and possess a degree of digital literacy to participate effectively in remote therapy sessions. Although advancements in technology have made these prerequisites increasingly accessible, disparities persist, potentially hindering certain individuals' participation. The digital divide, compounded by socioeconomic disparities, can exacerbate healthcare inequalities, raising relevant ethical concerns [24].

III. Material and Methods

The robotic hand is constructed using open source 3D prints from the InMoov project [25] and Parallax Inc 4 servomotors.

The robotic hand is operated by implementing computer vision, using the OpenCV library (Version 4.8.1), to detect hand movement, which is then translated into binary finger movement (i.e., open or closed) in the robotic hand. The script, developed in Python, utilizes an Intel D435 camera along with MediaPipe for hand tracking and palm detection, selected for its superior image quality and speed, making it well-suited for tracking rapidly moving fingers. It detects 21 hand landmarks to identify open or closed fingers based on their positions. Finger counting is performed using a skeletal mesh model, and the status of fingers is determined by comparing the positions of the fingertips and phalanges. The script then sends a string to an Arduino script to represent the hand's state, with each digit in the string representing a finger's status (open or closed).

The script imports libraries for computer vision and hand tracking, including 'cv2' for image processing, and custom modules from 'cvzone' (Version 1.6.1) for hand detection and tracking. It initializes video capture, sets parameters for hand detection, and uses a loop to capture frames, detect hands, and count open fingers. The hand detection results are used to control an Arduino Uno via serial communication, displaying the video feed in real-time with overlaid hand landmarks and the detected hand contours.

The Arduino script controls the servomotors based on the data received from the hand-tracking script. It reads serial data, identifies commands for finger positions, and adjusts the servomotors accordingly. The setup includes an Arduino Uno, Parallax servomotors, and an Adafruit servo shield, chosen for their cost-effectiveness, quality, and capability to handle multiple servomotors with an external power supply. The system translates digital instructions into motion, controlling servomotors to replicate hand gestures. The total cost of the components amounts to approximately €525, with the Intel D435 stereo camera being the most financially significant component at around €390. However, a basic webcam can be implemented as a viable substitute, reducing the total cost to €150. Although this cost reduction slightly compromises image quality, it still enables satisfactory finger tracking and movement detection, making it a practical and cost-effective alternative. This approach is significantly more affordable than virtual reality mirror therapy sets, which range from $252 [26] to considerably higher prices depending on technological complexity [27]. In particular, the system achieves a minimal latency of 90 milliseconds, significantly below the 300-millisecond threshold beyond which visuomotor delays become perceptible to users [28].

The research comprises two controlled within-subject crossover studies aimed at assessing the participants' sense of embodiment and their memorization performance when interacting with the robotic hand. All participants were recorded as right-hand dominant. Before starting the experiments, participants were asked about their gender and age group, 22 participants being male (73%) and the other 8 female (27%). Most of the participants belonged to the 18-24 age group (53%), the rest was made up of the 25-34 age group (37%), the 35-44 age group (7%) and the 45-54 age group (3%). All participants were university students, except for one. Before participation, all participants filled out a signed consent form. This research work was exempted from ethical approval by the Danish Research Ethics Committee because data was collected solely for technical purposes and were not intended for use in a clinical setting.

The methodology involved dividing participants into two groups, each undergoing a test and control study in both experiments, with the order of participation reversed between the groups. The two experiments were conducted successively, starting with the first experiment.

Experiment 1 sought to determine whether participants experienced a sense of embodiment with the robotic hand. Participants were seated with their hands on a table in front of them, but unlike the usual procedure their hands were facing upwards, not downwards. A divider and a long-sleeved shirt worn backward were used to obscure their right hand and replace its visual position with the robotic hand (Figure 2). This setup was aimed at minimizing distractions and maintaining the illusion. An Intel RealSense D435 camera captured the movements of the participants' hands, allowing them to control the robotic hand. The experiment consisted of one control phase and one test phase, each lasting 5 minutes. In the control phase, both the participant's right hand and the robotic hand were simultaneously stroked with a paintbrush to elicit the rubber hand illusion, and in the test phase, participants had full control over the robotic hand's movements. The order of the control and test phases was counterbalanced between the participants to minimize order effects. Half of the participants performed the control phase first, followed by the test phase, while the other half performed the test phase first, followed by the control phase. Both phases were followed by a questionnaire based on the questionnaire used by Botvinick and Cohen [5] to capture the participant's experience. Questionnaire responses were collected using a 7-point Likert scale, with answers numerically translated such that 7 represented 'strongly agree' and 0 represented 'strongly disagree'. A Wilcoxon Signed-Rank test was used to analyze the data from Experiment 1. In the control study, the robotic hand is referred to as ***passive***, since the participant is stimulated by touch administered by the researcher through paintbrushes. For the test study, the robotic hand is referred to as ***active***, since the participant is stimulating the robotic hand themselves by movement of the fingers of their right hand (Figure 2).

Experiment 2 focused on assessing whether interaction with the robotic hand improved participants' memorization task performance compared to observing a prerecorded video of a human hand. The setup included an iPad with video clips for the control study and the robotic hand for the test study, both displaying sequences of finger movements classified into easy, medium, and difficult instructions. The robotic hand was operated by the researcher. A task of easy complexity encompassed three to four distinct operations, while tasks of medium and difficult complexity comprised six and nine

Fig. 2. Front view (left) and top view (right) of the setup of Experiment 1. Following the standard rubber hand illusion procedure, a divider hides their right hand, replacing it with the robotic hand.

operations, respectively. Participants were exposed to a total of 15 sequences across these categories and asked to remain still (no finger movements) during observation in both video and robotic hand conditions. They were then requested to replicate each sequence with their right hand after observing the demonstrated sequence. For each sequence in Experiment 2, a participant's score was calculated as the percentage of correctly replicated finger movements out of the total number of movements in that sequence. The sequence presentation order was randomized using a Latin Square design to avoid order effects. An ANOVA was used to analyze the data from Experiment 2.

IV. Results

Before the analysis of data from Experiment 1, participants were first screened for 'responders' and 'rejecters' based on the work of Kalckert and Ehrsson [29]. Rejectors are classified according to the criteria that they did not answer a single individual question on the positive spectrum of the Likert scale. Although some strong and mild responders were found, no rejecters were found in the data. All 30 participants were used in the analysis. The results indicated a significant sense of embodiment with the active robotic hand in three aspects: feeling of having an additional hand or arm (Passive: Mean = 3.5, SD = 1.77; Active: Mean = 4.5, SD = 1.7), sensation of the hand becoming 'mechanical' or 'artificial' (Passive: Mean = 3.6, SD = 1.65; Active: Mean = 4.7, SD = 1.7), and the resemblance of the robotic hand to the participant's own hand (Passive: Mean = 2.7, SD = 1.3; Active: Mean = 3.1, SD = 1.6). Furthermore, 20 of the 30 participants felt that the active robotic hand was more integrated into their body image compared to the passive robotic hand.

Data from Experiment 2 underwent variance analysis (ANOVA) to assess performance in a memorization task with either video instructions from the iPad or robotic hand guidance. No significant differences were observed in the easy tasks between mediums (iPad: 97.47%, Robotic Hand: 98.62%; $F_{1,56}$ = 1.373, ns). However, significant differences were observed in medium (iPad: 83.56%, Robotic Hand: 89.04%; $F_{1,56}$ = 4.047, p $<$ .05) and difficult tasks (iPad: 67.18%, Robotic Hand: 79.89%; $F_{1,56}$ = 19.463, p $<$ .05), indicating enhanced performance with the robotic hand. No significant training effect was found.

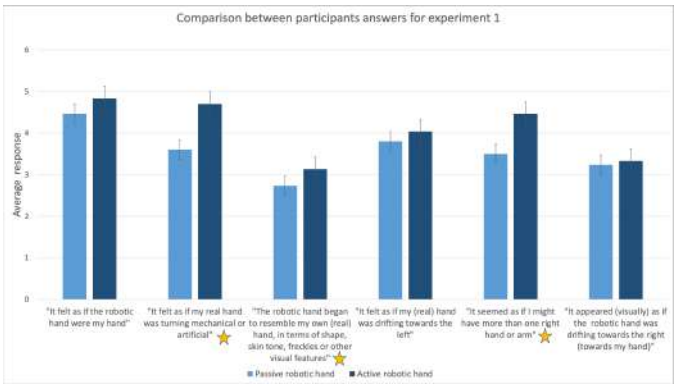

Fig. 3. Answers for 6 questions from the questionnaire proposed by Botvinick and Cohen [5]. A star marks results with a significant difference (p $<$ .05) between the passive (light blue) and active (dark blue) version of the robot hand.

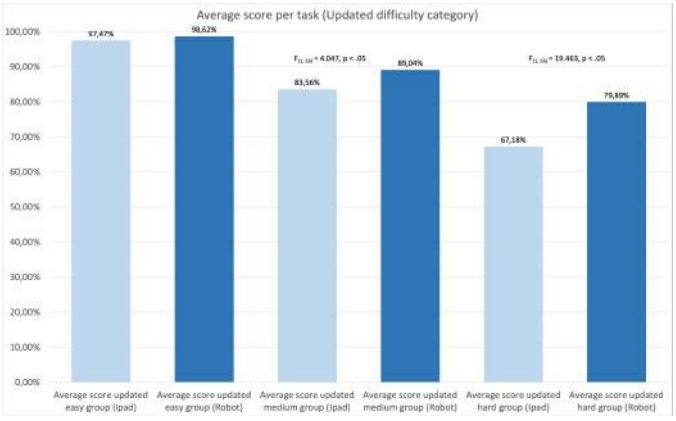

Fig. 4. Average correct replications of finger movement instructions per task (easy, medium, difficult) are shown. Light blue columns represent video clip instructions, and dark blue columns represent robotic hand instructions.

V. Discussion

Experiment 1's findings align with the foundational rubber hand illusion experiments by Botvinick and Cohen [5], demonstrating that the active robotic hand fosters a greater sense of embodiment and immersion compared to its passive counterpart. Participants reported a heightened sense of embodiment with the active robotic hand, in particular, noting its more convincing appearance and the sensation of having an additional limb. These results suggest that active interaction with the robotic hand not only reinforces the illusion of ownership, but also enhances the sensory integration necessary for a convincing experience of body ownership.

Qualitative feedback from participants further underscores the illusion's efficacy, with reports of the active hand feeling like a part of their body, indicating a strong sense of embodiment. However, discrepancies in timing and mechanical feedback occasionally disrupted this illusion, highlighting areas for improvement in the robotic hand's design.

Arata et al. [8] also demonstrated the RHI using a robotic hand, further validating this approach. However, while Arata et al.'s robotic hand was limited to tapping the index finger, our system allows simultaneous and individual movement of all five fingers, potentially contributing to a more complex and robust illusion. Furthermore, although both studies employed the Botvinick and Cohen questionnaire, our study yielded higher scores, particularly for questions 3 ('I felt as if the rubber hand were my hand') and 4 ('It seemed as if I might have more than one right hand or arm'), compared to those reported by Arata et al. This difference may be attributed to the increased dexterity and realism afforded by our five-fingered robotic hand, which more closely mimics natural human hand movements and coordination.

The results of Experiment 2 indicate that the participants performed better in the memorization tasks with the robotic hand, compared to passively watching a video instruction, suggesting that physical interaction and embodiment effects contribute to cognitive engagement and learning efficiency. This aligns with existing research on active learning, which shows that physical involvement and sensory integration can improve memory and learning outcomes [30].

The study highlights the importance of agency in enhancing the sense of ownership and embodiment. Active control over the robotic hand not only deepened the illusion but also introduced a dynamic element to the participants' experience, merging sensory feedback with motor control to reinforce the integration of the robotic hand into the body schema. This suggests a promising avenue for rehabilitation technologies, emphasizing the importance of user control and interaction in designing effective assistive devices. Furthermore, the robotic hand provides an alternative to virtual reality for patients who are uncomfortable with or unable to use headsets [31].

VI. Future work

While the study provides valuable information on the effects of embodiment and technology on perception and learning, it is subject to limitations. The use of a predominantly student sample and the reliance on subjective measures of embodiment highlight the need for further research across diverse populations and with more objective measurement techniques.

Given the promising results in the implementation and performance of motor tasks, future work should prioritize clinical translation and patient-centered design. Although our study provided initial information using a brief experimental setup, conducting long-term impact studies with stroke patients in real-world rehabilitation settings is essential. These trials can provide valuable data on the effectiveness, safety, and user experience of the robotic hand in diverse patient populations, and would help evaluate the sustainability of the improvements achieved through robotic-assisted rehabilitation.

Researchers and therapists can track patient progress over long periods to assess the durability of motor recovery and functional improvements. Crucially, these clinical trials should incorporate detailed patient feedback on usability, comfort, and perceived benefits of the robotic hand. Understanding patient needs and preferences will be essential to tailor technology to individual rehabilitation goals.

Future studies should also explore the impact of personalized ergonomic design on user experience and adherence to rehabilitation protocols. Patient feedback can be used to inform design iterations, ensuring that the robotic hand is comfortable, intuitive to use, and effectively supports individual motor impairments.

Furthermore, involving therapists and medical experts can lead to a deeper understanding of the clinical implications and practical challenges associated with robotic-assisted rehabilitation. For example, therapists could provide insights into how the robotic hand can be best integrated into existing rehabilitation workflows and used to augment traditional therapy techniques.

To enhance connection and embodiment, both mechanical and cosmetic improvements are necessary. In particular, applying soft robotics could offer more natural movements and a lifelike appearance, potentially improving user experience and the illusion's effectiveness.

The insights gained from clinical trials and patient feedback can then be used to guide future technological development, ensuring that improvements are driven by real-world needs and lead to tangible benefits for stroke survivors. This iterative process of clinical evaluation, patient feedback, and technological refinement will be critical to realizing the full potential of robotic embodiment in stroke rehabilitation.

VII. Conclusion

During this study, a successful prototype robotic hand was built using inexpensive 3D-printed parts and appliances. The hand was able to mimic the opening and closing of fingers of a human hand with a latency of only 90ms, making it suitable to be used as a tool to research embodiment with active versus passive stimuli, as well as memory retrieval.

The results indicate that the active version of the robotic hand created a higher sense of embodiment than the passive version. Additionally, the robotic hand yields significantly higher accuracy in memorization tasks compared to video clip instructions.

In conclusion, the results of this study suggest that the robotic hand could be a valuable and useful tool for stroke patients during their rehabilitation process, adding a personalized experience with the help of active stimulation combined with low costs.

Lower-Limb Motor Imagery-based Brain-Computer Interface to Control Treadmill Velocities

Aura Ximena González-Cely *Graduate Student member, IEEE*[1], Surjo R. Soekadar[2], Denis Delisle-Rodriguez[3], and Teodiano Bastos-Filho[1]

***Abstract*— Lower-limb rehabilitation traditionally relies on physical therapy, but motor imagery(MI)-based brain- computer interfaces (BCIs) promise to facilitate neuroplasticity and adaptation by closing the perception-action cycle. Here, we present a BCI system based on kinesthetic MI that enables treadmill velocity control, establishing a closed-loop feedback mechanism. The system was tested in a healthy participant translating mu (8-12 Hz) and high-beta (18-24 Hz) rhythm modulation into treadmill velocity control commands. Feature extraction techniques, including power spectral density (PSD) and Riemannian geometry (RG), were used for MI- and resting state classification. Additionally, Logistic Regression (LR), k-nearest neighbors, support vector machine, and Linear Discriminant Analysis (LDA) were employed and optimized for accuracy. The results showed increased mu and high-beta activation modulation at the vertex. The online RG+LDA classifier achieving an average accuracy of 72%, while the pseudo-online RG+LR reached 95%. The study's novelty lies in combining kinesthetic MI with treadmill control and employing RG for feature extraction, demonstrating its potential to enhance cortical modulation during rehabilitation. Future work will have to validate the system in poststroke patients for clinical applicability.**

I. INTRODUCTION

Stroke is one of the leading causes of locomotor impairments worldwide, commonly resulting in clinical conditions, such as hemiparesis and hemiplegia. Common symptoms are muscle weakness, impaired coordination, abnormal muscle tone, and posture, which can significantly hinder stroke survivors' mobility. As a consequence, 50% of stroke survivors use assistive devices as wheelchairs, with only 15% being independent while walking, 10% going outdoors, and 5% going upstairs from the total population [1]. Effective physical rehabilitation is therefore essential for restoring lower-limb functions toward independence and enabling stroke survivors to engage in Activities of the Daily Living (ADL) [1].

Motorized and electrical devices such as treadmills, exoskeletons, mini-motorized exercise bikes for movement execution, and Functional Electrical Stimulation (FES) to induce muscle contractions [1]–[10], have been used in MI-based Brain-Computer Interface (BCI) rehabilitation to assist movement. These brain controlled devices offer a feedback considering the brain signals, typically recorded via Electroencephalography (EEG). By detecting the user's Motor Imagery (MI), which is the action of imagining a limb's movement [1], [5], [11], EEG-based Brain-Computer Interface (BCI) converts these patterns into electrical commands to trigger a device, changing the ongoing interactions, with the opportunity of recovering patient's motor skills [1], [2], [12].

BCIs commanding treadmills has shown promise for activating the sensorimotor cortex and improving gait in post-stroke patients [1]. Moreover, EEG power-based analyses, such as Power Spectral Density (PSD) and Event-Related Synchronization/Desynchronization (ERD/ERS), have been used to track brain responses and to provide brain-signal related feedback during rehabilitation [3], [6], [7], [10].

A BCI is commonly composed of a first stage, called in this study Condition 1, which acquires EEG data for subsequent system calibration. Following, there is an operation stage, called in this study Condition 2 which uses the calibrated BCI to modulate cortical rhythms and provide feedback. The system calibration uses classification algorithms to discriminate between different mental tasks, very often MI and resting [4], [10], [11], while in the lower-limb area, walking speeds [13], [14]. Additionally, classifiers such as Linear Discriminant Analysis (LDA) [4], [7], [11], Support Vector Machine (SVM) [10], k-Nearest Neighbors (kNN) [14], and Logistic Regression (LR), among others classifiers, have been employed in BCIs. These classifiers use power-based analysis, such as PSD, ERD/ERS or powerful techniques based on covariance matrices as Common Spatial Patterns (CSP) [3], [7], and Riemannian Geometry (RG) [4], [14].

Previous research has primarily focused on discriminating motor imagery (MI) tasks, but little studies have integrated Neurofeedback (NF) with MI classification to dynamically adjust treadmill speed in real-time. The key challenge lies in accurately classifying walking-based MI while simultaneously applying Kinesthetic Neurofeedback (KNF), where treadmill velocities are modulated according to the user's MI performance. This approach has the potential to enhance the user's engagement, and promote cortical activation during MI tasks. To address this gap, our study proposes a NF system that leverages power changes in the central motor cortex to enable control of treadmill speed, providing real-time feedback based on the user's MI performance.

II. PROPOSED BRAIN-COMPUTER INTERFACE

A. Treadmill setup

An electric-powered treadmill (from Usilever Equipamentos, Brazil) was used in this study, with its circuit modified to allow for speed control via brain signal classification. The treadmill's circuit has a potentiometer to manually control its speed by adjusting voltages in range from 0 to 12 V DC, which is now linked through an in-house electronic circuit built to control the treadmill velocity. An ESP32 generates Pulse Width Modulation (PWM) signals between 0 and 3.3 V, which are converted into DC through a resistor-capacitor (RC) filter and amplified to match the treadmill's voltage range (0-12 V). This setup enables precise, real-time treadmill speed control in response to EEG signals.

The control system communicates with the treadmill wirelessly through User Datagram Protocol (UDP), which was chosen for its low latency and reliability in sending commands [11], in addition to provide safety to the patient. The main control unit processes EEG data, classifies MI, and conveys speed commands to the treadmill. The BCI pipeline, which consists of EEG acquisition, MI recognition, and treadmill command transmission, ensuring seamless feedback to the user during the task.

B. Participant

A healthy subject (26 years old, male) voluntarily participated in this study, without previous experience with MI. Ethical approval was obtained from the Research and Ethical Committees of the Federal University of Espirito Santo, Brazil (registry number CAAE: 46099421.9.0000.5542), and the study followed the Declaration of Helsinki.

C. EEG acquisition

EEG signals were acquired using a 16-channel Cyton board (OpenBCI, US), at a 125 Hz sampling rate. This board was selected for its compatibility with OpenViBE software, which supports seamless integration with custom electronic control systems through Python [4], [8], [13]. EEG electrodes were positioned on the motor cortex and sensorimotor area associated with lower-limb movement, according to [5], [6], [11], [15]. The EEG channels recorded were FP1, FP2, F3, F4, FC1, FCz, FC2, C3, C1, Cz, C2, C4, CP1, CP2, and Pz, followed by ground (GND) and reference (REF) electrodes.

D. Experimental protocol

Fig. 1A shows the protocol performed while using the BCI composed of three stages called Condition 1, calibration, and Condition 2. Condition 1 started with 120-s baseline, where the participant remained in rest state. This was followed by seven trials, each one consisting of 20-s of active walking followed by 20-s of walking-based MI. During MI, the treadmill was controlled by a KNF model, providing changes in treadmill speed based on brain power relative changes using three speeds considered as high, moderate, and low velocity. These velocities are linked to MI perfomance. The participant had a 400-s rest period to prevent mental fatigue, in which EEG data acquired during Condition 1 were used to calibrate the system. After calibration, Condition 2 allowed the system to discriminate between MI and resting.

The participant performed three trials, each with alternating intervals of 20-s of MI and KNF, which was activated while MI was classified, followed by 20-s of mental rest and active walking.

E. Condition 1 and system calibration

Fig. 1B shows the pipeline implemented in the system calibration using the EEG dataset acquired during Condition 1, as an input to recognize between MI and resting, where the period of baseline is considered as the resting class. The system's calibration considers the use of a 5-fold cross-validation to avoid overfitting, data leaking, and generalize better the system, as done in [3], [4], [14]. This stage generates the classification model and KNF parameters to be used in Condition 2.

1) Pre-processing stage: The pre-processing stage started with a segmentation to split the dataset into 80% for training, and 20% for testing. From the previous 80%, a new split was performed to obtain new training and validation datasets. With each segment of data, a 1-second sliding window (with 50% overlap) was applied to segment the data for processing, as performed in [4], [7], [11]. Using each window of data, a Butterworth zero-phase band-pass filter was used between 7 to 30 Hz to isolate mu and beta bands [3].

2) Feature extraction and Classification: RG based on covariance matrices that are projected in the tangent space was used for feature extraction [4], [14]. LDA was chosen for classification due to its use in similar studies related to lower-limb BCIs [4]. Accuracy (ACC) was used as metric to determine the best classifier performance. This way, ACC was obtained from each fold, using a 5-fold cross-validation, and the respective classification model was stored and implemented in Condition 2.

F. Neurofeedback Technique

The NF pipeline shown in Fig. 1C was implemented to provide treadmill speed adjustments based on MI power levels in both Conditions 1 and 2, while the participant imagined performing the walking task. It is worth mentioning that treadmill velocities were not classified in our study, which means that only MI and resting were classified, which were used to trigger KNF.

In Condition 1, EEG signals were processed using a 1-s window, calculating the Relative power changes (R) as shown in (1), for mu and beta bands, using a Laplacian filter around Cz, as suggested in [4], [6]. These power changes are based on the difference between Active Walking (AW) and MI, as shown in (1). Based on these values, interpolation of 25, 50, and 75% were used to generate three velocities levels: low, moderate, and high, which are based on the participant's performance. Brain power changes were mapped to speed levels, providing the participant with immediate feedback. This strategy is applied to guide the modulation of cortical rhythms of interest, with a focus on achieving the highest velocity.

$$R(\%) = \left| \frac{R_{MI} - \overline{R}_{AW}}{\overline{R}_{AW}} \right| \times 100 \ , \qquad (1)$$

In Condition 2, MI classification activates KNF to provide treadmill velocity changes, also considering previous KNF parameters obtained from Condition 1, which are related to the closer patterns between MI and AW. These parameters were calculated as shown in [4].

G. Condition 2

Fig. 1D shows the pipeline that starts filtering EEG data windows and feature extraction stage, followed by the use of the classification model (obtained in the system's calibration), which discriminates between subject's resting and MI. Whether MI is classified, the NF calculation is performed, and the treadmill is commanded. The participant was verbally guided to focus on walking MI, not related to the velocity, but with the aim to increase the treadmill velocity.

III. PSEUDO-ONLINE ANALYSIS

A. Feature Extraction

Two types of features were analyzed in this study to enhance the system in future implementations. 1) PSD based on the brain signals power using the Fast Fourier Transform (FFT) in mu (8-12 Hz) and beta (18-24 Hz) bands [3], [10], [16], 2) RG. It is worth mentioning that PSD used pre-processed data considering a Common Average Reference (CAR) filter to remove common interference [6], as well as a Butterworth band-pass filter. However, RG features were obtained only considering the Butterworth band-pass filter [4], [14].

B. Classification

LR, SVM, kNN, and LDA are used in this study, due to their good performance in binary classification problems [2], [11], [14], [16]. LR and LDA do not use a hyperparameter stage because both classifiers are linear, whereas kNN and SVM implemented a hyperparameter tuning. The hyperparameters studied here for kNN were "k" neighbors (1,3,5,7,9). For SVM, the analysis was focused on the type of kernel (linear, polynomial, rbf, or sigmoid).

C. Evaluation metrics

The classification model's performance was evaluated using ACC and Area Under the Curve (AUC). Latency was also assessed, measuring the delay between EEG signal acquisition and treadmill activation to ensure real-time response capability. In addition, R changes were calculated based on (1). In the cortical activation analysis, R_{MI} represented in (1) was changed for MI data of each condition, which were represented in topographic maps considering a mean of all trials.

IV. RESULTS AND DISCUSSION

A. Cortical Activation Patterns

The cortical activation results demonstrate distinct patterns between MI and resting across frequency bands. As shown in Fig. 2, higher R appeared in the mu band in the lateral and parietal areas, and lower R in the low-beta and high-beta band. In addition, lower R are focused around Cz in the

mu band, in Condition 2, compared with Condition 1. This behavior is similar in the low-beta with a increased R around Cz and C2 channels. This negative R changes in the mu band are aligned with studies associating this cortical activity with motor tasks, suggesting the potential utility of focusing feedback on central regions to enhance MI performance [7].

Condition 2 is more focused on the central part of the brain, specifically in the Cz electrode location, in the mu band as shown in [1], [4], [7], [16]. Higher activation was presented in the mu band, focusing on the parietal and lateral brain regions, also related to attention levels, which agrees with other outcomes [7], [9]. Other studies have shown parietal and lateral activations while performing walking-based MI tasks [1], [4].

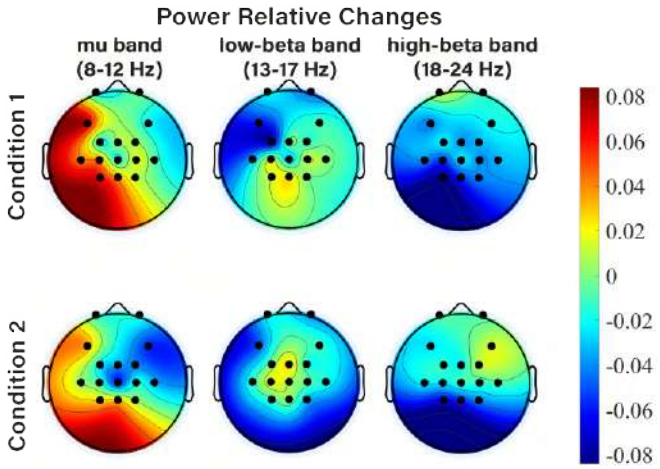

Fig. 2: Topographic maps based on R in three stages: Condition 1, system calibration, and Condition 2 in the mu, low-beta, and high-beta bands.

B. BCI performance

In our study, in Condition 2, RG+LDA obtained a mean ACC close to 0.72 whereas the literature has implemented the same combination using an exoskeleton with Spinal Cord Injury (SCI) survivors with ACC higher than 0.7 [4]. For this reason, we implemented in this preliminary study the same combination of RG+LDA due to some similarities in terms of the walking task, ACC outcomes, and KNF principle.

Our system was tested offline and online whereas other approaches implemented only offline or pseudo-online analysis [3]. Studies employing other feature extraction or classification techniques, such as the use of Filter Bank Common Spatial Patterns (FBCSP)+LDA using a treadmill with a mean ACC of 0.68 [2], CSP+LDA with ACC close to 0.75 [7], and Hjorth parameters with ACC close to 0.68 [3], suggested that our results are promising for enhancing ACC outcomes with post-stroke patients, providing a more reliable basis for motor rehabilitation using BCIs.

In terms of time response, the system's calibration was processed in 10 s to obtain the classification model and parameters for Condition 2, guaranteeing a low calibration time for clinical use. The latency since EEG data are acquired to trigger the treadmill was close to 250 ms while pre-processing data windows, extracting features, classifying data, and sending the output classifier translated into a velocity command to the treadmill. Such responsiveness is crucial for MI-based immediate feedback to help participants sustain MI and enhances engagement. Other studies in the literature have shown calibrations with higher time responses [17] or the inability to control the end-effector [4].

C. Pseudo-online analysis

The pseudo-analysis was performed to enhance the BCI in future implementations, and these outcomes indicate that RG features outperformed PSD in terms of ACC and AUC, with mean ACC values exceeding 0.8 for RG features as shown in Fig. 3. LR and SVM achieved the highest ACC, with 0.95 and 0.94, respectively, while implementing RG features, indicating that these combinations are particularly suitable for distinguishing MI from resting states. These results corroborate findings from previous BCI studies that also found higher accuracies with RG as a feature [13], [14]. In contrast, PSD features yielded lower performance, with ACC values for LDA and kNN reaching 0.72 and 0.71, respectively. Compared to other BCI implementations, our results with RG+LR and RG+SVM combinations show a promising improvement in classifier performance, especially for real-time applications in rehabilitation.

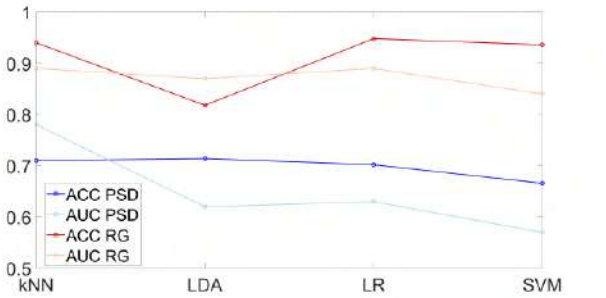

Fig. 3: ACC and AUC outcomes per classifier and feature extraction technique.

Our findings support the use of treadmill-based MI neurofeedback for lower-limb rehabilitation, with potential benefits over stationary or restricted systems, such as cycling and exoskeletons. Walking tasks have demonstrated muscle strengthen as well as improvement of physical condition, which are vital for post-stroke patients, potentially enhancing neuroplasticity through active participation and MI practice. Furthermore, controlling treadmill speed through MI provides a form of interactive feedback that can better maintain the user's participation over static feedback types, which can lead to muscle or mental fatigue [1]. Other systems such as pedaling bicycles or exoskeletons cannot perform the same process, even demonstrating relevant outcomes and the advantage of being implemented for both SCI survivors and/or impaired post-stroke patients.

In terms of physical limitations, we avoided the use of exoskeletons, and focused on a comfortable system to use,

whereas other studies lack in the use of skin electrodes, [10], [18] as well as wearable exoskeletons, which delay the preparation time and could generate fatigue [6], [11]. Our system utilizes velocity changes as a way of NF to assist the modulation of EEG bands of interest, whereas other studies implement vibrotactile feedback [10] or visual NF [4], which could generate visual or muscle fatigue.

It is worth noting that our NF system is designed to increase treadmill velocities in response to MI execution during Condition 2. It is worth mentioning that triggering the treadmill was not the primary objective of this proposed MI-based BCI, but rather the increase in velocity served as a key goal. Additionally, KNF is implemented in both conditions, to first guide and train users in modulating the targeted cortical rhythms, and second, to increase the task difficulty using the calibrated system, thereby promoting improved MI performance. This approach ensures both muscle activation, comparable to conventional physiotherapy, and modulation of cortical rhythms to enhance neuroplasticity.

As a limitation of this research, our study lacks in the number of healthy subjects that tested the system and the number of sessions achieved, which restricts generalizability. In addition, there was not implementation in real-time of the combination of RG+LR which achieved the highest offline performance. It is worth commenting that our treadmill also has a body-weight support that could be used for SCI survivors, and also implementing FES to generate a virtual gait. Future studies will expand the participation pool, including healthy subjects, post-stroke and SCI survivors, to assess the broader applicability of this approach. Furthermore, collaboration with clinical professionals will help refine the BCI, ensuring that it meets rehabilitation goals effectively.

V. CONCLUSION

This study implemented a real-time MI-based BCI that adjusts treadmill speeds as a way of neurofeedback, showing promise for lower-limb rehabilitation. By focusing on changes in cortical activation at the Cz electrode, the system can increase or decrease treadmill velocity based on MI, allowing for dynamic, responsive interaction. With Riemannian Geometry and Linear Discriminant Analysis, a mean ACC of 0.72 was achieved, while recognizing MI and resting classes.

Despite these positive findings, the study was limited by its single-participant sample and preliminary classifier configurations. Future implementations will expand participant diversity, particularly including SCI and post-stroke survivors, to evaluate generalizability. We will also explore additional classifier combinations, such as Riemannian geometry with logistic regression, and integrate body-weight support, enhancing system adaptability for individuals with severe motor impairments. We believe that these developments could make MI-based BCI valuable tools in clinical rehabilitation settings, potentially improving motor recovery and quality of life for patients with mobility challenges.

Muscle Activation and Postural Sway in Response to Task Complexity: A Study of Balance Control in Older Adults

Longbin Zhang[1,2,3], Ananda Sidarta[2], Yu Chin Lim[2], Carol Er[2], Xiaoyue Yan[2,3], Tsung-Lin Wu[2,3], and Wei Tech Ang[2,3]

***Abstract*— In this study, we investigate muscle activation patterns and postural sway in older adults across different stance conditions with varying challenges. Muscle activity from lower limb and trunk muscles was recorded in seven older adults during four stance tasks: double stance, tandem stance, tandem stance with a cognitive task, and tandem stance with combined cognitive and motor tasks (TSCM). We analyzed CoP (centre of pressure) features, EMG (electromyography) patterns, and the coherence between EMG-CoP, to gain insights into neuromuscular coordination and balance control. Our findings indicate that task complexity significantly impacts postural stability, with tandem stances—particularly TSCM—leading to increased instability along the anterior-posterior axis. Key stabilizing muscles, such as the gastrocnemius medialis and tibialis anterior, showed heightened activation and strong EMG-CoP coherence under complex tasks, highlighting their essential role in counteracting gravitational forces to maintain balance. A lateral asymmetry in muscle activation was also observed, with left-side muscles consistently showing greater activity than right-side counterparts, suggesting lateralized contributions to postural control. These results emphasize the importance of specific muscles for stability in challenging postural tasks and may offer valuable insights for designing targeted interventions, including robotic rehabilitation systems and assistive technologies, to enhance balance and reduce fall risk in older adults.**

I. Introduction

Postural control is a complex function that involves maintaining the vertical projection of the center of gravity within the base of support, ensuring stability during both static and dynamic activities [1]. Falls, the most severe consequence of postural control disorders, pose a significant threat to the independence of older adults and are an escalating public health concern, often resulting in severe injuries, diminished quality of life, and reduced mobility [2]–[4]. This highlights the critical need to study postural control in this population. Maintaining postural control requires intricate coordination between the sensory systems (visual, vestibular, and proprioceptive), the central nervous system, and the musculoskeletal system [5]. Kinematic measures such as the base of support (BoS), center of mass (CoM), and center of pressure (CoP) are crucial for evaluating postural control, with the CoP frequently acting as a key indicator. [6]. Recently, growing interest has focused on exploring the neural mechanisms underlying postural control using tools like electroencephalography and electromyography (EMG), which provide valuable insights into cortical and muscular activities involved in maintaining stability [3], [7]. Understanding these processes is crucial for diagnosing and treating balance disorders and enhancing assistive technologies such as neuroprosthetics and rehabilitation robotics.

EMG-CoP coherence has been studied in older adults to assess how muscle strength affects balance. Skeparianos et al. [8] found that stronger ankle muscles, particularly plantar flexors and dorsiflexors, are associated with reduced postural sway, especially in challenging stances such as tandem and one-legged standing. Sozzi et al. [9] further examined leg muscle activity during tandem stance and highlighted that while the soleus muscle maintains upright posture with tonic activity, the tibialis anterior and peroneus longus muscles contribute to balance control through reciprocal actions in the medio-lateral direction. Their findings suggest that muscular strength and coordination are critical for maintaining postural stability in older adults. These studies highlight the importance of muscular-postural sway coherence in understanding postural control in older adults, suggesting the potential for training interventions, particularly given the differences in athletes. Indirectly, such a measure may reflect the balance ability of older adults while doing tasks of varying complexity. Therefore, it is essential to investigate muscular-postural sway coherence in older adults during balance tasks.

Cognitive decline, a natural consequence of aging, further complicates balance control by impairing memory, attention, decision-making, and executive functions, all of which are crucial for daily activities [10]. Cognition plays a vital role in postural control by integrating sensory information, facilitating decision-making, and enabling motor planning, allowing older adults to assess risks, maintain attention, and adapt movements based on past experiences. Increased cognitive load, such as when multitasking, can compromise balance. Effective cognitive processes are thus essential for maintaining stability and preventing falls [11].While many studies have examined interventions to slow cognitive decline, limited research has explored how muscular-postural sway coherence interacts during dual-task activities that combine cognitive and motor demands. Understanding how cognitive and motor tasks jointly influence balance control is vital for identifying early markers of decline and developing interventions to maintain stability in older adults.

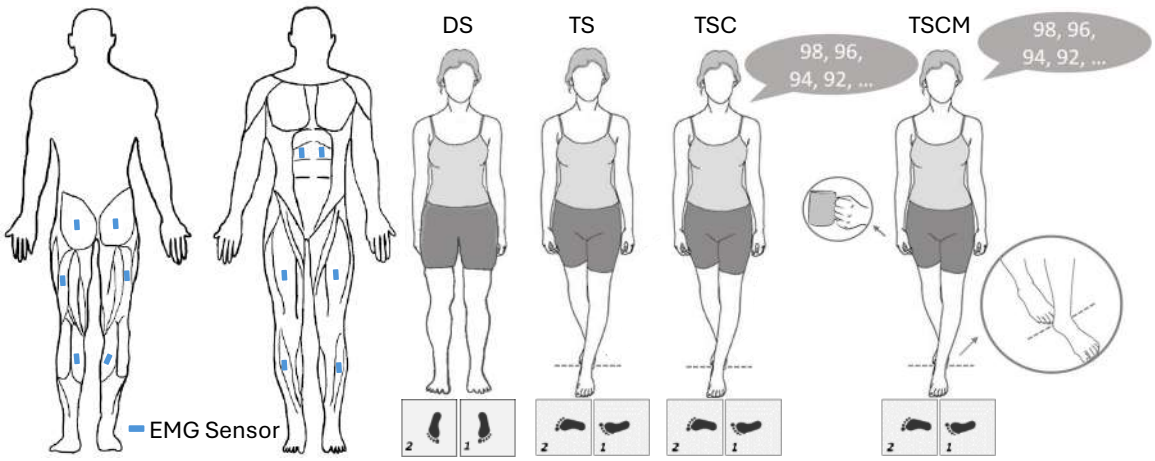

Fig. 1. Experimental setup for assessing stance stability. Electromyography signals were recorded from lower limb and trunk muscles along with center of pressure data during four stance tasks: double-leg stance (DS), tandem stance (TS), tandem stance with a cognitive task (TSC), and tandem stance with combined cognitive and motor tasks (TSCM).

The objective of this study is to examine how different stance tasks with varying difficulty impact muscle activation patterns, postural sway characteristics, and EMG-CoP coherence in older adults. This involves analyzing the role of lower limb and trunk muscles, as well as center of pressure features, across different stance conditions that include cognitive and motor demands.

II. Methods

A. Experimental Setup

Seven sedentary older adults (sex: 2F/5M; age: 64.7 $\pm$ 4.0 years; weight: 62.3 $\pm$ 11.3 kg; height: 163.7 $\pm$ 9.2 cm) were recruited. All participants provided informed written consent. Data collection was conducted at the Rehabilitation Research Institute of Singapore, with the study approved by the Nanyang Technological University Institutional Review Board (IRB-2022-382). Participants were instructed to perform a series of static balance tasks, comprising double-leg stance (DS), tandem stance (TS), tandem stance with a cognitive task (TSC), and tandem stance with both cognitive and motor tasks (TSCM), with a pseudorandomized sequence across participants. In all tasks, participants had to maintain an upright steady posture as much as possible, with eyes open looking at a fixation cross in front of them. They stood with each foot occupying a force platform (9260AA6, Kistler Instruments AG, Winterthur, Switzerland) embedded underneath the ground. The force platforms recorded the time-varying CoP of the participants with a sampling frequency of 2000 Hz. All participants were right-hand and right-leg dominant.

In the DS task, participants were asked to stand quietly and maintain their posture for 60 s. During the TS task, the individual stood in a tandem position, i.e. their dominant foot was positioned in front of the other, with both feet pointing forward, and arms resting at their sides. Each foot was placed on each square (Fig. 1). The TSC task was essentially a tandem stance with an additional memory test. Here, they were asked to do a tandem stance as before, while memorizing a series of numbers presented to them throughout the task. After the task completion, they had to verbally recall the numbers presented earlier. Finally, in the TSCM, participants were asked to do TSC with an additional motor task in the form of holding a cup filled with water with the dominant hand. The TS, TSC, and TSCM consisted of 2 repetitions of 40 s each, and the average of the results was used for representation. A short demonstration was given by the experimenter and each participant was allowed to practice the posture once. All participants were able to complete every task within the required duration.

EMG recordings were obtained using 12 wireless surface EMG electrodes (Cometa Systems, Italy). After appropriate skin preparation, electrodes were placed bilaterally on the muscle bellies of eight muscle groups, aligned parallel to the direction of muscle fibers. The muscle groups tested included the Gastrocnemius Medialis (GM), biceps femoris (BF), gluteus maximus (GluM), tibialis anterior (TA), rectus femoris (RF), and Rectus Abdominis (RA). EMG signals were recorded at a sampling frequency of 2000 Hz. Electrode placement was conducted following SENIAM (Surface EMG for Non-Invasive Assessment of Muscles) project recommendations. The EMG data were band-pass filtered (5–400 Hz) to isolate relevant frequencies, and then rectified using full-wave rectification, a process that has been shown to enhance information about the temporal patterns of grouped motor unit firing [12]. To obtain the muscle activation envelope, the rectified EMG was further low-pass filtered at 6 Hz and normalized to the maximum EMG value across all movement trials [13]–[15].

B. CoP Sway Features

The anterior-posterior (AP) and mediolateral (ML) CoP signals, derived from force and moment data, were low-pass filtered at 15 Hz using a fourth-order, zero-phase lag Butterworth filter. We then calculated the CoP area and mean

frequency for the whole body, as well as the mean distance, the range of maximum deviation, mean velocity in AP and ML directions, and power frequency dispersion in both directions [16]. These CoP features were analyzed and compared across all tasks. Shapiro-Wilk tests were applied to assess the normality of CoP features. For group comparisons, paired t-tests were used for features with normal distributions, while Wilcoxon signed-rank tests were applied for non-normally distributed features. Statistical significance was determined at $p < 0.05$ with Bonferroni correction applied for multiple comparisons.

C. EMG-CoP Muscular-postural Sway Coherence

To assess the coherence between EMG signals and CoP sway, we calculated the EMG-CoP coherence for each muscle with respect to the postural sway of the corresponding foot. For example, coherence between the GM on the left side was analyzed in relation to the CoP of the left foot across the frequency spectrum. Coherence, a measure of the linear association between two signals across frequencies, was calculated using the following formula:

$$Coh_{S1,S2}(f) = \frac{|P_{S1,S2}(f)|^2}{|P_{S1}(f)| \times |P_{S2}(f)|} \quad (1)$$

$$P_{S1,S2}(f) = \frac{1}{n}\sum_{i=1}^{n} S1_i(f) \cdot S2_i^*(f) \quad (2)$$

where $Coh_{S1,S2}(f)$ represents the coherence between EMG ($S1$) and CoP ($S2$) at frequency f; $P_{S1,S2}(f)$ is the cross-spectrum density of the signal, $P_{S1}(f)$ and $P_{S2}(f)$ are the auto-spectral densities of the EMG and CoP signals, respectively. Coherence values are normalized and bounded between 0 and 1, where a value of 1 indicates a perfect correlation between EMG and CoP at a given frequency, and a value of 0 indicates no correlation.

III. Results

A. CoP sway measures

In the ML direction, the mean distance significantly increased in TS compared to DS ($p < 0.01$). In the AP direction, the mean distance was significantly higher in TS ($p = 0.03$), TSC ($p = 0.02$), and TSCM ($p = 0.02$) than in DS. Additionally, mean distance values in the AP direction were larger than those in the ML direction across TS, TSC, and TSCM (Fig. 2).

The range, defined as the distance between maximum deviations, was significantly greater in TS, TSC, and TSCM compared to DS in both the ML and AP directions (all $p < 0.01$). Notably, the range values in the AP direction exceeded those in the ML direction across TS, TSC, and TSCM.

Similarly, in mean velocity, the data showed significantly higher values in TS, TSC, and TSCM than in DS for both directions. Mean velocity in the AP direction was also consistently higher than in the ML direction across these stances. Compared to DS, power in the AP direction was significantly higher in TSC ($p = 0.04$) and TSCM ($p = 0.02$), and was also elevated, though not significantly, in TS ($p = 0.06$). In the ML direction, power was significantly greater in TS compared to DS ($p = 0.03$). Additionally, power magnitude in the AP direction was consistently larger than in the ML direction across TS, TSC, and TSCM.

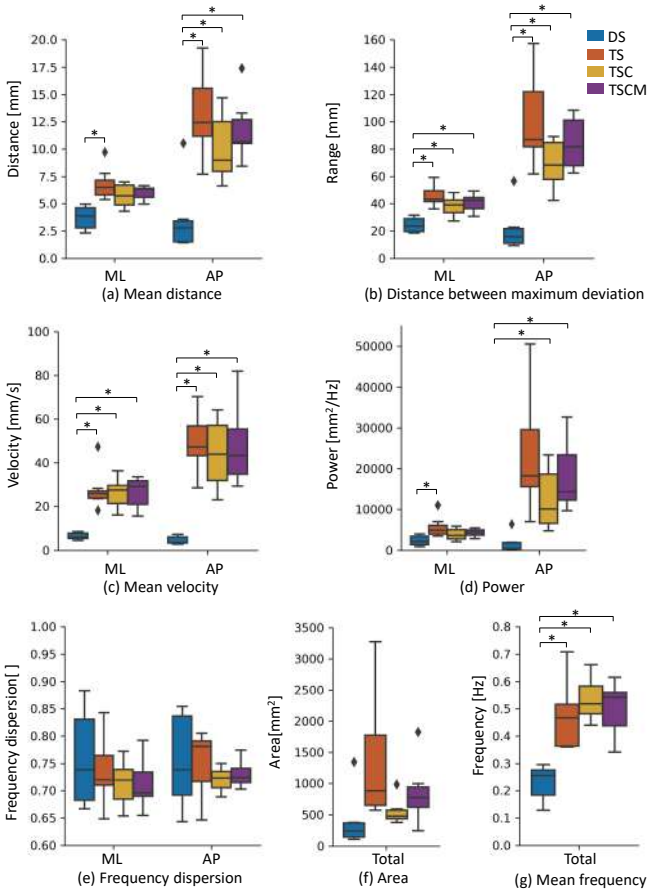

Fig. 2. Center of pressure (CoP) features for all subjects across four tasks: DS (double stance), TS (tandem stance), TSC (tandem stance with cognitive task), and TSCM (tandem stance with cognitive and motor tasks). The features displayed are: (a) mean distance in anterior-posterior (AP) and mediolateral (ML) directions, (b) range of maximum deviation in ML and AP, (c) mean velocity in ML and AP, (d) power in ML and AP, (e) frequency dispersion in ML and AP, (f) area, and (g) mean frequency. Asterisks (*) indicate statistically significant differences between the two groups, determined using paired t-tests for normally distributed data or Wilcoxon signed-rank tests for non-normally distributed data, with Bonferroni correction applied.

The area was larger in TS, TSC, and TSCM compared to DS. Interestingly, the sway area in TSC and TSCM was lower than in TS. The mean frequency of postural sway was significantly higher in TS, TSC, and TSCM compared to DS (All $p < 0.01$). Furthermore, mean frequency followed an ascending pattern, with TSC being higher than TS and TSCM being higher than TSC. No significant differences were observed in frequency dispersion across the stance conditions.

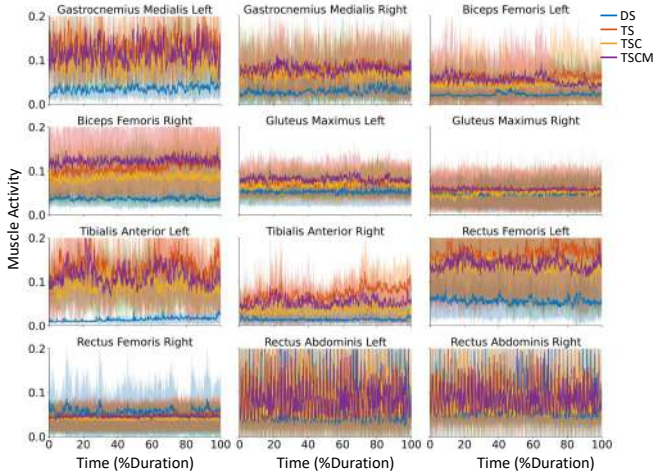

Fig. 3. Muscle activities (normalized to maximal value across all trials) across all subjects for four tasks: DS (Double Stance), TS (Tandem Stance), TSC (Tandem Stance with Cognitive Task), and TSCM (Tandem Stance with Cognitive and Motor Tasks). Results were presented as mean ± standard deviation for each muscle across all subjects.

B. Muscle patterns

Muscle activity patterns were generally similar across the TS, TSC, and TSCM conditions in the GM, TA and BF on both the left and right sides, as well as in the RF and GluM on the left side. However, these muscles exhibited notably higher activity in the TSCM condition compared to the DS condition (Fig.3).

Differences in muscle activity across conditions were minimal in the RF and GluM on the right side and the RA on both sides, with only slight variations observed across the conditions.

An asymmetry in muscle activity was also observed, where the left-side muscles—particularly the GM, TA, and RF—exhibited higher activity levels than their counterparts on the right side under the TS, TSC, and TSCM conditions.

C. EMG-CoP muscular-postural sway Coherence

The EMG-CoP coherence of lower limb muscles was found up to around 20 Hz across all tasks: DS, TS, TSC, and TSCM. Among the muscles, the GM consistently demonstrated the highest coherence with CoP, followed by the TA and RF (Fig. 4).

In the GM, coherence with CoP was generally higher in the TS, TSC, and TSCM conditions compared to DS. On the left side, coherence was highest in TSCM compared to TS and TSC, whereas on the right side, coherence in TSCM was lower than in TS and TSC. Coherence of BF and GluM with CoP was slightly higher on the left side compared to the right. Minimal coherence was observed in the RA across all tasks.

IV. Discussion

In this study, we explored the relationship between postural sway, activation patterns of lower limb and trunk muscles, and EMG-CoP coherence in older adults during various stance tasks: double stance, tandem stance, tandem stance with a cognitive task, and tandem stance with combined cognitive and motor tasks. Our findings revealed that postural sway measures—including mean distance, range, mean velocity, sway area, and mean frequency—were generally higher in TS, TSC, and TSCM compared to DS, reflecting the increased challenge of maintaining stability on a narrow base of support. In line with this increase in sway, muscle activity in most lower limb muscles was also elevated in TS, TSC, and TSCM relative to DS, suggesting greater neuromuscular demand to stabilize the body under more challenging conditions. Furthermore, EMG-CoP coherence analysis indicated that lower limb muscles exhibited coherence with CoP up to around 20 Hz across all tasks, with the GM demonstrating the highest coherence. This suggests that the GM plays a key role in coordinating muscular responses to maintain postural stability. These findings provide valuable insights into the roles of different muscles in stabilizing posture under varied conditions and emphasize the potential importance of task-specific muscle activation for postural control. Such insights could inform injury prevention strategies and rehabilitation programs by identifying muscles that are crucial for maintaining balance, particularly under challenging conditions like narrow stances or multitasking.

Task complexity and stance type substantially influence postural control, leading to increased instability and more frequent postural adjustments, particularly along the AP axis. However, no significant effect of concurrent motor or cognitive tasks on balance parameters was observed. Both mean distance and range increase notably in TS, TSC, and TSCM tasks, particularly in the AP direction, suggesting that tandem positioning, with its restricted base of support, presents greater stability challenges along this axis. Similarly, mean velocity rises across TS, TSC, and TSCM, indicating a heightened need for postural corrections as task demands increase. The higher power in the AP direction under TSC and TSCM further highlights the additional balance control demands imposed by complex task conditions. Interestingly, while sway area peaks in TS, it slightly decreases in TSC and TSCM, suggesting that additional tasks may lead to a more concentrated, yet still broad, sway pattern. The lack of a significant effect of concurrent motor or cognitive tasks on balance parameters is consistent with the findings of Xu et al. [17], who examined balance ability and prefrontal cortex activation under single- and dual-task conditions. Their results similarly indicate that dual-tasking does not significantly impact balance performance in healthy older adults, suggesting that balance control may operate implicitly, even when additional cognitive tasks are introduced. This aligns with the Task Prioritization Model [18], which posits that as postural threat increases, older adults prioritize postural stability over cognitive performance. We acknowledge that the small sample size may limit the ability to detect finer differences among TS, TSC, and TSCM. Further research with larger cohorts is necessary to confirm these trends and explore potential subtleties in task-dependent balance control mechanisms.

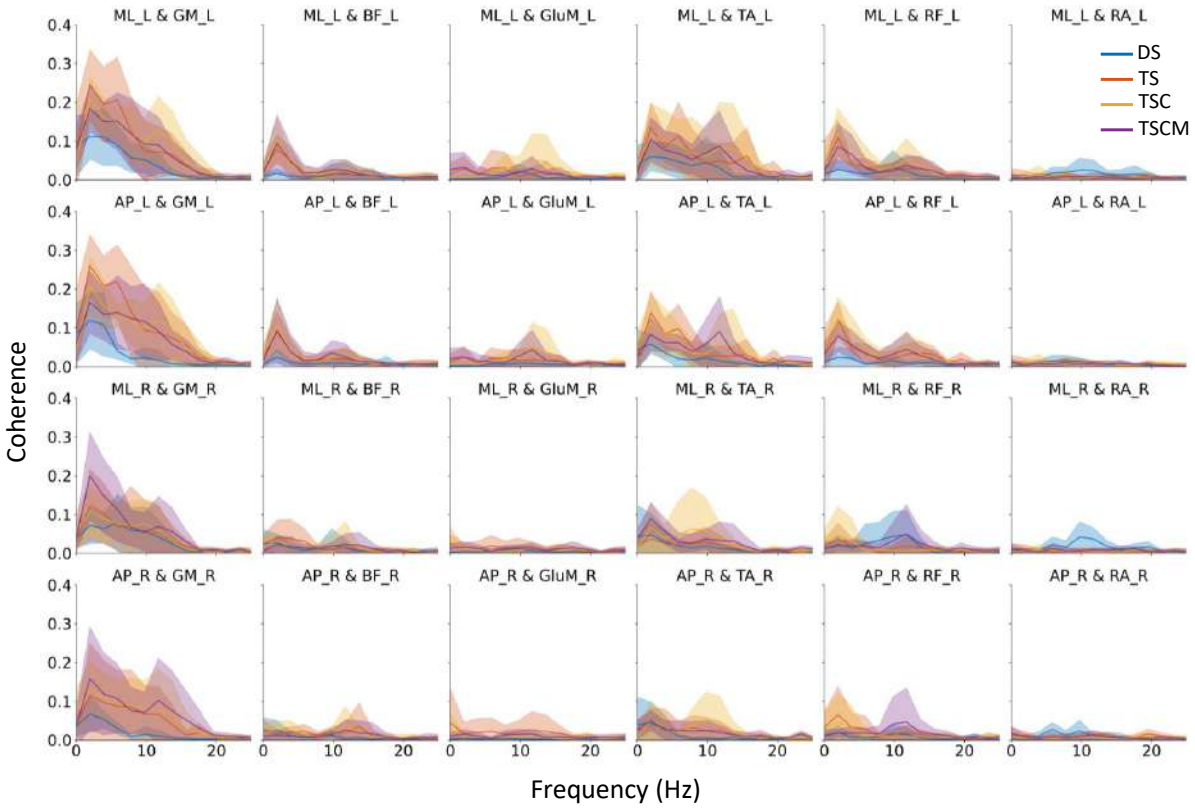

Fig. 4. Coherence between electromyography (EMG) and center of pressure (CoP) data across all subjects for four tasks: Double Stance (DS), Tandem Stance (TS), Tandem Stance with Cognitive Task (TSC), and Tandem Stance with Cognitive and Motor Tasks (TSCM). Results were presented as mean $\pm$ standard deviation across all subjects. ML_L and ML_R represent the mediolateral directions of CoP on the left and right sides, respectively; similarly, AP_L and AP_R indicated the anteroposterior directions. Muscle activity was represented by GM_L and GM_R for Gastrocnemius Medialis on the left and right sides, and corresponding labels for Biceps Femoris (BF), Gluteus Maximus (GluM), Tibialis Anterior (TA), Rectus Femoris (RF), and Rectus Abdominis (RA).

Muscle activity levels vary with task complexity, with greater engagement noted in the TSCM condition compared to DS, especially in the GM, TA, and BF on both sides and in the left RF and GluM. This pattern indicates that more complex tasks requiring both cognitive and motor coordination (TSCM) demand increased muscle activation to maintain postural stability. The minimal differences in activity across conditions in the bilateral RA, along with the low EMG-CoP coherence, suggest that the RA may be less responsive to changes in task complexity. The moderately high normalized values observed in the bilateral RA may be attributed to normalization relative to the maximum value across all trials, as RA activity remained generally low and stable. Additionally, asymmetry in muscle activity was observed, with left-side muscles (non-dominant leg), particularly the GM, TA, and RF, showing consistently higher activation than their right-side counterparts during TS, TSC, and TSCM. This asymmetry may reflect inherent lateral dominance or compensatory strategies, suggesting that the non-dominant side plays a more active role in stabilizing posture under complex conditions, such as tandem stance. These findings are consistent with Sozzi et al. [9], who reported higher EMG activity in the non-dominant leg, indicating that it serves as the primary stabilizer in tandem stance, thereby assuming a greater postural load.

A notable coupling between muscle activation and postural sway was observed, especially in the GM, with coherence up to approximately 20 Hz across all tasks. In a related study, Watanabe et al. [12] investigated the coordination of plantar flexor muscles—specifically the medial and lateral gastrocnemius and soleus—and their relationship with postural stability during bipedal and unipedal stances, finding coherence levels up to about 10 Hz in elderly adults. Our study expands upon this by including additional muscles to provide a more comprehensive analysis of the relationship between muscular activation and postural sway coherence. In this study, the GM displayed the highest EMG-CoP coherence among the lower limb muscles, underscoring its critical role in postural adjustments. This finding aligns with previous research suggesting that the gastrocnemius is a primary contributor to modulating AP sway, particularly during challenging balance tasks [19]–[21]. Both the GM and TA demonstrated higher coherence levels than other muscles, indicating their prominent involvement in stabilizing posture under increased task demands. This is consistent with studies that reported elevated EMG amplitudes in the GM and TA compared to the RF and BF across balance tasks. The greater activation in the ankle muscles may be due to the reliance

on an ankle strategy to counteract gravitational torque in an upright stance, an essential mechanism in maintaining balance [22]–[24]. Notably, a task-related asymmetry emerges in the GM, with left-side coherence peaking in TSCM, while right-side coherence is lower in TSCM than in TS and TSC, suggesting potential lateralized differences in muscle-sway coordination under high task demands. Other muscles, like BF and GluM, exhibit slightly higher coherence on the left side, pointing to a subtle lateral asymmetry in postural sway synchronization, while the RA shows minimal coherence across all tasks, indicating a limited role in postural sway regulation. These findings suggest that while GM is central to postural control across tasks, asymmetric coherence patterns may reflect compensatory strategies or task-specific muscle contributions to stability.

V. Conclusion

We investigated how different stance tasks affect postural sway, lower limb and trunk muscle activation, and EMG-CoP coherence in older adults, highlighting the distinct roles of muscle activation patterns and muscle-postural sway coherence in maintaining balance under varying levels of task complexity. The findings indicate that tandem stances, especially when coupled with cognitive and motor tasks (TSCM), significantly challenge postural stability, demanding higher activation in key stabilizing muscles like the GM and TA. These muscles, particularly the GM, demonstrated high coherence with CoP sway, reflecting their importance in counteracting gravitational forces and stabilizing posture. Notable asymmetries were observed, with left-side muscles showing heightened activation, suggesting lateralized contributions to balance. The lack of differences in sway with the additional cognitive task may suggest that balance control is implicit. The coherence analysis further underscores the reliance on the ankle strategy for AP sway control, particularly under challenging conditions. Together, these results emphasize the critical contributions of specific muscles in stabilizing posture, particularly in complex tasks, offering insights for targeted interventions and training focused on enhancing balance in populations at risk of instability.

Design and benchmarking of a two degree of freedom tendon driver unit for cable-driven wearable technologies

Adrian Esser[1,*], Chiara Basla[1], Peter Wolf[1], Robert Riener[1,2]

***Abstract*—Exosuits have recently been developed as alternatives to rigid exoskeletons and are increasingly adopted for both upper and lower limb therapy and assistance in clinical and home environments. Many cable-driven exosuits have been developed but little has been published on their electromechanical designs and performance. Therefore, this paper presents a comprehensive design and performance analysis of a two degree of freedom tendon driver unit (TDU) for cable-driven wearable exosuits. Detailed methodologies are presented to benchmark the functionality of the TDU. A static torque output test compares the commanded and measured torques. A velocity control test evaluates the attenuation and phase shift across velocities. A noise test evaluates how loud the TDU is for the wearer under different speeds. A thermal stress test captures the cooling performance of the TDU to ensure safe operation at higher loads. Finally, a battery endurance test evaluates the runtime of the TDU under various loading conditions to inform the usable time. To demonstrate these tests, a modular TDU system for cable-driven applications is introduced, which allows components such as motors, pulleys, and sensors to be adapted based on the requirements of the intended application. By sharing detailed methodologies and performance results, this study aims to provide a TDU design that may be leveraged by others and resources for researchers and engineers to better document the capabilities of their TDU designs.**

I. Introduction

In the past decade, exosuits have emerged as a technology to support individuals with partial motor functions, enhancing their ability to participate in daily activities. Unlike traditional rigid exoskeletons, exosuits offer a lighter, more flexible, and affordable solution that prioritizes user comfort and accessibility for everyday use. These qualities make exosuits versatile tools with potential for broad adoption across multiple applications. Based on actuation methodologies, exosuits are classified into cable-driven, pneumatic, twisted strings, and shape-memory alloy systems [1]. Recent advances in electric motor control and the flexible routing of cables have expanded cable-driven exosuits, which are currently the most widely adopted form [1].

This work was supported as a part of NCCR Robotics, a National Centre of Competence in Research, funded by the Swiss National Science Foundation (grant number 51NF40_185543).

Exosuits have been developed for both lower and upper limb assistance. Lower limb devices often actuate single joints, like the ankle [2], [3] or hip [4]–[6], and can also integrate multi-joint actuation for comprehensive support, such as hip-ankle [7] or hip-knee systems [8]–[10]. For upper limbs, exosuits typically have one or two actuated joints with a range of configurations to support various arm movements effectively. Examples include elbow flexion [11], shoulder-elbow flexion [12], [13], wrist support [14], and shoulder elevation [15], [16]. Each of these examples has one or two degrees of freedom (DOF), referring to the number of actuators embedded in the exosuit. Each actuator can affect multiple joints and facilitate multidirectional movement based on tendon routing along the limb (Fig. 1).

All portable cable-driven exosuits include an actuation system, referred to as tendon driver unit (TDU). This commonly houses electronics, motors, batteries, and one or more cables routed to flexible joint attachments. Despite notable progress, documentation and transparent sharing of exosuit TDU design, performance metrics, and benchmarks remain limited. This lack of detail impedes researchers and engineers from replicating existing systems, refining devices, and building on shared knowledge within the field.

To address this gap, we outline benchmarking tests to evaluate performance. In addition to standard performance metrics, such as torque and velocity, we recommend further tests to assess noise, battery life, and thermal management, all critical considerations for portable exosuit applications suited for clinic or home use. Factors such as torque and velocity performance are important to evaluate because they fundamentally determine the range of anthropometrics that can be supported by the device (i.e., how heavy or tall the user is) and what types of movements may be performed (i.e. how fast one can lift the arm or walk). Factors such as noise, battery life, and thermal management are included as well as they are often overlooked, but also are necessary for device usability and acceptance. By sharing these methodologies, we aim to foster performance transparency and comparability within the exosuit field, facilitating improved design choices, accelerated advancements, and enriched technical documentation through accessible research and open-source repositories.[1]

Alongside the methodologies, we present a lightweight,

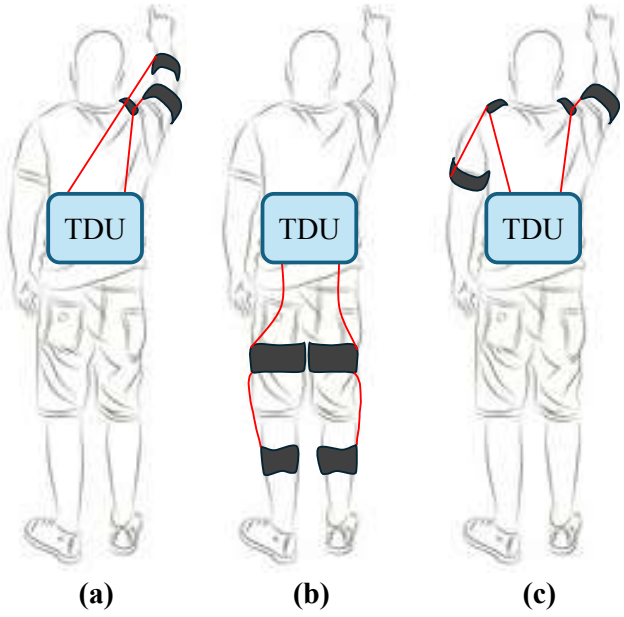

Fig. 1. Three conceptual designs demonstrating examples of how a two DOF TDU may support multiple joints: **(a)** shoulder and elbow on one arm, **(b)** hip and/or knee on the legs, or **(c)** shoulder elevation on both arms.

Fig. 2. An example of how the TDU can be mounted on the body in real life. In this application, the TDU is used, along with a textile interface, to support the right and left shoulder joints against gravity during shoulder elevation.

adaptable TDU design with two DOF. This TDU supports multiple configurations, making it suitable for both upper and lower limb exosuits. It can be customized to accommodate different applications and user needs through modular features that enable the swapping of components to adjust battery capacity, voltage, and output torque, along with a flexible programming interface to support diverse performance and sensor requirements.

II. Tendon Driver Unit Design

A. Description of Components

The main body of the TDU was 3D printed (Prusa MK4S) out of black polylactic acid (PLA) (Fig. 3 and Tab. I). Other custom designed printed parts include the protective covers for the fans, the 30mm cable pulleys, the cover for the battery management system (BMS), and the cover for the battery module. The cover for the TDU was laser cut (Trotec Speedy 400) with 3mm thick transparent acrylic. The 7S1P battery pack (24V. nominal) is custom assembled from LG MJ1 18650 battery cells (3500mAh) and a 24V. 7S BMS (Vruzend). Controlling the TDU is a Raspberry Pi 4B (8Gb RAM) with a RTL881cu USB WiFi network card (PiShop.ch), allowing the TDU to simultaneously connect to a Wifi network and broadcast an independent access point. Power is provided to the microcontroller with a 5V 3A step down buck converter module (PiShop.ch). The regulated 5V module also powers the four PWM HighPi brushless fans (1.4CFM per fan, PiShop.ch), which pull in air from the side of the case, and expel it near the top by the motors. The TDU houses two U8 Lite L KV95 direct drive motors (1.5Nm rated torque, 3Nm peak torque, from MAB Robotics) which are controlled with MD80 brushless motor controller drives (MAB Robotics). Communication to the motors is performed over a controller area network (CAN) protocol with a CANdle hat for the Raspberry Pi (MAB Robotics).

III. PERFORMANCE TESTING METHODOLOGIES

The protocols for all performance tests are detailed in the subsections below. The left and right motors are referred to as Motor 1 and Motor 2 respectively, when viewing Fig. 4.

The open-loop torque controllers and close-loopthe mea velocity controllers used in the following performance tests were not developed by the authors, but used directly from the manufacturers of the motor and controllers, available here: https://mabrobotics.github.io/MD80-x-CANdle-Documentation/intro.html

A. Open-Loop Static Torque Performance

This test evaluates the precision and accuracy of the motors when producing static torques. Actuator torque is not directly measured using the MD80 controller, but rather estimated by measuring the motor phase currents. This can be a suitable proxy for the torque of the drive when a low gear ratio is used (i.e. the motor is backdrivable) [17]. For this test, a pulley with a diameter of 3cm was printed and fixed on the rotor of the TDU motor. The TDU was fixed horizontally, and connected to a digital crane scale (ZW 5.0 force gauge from HKM Messtechnik, 500N nominal, 0.1N step) via a cable (1.5mm Dyneema, extremtextil). A series of increasing fixed torques were commanded (0.25Nm to 2.0Nm in 0.25Nm increments), the system was given 30s to settle, and the load on the scale was recorded. Five repetitions were performed for each condition to ascertain the repeatability of the system. The measured tensile load from the crane scale was converted to the actual output torque of the motor given the pulley diameter of 3cm, and this was compared to the commanded torque of the motor. The protocol was repeated twice, once for each motor in the TDU.

B. Closed-Loop Velocity Control

This test evaluates the attenuation and phase shift of the motor when tracking velocity reference signals with varying frequencies and amplitudes. This is an important test to understand if a particular actuator can meet the requirement speeds and frequencies of the intended application. Sinusoidal velocity reference signals were commanded to the drives while in velocity PID control. The signals had amplitudes ranging from 5rad/s up to 30rad/s in 5rad/s increments and 20 frequencies ranging from 0.1Hz to 10Hz in even log-space increments. For each commanded signal 10 full cycles of the motor response velocity were collected. Then the gain and phase shift of the actual motor velocity was computed relative to the reference velocity signal and averaged between both motors. The tests were done without the pulleys attached to the rotors.

C. Thermal Cooling

This test evaluates the thermal cooling effect of the fans in the TDU. Thermal management is essential for safe continued operation of motors under higher loads and for longer times. The TDU was fixed flat on a table, and both motors were connected to each other outside of the TDU with a re-direct

pulley. The left motor was controlled in torque to a constant 1.5Nm (rated torque from the manufacturer), while the right motor was controlled in position executing a sinusoidal profile with an amplitude of 2πrad and a period of 4s. The test was performed dynamically to ensure even heating of all motor windings. The motor stator temperature was recorded with a NTC100K thermistor integrated with MD80 controller. The TDU was turned on with all four fans running (100% duty cycle), and given 5min for the motor temperature to stabilize with the airflow. Then the system was held dynamically under tension until the first of the two motors hit 80°C, then the tension was released from the system and the motors were allowed to cool. Then the fans were disabled, and the test was repeated again without the cooling airflow.

D. Noise

This test evaluates the noise level of the TDU in various dynamic conditions. Noise level can impact usability and comfort if too loud by obstructing conversations, and in extreme cases lead to gradual hearing loss. Noise level testing was done in a sound isolated room using a NTI XL2 audio analyzer. The microphone was placed horizontally on a table, with the head of the microphone 50cm away from the top of the TDU, and centered between the two motors. The TDU was lying flat on the table with the acrylic cover facing up. Both the microphone and TDU were set on a thin piece of foam to prevent vibrations from passing through the table. All tests were triggered remotely from outside of the isolated room.

For all tests, the equivalent continuous sound pressure level was recorded over a 20 second window. First, the sound floor of the room was captured with the TDU off. Second, the noise level was captured with the TDU on with fans (100% duty cycle) but both motors disabled and stationary. Finally, the noise level was recorded for both motors, individually and together, over the set of speeds: 5, 10, 15, 20, 25 and 30 rad/s.

For all measurements the sound floor of the room with the TDU off (L_{room}) was subtracted from the noise level of the TDU in its respective operating condition (L_{meas}) using the following equation:

$$L_{meas} - L_{room} = 10 \cdot \log_{10}(10^{\frac{L_{meas}}{10}} - 10^{\frac{L_{room}}{10}}) \quad (1)$$

E. Battery Life

Evaluating the battery life under different loading conditions can give developers better guidance in specifying motors and battery cells in TDU design. The runtime of the TDU was tested for four different conditions: idle, 2kg, 4kg, and 6kg dynamic loading. The three loading conditions correspond to theoretical average motor torques of 0.29Nm, 0.59Nm, and 0.88Nm respectively, spanning the usable torque range of the motors. For the idle condition, the TDU was left on with the microcontroller and fans running, but the two motors disabled. For the dynamic loading conditions, the TDU raised and lowered the weights according to a sinusoidal position profile with an amplitude of 2πrad and a period of 6s. The TDU was fixed horizontally on a table, and the weights were lifted vertically, using a re-direct pulley mounted on the edge of the table to convert the horizontal pulling force to a vertical force. For all tests, the TDU was first fully charged (29.1V) and then we measured the time it took to discharge until the BMS hit the low voltage cutoff (17.5V) after which the TDU would shut off to protect the cells from over-discharge.

IV. Results and Discussion

All tests were done with the TDU in a horizontal orientation, but as Figure 1 and 2 suggest, when the TDU is in use it would likely have a vertical mounting on the body (so that the tendons exit either towards the legs or the shoulders). In general, loads were applied to the motors using redirect pulleys so that the loads could be moved against gravity, but the TDU could be mounted and secured on the table in a horizontal orientation (for practicality of performing the test in a controlled environment). It is likely that the re-direct pulleys introduced a small amount of friction to the test setup, so the true performance of the TDU might be slightly better than these test results suggest (across all tests that involved loading the TDU motors). Despite this, the additional friction that would be introduced to the cable transmission system, for example in Figure 2 where the tendons are routed from the back all the way over the shoulders, should be much greater than the friction introduced by a single re-direct pulley used for these tests. Thus it is anticipated that these results still present an upper bound on the performance of the TDU unit (for this configuration of batteries and motors), and the general methodologies still provide a meaningful method to bound the performance of the TDU and understand for what scenarios and applications it could be used for.

In order to present a complete TDU in this paper, certain design choices (like the choice of motor, battery cells) had to be fixed. For example, ungeared U8 Lite L KV95 direct drive motors controlled with MD80 brushless motor controller drives (MAB Robotics). For applications with higher torque requirements, one could instead spec the AK60-6 V1.1 CubeMars motor from MAB Robotics (3Nm rated / 9Nm peak torque). This would only involve re-sizing the case, modifying the mounting points, and potentially designing a pulley with a different radius if necessary. Designers can in principle use any motor / controller combination that communicates with a CANBUS, with the addition of a CAN transceiver between the Raspberry Pi and the motor controllers, so one would not be limited to motors and controllers from MAB Robotics as well.

A. Open-Loop Static Torque Performance

The static torques delivered by the drive are consistent and repeatable, albeit under-deliver consistently (Fig. 5). There was a high goodness of fit for both motors, with coefficients of determination of 0.99984 and 0.99975 for the left and right motors, respectively. These correspond to the following relationships:

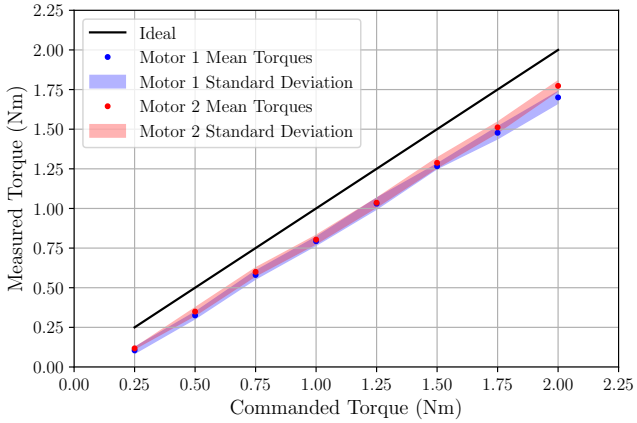

Fig. 5. Static torque test results demonstrating the relationship between commanded motor torque and measured output torque based on cable tension measurements.

$$\tau_{act} = \begin{cases} 0.915 \cdot \tau_{cmd} - 0.120, \text{left motor} \\ 0.938 \cdot \tau_{cmd} - 0.120, \text{right motor} \end{cases} \quad (2)$$

where τ_{act} is the measured motor torque (Nm) and τ_{cmd} is the commanded motor torque (Nm). This indicates that an inverse linear model may be used to correct the commanded torque depending on the desired output rotor torque, especially if a distal load sensor will not be used to measure cable tension. The offset may come from rotor stiction (since the measurements were made at stall) or from modelling errors on the MD80 controllers.

B. Closed-Loop Velocity Control

For a fixed signal frequency, higher peak rotor speeds had lower attenuation and phase shift (Fig. 6 and 7). This is likely a result of using a direct-drive motor and thus the cogging torque acts as a disturbance at lower speeds. For shoulder elevation, Georgarakis and colleagues estimated a minimum movement bandwidth requirement of 0.67Hzm and that elevating the arm to 68° at a peak speed of $171\frac{^\circ}{s}$ would take 0.4s [18]. Assuming that an implementation requires 20cm of cable travel (with a 30mm diameter pulley) to elevating the arm in this time, the required rotor speed would be $5.3\frac{rad}{s}$. At this frequency and speed, the motors perform with almost no signal attenuation, and a phase shift of between 5 and 10 degrees. For lower-limb applications, sources estimate that step frequencies can range between 0.3Hz (incidental stepping) and 2.0Hz (brisk walking) in both healthy and impaired adult populations [19], [20]. Within this range of frequencies, the phase shift does not exceed 15° across all peak rotor speeds, but for the higher range of walking speeds, amplitude attenuation starts to drop off for the lower range of peak rotor speeds. Ultimately, these results also need to be considered in the context of the final exosuit design, as it depends on the kinematics of the cable routing, supported joints, and the anticipated application.

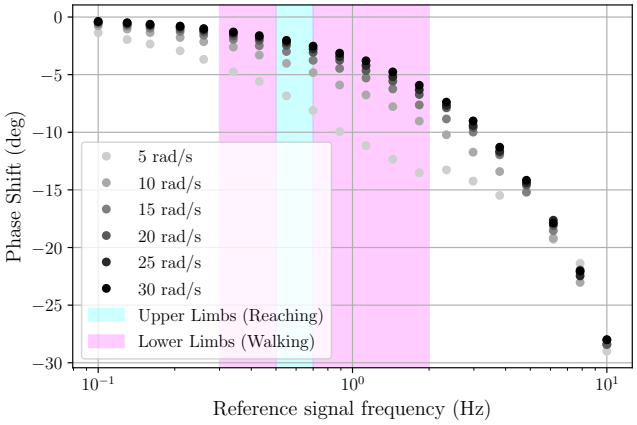

Fig. 7. Phase-shift Bode plot demonstrating the increasing lag with increasing driving frequency, across a range of velocity amplitudes.

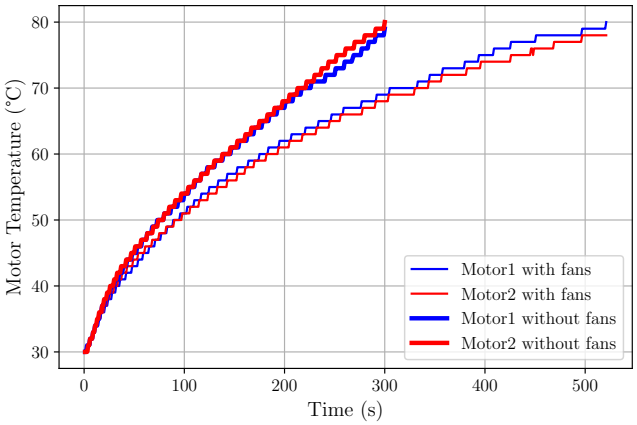

Fig. 8. Temperature rise curves for both TDU motors while under a constant dynamic load, with and without the cooling airflow from the side-mounted fans.

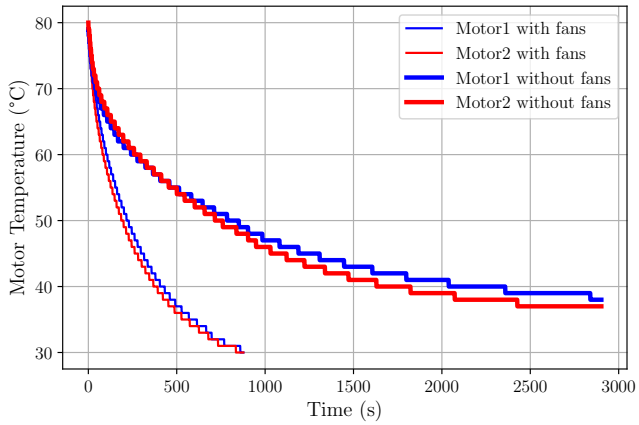

Fig. 9. Temperature fall curves for both TDU motors after heated under a constant dynamic load, with and without the cooling airflow from the side-mounted fans.

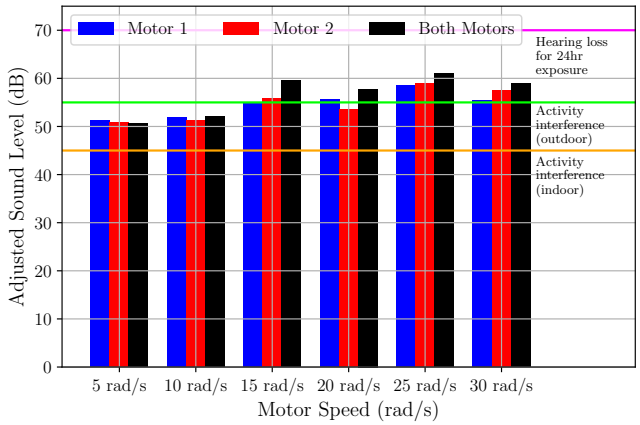

Fig. 10. Noise test results for the individual and combined motors across different operating speeds.

C. Thermal Cooling

The cooling effect of the fans is demonstrated in the temperature rise and fall times (Fig. 8 and 9). During the tests, the ambient air temperature was measured at 23°C. Without the fans enabled it took only 300s for the stator temperature to rise from 30°C to 80°C, while with the fans enabled it took 520s for the same change in temperature. The effect of convective cooling is also apparent during the cooling phase, as the fans could bring the stator temperature from 80°C back down to 30°C in 850s, whereas with only conductive cooling it took approximately 2000-3000s for the temperatures to fall back down below 40°C. These results in absolute terms depend on the ambient air temperature, how much heat is allowed to develop in the stator of the motor, and how fast the fans are controlled. For this particular test, the cutoff was set to 80°C, since PLA has a glass transition temperature of approximately 60°C (to avoid the case yielding or failing during the test).

Based on the thermal results from this test, it is clear that if the device will be used continuously at torques around 1.5Nm, a combination of active cooling (with fans) and perhaps controlled thermal throttling would be necessary for safe, long-term use (exceeding 10 minutes). This could be done by specifying stronger fans to improve airflow (and thus cooling), but this could come at the cost of increased noise during high-torque performance. Alternatively, one could implement a thermal throttling / rollback of the applied torque when the temperatures exceed a certain threshold (i.e. linearly reduce the output torque from 100% of commanded torque to 50% of commanded torque when the temperature is between 80 deg C and 120 deg C respectively). The specific implementation of such a the thermal control law would have to be researched and tested in further detail, but the general idea would be to trade-off performance for thermal management if the system overheats.

D. Noise

With the TDU on and only the fans running, the system had a noise level of 43.7dB. Across all active conditions tested, the TDU demonstrated sound levels ranging from 50.7dB up to 61.1dB. The US EPA identifies a constant 70dB over 24h as the upper level of environmental noise which will not cause any measurable hearing loss over ones life. Furthermore, levels of 55dB outdoors and 45dB indoors are identified as preventing activity interference and annoyance (ie these levels of noise permit spoken conversation and other activities such as sleeping, working and recreation) [21]. Thus the current design of this TDU should not over time cause any permanent hearing loss due to use, although during faster movements, the sound produced by the motors might hinder / obstruct conversations.

TABLE II
TDU RUN-TIME UNDER DIFFERENT LOADING CONDITIONS.

Condition	Mean Motor Torque (Nm) ± Standard Deviation (Nm)	Runtime (HH:MM:SS)
Idle	$8.16 \cdot 10^{-6} \pm 0.00128$	11:20:23
2kg	0.306 ± 0.0634	08:06:11
4kg	0.627 ± 0.0743	04:39:34
6kg	0.943 ± 0.0941	02:38:20

E. Battery Life

The battery life of the TDU depended greatly on the average external load imposed on it (Table II), ranging from over 11hr of idle / standby time, down to just over 2.5hr with a constant load of 0.943Nm on both motors. Ultimately, the battery life of the TDU in an exosuit application will also depend on other factors, such as the intended support levels, the user anthropometrics, the transmission efficiency, frequency of use, battery cell chemistry, or if the voltage range is padded. Future designs could also explore custom flat Lipo packs arranged in series and parallel to achieve the desired voltage and capacity.

V. Conclusion

This study presents a series of benchmarking tests that may be used to document the performance capabilities of cable-driven TDUs. The proposed tests capture static torque control, bandwidth of velocity control, thermal management, noise, and

battery life. As well, we present a lightweight and customizable TDU designed for cable-driven wearable applications, showcasing a modular design that allows flexibility in motor selection, pulley configuration, and sensor integration. The modularity of this TDU enables it to be easily adapted for various applications in upper and lower limb exosuits.

Our results reveal that the TDU provides accurate and repeatable torque control. Velocity control has a very high bandwidth, well covering the range of speeds required for upper and lower-limb movements. The cooling system proved effective, with fans extending operational duration under higher loads. Noise measurements indicate that, while the TDU is mostly unobtrusive, improvements could be made to reduce motor sound during high-speed operations. Furthermore, the battery tests confirm adequate runtime for practical, day-long use under moderate loading conditions.

The open sharing of our TDU's design and testing methodologies contributes to a collaborative approach within the exosuit research community. By making these resources publicly available we seek to promote advancements in assistive wearable technologies.

ACKNOWLEDGMENTS

The authors would like to thank Michael Herold-Nadig for his continuous support with debugging and integration of the electronics in the TDU. We thank fellow colleagues Alexander Breuss and David Rode for their support with the software and programming, and students Kai Stewart and Matthias Jammot for their contributions to the project. Finally, we acknowledge the constant emotional support of our lab dog Copper.

***Abstract*— Myocontrol based upon machine learning usually requires a large initial labeled dataset to build its model and prescribes that said model will never change in the course of time. This approach has several limitations, e.g., the difficulty of building such a proper dataset and the low generalization power of the obtained model against the variety of situations encountered by the user in daily life. In this work we introduce an interactive, incremental learning method for intention detection in real-time, along with some optimization techniques. The method enables users to quickly update the myocontrol system on demand, reducing the impact of the non-stationarity of input signals, improving the generalization power and providing an interactive experience to the user.**

Keywords—Prosthetic control, incremental learning, EMG intent detection

Research and commercial efforts in upper-limb prosthetics strive to create highly functional replacements for missing limbs. These advanced prostheses, often equipped with multiple motors and designed for various levels of amputation, exhibit advanced dexterity and prehensile abilities. They can replicate a significant portion of the mechanical performance of natural limbs, offering, in principle, high biomimicry [1]. What is still missing is an effective way to volitionally control complex, multi-motor prostheses in a *natural* fashion (accurately, simultaneously and proportionally), due to the lack of a suitable method of extracting enough independent motor commands from the residual user biosignals [2]. In practice, a user's intended movement triggers contractions in residual muscles, which can be recorded and interpreted by surface electromyography (sEMG) sensors. Early control strategies, such as dual-site direct control or methods based on finite state machine, rely on the sequential selection of motors or grips through brief co-contractions of antagonist muscles. Despite their utility, these methods lack intuitive and simultaneous control capabilities. To address this, pattern recognition (PR) techniques based on machine learning (ML) have been largely employed, mapping specific movements to distinct muscle activation patterns and enable multi-joint control [3]. However, as most systems use classifiers, they do not allow simultaneous control of multiple actions. To address this issue, regression-based approaches have been used, since these algorithms do not map discrete movements to muscular patterns, but rather estimate a proportional activation for each degree of freedom, providing the user with a continuous, physiologically acceptable manifold of actions [4]. Another limitation is that both classification and regression-based control systems typically use "monolithic" training approaches. They require a comprehensive, labeled dataset covering all desired actions to be gathered in the beginning, thus keeping the trained model fixed in the course of time. This approach severely limits the generalization power of the underlying ML model over time. Indeed, in real-life scenarios, multiple disturbances, deriving from the variability of sEMG signals over time, seriously affect the pre-trained model accuracy [5, 6]. In contrast to monolithic learning, an alternative, less explored class of algorithms, involves the usage of regressors in combination with incremental learning techniques [7]. Incremental learning allows ML models to be updated and downdated on demand, i.e., to quickly adapt the model to novel data distributions, avoiding the training from scratch. In myoelectric control, the effectiveness of incremental training to counter non-stationarity in the data distribution has been shown in [8, 9] [10, 11] and more recently on high-density sEMG configuration in [12]. These works show that both intact and limb-absent users benefit from on-demand updates, showing better acceptance, faster task completion times and higher trajectory quality on both lab-designed and daily living tasks. However, these approaches still do not explore the possibility of dynamically labeling new set of input data on-the-fly and adapt the model weights as needed; moreover, a serious analysis of the computational requirements of incremental learning approaches versus the traditional ones is missing. In Castellini 2016 [7], it is suggested the concept of *interactive learning*, in which the user can trigger the adaptation of the underlying ML model, notifying to the

This work was supported by the Istituto Nazionale Assicurazione Infortuni sul Lavoro, under grant agreement PR23-PAS-P1 DexterHand and by the German Federal Ministry of Education and Research (BMBF) under the Robotics Institute Germany (RIG). Figure 1 Interactive Incremental Learning Algorithm concept: whenever training is needed, the user, according to its movement intention, simultaneously executes the muscle activation pattern and communicates the selected action to the algorithm. After target remapping, the target vector t is sent to the incremental learning algorithm. At the same time, ARV of EMG signals are measured by the sensors. Features are extracted from signals, to obtain the input vector x'. The incremental learning algorithm updates the model weights w and updates the predictions y' accordingly. During normal operation, predictions are made using last model weights and prosthesis is controlled to execute the required action.

system the action to be mapped to the current muscular pattern. The author suggested also a set of requirements that the system should respect, being adaptive, quickly calibrated, bounded in memory and time, and, of course, incrementally trainable. This study aims to provide a starting point towards the design of an adaptive, real-time, interactive, incremental learning system usable in a real prosthetic scenario. To this end, we collected EMG data from able-bodied and trans-radial amputees during hand and wrist movements, implementing an offline simulation of an *interactive incremental learning algorithm* (I2LA) pipeline (Figure 1). Beginning with an empty model, we simulated user interactions for real-time labeling to identify best algorithm configurations. We compared different approaches to feature extraction and target remapping, proposing a methodology to explore sensitivity to hyperparameters tuning. We assess performance through standard regression metrics, demonstrating the algorithm ability to adapt model weights in real-time to new EMG data and accurately remap predictions to previously unseen patterns, with the final goal of controlling an advanced hand and wrist [13] trans-radial prostheses.

I. Materials and Methods

A. Participants

We recruited 20 healthy participants (ages 22–33, mean age 27.1 ± 3.2) and 10 individuals with unilateral trans-radial amputation of the dominant limb, all experienced in using active prostheses. Each participant provided written informed consent prior to the study, which followed the principles of the Declaration of Helsinki and received approval from the Bologna-Imola ethics committee (CP-PPRAS1/1-01).

B. Experimental Setup

Figure 2 illustrates the experimental setup. Six pre-amplified bipolar EMG sensors (13E200=50 AC Ottobock or equivalent IIT miniature circular sensors [11]) were positioned approximately 5 cm below the olecranon around the forearm or stump. These sensors, which are commonly used in prosthetic applications, recorded averaged, rectified, and amplified muscle activity (ARV) during hand open-close (HOC), wrist pronation-supination (WPS), and wrist flexion-extension (WFE) movements. The muscles monitored were identified through manual and visual inspection, (Figure 2B) targeting Extensor Carpi Radialis Longus (E0), Extensor Digitorum (E2), Extensor Carpi Ulnaris (E4), Palmaris Longus and Flexor Carpi Ulnaris (E1), Flexor Carpi Radialis (E3), and Brachioradialis (E5). Participants performed 10 repetitions for each of the 6 movements, with 2-second intervals of recorded muscle activity. Movement cues were displayed on a PC interface that presented an animated Hannes prosthetic hand [1], guiding each movement. The EMG signals were sampled at 1 kHz with a 12-bit resolution using a custom microcontroller board, also used to control the prosthetic arm. Additionally, we recorded 16 repetitions of a resting state (2 seconds each) interspersed with gesture repetitions to introduce rest periods after each contraction. The data was wirelessly transferred to a PC via Bluetooth and labeled according to the task performed.

C. Interactive Incremental Learning Algorithm for Prosthetic Control

This study investigates a scenario where the user can update the control model in real-time, sending feedback to the machine, via a human machine interface, labeling new actions as they are performed. Therefore, we are looking for an algorithm which can be incrementally trained and updated, i.e. which can quickly adapt its weights according to a new $(\boldsymbol{x}, \boldsymbol{t})$ pair, with $\boldsymbol{x}$ the input vector of dimensionality d and $\boldsymbol{t}$ the target vector of dimensionality m. To this end, we implemented an incremental version of the Ridge Regressor algorithm (RR), a regularized variant of least-squares regression. In the monolithic general form, for a single action $(m = 1)$, with a training set of N samples and input vector of dimension d, we define the matrix $X \in \mathbb{R}^{N\,x\,d}$ representing the training set, and the targets vector $\boldsymbol{t} \in \mathbb{R}^N$.
The RR model $\boldsymbol{w}$ is then defined by:

$$\boldsymbol{w} = (X^TX + \lambda I)^{-1}X^T\boldsymbol{t} \qquad (1)$$

A prediction $y' \in \mathbb{R}$ associated to a new sample of the input vector $x' \in \mathbb{R}^d$, is then given by the formula:

$$y' = w^T x' \qquad (2)$$

To transform the monolithic RR model in an incremental one, we exploit a very simple solution (rank-1 update method), in which the arrival of a new pair of input sample and target (label) is considered as a perturbation of the inverse matrix $(X^T X + \lambda I)^{-1}$. In fact, Equation (1) can be rewritten as

$$w = (X^T X + \lambda I)^{-1} X^T t := Ab \qquad (3)$$

Where $A = (X^T X + \lambda I)^{-1}$ and $b = X^T t$.
Given a new sample and target pair (x', t), the updated model $w' = A'b'$ is given by applying the Sherman-Morrison formula [14]

$$A' = A - \frac{(Ax' x'^T A^T)}{1 + x'^T A x'} \qquad (4)$$

$$b' = b + x' t \qquad (5)$$

The initial matrix is set to obtain the empty model at the beginning of time $w_{t0} = 0$, therefore $A_{t0} = \frac{1}{\lambda} I$ and $b_{t0} = 0$. Figure 1 illustrates the algorithm's operation: during use, the model predicts movement intention based on the latest model weights, w, through Equation (2). The model updates with new sample-target pairs (new data stream) as needed, recalculating w' via Equation (4) and (5). For multiple actions, *m* independent instances of the RR model are trained for each action. The algorithm was implemented and analyzed using Matlab R2024b (Natick, MA, USA) on a desktop with an Intel i5-9400 CPU.

D. Model training and validation

Starting from the dataset of each subject, we define an empty model and simulate the effect of communicating to the algorithm the selected action during muscle activation, sample by sample. For each action, participants performed 10 repetitions, with 5 used for training and 5 for validation. The training and validation repetitions were randomized. During the training phase, the model adjusts its coefficients in real-time with new EMG data samples. In the validation phase, the model uses the latest weights to make predictions, which are then compared to target values to assess accuracy.

E. Interactive Incremental Learning Algorithm Pipeline

We tailored our pipeline to meet specific needs for computational efficiency and real-time processing, relying on only the (x', t) pairs available at each time instant. Then, we analyzed the impact of combining different feature extraction methods with various *target remapping* strategies, i.e., different ways of delivering information about the selected actions to the algorithm. For what concerns feature extraction, after normalizing EMG signals to the range [0.0, 1.0], we compared various methods (linear, quadratic, cubic, and Random Fourier Features (RFF) [15]). RFF projects input data into a higher dimensionality feature space, enabling the usage of linear methods, such as the incremental learning algorithm, to solve non-linear problems. We chose polynomial methods and RFF because they are fast to compute with limited resources. We also tested the sensitivity of feature dimensionality parameter D on RFF up to 300. TABLE II lists the methods investigated and the complexity obtained with 6 EMG sensors as input. As for target remapping, we explored also different target value assignment strategies. In *single action* variant, only the regressor for the selected action was trained, with target value of 1.0. In *all actions* variant, we train all regressors simultaneously, by assigning 1.0 to the selected action and 0.0 to the other actions. In *antagonist compensation* variant we set the target value to 1.0 for the selected action and -1.0 for the antagonist action, 0.0 to the others.

F. Best algorithm variant search and hyperparameters tuning

To optimize RFF feature extraction, we tuned two hyperparameters: γ (controlling the locality of Radial Basis Function kernel approximation, with high values leading to more localized features) and D (feature dimensionality). Using 5-fold cross-validation over the training set (5 of the 10 repetitions), we optimized γ over a coarse search range $\gamma \in [2^{-8}, 2^{-7}, \dots, 2^{7}]$ and refining the search over $\gamma \in [2^{0}, 2^{0.3}, \dots, 2^{4}]$. We determine the optimal γ values separately for able-bodied (AB) and limb different (LD)

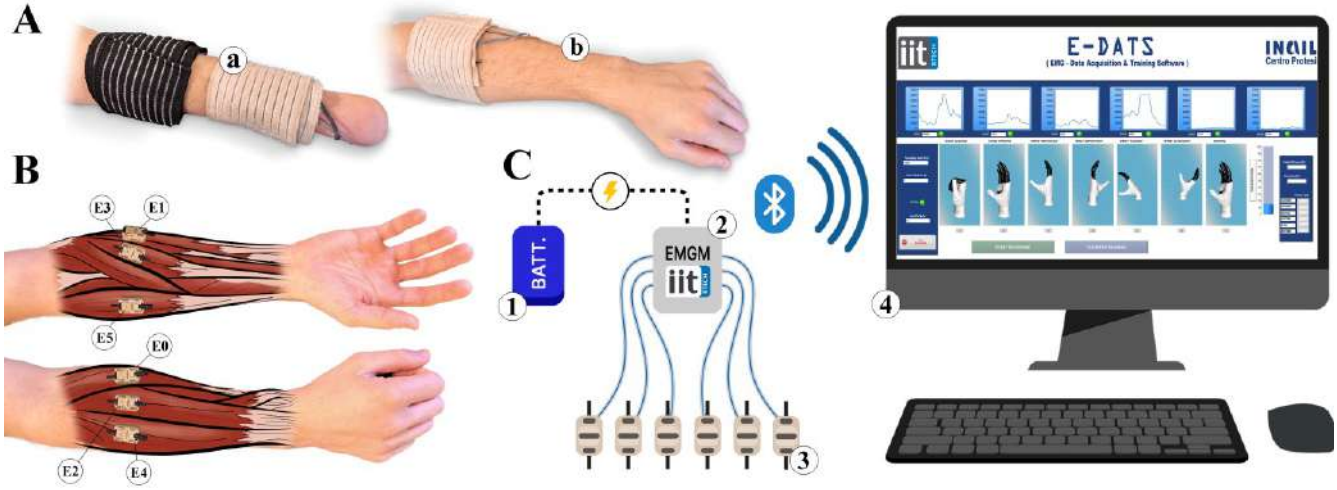

Figure 2 Experimental Setup: (A) LD (a) and AB (b) subjects wore 6 ARV EMG sensors targeting 6 main muscles (B). (C) Signals are sampled via a custom microcontroller board (2) and streamed to the PC via Bluetooth. A custom GUI (4) was used to record signals and synchronize the 6 actions plus rest.

subjects to account for the variability of the EMG signals between the two groups. The performance of each feature extraction and target remapping method was then assessed under these optimal γ values. The prediction accuracy is affected by dimensionality of the input data. However, the complexity, computing time and memory footprint needed to run the algorithm in real-time increases quadratically with *D*, and a careful tradeoff is needed to avoid wasting precious computational resources. To this end, we report the performances with different values of *D* up to 300 (21, 27, 83, 100, 300), using the best γ_{AB} , γ_{LD} value for the two populations, respectively. D values up to 83 are selected to ensure a fair comparison between RFF and the polynomial variants, maintaining the same output features dimensionality (see TABLE II).

G. Regularization parameter optimization (λ)

For final optimization, we adjusted the Ridge Regression regularization parameter λ through 5-fold cross-validation on the training set, using the best pipeline configuration.

H. Accuracy Evaluation Metrics

We evaluated model accuracy with adjusted R^2 and Bayesian Information Criterion (BIC), which are typically used to assess regressor performance.

II. Results

A. RFF hyperparameters tuning

TABLE I illustrates the results of the RFF hyperparameter optimization, including the optimal γ values, average adjusted R^2, and standard deviation across different feature dimensionalities (D) for both able-bodied and limb-different groups. Figure 3 shows an example of the grid search output for D=83: we observe that performance varies substantially with γ and reaches a global maximum within the fine-tuning interval. Accuracy was generally higher and with lower variability for able-bodied participants compared to limb-different participants. In TABLE I is reported the relationship between prediction accuracy and D, showing that increasing D enhances accuracy, as expected. However, beyond D=83, further increases in D yield no statistically significant

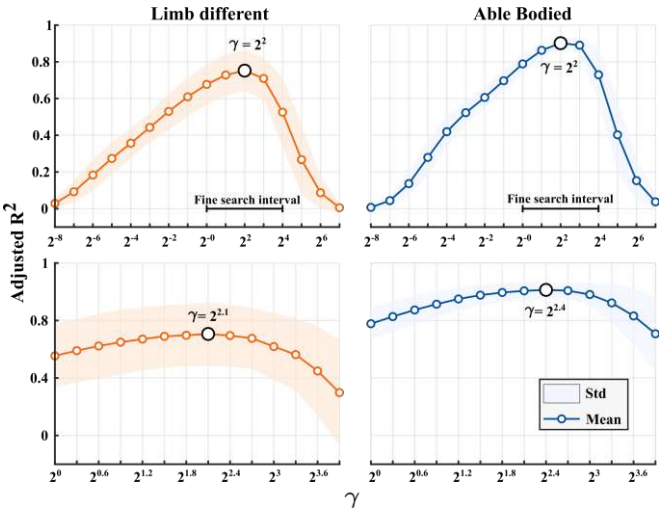

Figure 3 Random Fourier Features hyperparameters optimization. Accuracy for LD and AB subjects vs. γ parameter for D=83. Solid lines are the mean value among subjects; shaded area is the standard deviation.

TABLE I Optimal gamma values and accuracy of random fourier features variants

RFF D	γ_{LD}	γ_{AB}	R^2adj_{LD}	R^2adj_{AB}
21	$2^{1.2}$	$2^{1.5}$	0.6571 (±0.1140)	0.8090 (±0.0343)
27	$2^{1.2}$	$2^{1.8}$	0.6883 (±0.1109)	0.8245 (±0.0397)
83	$2^{2.1}$	$2^{2.4}$	0.7532 (±0.1108)	0.9065 (±0.0297)
100	$2^{2.1}$	$2^{2.4}$	0.7542 (±0.1122)	0.9130 (±0.0242)
300	$2^{2.4}$	$2^{2.7}$	0.7755 (±0.1121)	0.9343 (±0.0202)

improvement (p-value > 0.05), suggesting that additional complexity could result in unnecessary computational costs without accuracy gains.

B. Best feature extraction and target remapping combination

Figure 4 shows the combined analysis of feature extraction and target remapping strategies, with results separated for able-bodied and limb-different participants. Box plots display the adjusted R^2 and BIC metrics. The single action target remapping strategy yielded low accuracy across all feature extraction methods. In many cases, the adjusted R^2 mean was negative, indicating the model performed worse than a simple average of the outcome variable. In contrast, methods that assigned target values to all actions simultaneously significantly improved performance, supporting the hypothesis that muscle activation patterns for different actions interfere with one another. Thus, each incremental RR model must be trained in parallel across all actions with each (x', t) input sample to obtain useful results. We observed no significant difference in performance between assigning zeros to non-selected actions (all actions) and assigning a negative value to antagonistic actions (antagonist compensation). Adjusted R^2 and BIC metrics revealed similar qualitative trends across methods, underscoring their consistency in highlighting the most effective approaches. To compare polynomial methods with Random Fourier Features, we matched D values between RFF and polynomial feature extraction techniques. Figure 4 demonstrates that RFF consistently outperformed polynomial methods, showing statistically significant differences in accuracy (1-way ANOVA, p-value<0.001 in AB). Based on these findings, we identified the best model configuration that minimizes computational complexity and memory use while maintaining high predictive accuracy. This configuration uses the RFF feature extraction method with *D*=83, $\gamma_{LD}=2^{2.1}$, $\gamma_{AB}=2^{2.4}$, and *all actions* target remapping method.

C. Regularization parameter cross-validation (λ)

Regarding the cross validation of λ parameter, we found similar performances for a broad range of values, spanning from 2^{-12} to 2^{-3}. It is convenient to choose the higher λ value maintaining acceptable performances to prevent overfitting.

D. Model real-time update

Figure 5 illustrates the algorithm's operation using the best model configuration with RFF feature extraction (D=83, all-actions target remapping) on a training dataset from a limb different participant. Figure 5B shows the evolution of model weights for each action, where each color represents a distinct weight. At the starting point (t = 0s), all model weights are set to zero, so no action is predicted, regardless of the EMG

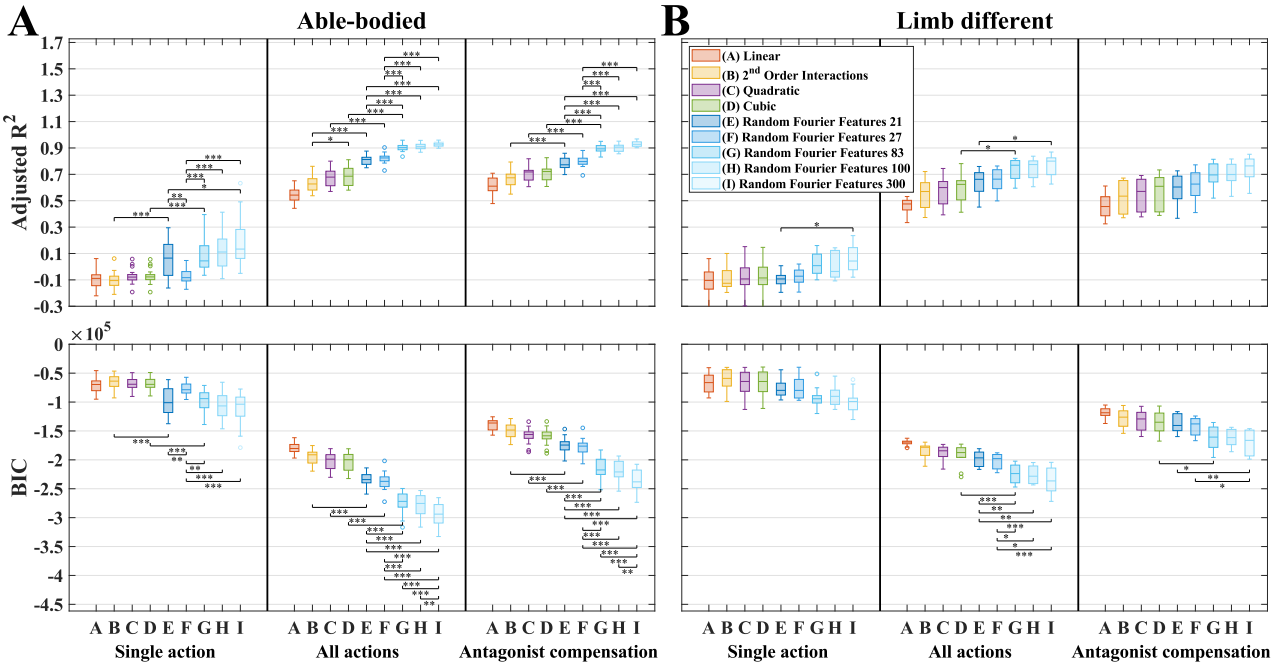

Figure 4 Algorithm performance vs feature extraction and target remapping methods: whisker plots of adjusted R^2 and BIC are represented separately for AB (A) and LD (B) population. (* p-value<0.05, ** p-value<0.01, *** p-value<0.001)

inputs. From t = 0s to t = 10s, the hand close action is incrementally trained based on EMG inputs, causing the weights to adjust almost immediately and stabilize into a reliable prediction. Between t = 10s and t = 20s, training for the hand open action begins with a target value of 1.0. The model modifies weights to establish a stable hand open prediction, while simultaneously realigning weights for the previously learned hand close action (now with a target of zero) to distinguish between the two learned actions. In each subsequent 10-second interval, the remaining actions are trained similarly. This progressive adjustment of model weights demonstrates how the model adapts in real time to new targets and muscular patterns.

III. Discussions

Results demonstrate the effectiveness of using RFF for feature extraction, showing significant performance improvements over polynomial feature extraction methods, both in able-bodied and limb-different participants. The superior performance of RFF over polynomial features suggests its capacity to approximate non-linear relationships in myoelectric data providing a robust basis for enhancing control accuracy. The influence of the gamma (γ) parameter on RFF performance was significant, highlighting the importance of tuning this parameter to maximize model accuracy. Our findings indicate that once the best γ is identified for a given D (dimensionality), this parameter generalizes well across users with similar characteristics, such

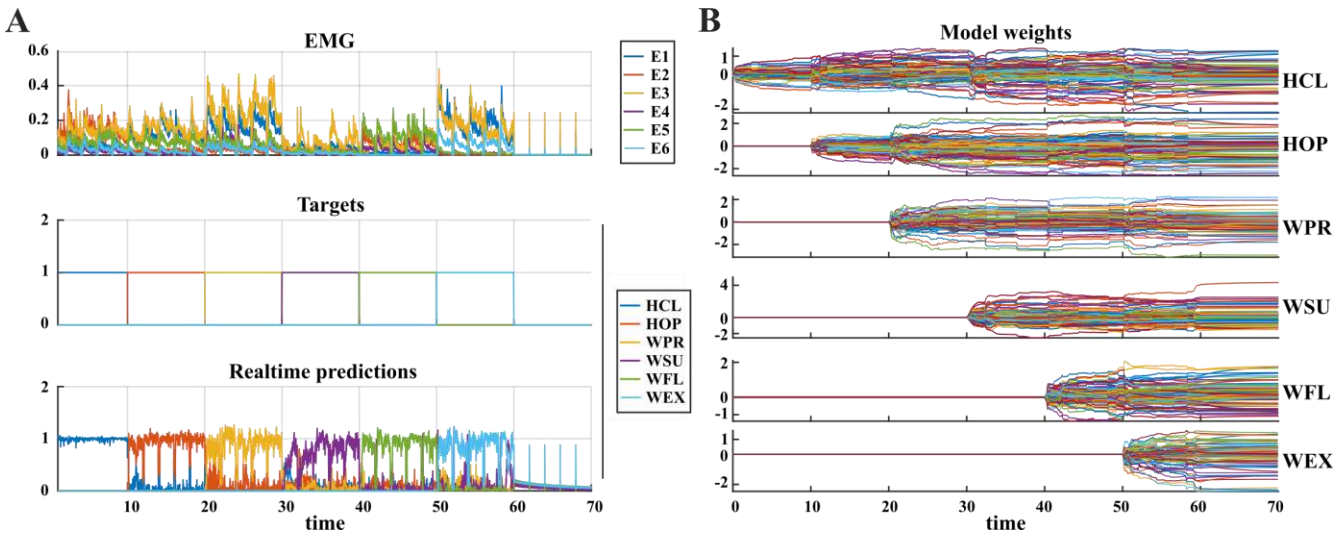

Figure 5 Incremental Learning Algorithm real-time prediction: (A) EMG signals, targets and actions prediction in real-time; (B) model weights evolution for each action. The model dynamically evolves its weights according to the prescribed action and updates the prediction simultaneously.

TABLE II FEATURE EXTRACTION METHODS AND COMPLEXITY

Feature type	d(n)	d(6)
Linear	n+1	7
Interaction 2*nd* order	C(n+2,2) - n	22
Quadratic	C(n+2,2)	28
Cubic	C(n+3,3)	84
RFF (D=21)	D+1	22
RFF (D=27)	D+1	28
RFF (D=83)	D+1	84
RFF (D=100)	D+1	101
RFF (D=300)	D+1	301

as able-bodied or limb-different groups, and for similar task demands. This generalizability reduces the need for repeated, individualized parameter tuning while still supporting a high level of accuracy and user-specific adaptation. While increasing the D value generally improved performance, this effect stabilized after specific D value corresponding to 83 yielding diminishing returns on accuracy. Higher D values will result in increased computational complexity, longer processing times, and higher memory requirements, which could limit real-time application feasibility in prostheses. Therefore, a balance must be established, selecting the best D value that achieves robust performance. Our study indicates that D = 83 is an efficient tradeoff, making it well-suited for embedded processing in low-power environments. A comparative analysis of results from able-bodied and limb-different subjects revealed similar accuracy trends, although able-bodied participants consistently achieved higher prediction accuracies and less variability. This discrepancy reflects the differences in muscle physiology and signal quality between able-bodied and limb-different users, particularly in terms of muscle mass and EMG signal consistency. However, the similar trends observed in both groups suggest that the incremental learning algorithm and selected feature extraction techniques can be applied effectively across a range of users with appropriate parameter adjustments. The target remapping strategy was also a critical factor in model performance. Our results indicate that training all regressors simultaneously and assigning positive target values for the selected action, combined with null targets for other actions, produced more accurate predictions than exclusive remapping for each action separately. The main limitation to the generalization of the results is the usage of gestures obtained from a single stationary position of the limb, without the prosthesis weight: this will be addressed in future works applied to the prosthetic scenario.

IV. CONCLUSIONS

In conclusion, this work presents an innovative approach to incrementally training intention-detection models for prosthetic control, which could empower users to personalize the internal intention detection model with minimal or no assistance. By embedding this incremental learning algorithm in a prosthetic device and designing an intuitive interface for selecting actions, users could independently train their prostheses to recognize and respond accurately to their specific EMG signal patterns. This would mean each model could be tailored to the individual's unique muscle responses and configurations, while being easily and quickly retrained by the user. This on-the-fly adjustment would enable near-instantaneous updates to the model, potentially requiring minimal computational power and memory. By offering real-time adaptability, this approach addresses one of the biggest challenges in myoelectric control: maintaining stable, responsive prosthetic performance adapting to the variable nature of the EMG control interface. Moreover, the usage of regression can enable simultaneous and proportional control, when associated with an appropriate prosthesis control strategy. In essence, this approach could significantly enhance the usability and effectiveness of myoelectric prostheses, providing a path for users to take control of their own customization and fine-tuning. With the ability to refine and update their prosthesis's functionality in response input variations, users could experience a higher level of control and precision in everyday prosthetic use, without the need for lengthy recalibration sessions or reliance on external support. Future work will implement these algorithms in real-time on a realistic prosthetic device, exploring the capability of an interactive retrain system to align muscular patterns to user intention incrementally and almost instantaneously.

Machine Learning-Based Estimation of Upper Extremity Function in Stroke Rehabilitation Using Body-Worn Inertial Sensors

Shusuke Okita[1,2], Jared Berry[3], Rushmin Khazanchi[4], Francesco Lanotte[1,2], Megan K. O'Brien[1,2], and Arun Jayaraman[1,2,5,*]

***Abstract*— Neurological injuries such as stroke are a leading cause of disability, significantly impairing upper extremity (UE) function. Standardized clinical assessments are essential to evaluate patient function, monitor progress, and tailor interventions; however, these assessments are time-consuming to administer and require specialized training, limiting their accessibility. We developed a machine learning model to estimate Action Research Arm Test (ARAT) scores with wearable inertial sensors, aiming to reduce patients' and clinicians' workloads in rehabilitation. Twenty-three patients with chronic stroke performed the ARAT with ActiGraph sensors on their wrists and waist. Models used these data to predict the total ARAT score from a minimal set of UE tasks, selecting one item from each ARAT sub-test (grasp, grip, pinch, and gross movement). A nested cross-validation was used to optimize item selection, feature selection, and hyperparameters. The optimized model achieved a median absolute error of 3.81 points, and a coefficient of determination of 0.93 to estimate the total ARAT score. SHapley Additive exPlanations (SHAP) values identified key contributors to the predictions in each ARAT sub-test. The proposed approach demonstrates the potential of combining wearable sensor data with machine learning to facilitate more frequent and efficient monitoring of rehabilitation progress throughout the care continuum.**

I. Introduction

Neurological conditions, such as stroke, are a major cause of disability worldwide [1]. The high prevalence of motor impairments following stroke highlights the critical need for effective rehabilitation strategies [2], and emphasizes the importance of accurate and efficient assessment tools to guide treatment and monitor patient progress throughout the rehabilitation [3]. Clinical assessment of motor function traditionally relies on standardized, manually administered tests by clinicians [2], [4]. These assessments evaluate motor function through a series of motor movements, with clinicians scoring each component individually [5]. While frequent and continuous assessments are indispensable for monitoring recovery and tailoring rehabilitation programs [6], their time-intensive nature contributes to clinician burnout [7] and reduces the time available in the clinic for therapy or other care. Furthermore, these assessments require specialized training, making them less accessible in research or non-clinical settings.

Recent advances in wearable technology and machine learning algorithms have opened new avenues for automating measuring clinical assessments [8]. The Automate-Illuminate-Predict (AIP) framework, proposed by O'Brien et al., offers a comprehensive approach for extracting meaningful healthcare analytics from wearable sensors [9], encompassing three key processes: (1) automate traditional clinical measures, (2) illuminate novel correlates of disease and impairment, and (3) predict future outcomes (e.g., at discharge). To enhance the accessibility of functional assessments while saving time, the AIP framework recommends monitoring patients through brief, simple movements using a minimal set of sensors.

When considering this framework in the analytics for upper extremity (UE), several studies have demonstrated the feasibility of automating clinical outcomes using wearable inertial sensors [10], [11]. However, these studies exhibit limitations when it comes to directly applying the AIP framework. First, existing research often leverages sensor data collected across all items of a standardized clinical assessment to evaluate functional status [11]. This is unlikely to reduce clinicians' workload, as it still necessitates conducting the full assessment, with the addition of placing sensors. Second, the most informative sensor data for accurate functional outcome estimation remains unclear. Utilizing multiple sensor units affects model complexity and time to set-up, hindering the perceived usability by both clinicians and patients. Determining the optimal activities and sensor placement is key, both for minimizing data requirements without compromising accuracy [12], and for guiding additional illuminative or predictive measures to enhance clinical insights.

Our study addresses these limitations by training and validating machine learning algorithms to estimate scores for the most common UE clinical assessment in stroke, the Action Research Arm Test (ARAT) [5]. Following the "automate" component of the AIP framework, we used body-worn inertial sensors to collect input data for training a machine learning algorithm, and then identified the optimal item to automatically estimate scores from each ARAT sub-test (i.e., grasp, grip, pinch, and gross movement). Specifically, we aimed to: (1) utilize single items to estimate scores from each sub-test, (2) identify the most informative ARAT items for automated assessment, and (3) conduct feature importance

analysis to determine the most meaningful sensor-derived features for model construction.

II. Methods

A. Participants

We recruited 23 individuals with chronic stroke at the Shirley Ryan AbilityLab in Chicago, Illinois (Table I). Inclusion criteria required participants to safely walk for 10 meters with or without assistance. Exclusion criteria included pregnancy, nursing, or skin allergies that would prevent safe sensor use. The study was approved by the Institutional Review Board of Northwestern University (STU00216350), and all participants provided written informed consent.

TABLE I
Participant Demographics

	n=23
Age (years)	60.9 ± 9.9
Sex (Male/Female)	11/12
Height (cm)	169.0 ± 10.3
Weight (kg)	87.0 ± 23.1
Years since Stroke	9.7 ± 6.4
Stroke Type (Ischemic/Hemorrhagic)	12/11
Paretic Side (Left/Right)	13/10

B. Experimental Protocol

Participants completed the ARAT test with their impaired arm only during a single study visit. The test comprises 19 items across four sub-tests: grasp, grip, pinch, and gross arm movement (Table II). A clinician administered and scored each item (0–3) using standardized procedures [13]. They used their impaired hand while wearing ActiGraph GT9X Link IMUs (ActiGraph LLC, Pensacola, Florida), recording data at 100 Hz. The IMUs were attached with straps on both wrists and around the waist. If participants were unable to perform a specific item due to motor impairment, that item was skipped and no sensor data were recorded. Table II shows the completion rates (CRs) for each ARAT item, with rates ranging from 52.2% to 100%. The gross movement sub-test had the highest CRs (95.7-100%), while the pinch sub-test showed the lowest (52.2-69.6%).

C. Data processing

Raw data from IMUs were downloaded, and manually segmented according to ARAT item timestamps. To avoid explicit directionality, we computed the Euclidean norm of triaxial accelerometer and gyroscope signals [14]. Magnetometer data were excluded since these readings can be affected by ambient ferrous materials. Features were extracted from both time and frequency domains, supplemented by clinical information (Table III), following IMU analysis protocols in existing studies [11], [15].

TABLE II
ARAT Items and Completion Rate (CR)

Sub-Test (pts)	**Test #**	**Item Description**	**CR[a] (%)**
Grasp (18 pts)	1	Block, 10 cm^3	91.3
	2	Block, 2.5 cm^3	95.7
	3	Block, 5 cm^3	73.9
	4	Block, 7.5 cm^3	69.6
	5	Cricket ball	65.2
	6	Sharpening stone	69.6
Grip (12 pts)	7	Pour water from one glass to another	82.6

[a]Based on 23 participants per item; [b]Gross Movement.

D. Model Development (Figure 1)

Our modeling approach focused on developing separate models specific to each ARAT sub-test (i.e., grasp, grip, pinch, and gross movement), while optimizing various sensor configurations, including impaired wrist only, both wrists, and impaired wrist with waist sensor. For each configuration, we analyzed 19 items and identified the item yielding minimum error against ground truth scores per sub-test. Then, we combined the predictions from these optimized sub-test models to estimate total ARAT scores.

To validate the model, we implemented a Leave-One-Subject-Out-Cross-Validation (LOSOCV) pipeline. To handle missing data from uncompleted items (Table II), we used multivariate iterative imputation through the scikit-learn IterativeImputer (version 1.2.0) with Python 3.11 [16]. This approach estimates missing values by modeling each feature with missing values as a function of other features in a round-robin fashion. After imputation, features were processed using robust scaling. These processing steps were conducted exclusively on the training data in each loop. Then, feature selection was conducted in two stages: first, using unsuper-

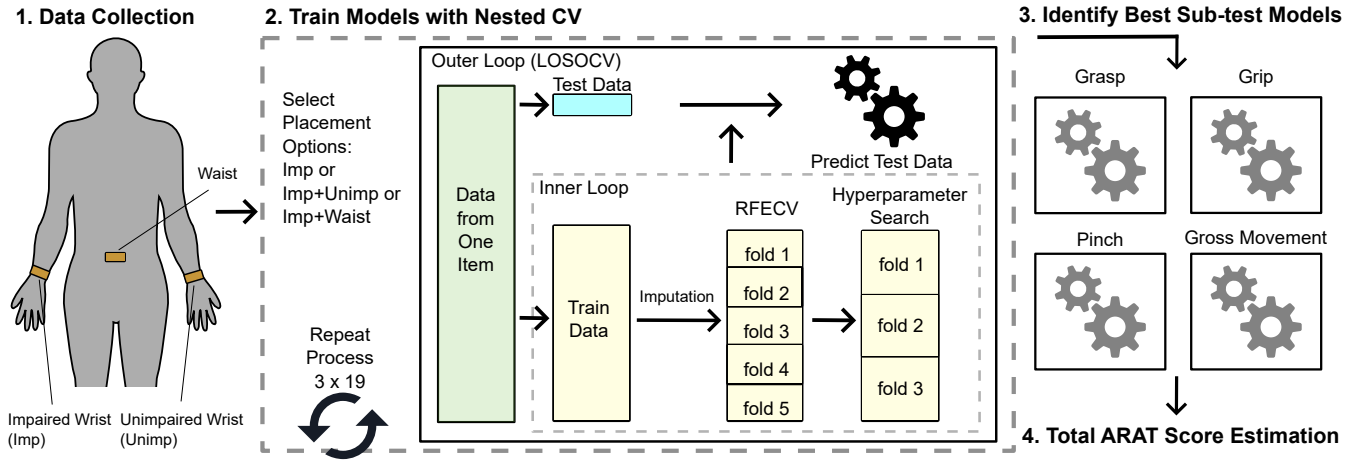

Fig. 1. Data processing pipeline for ARAT score estimation. The pipeline consists of four main steps: (1) Data collection from IMU sensors placed on impaired wrist, unimpaired wrist, and waist; (2) Model training using nested cross-validation, incorporating recursive feature elimination (RFECV) and hyperparameter optimization with Optuna; (3) Model selection identifying optimal performing items for each sub-test; and (4) Total ARAT score estimation by combining sub-test predictions.

vised methods including correlation matrices and variance thresholds, and second, through supervised recursive feature elimination with nested 5-fold cross-validation (RFECV).

Model optimization was achieved through 3-fold cross-validation hyperparameter tuning using Optuna [17]. We chose the Random Forest algorithm for its ability to capture non-linear relationships and robust performance with high-dimensional feature spaces [10], [18]. The hyperparameter search spaces are detailed in Table IV.

Based on the LOSOCV performance, we identified optimal configurations for hyperparameters, item selection, and feature elimination across the entire dataset. To investigate feature importance patterns comprehensively, we trained a final model using the complete dataset, allowing us to leverage all available data to understand feature contributions. For this final model, we conducted recursive feature elimination to identify the optimal feature subset yielding the minimum Mean Absolute Error (MAE) for each sub-test. We then analyzed feature importance on these optimized models using SHapley Additive exPlanation (SHAP) values [19]. All developments were conducted on a workstation running Ubuntu 24.04.1 LTS with an NVIDIA TITAN V GPU, and a CUDA version of 12.4.

E. Evaluation Metrics

Model performance was evaluated using MAE and Median Absolute Error (MedAE) to quantify the average magnitude of prediction errors, while the Coefficient of Determination (R^2) measured the proportion of variance explained by the model.

III. RESULTS

ARAT scores among participants varied widely (mean = 25.91, SD = 22.44), with grasp and pinch sub-tests showing the highest variability (SD = 7.95 and 7.39), and gross movement the least (SD = 2.78) (Table V). The nested CV yielded optimized random forest models across sub-tests (Table VI).

R^2	0.80	0.77	0.93	0.64	**0.93**

[a]Gross Movement.

A. Model Performance

Model performance varied across ARAT items and sensor configurations (Table VII). For the grasp sub-test, Item 5 using both impaired and unimpaired wrist sensors achieved the lowest MAE (2.43 points). In the grip sub-test, Item 9 with both wrist sensors performed best (MAE = 1.71 points). Pinch sub-test optimization occurred with Item 14 (MAE = 1.64 points), and gross movement performed best with Item 18 (MAE = 1.23 points). These items were selected as representative tasks for their sub-tests.

The aggregated model estimated the full ARAT score with an MAE of 4.55 points, MedAE of 3.81 points, and an R^2 of 0.93 (Table VIII). Sub-test performances varied, with the pinch sub-test showing the highest accuracy (MAE = 1.16, R^2 = 0.93), followed by gross movement (MAE = 1.25, R^2 = 0.64), grip (MAE = 1.48, R^2 = 0.77), and grasp (MAE = 2.4, R^2 = 0.80).

B. Feature Selection and Importance

Figure 2 shows stable performance across number of features; thus, we selected minimal sets achieving the lowest MAE: grasp – one feature (absolute range), grip – four features (spectral centroid, absolute range, principal frequency, kurtosis), pinch – one feature (spectral entropy), and gross movement – three features (mean angular velocity, IQR, ZCR). SHAP analysis (Figure 3) revealed key features: grasp – unimpaired wrist's absolute range of normalized angular velocity during Item 5; grip – features from both wrists during Item 9; pinch – impaired wrist's spectral entropy during Item 14; gross movement – unimpaired wrist's mean angular velocity, IQR, and ZCR during Item 18.

IV. DISCUSSION

We developed machine learning models to estimate ARAT scores for individuals with stroke using a minimal sensor configuration; with additional model training, we expect this approach can be used to estimate UE function in other clinical populations as well (e.g., Parkinson's disease). Accurate ARAT estimation is possible using one item per sub-test, and adding sensors (unimpaired wrist or waist) further improves performance (Table VII). The MAE of 3.8 points in full score estimation is comparable to existing studies [10], [11] and falls below the minimally clinically important difference (MCID) of the ARAT (6 points) [5], validating our approach for assessment while minimizing required test items; as long as the estimation error remains within the MCID, the

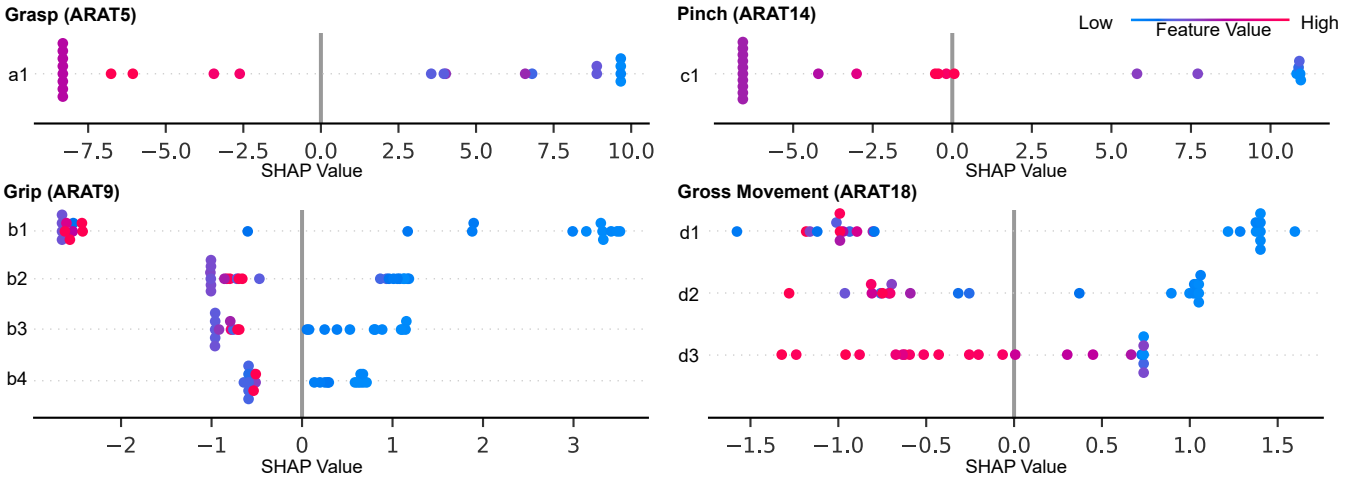

Fig. 3. SHAP analysis across ARAT sub-tests. Each point represents a SHAP value, with color gradient from blue (low) to pink (high) indicating feature values. (a1-d3) correspond to features specific to each item. a1: Absolute Range of Normalized Angular Velocity (Unimpaired Wrist); b1: Spectral Centroid of Normalized Acceleration (Impaired Wrist); b2: Absolute Range of Normalized Angular Velocity (Impaired Wrist); b3: Principal Frequency of Normalized Angular Velocity (Impaired Wrist); b4: Kurtosis of Normalized Angular Velocity (Unimpaired Wrist); c1: Spectral Entropy of Normalized Angular Velocity (Impaired Wrist); d1: Mean of Normalized Angular Velocity (Unimpaired Wrist); d2: IQR of Normalized Acceleration (Unimpaired Wrist); d3: ZCR of Normalized Angular Velocity (Unimpaired Wrist).

assessment is unlikely to affect clinical interpretation.

An unexpected finding was the enhanced model performance when including sensor data from the unimpaired wrist, particularly in the grasp sub-test (Table VII). While the ARAT in our study only scored the impaired arm's performance, this improvement suggests the model may consider compensatory movements during task execution in estimating the score. The SHAP analysis showed that decreased feature values generally corresponded to improvement of SHAP values. However, as this analysis was conducted on the final model after optimization, these patterns require validation on external datasets.

In the grasp model, the absolute range of angular velocities in the unimpaired wrist likely indicates compensatory movements, such as increased trunk rotation when patients struggle with grasping objects [20]. The grip model's reliance on spectral centroid, absolute range, and principal frequency from the impaired wrist sensor may reflect less controlled motions, movement stability, and compensatory behaviors. For the pinch model, spectral entropy likely measures movement complexity and smoothness on the unimpaired wrist [21], with higher values indicating motor control issues such as tremors that impair pinch tasks. The gross movement model's features (mean angular velocity, IQR, and ZCR of acceleration) appear to capture wrist movement variability [22].

While we focused on task-agnostic features that could be computed across any UE task being performed, incorporating task-specific features (e.g., forearm elevations, wrist orientations, finger movements [10], [23]–[25]) could enhance model performance and provide deeper insights into movement patterns. Additionally, exploring sensor placement on the shoulder, or chest could offer valuable information about compensatory movements, potentially improving ARAT score estimates. However, adding sensors introduces additional administration time and complexity. Future research should investigate optimal sensor placement while maintaining minimal setup requirements, similar to the study in LE function using three sensors [14].

The relatively small sample size (n=23) and uneven representation across ARAT score ranges, particularly in the grasp sub-test, may have affected model performance. A larger, more diverse sample could improve model robustness and generalization. Furthermore, our focus on chronic stroke patients, whose movement patterns may differ from acute cases, suggests the need to investigate this approach with acute stroke populations. While previous research has demonstrated predictive performance with acute stroke participants [11], verification with a larger acute stroke patient cohort is essential for implementation through the care continuum.

Acknowledgment

This data was collected as part of the Center for Smart Use of Technologies to Assess Real World Outcomes (C-STAR), which is funded by the National Institutes of Health (Grant #P2C HD101899) supported by NICHD and NINDS. We extend our gratitude to all the participants who contributed to the data collection process.

The Role of Muscle Property Changes in Identifying Motor Adaptation Stages for Myoelectric Control

Johanna Happold[1,2], Patricia Capsi-Morales[1,2] and Cristina Piazza[1,2]

***Abstract*— Despite technological advancements in assistive robotics, patients still face considerable challenges in their control, with proficiency varying widely among individuals. While training programs include task-related performance metrics to evaluate individuals' skill levels, these may overlook critical adaptations at the muscle. This study explores neuromuscular adaptations in forearm antagonist muscles during a 3-degree-of-freedom myoelectric control task. Participants completed a 45-minute training session and were categorized as rapid learners or plateau learners based on their performance evolution. We then evaluated changes in muscle properties within groups, including stability, antagonistic co-contraction, and neural synchronization. Rapid learners showed lower initial proficiency and improved task performance metrics, with reduced muscle variability and increased co-contraction, suggesting greater movement consistency. In contrast, plateau learners achieved a higher baseline performance with minimal improvements. These individuals reported decreased co-contraction levels and phase locking between antagonistic muscles, indicating task endurance and more fine motor control over time. These findings highlight differences in neuromuscular adaptations among individuals, possibly aiding clinicians in assessing therapy effectiveness.**

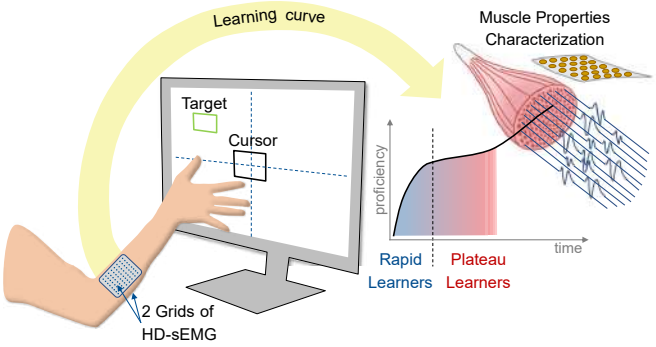

Fig. 1. Schematics of the experimental setup and study concept. Two HD-sEMG sensors were placed on the extensor and flexor muscles of the forearm. Participants were tasked to move a cursor to reach to different targets by simultaneous control of three DoFs involving wrist (extension, flexion, abduction, adduction) and hand (open, close) movements. After the experiment, participants were divided into *rapid* and *plateau learners* based on proficiency evolution, and underlying muscle properties were analyzed.

I. INTRODUCTION

Modern rehabilitation therapies offer a wide range of specialized and personalized care for patients with motor impairments or limb loss [1], [2]. These therapies leverage man-machine interfaces and biofeedback systems to stimulate neural pathways, supporting the recovery of motor function and adaptation to assistive devices like robotic aids or prosthetics. Among control options, muscle interfacing using surface electromyography (sEMG) is widely used for decoding motor intention into actionable control data [3]. However, direct control strategies often rely on simplistic methods, restricting users to a small set of predefined actions [4], [5]. A promising alternative is the application of machine learning techniques, such as classification and regression [6]–[9]. Among various applications, the field of prosthetics has been a primary driver for the development of more sophisticated motor intention decoders. Classification approaches map sEMG signals into discrete movement classes, enabling the execution of a larger variety of actions [4]. However, this results in a sequential control structure, reducing the fluidity of transitions between movements [10], [11]. Regression-based techniques offer more dynamic solutions, enabling proportional and simultaneous activation of multiple but fewer degrees-of-freedom (DoFs), mimicking the coordinated control of human motor behavior [10], [11].

Despite technical advancements in controllers, effective use of assistive devices requires comprehensive user training, particularly in the early stages of device adoption [12], [13]. Evidence shows considerable differences in the acquisition of new motor skills among individuals [14], [15]. This is also reflected in the variability in baseline myoelectric capacity and the rate of improvement observed during training [16], [17]. Standard methods to assess proficiency involve task-specific performance metrics [18], [19]. However, they may overlook critical aspects such as changes in muscle coordination, long-term task endurance, and neuromuscular adjustments required for effective myoelectric control.

In this study, we investigate neuromuscular control changes and their relationship with task performance during a 3-DoFs regression-based training program (Fig. 1). We evaluated 10 able-bodied participants, executing a goal-reaching task for 45 minutes. Based on performance evolution, we split them into two groups and analyzed differences in neuromuscular adaptation regarding contraction stability, antagonistic co-contraction, and neural synchronization, inspired by [20], [21]. With this, we aim to enhance understanding of training progression and skill acquisition at the muscular level, supporting more targeted training assessments.

II. Material and Methods

A. Study Procedure

The study involved 10 able-bodied participants (7 male, 3 female), with a mean age of 26.7 $\pm$ 3.4 years. All participants were right-handed and had little to no prior experience with myoelectric control. The study protocol was approved by the Ethics Committee of the Technical University of Munich (ref. number 2023-223-S-KH), and all participants gave consent.

The experiment started with an initial phase of data collection to train the control algorithm, followed by a real-time goal-reaching task involving 3-DoF control over wrist and hand gestures. Participants were comfortably seated with their elbows resting on a table. Myoelectric activity of the forearm's extensor and flexor muscles was recorded using high-density sEMG (HD-sEMG) electrodes (Fig. 1).

1) *Calibration Session*: the session started with a 5s recording of resting muscle activity, followed by a 5s recording to measure the maximum voluntary contraction (MVC) during wrist extension. Subsequently, participants performed six distinct gestures: wrist extension, flexion, abduction, adduction, and hand opening and closing. Each gesture followed a trapezoid-shaped target of 2s rest, a 5s ramp-up, a 5s plateau phase at 60% of MVC, a 5s ramp-down, and another 2s rest phase, with visual feedback on their median sEMG activity on a monitor. Each gesture was recorded three times. A regressor was trained for real-time control of the cursor.
2) *Familiarization Session*: participants had two minutes to familiarize themselves with the user interface and trained controller.
3) *Assessment Session*: participants were tasked with moving a cursor to match a series of targets. Each target remained visible for 15s, during which participants had to reach the target and maintain a stable posture until the end of the trial. A total of ten targets were used: six for 1-DoF movements (each gesture) and four requiring activation of 2 or 3 DoFs (Fig. 2 bottom left). The targets can be reached at 30% of the MVC, with a bar displaying real-time mean sEMG levels for consistent effort.
4) *Training Session*: participants were asked to match and hold the targets for 2s within a 20s window. A trial was considered successful if the cursor's deviation was within 10% of the target size in all three dimensions. The first two training sessions consisted of nine targets, while the third and fourth sessions included 18 targets each. The task space was divided into nine sections, corresponding to nine targets, to ensure complete coverage of the reaching space (Fig. 2 bottom right). The target locations were kept consistent across training sessions, though the order was randomized for each session and identical for all participants.

A total of five assessment and four training sessions were conducted alternately (Fig. 2 upper panel), with the entire experiment lasting approximately 90 minutes.

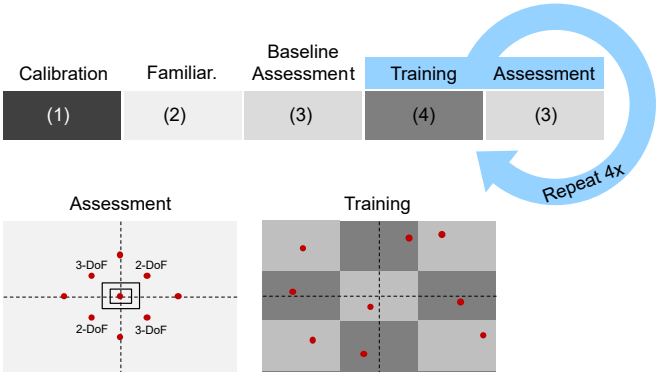

Fig. 2. Study procedure and schematic representation of task space. The study pipeline is illustrated in the top panel, with numbered steps corresponding to the sessions detailed in Section II-A. Participants began with a calibration session to collect data for calibrating the control algorithm, followed by multiple session of a 3-DoF goal-reaching task. The bottom panel shows target placement for both session types. Assessment sessions included ten targets: six 1-DoF, two 2-DoF, and two 3-DoF targets, with example target visualization shown for opening and closing of the hand. Training session targets were distributed across nine regions of the task space to ensure full coverage.

B. High-Density sEMG Recordings

Muscle signals were recorded using HD-sEMG electrodes to ensure full muscle coverage and achieve greater spatial resolution compared to traditional single-channel electrodes. This reduces the risk of electrode placement errors, effectively capturing activity across the targeted muscle regions. HD-sEMG signals were recorded using two 2D adhesive grids of 64 electrodes (HD10MM0808; OT Bioelettronica) placed on the extensor and flexor muscle group of the forearm. Monopolar sEMG signals were recorded via a multichannel amplifier system (2 Muovi+, OT Bioelettronica), amplified, and bandpass filtered at source prior to offline analysis. Reference electrodes were placed on the participants' wrists, and signals were sampled at 2000 Hz.

C. Motion Estimation and Control Algorithm

A multi-output regressor was designed to predict the activation levels of 3 DoFs simultaneously using a Support Vector Regression (SVR) model with radial basis function (RBF) and C = 5, ε = 0.01. These hyperparameters were optimized through a grid search strategy based on a separate dataset that included one repetition of all six gestures from an individual not involved in the main study.

We initially selected 22 features based on [22], comprising 17 time-domain features and five frequency-domain features. To reduce redundancy, we computed the correlation between the extracted features and eliminated those with a correlation coefficient exceeding 0.9. A permutation importance analysis on the remaining subset identified the four most important features. These features included Integral Absolute Value (IAV), Slope Sign Change (SSC), Willison Amplitude (WAMP), and Power Spectrum Deformation (OHM). This feature selection process was performed on the same dataset used for hyperparameter tuning.

D. Generation of Training Data

To ensure robust training samples for the regressor, initial preprocessing involved the removal of noisy channels. Channels were evaluated for outliers in RMS values and low-frequency drift, and discarded if identified as such. Only 1-DoF movements were recorded as training data to reduce time requirements in the study. However, concurrent activation of multiple DoFs is essential for effective simultaneous control. To simulate simultaneous activation, we employed data augmentation inspired by [23]. The generation of multi-DoF data was performed as described in Eq. 1 and Eq. 2.

$$X_{ij} \approx \alpha_1 * X_i + \alpha_2 * X_j \tag{1}$$

$$X_{ijk} \approx \alpha_1 * X_i + \alpha_2 * X_j + \alpha_3 * X_k \tag{2}$$

Here, $\{X_i, X_j, X_k\} \in \mathbb{R}^{nxd}$ represent the sEMG signals corresponding to 1-DoF activations, where $\{i, j, k\} \in \{wrist_extension, wrist_flexion, wrist_abduction, wrist_adduction, hand_open, hand_close\}$. The parameters d and n denote the number of sEMG electrodes and data samples, respectively. $\alpha_x \in \{0.3, 0.7\}$ with $x \in \{1, 2, 3\}$ denote the weighting factors of the signals. The resulting mixtures X_{ij} and X_{ijk} represent the generated multi-DoF signals. Note that only movements from different DoFs were combined for data augmentation. Combinations involving opposite movements within the same DoF (e.g., extension and flexion) were excluded, as such combinations are physiologically implausible. Recordings were synthetically labeled to indicate the performed gestures and estimated force (no kinematics or kinetics were captured). The resting state was labeled y = 0, while the plateau phase of the trapezoid-shape target (60% of MVC) was labeled y = 1 or y = -1, according to the DoF direction. For example, a synthetic combination of extension and abduction with weights $\alpha_1 = 0.3$ and $\alpha_2 = 0.7$ was labeled [0.3, 0.7, 0]. The labels were scaled according to the force level of the ramp-up and ramp-down phases of the trapezoid. The signals of the augmented dataset were segmented into non-overlapping windows of 250ms to maintain a processing delay under the 300ms threshold, considered undetectable by humans [8]. Each segment was bandpass filtered using a 3rd-order Butterworth filter with cutoff frequencies between 5 and 500 Hz, and powerline interference was removed using a notch filter. Following this, the four selected features were computed for each channel within each window.

E. Task Performance Analysis and Subject Grouping

To evaluate participants' performance, we computed three performance metrics, including success rate (SR), path efficiency (PE), and success time (ST). PE and ST were analyzed only for successfully matched targets. Participants were categorized as either *rapid* or *plateau learners* based on their performance evolution within the training period recorded. *Rapid learners* are characterized by a marked improvement in task-related performance metrics, typically observed during the initial phase of adaptation. In contrast, *plateau learners* demonstrate steadier performance levels, indicative of the plateau phase often linked with already higher proficiency. We defined a performance evolution measure (PEM) (Eq. 3) to quantify overall changes. To ensure comparability, each performance metric was normalized to $[0, 1]$ across all participants. PE and ST were averaged across all targets within a training session. The PEM score was computed by summing the changes across the different performance metrics, with ST included as a negative term since lower values indicate better performance.

$$PEM = mean(\Delta PE) - mean(\Delta ST) + \Delta SR \tag{3}$$

where $\Delta(metric) = metric_{tf} - metric_0$, with $metric \in \{PE, ST, SR\}$. Here, $metric_0$ and $metric_{tf}$ represent the values from the first and last training sessions, respectively.

F. Muscle Property Analysis

For the analysis of muscle properties, the raw sEMG data was first checked for noisy channels by assessing outliers in RMS values and low-frequency drift. The remaining channels were filtered using a 3rd-order Butterworth bandpass filter with cutoff frequencies at 5Hz and 500Hz. A notch filter was used to remove powerline interference. For the analysis, we used the last 10s of each target, assuming that stable postures were achieved after the first 5s. To evaluate changes in muscle properties during motor adaptation, we computed three different sEMG metrics:

- Standard deviation (STD) of the sEMG signals: reflects movement stability, with higher values indicating greater variability. STD was calculated for each sEMG channel and averaged across all channels.
- sEMG signal correlation: was assessed between sEMG signals within (PCC_flex, PCC_ext) and between (PCC_aa) antagonistic muscle groups using the Pearson correlation coefficient (PCC). Correlations were computed for all channel combinations, and the resulting values were averaged.
- Phase locking value (PLV): offers insights into muscle synchronization. PLVs were computed for the beta band (15-30 Hz), strongly linked to voluntary movement and corticospinal activity, coordinating rhythmic interactions between the motor cortex and muscles [21], [24]. PLVs were computed for all channel combinations between antagonistic muscles with values ranging from 0 (no synchrony) to 1 (perfect synchrony).

III. Results

A. Performance Evaluation

As introduced in section II-E, participants were divided into two equally sized groups based on their PEM scores. The five participants with the highest PEM score were classified as *rapid learners*, while the five participants with the lowest PEM score were categorized as *plateau learners*. Individual PEM scores and group assignments are presented in Table I. A two-sample t-test showed a significant group difference in

PEM ($p = 0.007$) and PE ($p = 0.047$). Moreover, one-way ANOVA for baseline performance (session 0) with group as the factor indicated that *rapid learners* demonstrated significantly lower PE scores compared to *plateau learners* ($p = 0.002$) and significantly longer ST ($p < 0.001$). By session 4, however, an equivalent test showed no significant difference between groups.

TABLE I
PERFORMANCE EVOLUTION SCORES AND ASSOCIATED GROUPS

Subject	PEM	Group
P1	0.56789	Rapid Learner
P2	0.77133	Rapid Learner
P3	1.62351	Rapid Learner
P4	-0.45312	Plateau Learner
P5	-0.42903	Plateau Learner
P6	0.48756	Rapid Learner
P7	1.78246	Rapid Learner
P8	0.37628	Plateau Learner
P9	-0.04786	Plateau Learner
P10	0.15456	Plateau Learner

Within the *rapid learners* group, RM-ANOVA with factor training session indicates significant differences across training sessions for SR ($p = 0.045$), PE ($p = 0.019$), and ST ($p = 0.010$). However, post-hoc pairwise t-tests with Bonferroni correction did not reveal significant differences within session pairs. Correlation analysis was conducted through PCC to identify trends in participants' performance. Training sessions demonstrated a significant positive correlation with PE ($p = 0.002, Pearson - Coeff = 0.226$) and a significant negative correlation with ST ($p < 0.001, Pearson - Coeff = -0.250$) (Fig. 3 left). For *plateau learners*, an RM-ANOVA did not reveal differences across training sessions for any of the performance metrics. Likewise, training sessions did not show a significant correlation with any performance metric (SR $p = 0.659$, PE $p = 0.898$, ST $p = 0.944$) (Fig. 3 right).

B. Muscle Properties Characterization

Changes in muscle properties were analyzed for *rapid* and *plateau learners* separately and are reported in Fig 4. First, fatigue over the assessment trials was evaluated by computing the mean frequencies of the sEMG signals [25], with both groups showing no evidence of fatigue. The *rapid learners* exhibited a baseline average mean frequency of 108 Hz, which remained stable throughout the training ($\Delta F = 0.7Hz, Pearson - Coeff = 0.03, p = 0.659$). *Plateau learners* had an initial mean frequency of 106 Hz, with $\Delta F = 3Hz$ ($Pearson - Coeff = 0.06, p = 0.347$). Since no signs of fatigue were detected in either group, its impact on muscle property analysis is considered negligible.

Two-sample t-test was performed to identify group differences in muscle property metrics. Significance were revealed between the two groups for PCC_flex ($p < 0.001$), PCC_aa ($p < 0.001$), and PLV ($p < 0.001$). In the *rapid learner* group, RM-ANOVA did not show significant differences across sessions. However, a significant negative correlation between the STD of sEMG signals with assessment sessions was revealed ($p = 0.031$, Pearson-Coeff = -0.139), indicating

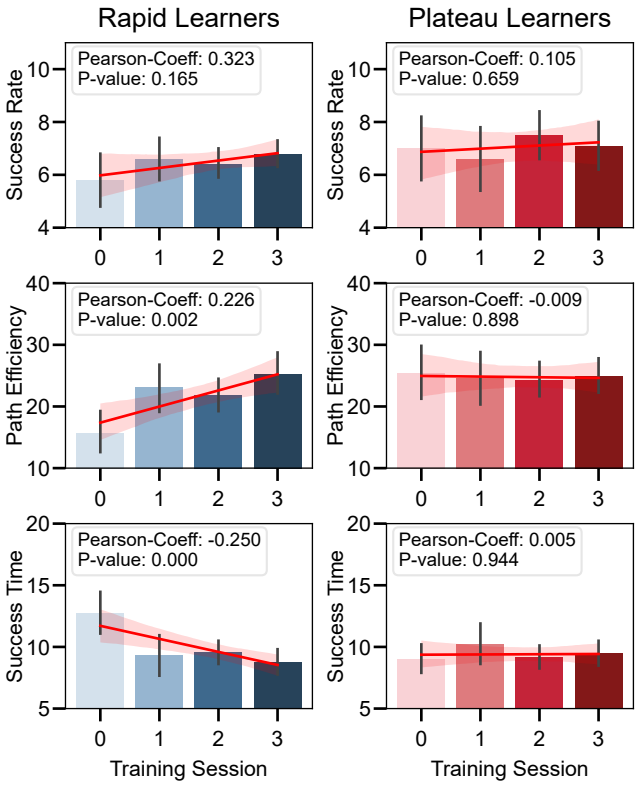

Fig. 3. Task performance metrics. The number of samples in each bar will be noted as $N_{session}$. SR, PE, and ST across training sessions are visualized for *rapid learners* (left column, SR: $N_{all} = 5$, PE/ST: $N_0 = 29, N_1 = 33, N_2 = 64, N_3 = 68$) and *plateau learners* (right column, SR: $N_{all} = 5$, PE/ST: $N_0 = 35$, $N_1 = 33$, $N_2 = 75$, $N_3 = 71$).

improved stability over time. The correlation between sEMG signals across electrodes within a single grid - whether placed over extensor or flexor arm muscles - remained stable, with no significant correlation across sessions (PCC_flex $p = 0.061$, PCC_ext $p = 0.202$). However, PCC_aa showed a significant positive correlation with assessment sessions ($p = 0.002$, Pearson-Coeff = 0.192), indicating increased co-contraction by the end of the experiment. The PLVs exhibited a weak correlation with assessment sessions ($p = 0.050$).

In the *plateau learner* group, RM-ANOVA did not reveal significant differences across testing sessions for any metric. Similarly, no significant correlation across assessment sessions and the STD of sEMG signals ($p = 0.347$) or the correlation of sEMG signals within the grids (PCC_flex $p = 0.682$, PCC_ext $p = 0.947$) was revealed. In contrast to the *rapid learner* group, PCC_aa is significantly negatively correlated with assessment sessions ($p < 0.001$, Pearson-Coeff = -0.409). Likewise, PLVs showed a significant negative correlation with assessment sessions ($p < 0.001$, Pearson-Coeff = -0.289).

IV. DISCUSSION & CONCLUSION

This study examined changes in forearm antagonist muscle properties in relation to task-specific performance metrics in a 3-DoF goal-reaching task, centering on three key characteristics: stability, co-contraction, and neural synchronization.

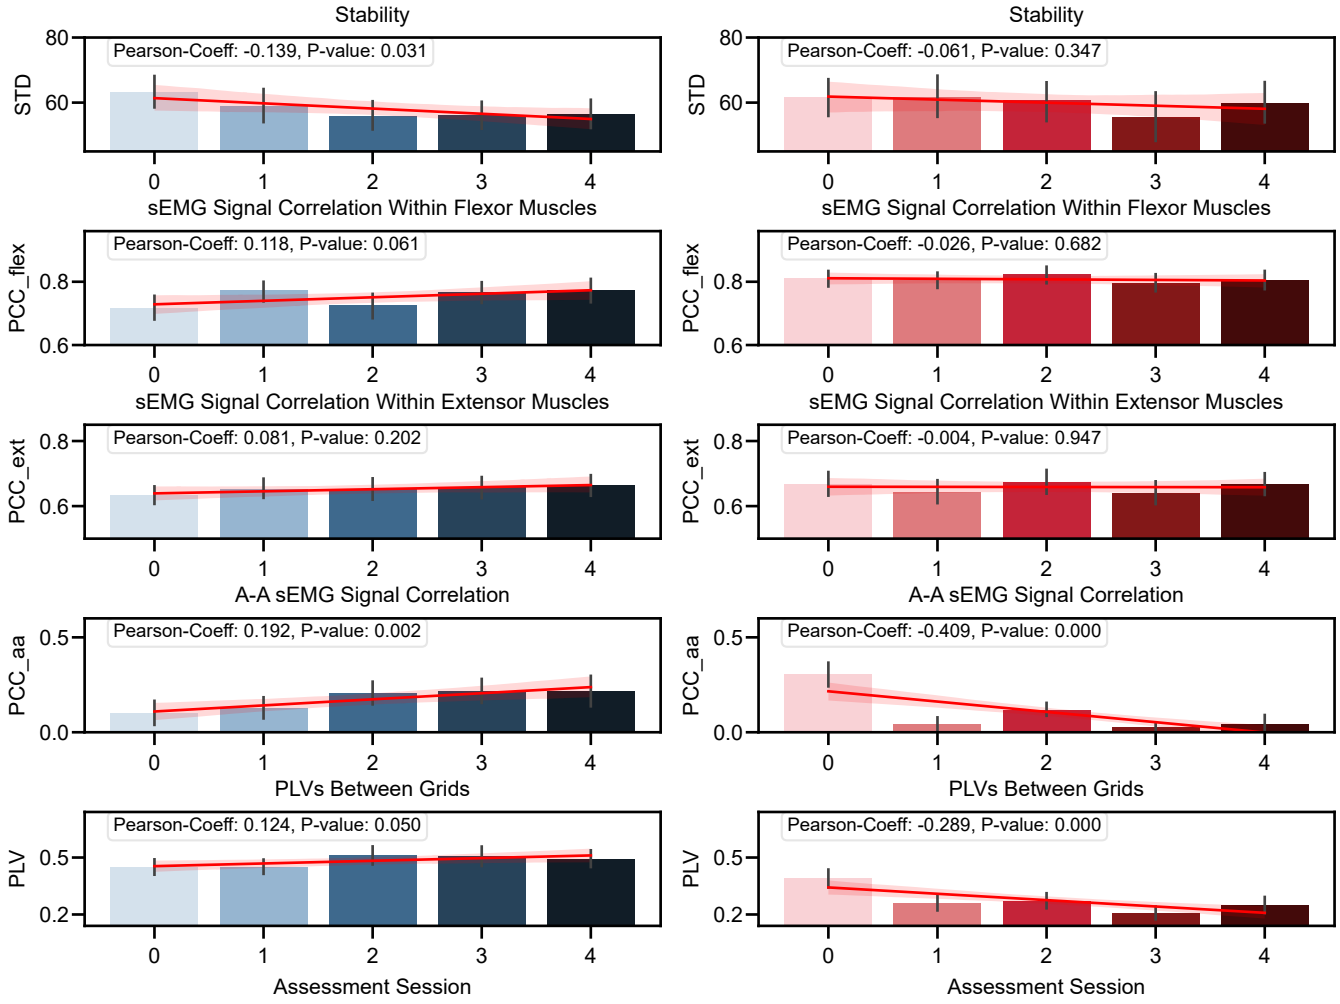

Fig. 4. Analysis of muscle properties across assessment sessions. Evaluated muscle properties included the STD of sEMG signals (row 1), intra-grid sEMG signal correlations (PCC_flex row 2 and PCC_ext row 3), inter-grid sEMG correlations (PCC_aa row 4), and PLVs between grids (row 5). The left column shows results for *rapid* and the right for *plateau learners*. Each bar includes 50 datapoints.

To account for individual differences in training responses [17], participants were categorized as *rapid* and *plateau learners*, based on their PEM score. Significant differences in PE/ST baseline and PE evolution across training sessions between groups highlight the need for subject-specific clustering in assessing myoelectric control and motor adaptation. The positive correlation in PE and negative correlation in ST across sessions for *rapid learners* indicate that training effectively improved task-specific metrics for this cohort. In contrast, the *plateau learner* group showed no significant changes in task-specific performance metrics. While task-level evaluations alone might indicate insufficient adaptation for this group, motor adaptations primarily occur at the muscular level rather than in immediate performance metrics.

Muscle property analysis in *rapid learners* reveals a negative correlation for the STD of sEMG signals across assessment sessions, demonstrating increased stability in muscle contractions and more consistent movement patterns by the end of the 45-minute training period. While no significant relationship in PCC_flex and PCC_ext with sessions was observed, a significant positive correlation was revealed in PCC_aa across assessment sessions. This suggests increased co-contraction, leading to greater joint stiffness [26], which can enhance stability and thereby improve overall task performance [27]. In contrast, PLVs observed across sessions indicate that participants rely on an almost consistent coordination of neural pattern over time, reflecting a neuromuscular approach that prioritizes stability over fine-tuning control.

Muscle property analysis in *plateau learners* reveals no significant correlation between the STD of sEMG signals and training sessions, consistent with the stability in performance. Although *rapid learners* rely on increased co-contraction for stability, this can reduce individual muscle activation in tasks requiring fine control. *Plateau learners* start with higher task performance, potentially needing less co-contraction to stabilize movements, suggested by a negative correlation of PCC_aa across sessions. This, combined with the decrease in PLVs over training, suggests greater independence in

activating antagonistic muscles, resulting in smoother and still precise movements but reducing the risk of fatigue.

Despite both groups reached similar performance by the end of the experiment, they seem to represent distinct motor adaptation stages. *Rapid learners* prioritize stable muscle activation for movement consistency, helping them reach a solid level of task performance. In contrast, *plateau learners* start with higher baseline performance, making further improvements in performance metrics more challenging. Nonetheless, we demonstrated that their progress is observable at the muscular level, where they refine control strategies to possibly enhance endurance and independence in muscle contractions for finely tuned control. These differences should be carefully considered when evaluating adaptation and learning effects, as some individuals may not exhibit task-specific improvements yet still benefit from training in terms of muscle conditioning and control strategies.

Note that in this preliminary investigation the sample size was limited to 10 participants, which might influence statistical power. Additionally, the training duration was restricted to 45 minutes, which does not capture the long-term effects of training. This study focused on one type of controller and a single task modality, limiting the generalizability of the findings. Therefore, future research should incorporate these factors to better understand motor adaptation strategies across various settings and populations. Furthermore, it should investigate whether *rapid learners* eventually reach a phase where task performance stabilizes and adaptation shifts toward finer neuromuscular changes or if this group represents a fundamentally different adaptation behavior. To further deepen the understanding of neuromuscular reorganization during motor adaptation, future studies should incorporate motor neuron activity into the analysis to validate how neural drive adapts over time in response to training demands. Our insights could inform the design of tailored training protocols and assessment methods for assistive devices involving myoelectric control and help clinicians to better evaluate the depth and efficacy of the training provided.

Neural Network Sparsity in Brain-Body-Machine Interfaces

Laura C. Petrich[1,4,*], Samuel Neumann[1,4,*], Patrick M. Pilarski[1,2,4], and Alona Fyshe[1,3,4]

***Abstract*— Brain-body-machine interfaces acquire, process, and translate brain signals for individuals with severe motor impairments to communicate and control the assistive technology that supports their daily life activities. Electroencephalography (EEG) is a standard approach for acquiring such brain signals due to its low cost and high temporal resolution. EEG signals can be thought of as a proxy for the user's intent. One established method for translating this intent into inferences and actions are neural networks. However, densely connected neural networks can be computationally expensive—a problem for real-time, deployed brain-body-machine interface systems. In this paper we investigate the use of *sparsity* in neural networks for EEG-based motor classification, with the goal of reducing the number of neuronal connections without sacrificing a system's performance. We compare two sparsity-inducing algorithms, weight pruning and sparse evolutionary training, with a dense neural network under three experimental conditions. Overall, our results show that sparse neural networks can achieve higher performance accuracy and generalization than their densely-connected counterparts for an EEG-based classification task. We found that sparse evolutionary training achieves the highest and most stable performance across all experiments. Introducing sparsity into the network is a viable option for efficient EEG-based control, with promising applications in a range of related rehabilitation and assistive technologies. This brings us closer to helping individuals with severe motor impairments reclaim independence through more computationally realizable methods of interacting with their technology and the world around them.**

I. Introduction

Brain-body-machine interfaces (BBMIs) are an emerging technology aimed at enabling the control of external devices via acquired brain signals and other signals from the human body [1]. BBMIs have improved the quality of life for individuals with physical disabilities by increasing their personal autonomy [2]. The overarching goal of a BBMI system is to offer an alternative means of communication in order for the user to interact with their environment. A BBMI system is composed of three components: signal acquisition, signal processing (involving feature extraction, classification, and translation), and the control application [1]. The overall performance and success of a BBMI relies on the quality of signals acquired from the brain or body as these are used to interpret the user's intent. In this work we compare the performance of three neural network training regimes, shown in Fig. 1, on a BBMI task.

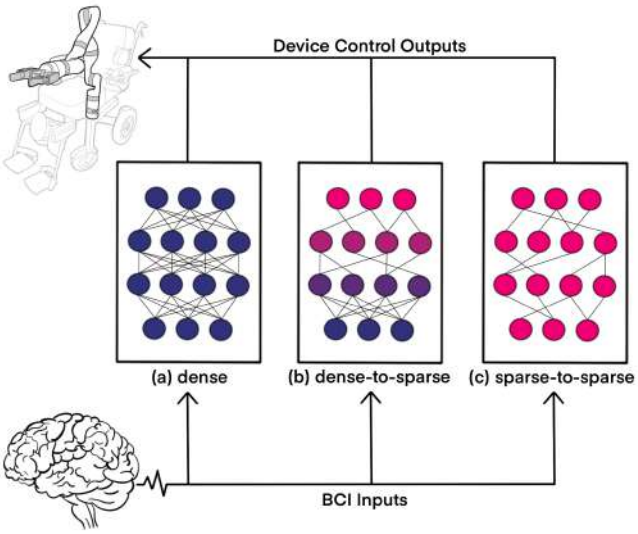

Fig. 1: Sparsity can be dynamically introduced into (a) *densely* connected neural networks by either starting with a dense layer and pruning network connections, known as (b) *dense-to-sparse* training, or initializing a sparse topology and iteratively pruning and regrowing connections, i.e., (c) *sparse-to-sparse* training. In this work we compare the performance of these three training regimes on a brain-computer interface task mapping electroencephalography signals (BBMI inputs) to upper limb motion events (device control outputs).

Electroencephalography (EEG) is a method of capturing the brain's electrical activity (i.e., signal acquisition) through wet or dry electrodes placed on the scalp [3]. It is popular for real-time control as EEG systems are relatively low-cost, non-invasive, and portable [4]. EEG signals have a high temporal resolution, however, they are inherently noisy and have poor spatial resolution [5]. Signal processing extracts a clean signal from a noisy EEG recording and then generates a mapping to the user's intent [6]. First, a preprocessing step is performed, involving channel selection (i.e., determine features relevant to the task of interest), signal frequency filtering (i.e., what filters should we apply to remove noise), and artifact removal (i.e., identify and remove irrelevant noise artifacts) [7]. Once the relevant features are extracted they can be classified and translated into motor commands to send to an external device (i.e., the control application), e.g., to control a smart wheelchair or robotic arm [1].

Due to the high-dimensionality, non-stationarity, and complexity of EEG data, dense neural networks are often used

for classification [8]. However, these networks can be computationally expensive and have large memory requirements. For practical control with EEG-based BBMI systems, low memory and computation requirements are necessary. The deployed system will need to be portable for improved usability, particularly for applications that do not have a local computer or internet connection. BBMI systems should be able to predict the user's intent accurately and react quickly to a user's input or feedback. Sparse neural networks are an emerging research area in machine learning that address both of these constraints [9], making them particularly well suited for BBMI control.

In a sparse neural network, each neuron is connected to a subset of neurons in the proceeding layer. This is in contrast to dense neural networks where each neuron is connected to all of the neurons in the proceeding layer. Sparse neural networks can be more energy efficient than dense neural networks, using a fraction of the memory and compute while reaching higher levels of performance and generalization [9]–[12]. In a recent survey on sparsity in deep learning, Hoefler et al. [13] found "that today's sparsification methods can lead to a 10-100x reduction in model size, and to corresponding theoretical gains in computational, storage, and energy efficiency, all without significant loss of accuracy" (p. 2–3). Furthermore, sparse neural networks may be more resistant to interference and catastrophic forgetting than their fully connected counterparts [14]–[16]. Finally, dense neural networks generally require large amounts of training data to generalize well, an important consideration in the application of BBMI systems where training datasets are usually small [8].

In this work *we investigate how sparsity affects the performance and generalization capabilities of neural networks in a classification task with EEG data.* Our key contribution is an empirical comparison of two techniques for adding sparsity to neural networks used for EEG-based classification, specifically examining their performance in the presence of variability both within individual participants and across different participants. We hypothesize that, when training and testing on a fixed pool of participants, with fewer neuronal connections sparse neural networks can attain higher levels of prediction accuracy and generalization compared to a dense neural network.

II. Sparsity in neural networks

Sparsity can be introduced into neural networks either *statically* or *dynamically*. Static sparse networks have fixed sparse connections between neurons and are not adapted during training [17]. Sparsity in these networks is due to deliberate architecture choices. In contrast, dynamic sparse networks have sparse connections that are learned through a gradual prune-and-regrow procedure [13]; it is this class of sparse networks we consider in the present study, due to their experimentally suggested utility within the animal brain. For example, Barth and Poulet [18] provide empirical evidence that the brain exhibits sparse firing of neocortical neurons, allowing for efficient representation of sensory information.

Algorithm 1: Sparse Evolutionary Training

Input: prune fraction ζ, prune frequency n, sparsity level ε, optimiser $\mathcal{O}$, loss $\mathscr{L}$
Initialize network with Erdős-Rényi topology with sparsity level ε
for *each training epoch* e **do**
  Train network parameters using $\mathcal{O}$ on $\mathscr{L}$
  if $e \equiv 0 \pmod{n}$ **then**
    Remove $\frac{100\zeta\%}{2}$ smallest positive weights
    Remove $\frac{100\zeta\%}{2}$ largest negative weights
    if e *is not the last epoch* **then**
      Add random new connections (weights) between consecutive layers equal to the amount removed
    end
  end
end

Algorithm 2: Weight Pruning

Input: prune fraction ε, prune epoch n, optimiser $\mathcal{O}$, loss $\mathscr{L}$, final network topology $\mathcal{T}$
for *each training epoch* e **do**
  Train network parameters using $\mathcal{O}$ on $\mathscr{L}$
  if $e = n$ **then**
    Remove $100\varepsilon\%$ of weights of lowest magnitude, ensuring that the resulting network has topology $\mathcal{T}$
  end
end

Dynamic sparse networks have also been argued to be more biologically plausible than static sparse networks, given the way that the animal brain is known to dynamically adjust its neuronal connections [19]–[21].

Dynamic Sparse Training (DST) refers to the simultaneous optimization of a dynamic sparse network's weights and neuronal connections. The Sparse Evolutionary Training (SET) algorithm of Mocanu et al., shown in Algorithm 1, is one of the seminal works in the DST line of research [10]. SET follows a *sparse-to-sparse* training regime (e.g., Fig. 1c), meaning that it initializes a neural network with a sparse Erdős-Rényi random graph topology [22] with sparsity level $\varepsilon \in (0, 1)$ and subsequently learns the weights and connections. Every n epochs, SET prunes and re-grows the connections. To do so, it first removes the $\frac{100\zeta\%}{2}$ smallest positive and largest negative weights (i.e., weights closest to zero) for $\zeta \in (0, 1)$. Next, an equal number of random connections are added back into the network, preserving the Erdős-Rényi topology. Conventional training then continues until the next pruning epoch. Mocanu et al. [10] show that networks trained with SET can match the performance of densely connected networks with a fraction of the number of neurons and far less memory and computation.

In contrast, *dense-to-sparse* training algorithms (e.g., Fig. 1b) begin by initializing a dense network then introduce sparsity by pruning network connections during training [23]–[26]. Such methods generally follow a three stage process. In the first stage, a densely connected network is

trained following conventional training procedures. During this stage, the learned network weights are considered to represent the importance of each connection where the importance of a weight is measured by its magnitude. In the second stage, the $100\varepsilon\%$ of unimportant connections are pruned at epoch n for $\varepsilon \in (0, 1)$. Finally, the pruned, sparse network is re-trained from either the current weight values or after re-initializing the weights. A typical weight pruning algorithm (WP) adapted from Han et al. [24], and the one we consider in this work, is shown in Algorithm 2.

III. Methods

A. Data characteristics and considerations

For this study work with the upper-limb prosthesis WAY-EEG-GAL dataset collected by Luciw et al. [27]. This dataset is well established in the community and has been used in classification tasks to achieve a high classification accuracy [28]–[30]. It was gathered with the intent of evaluating whether EEG signals can be used for upper-limb prosthetic device control. The data was collected with twelve right-handed participants and contains a total of 3,936 grasp and lift trials (328 trials per participant). Each participant completed ten series consisting of approximately 30 trials within each series. For each trial the participant reached out, grasped an object, lifted the object, and held it in the air for a few seconds before placing it back down and releasing the object. A hand motion event label was assigned to an EEG recording by Luciw et al. [27] using a combination of velocity and force data to determine the event onset. A subset of the original dataset was then extracted for a Kaggle competition where an event label was also assigned to an EEG sample if it was within 150 ms of the event onset [31]; it is this subset that we used for our study. For detailed information on the data collection protocol we refer the reader to the original article by Luciw et al. [27].

Since the events occur sequentially (i.e., time-series data), each EEG sample may be labelled with multiple events. In order to better isolate the effect of introducing sparsity, we extracted four event classes that did not have overlapping event labels for training our classifiers: HandStart (class 0), LiftOff (class 1), Replace (class 2), and BothReleased (class 3). The class label, class number, and number of samples for each class are summarized in Table I. Each sample (i.e., model input) contains 32 channels of raw EEG data from wet electrodes collected at a 500 Hz sampling rate with a corresponding event label (i.e., there is a signal-label sample every 0.002 seconds).

TABLE I: Class details for the dataset used in our multi-class classification problem. A weighted cross-entropy loss function was used to help address the class imbalance.

Class Label	Class Number	Number of Samples
HandStart	0	468000
LiftOff	1	388279
Replace	2	321905
BothReleased	3	321905

B. Data pre-processing

EEG data is known to be noisy and requires filtering in order to be sure that artifacts are not interfering with model predictions [32]. Head or wire movements as well as perspiration can cause low frequency noise artifacts. High frequency artifacts can be caused by muscle contractions in the vicinity of the EEG recording sites (electromyography artifacts), eye blinking or movement (electrooculography artifacts), and electromagnetic interference. During data collection for the original WAY-EEG-GAL dataset, no pre-processing (e.g., artifact rejection) steps were applied to the EEG signals other than the removal of "unneeded or extra samples at the beginning and end of each series" (p. 5) [27]. In line with standard practices, e.g., Janapati et al. [33], we applied a bandpass filter with a low frequency cutoff of 0.2 Hz and a high frequency cutoff of 50 Hz. The frequency cutoff of 0.2 Hz will remove low frequency movement artifacts, while the 50 Hz cutoff will remove high frequency noise artifacts from muscle contractions, eye movements, and electromagnetic interference.

C. Algorithms and hyperparameter tuning

To better understand how sparse neural networks can perform on an EEG-based classification task, we studied the learning process of two dynamic sparse training (DST) algorithms. The first algorithm is sparse evolutionary training (SET), shown in Algorithm 1. The second is a weight pruning (WP) algorithm, shown in Algorithm 2, similar to those used by Frankle and Carbin [26] and Han et al. [24]. Following the advice of Han et al. [24] who found that retraining pruned layers from the surviving parameters resulted in better performance; we did not re-initialize weights after pruning, rather training continued from the current weight values.

We compared these two DST algorithms with two baselines. The first baseline is a small densely connected network, which we denote as DN. The second baseline randomly predicted class labels according to their relative occurrence frequency in the dataset. This baseline served as a sanity check to ensure that each algorithm learned reasonable behaviour. All algorithms were implemented in `Flax` [34] using the `jaxpruner` library [35].

Due to the nature of our study, we were not interested in attaining state-of-the-art performance, rather, we wanted to characterize the learning processes of sparsity-inducing algorithms. For all experiments to remain interpretable, all neural networks were composed of two hidden layers. We performed a sweep of hidden layer sizes in $\{128, 256, 512, 1024\}$ and found that all networks performed best with hidden layers of size 1024 and that the computation time for all network sizes was similar. We constrained ourselves to hidden layers of 1024 and below to keep our study focused on relatively small computational loads that are deployable on embedded systems. For the rest of the experiments we set the hidden layers to size 1024. Each network predicted a softmax distribution over class labels. All neural networks were trained using the Adam

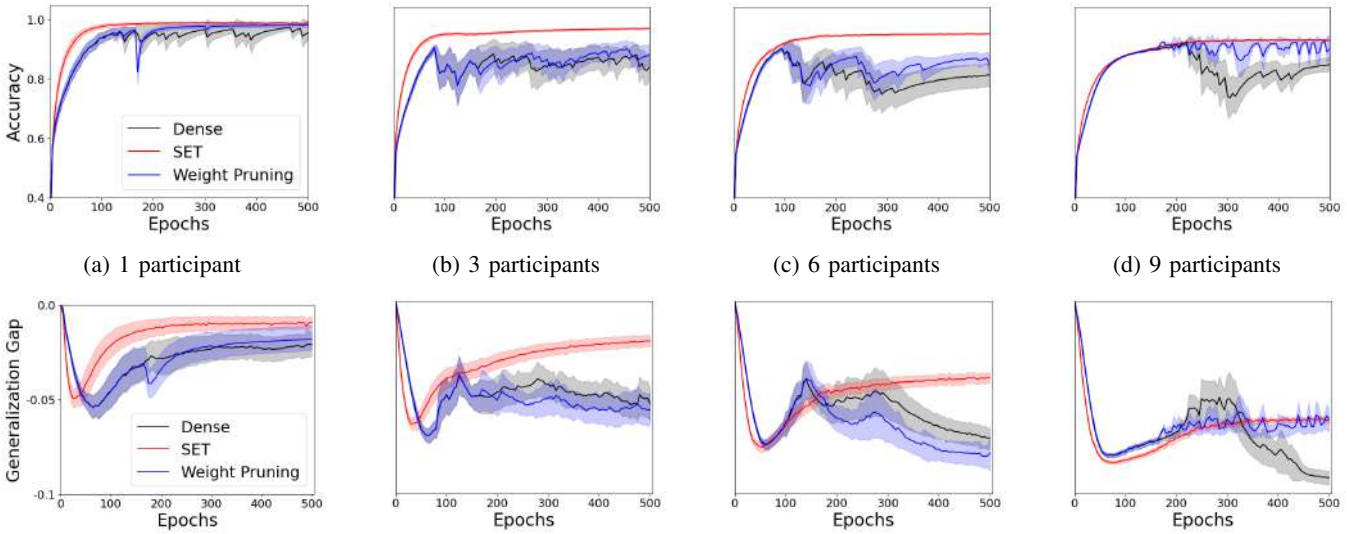
optimizer [36] from the `Optax` library [37] with default hyperparameters, except for the stepsize.

To tune the stepsize and sparsity specific hyperparameters, we conducted a grid search for multiple runs with three random seeds for Experiments 1 and 2, and fifteen random seeds for Experiment 3. We selected the tuned hyperparameters based on the highest average prediction accuracy achieved throughout training. For all experiments we swept stepsizes in $\{0.01, 0.001, 0.0001\}$. In our preliminary experiments, we evaluated the prediction accuracy of SET and WP for sparsity levels $\varepsilon \in \{0.25, 0.5, 0.75\}$ and percentage of dropped weights (SET) $\zeta \in \{0.15, 0.3, 0.5\}$. For both the sparsity level and percentage of dropped weights, we found that prediction accuracy was highest for the lowest two values and swept over those values for the final experiments. We further performed a sweep of batch sizes and found that full-batch updating resulted in highest prediction accuracy across all algorithms. However, in a number of experiments, full-batch updating was not possible due to the immense size of the training data. We therefore used a large batch size of 8192. We tested pruning weights every $\{1, 2, 5\}$ epochs for SET (since this algorithm prunes many times during training) and once at epoch $\{167, 333, 400\}$ for WP (i.e., pruning once $\frac{1}{3}$ $\frac{2}{3}$, or $\frac{4}{5}$ of the way through the total number of epochs).

For all experiments we used a weighted cross-entropy loss to help address the class imbalance, similar to that in the `scikit-learn` library [38]. The loss term for each class y was weighted by $\frac{N}{Cn_y}$, where N is the total number of data samples in the dataset, C is the number of classes, and n_y is the number of data points with label y. We used a stratified 80/10/10 train, test, and validation split for each experiment.

D. Experiment details

We conducted three different experiments to test the efficacy of sparsity in different settings. First, each algorithm was evaluated when training and testing data came from the same pool of participants. Next, we evaluated how each algorithm performed when classifying out-of-distribution data, where the training and testing datasets came from different pools of participants. Finally, we investigated how increasing amounts of training data from a single participant affected each algorithm's predictions on the same participant.



a) Experiment 1: Our first experiment addressed the question *how does each model perform within the participant pool it was trained on?* To answer this question, we trained and tested each algorithm on data from $N \in \{1, 3, 6, 9\}$ participants out of the first ten participants. The N participants were randomly sampled without replacement. We tuned hyperparameters over three random seeds. We then conducted an additional 20 experimental runs using the tuned hyperparameters and report performance metrics for these final 20 independent runs.

Due to the nature of the EEG data, we expected that increasing the number of participants in the training dataset would decrease prediction accuracy. This is because the model needs to account not only for variability that exists within an individual participant but also for variability between different participants. We were interested to see whether sparsity can help to counteract this effect. Indeed, for many of the highest performing submissions in the Kaggle competition, a separate network was trained for each participant [31]. Nevertheless, a BBMI system should be capable of being trained on multiple participants data in order to reduce the amount of training data required per individual.

b) Experiment 2: Our second experiment addressed the question *can each model efficiently generalize to the data of new, held-out participants?* For this experiment we took the tuned-and-trained models from Experiment 1 and tested how they performed on data from the two held-out participants 11 and 12. We expected each model to perform worse in this setting compared to Experiment 1, but we were interested in determining if sparsity helps to negate it (e.g., via improved generalization or reduced loss in prediction accuracy). This study allowed us to better understand how training data should be collected for real-world BBMI systems—from the end user or other participants. Improving generalization to new participants would be of great benefit to BBMI systems, as it is often challenging to have the end-user come in for multiple training sessions.

c) Experiment 3: Our final experiment sought to address the question *how does each algorithm perform with differing levels of training data for a single participant?* This experiment allowed us to better understand how each algorithm may behave in a real-world setting where the system could potentially learn and adapt to the behaviour of the end-user during deployment. For this experiment, data from a single randomly sampled participant from the first ten participants was split into training, validation, and test sets. The training set was composed of $p \in \{10\%, 20\%, 30\%, 50\%, 70\%, 80\%\}$ of the participant's data. The validation set was composed of 10% of the training set, and the test set was composed of the remaining data. Note that when the training data reaches 80% of the data this is equivalent to the 1 participant setting in Experiment 1. An increasing amount of training data should improve the performance of each algorithm, with diminishing returns. A well-performing algorithm, especially one suited for a deployable BBMI system, should reach reasonable performance with a moderate amount of training data. We repeated this experiment 15 times with different random seeds, tuning hyperparameters and reporting performance over all 15 seeds.

d) Evaluation metrics: Model performance was evaluated by prediction accuracy. Similar to Novak et al. [39] and Liu et al. [40], generalization is quantified as the *generalization gap*—the difference in prediction accuracy between the testing and training datasets. The generalization gap is expected to be less than zero, as it is unlikely that the test accuracy is greater or equal to the training accuracy. If a model were to perfectly generalize to unseen data, the generalization gap would be zero. We report mean evaluation metrics across runs with bootstrap confidence intervals. We used 10k resamples, batch sizes of 10, and 5% significance to construct confidence intervals, unless otherwise specified.

(a) 1 participant (b) 3 participants (c) 6 participants (d) 9 participants

(e) 1 participant (f) 3 participants (g) 6 participants (h) 9 participants

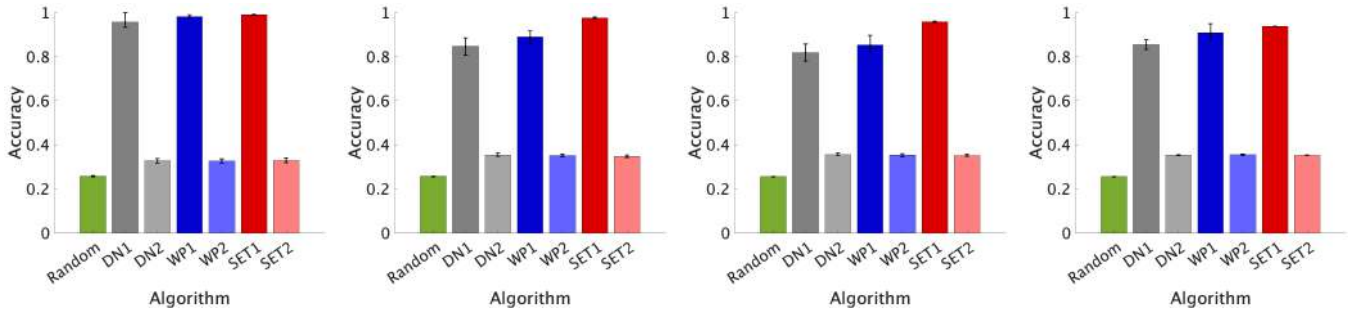
Fig. 2: Sparse Evolutionary Training (SET) displays consistently high accuracy and better generalization than other algorithms in Experiment 1, where both train and test data are from the same pool of participants. **Top Row**: Test accuracy over 20 independent runs. As more participants are added to the training dataset, the performance of SET stays consistently high with low variance. **Bottom Row**: Generalization gap (i.e., difference between the test and train accuracy) over 20 independent runs. SET is able to generalize more efficiently than either the dense network (DN) or weight pruning (WP). **Both**: Solid lines denote mean performance with shaded regions denoting 95% bootstrapped confidence intervals.

IV. Results

A. Experiment 1: Pooling participant's data

The top row of Fig. 2 shows the test accuracy for each algorithm over 20 independent runs with training/test data from 1, 3, 6, and 9 randomly sampled participants. WP performed similarly to DN in terms of prediction accuracy. In contrast, SET generally improved prediction accuracy compared to DN and learned noticeably faster than both DN and WP. Accuracy decreased for all algorithms when more participants were added into the training data. We hypothesize that this is because each algorithm had to better generalize among all participant's conditional data distributions.[1]

Whereas SET exhibited low variance in prediction accuracy with tight confidence intervals, DN and WP exhibited severe degradation in prediction accuracy at differing intervals throughout training as seen in the top row of Fig. 2. Notably, these dips are not apparent when using full-batch updating and happen across all classes (that is, the dips are not due to poor prediction accuracy for a single class). Such a phenomenon reduces the utility of both these algorithms to real-life BBMI systems.



The bottom row of Fig. 2 outlines the generalization gap for each algorithm. SET often exhibited a significantly lower magnitude generalization gap than either DN or WP (note where the confidence intervals do not overlap). WP and DN exhibited a similar-magnitude generalization gap, except when training on 9 participants. For all algorithms, the generalization gap increased with an increasing number of participants. Overall, SET obtains the best prediction accuracy and performance stability across all settings suggesting that it is a helpful training regime when adding more participants data into the training pool.

B. Experiment 2: Generalizing to held-out participants

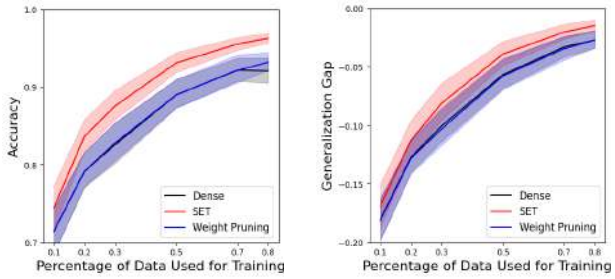
For this experiment we took the tuned-and-trained models from Experiment 1 and tested how well they performed on data from held-out participants 11 and 12. Fig. 3 shows the test accuracy of random predictions, DN, WP, and SET over 20 random seeds for both Experiment 1 and Experiment 2. Overall, we see a steep decline in accuracy when making predictions on held-out participant data, with algorithms performing only marginally better than the random baseline. For the 1-participant case, we see a $\sim 66\%$ decrease in prediction accuracy for all algorithms (comparing the Experiment 1 bars with corresponding Experiment 2 bars in Fig. 3).

Notably, this decline in prediction accuracy is not due to the held-out participants having poor quality data. We verified that each algorithm could learn on these participants' data, each reaching over 90% prediction accuracy. Overall, DN, SET, and WP each performed approximately equally when predicting on held-out participant data, with a slight increase in accuracy moving from the 1 to 3 participant setting (approximately 32% to 35%). This is unsurprising as EEG signals have been used for person recognition systems, suggesting there is sufficient variation in the signals between different people for classification. Considering these results in tandem with those of Experiment 1, we conclude that it

[1]Denote the theoretical distribution of EEG data (X) and labels (y) on this grasp-and-lift task as $p(X, y)$. Then the distribution of EEG data from a single participant S is $p(X, y \mid S)$.

(a) 1 participant (b) 3 participants (c) 6 participants (d) 9 participants

Fig. 3: The deep coloured bars (DN1, WP1, and SET1) show the Experiment 1 results while the faded bars (DN2, WP2, and SET2) show the Experiment 2 results. All network architectures show a steep decline in accuracy from the Experiment 1 results when making predicts based on out-of-distribution data from held-out participants. Bars show the accuracy of random predictions, dense network (DN1/DN2), weight pruning (WP1/WP2), and sparse evolutionary training (SET1/SET2) algorithms for Experiments 1 and 2, respectively, over 20 random seeds. Error bars denote 95% bootstrapped confidence intervals with 10,000 resamples.



might be beneficial to include *data from the end-user when training a BBMI control system in order to help reduce the loss in model performance.*

C. Experiment 3: Single-participant models

A successful BBMI system should be able to continually learn and adapt to the dynamic nature of its user. This experiment allowed us to quantify the gains in performance with increasing data from the end-user. Ideally, a BBMI system would be useful even with a low amount of training data, although what defines a model as *useful* will ultimately depend on the end application.

Fig. 4a shows the accuracy during learning for increasing amounts of training data. Even with a low amount of data, all algorithms attained reasonable performance. With just 10% of the training data (approximately 27 grasp and lift trials), all algorithms reached a prediction accuracy around 75%. As more training data was introduced, the accuracy of all algorithms continued to increase, as expected. The prediction accuracy of SET increased more quickly than that of DN and WP and was significantly higher for datasets composed of more than 10% of a participant's data (note how the accuracy confidence intervals do not overlap). For the largest dataset sizes, SET attained significantly higher levels of precision and recall than DN (with a significance level of 0.1); table omitted for concision.

Fig. 4b shows the generalization gap for DN, SET, and WP. Overall, the gap shrinks with increasing training data, indicating that all algorithms can better generalize with more training data. When 10% of the data was used for training, the generalization gap was around 20% across algorithms—indicating overfitting. When more than 70% of the data was used for training, the generalization gap was less than 5%, indicating that the algorithms could generalize to unseen data effectively. All three algorithms exhibited a similar generalization gap for increasing dataset sizes.

(a) (b)

Fig. 4: The amount of participant data used in training impacts both accuracy and generalization, as shown via Experiment 3 results with train and test data from a single participant. Prediction (a) accuracy and (b) generalization gap when trained on increasing amounts of training data. Solid lines denote mean performance with shaded regions denoting 95% bootstrap confidence intervals. (a) SET attained the highest accuracy for increasing dataset sizes; (b) each algorithm exhibited a similar generalization gap.

V. Discussion

An open question in the BBMI community is *from whom should data be collected* in order to reduce the effects of intra- and inter-participant variability when training a BBMI control model [41]. We showed how the algorithms under consideration were able to make accurate predictions for participant data on which each algorithm was trained. But, when testing on held-out participant data, each algorithm exhibited a significant, and considerably large, drop in prediction accuracy, precision, and recall. This suggests that such computational models should include some training data from the end-user. Pre-trained models should be either fine-tuned to the end-user prior to deployment, for example through transfer learning [42], or include data from the end-user while training the model. For best performance, we suggest training a model on as much data as possible from solely the end-user, although we do acknowledge this may

not always be a viable option. When training on data from multiple participants, SET could help to minimize the decline in prediction accuracy.

Overall, our empirical study suggests that sparsifying a neural network is a viable option for reducing the number of neuronal connections when training an EEG-based model without significant loss of performance. As suggested by Lasby et al. [9], selective reduction may support the active alignment of network architectures to deployed computational hardware. Our study also indicates that sparse neural networks have the ability to adapt more quickly during training than their densely connected counterparts. This brings us one step closer towards making a *direct impact on the lives of people living with severe motor impairments through the use of machine learning models trained on brain data.*

A. Ethical considerations

As machine learning models become more prevalent in every day life, they are being used to make decisions that affect not only individuals but also society as a whole. Thus, it is important to understand the potential sources of harm that could arise during different stages of the machine learning life cycle. Suresh and Guttag [43] present a framework for identifying seven sources of harm, three of which we take into consideration for this study. The first is *representation bias*, which we note in the participant pool recruitment of the WAY-GAL-EEG dataset [27]; the population that would end up requiring and using a model such as this for BBMI control is underrepresented and models trained on this set could fail to generalize well for an assistive rehabilitation technology user population. The second is *measurement bias*. By oversimplifying a complex motor action recorded via EEG signals into four simple labels, we run the risk of a trained model being a poor reflection of user intent as measured from the whole brain. The third is *deployment bias*. A key goal of this work is to develop efficient and accurate prediction models for use in a real-world BBMI control system. Such a system would involve a human user controlling a neuroprosthetic device via real-time EEG signals. Thus, it is important that future work consider the match between the prediction problem that the model solves and how it is being used during deployment. Reproducibility and transparency are also an important part of ethical research practices. To this end, we open-sourced all of our code for dataset loading, model training, and evaluation.[2]

B. Limitations and future work

Our empirical analysis contained factors that limit the immediate transferability of our findings to deployed environments. One choice made in our data pre-processing step was to remove all samples with overlapping or no event labels. While making evaluation more straightforward, this choice makes it more difficult to transfer the approach verbatim to a real-time control system as there will be a significant amount of out-of-distribution EEG signals being fed into the trained model. One intermediary step before moving to a BBMI application could therefore be to re-train these models using the full set of original event labels to see if our conclusions still hold. Future work should ideally focus on studying sparse neural network algorithms on a variety of larger BBMI datasets. Many of our conclusions are a direct consequence of training on a small dataset of twelve participants with a reduced number of class labels, and it is unclear if these conclusions will consistently present in larger, more diverse or contextual datasets. Future work should also consider systematic hyperparameter sensitivity analyses of these algorithms, to understand better how they would perform in real-world scenarios where tuning is impossible.

VI. Conclusion

In this work we evaluated the performance of two sparse neural network algorithms for an EEG-based upper-limb motion classification task. It is well-known that sparse neural networks can reduce the computational and memory requirements of deep-learning systems [9], [13], and our goal was to determine whether such networks are viable for adaptive BBMI systems. Our results show how sparse neural networks can achieve higher performance and generalization than dense neural networks on one EEG dataset. Furthermore, our experiments provide evidence that sparse neural networks can achieve high accuracy with low variance during learning, making these networks candidates for real-time BBMI systems which adapt to the end-user during deployment. For example, improvements in the performance and stability of EEG-based control for wheelchair-mounted robotic arms could help empower individuals to perform everyday tasks such as eating, drinking, and grasping objects independently. In addition to their use in rehabilitation and assistive robotics, we expect these insights into sparsity to inform the development of other non-medical biomechatronic and bio-inspired systems with limited on-board computational resources. We hope that the present research has therefore laid the groundwork necessary for conducting ambitious future studies into the intuitive and computationally efficient user control of BBMI systems such as robotic arms and other assistive technologies.

Acknowledgment

The authors would like to thank Johannes Günther, Matthew E. Taylor, and Alex Murphy for many helpful discussions and feedback on this paper. Special thanks to Shaylee Lorrain for graphical design assistance.

***Abstract*—Falls are a major health concern among older adults, particularly those with neurological conditions such as Parkinson's disease or stroke. Wearable airbags are a promising new technology that may help mitigate fall-related injuries. These devices use motion sensors, pre-impact fall detection algorithms, and CO_2-powered airbags to cushion the impact of a fall. However, this technology is only needed for people with a high risk of falls, and it is only useful if the pre-impact fall detection algorithm successfully detects the fall. Our prior work showed that some individuals benefit more from one pre-impact fall detection algorithm than another due to their unique movement characteristics and biomechanics. This study aims to determine who may be suitable users for this technology by predicting future fall risk and categorizing users as 'responders' or 'non-responders' based on their predicted algorithm performance. We recruited 22 participants with neurological conditions in a six-month study design. Using baseline physical assessments, survey scores, and principal component analysis, we trained a logistic regression model that distinguished high-risk 'fallers' from 'non-fallers' with an average F1 score of 0.76. The model also identified 'responder' individuals, whose fall patterns were accurately detected, achieving an F1 score of 0.75. These findings suggest that identifying high fall risk users whose falls are best identified by a fall detection algorithm can enhance device effectiveness and maximize benefits for users.**

I. INTRODUCTION

Fall-related injuries are a prominent issue for older adults, not only in the United States, but also the world, with approximately 37.3 million falls requiring emergency medical care worldwide each year [1]. As the global population of older adults continues to grow, with an anticipated increase from 1 billion adults aged 60 and over in 2020 to 1.4 billion by 2030 [2], the number of falls and fall-related injuries will continue to increase. Today, one in four adults over 65 experience a fall throughout the year in the United States [3], resulting in an estimated $50 billion spent on medical costs related to non-fatal fall injuries and $754 million on costs related to fatal falls [4]. Falls can have lasting physical and psychological consequences, such as chronic pain, reduced mobility, fear of falling, social isolation, and depression [5], [6]. Around 50% of hospitalizations after a fall are due to hip fractures, making them a critical problem to address [7]. The risk of falling increases as individuals are diagnosed with neurological conditions such as Parkinson's disease (PD) or stroke. Individuals with PD are twice as likely to fall compared to other neurological disorders [8]. Older adults with stroke are also at high risk, as they have a 1.5-4 times higher risk for falls in comparison to age matched peers [9]. Existing strategies to prevent falls, such as exercise and medication, have not been proven to be fully effective in the PD and stroke populations [10], [11]. As a result, methods to reduce fall injury are of interest. Hip pads are the most common method of fall injury protection, but most are uncomfortable and have low compliance rates [12]. An alternative is wearable airbags, which use pre-impact fall detection algorithms to determine when a person is falling and deploy airbags before the individual comes into contact with the ground. One commercially-available device that utilizes this type of system is the WOLK Hip Airbag (Wolk De Heupairbag; Wolk Company, Netherlands). The device was used in a pilot study across 11 long-term care facilities and

more than 900 individuals. While there was a limited number of devices available, the group with access to the wearable airbag experienced fewer hip fractures than the group without [13].

Our prior work has shown that fall detection algorithms can be more effective when trained for a specific patient population [14]. People with neurological conditions have differing biomechanics, even during a fall. This can be seen in individuals with stroke, as they have delayed postural reflex onset latencies, longer intra limb coupling durations [15], and various gait deficits [16]. This suggests that fall detection models should be specialized to the population using it to optimize its effectiveness, and that some individuals may get more benefit from certain algorithms. For this paper, we developed and tested a fall detection algorithm specialized to detect falls of individuals with neurological conditions.

In order to utilize this technology most effectively, we aim to first identify potential users with a high risk of falling in the near future. While most fall detection systems have focused on optimizing algorithm performance by adjusting biosensor locations, task types, or the algorithm design [17], disease-related gait and balance differences within study cohorts are often underestimated. For instance, fall risk factors in neurological conditions are associated with measures of balance [18], [19] and abilities related to activities of daily living (ADL) [20]. These gait and balance factors can be used to group individuals into two groups of high-fall and low-fall risk in the next six months, also known as 'faller' and 'non-faller' groups [21]. Identifying future fall risk groups can help identify appropriate users.

Moreover, fall patterns can vary among neurological conditions and severities [14], [22], [23] and some individuals may experience better performance from specific fall detection algorithms. This variation allows us to categorize and define users into 'responders' (those for whom the given algorithm is highly effective) and 'non-responders' (those for whom the algorithm is less effective) [24]. By understanding baseline measures in balance, quality of life, activities of daily living, we can predict which users will benefit most from the device.

The purpose of this study is to assess future fall risk and optimize the use and benefit of wearable airbag devices for individuals at high risk of falls. We aim to develop classification algorithms that utilize baseline physical assessments and survey scores to: 1) distinguish between 'faller' users–defined as those with at least one expected fall in the next six months–and 'non-faller' users, and 2) further stratify fallers into two subgroups: 'responders', who demonstrate clear differentiation of fall patterns from non-fall activities by the given fall detection algorithm, and 'non-responders', whose fall patterns are less differentiable by the given fall detection algorithm.

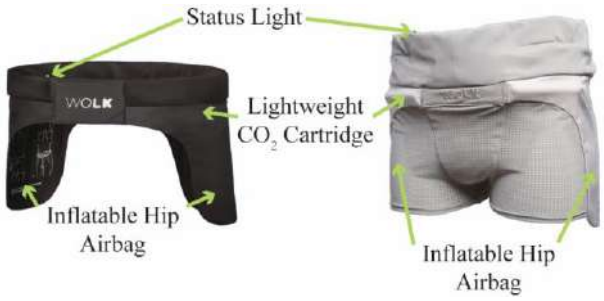

Fig. 1. **Airbag System Hardware**. The WOLK Active Airbag System is used in two models, a belt (left) or shorts (right). Both Systems deploy hip mounted airbags to protect the hips when a fall is detected.

II. METHODS

A. Participants

Individuals with Parkinson's disease (N = 10, Average age 72.4 ± 3.4 Standard deviation, 4 female) and chronic stroke (at least six months from diagnosis; N = 12, Average age 64.9 ± 14.5, 7 female) were recruited in the **community deployment pilot study**. Inclusion criteria included ages 18-85, with at least one self-reported fall in the last six months, homebound or community ambulators, with a waist circumference of 84-125 cm (due to the airbag device sizing). Individuals using a wheelchair for mobility in both indoor and outdoor areas, as well as individuals with colorblindness that would affect their ability to perceive the light status on the device were excluded from this study. Informed consent was obtained from all participants prior to participation, in accordance with guidelines from the Northwestern University IRB (NUIRB, IL, USA).

B. Device

The WOLK Hip Airbag (Wolk De Heupairbag; Wolk Company, Netherlands) was used in this study (Figure 1). This wearable airbag device can be worn discreetly under clothing, while offering hip protection. It uses three fixed Inertial Measurement Unit (IMU) sensors located on the lateral sides

TABLE I. LIST OF FALL AND NON-FALL EVENTS REPORTED OR COMPLETED BY PARTICIPANTS IN THE COMMUNITY DEPLOYMENT AND IN-LABORATORY STUDIES

Community Deployment Pilot Study		**In-Laboratory Study**	
Fall (All lost balance and landed on hip or rear)	**Non-Fall**	**Fall** (All landed on hip or rear)	**Non-Fall**
Walking Putting on clothing Reaching for an item Transitioning between positions Turning	Sit to stand Sit (static) Lying on back Jumping in place Picking up an object from floor Functional Gait Assessment items Mini Balance Evaluation System Test items	Sit to stand / Stand to sit Slipping Tripping Pushed over, with arms crossed	Sit to stand Walking Sitting (static) Lying on back Jumping in place Picking up an object from floor

of the hips and on the lower back (at the L3 vertebrae). The IMU sensors each contain an accelerometer and gyroscope sensor that collect data in the x, y, and z axes, with a sampling rate of 500 Hz. The two embedded CO_2 cartridges deploy the airbags after receiving commands from the embedded pre-impact fall detection algorithm. If a fall is detected, the IMU data is recorded and saved in an output file. For in-laboratory activities, individuals wore a modified WOLK device that records IMU data continuously.

C. Experimental Setup

This study collected data from real-world participants and incorporated previously collected data from simulated in-laboratory falls for analysis (Figure 2A). The two datasets involved different individuals and all fall and non-fall activities are listed in Table I.

1) Community Deployment Pilot Study:

The real-world falls data **was collected during the community deployment pilot study.** This pilot study was designed to capture six months of data for each participant, with a laboratory visit on the first day. During the laboratory visit, participants completed a series of physical assessments and surveys (Table II). During these physical assessments, individuals wore the modified WOLK device to record their movement data, and the assessment items were recorded and time stamped with a smartphone. These activities were used as replications of activities of daily living (ADLs). For the remainder of the six-month period, participants were provided with a wearable airbag device and instructed to use it as consistently as possible during daily life activities. Fall incidents at home or in the community were tracked by both the airbag device and self-reported during bi-weekly phone calls. The falls were specifically defined as events in which the participant lost balance, and their hip or rear made direct contact with the ground. These events will be referred to as "falls" in this study. "Non-fall" events included any false activations caused by dropping the device or other ADLs, as well as the replications of ADLs from the physical assessments.

2) In-Laboratory Study:

The in-laboratory dataset [14] was recorded with a separate cohort of individuals with PD (N = 19) and chronic stroke (N = 20), but only in the laboratory environment. Each participant was equipped with protective gear (e.g., helmet, neck/knee/elbow guards) and performed non-fall and fall tasks. "Fall" events were defined in the same way as the community deployment study. However, non-fall events were independent of the activation of the wearable device but still included ADLs (e.g., walking, sitting, picking an item off the floor) and near-falls (e.g., slips, trips, loss of balance that does not result in hitting the ground). All of the in-laboratory data were collected using the modified WOLK belt. We processed and integrated the community deployment pilot study data, and the in-laboratory fall data into the fall prediction algorithm.

D. Data Processing

1) IMU Data:

To identify the risk of falling and responder status of each participant, features were calculated from the baseline clinical measures, survey scores and IMU signals. Subsequently, three predictive machine learning classifiers were trained on those features. To minimize the number of features and increase the generalizability of the prediction models, only signals from the lower back IMU were used, and lateral sensors were removed. The IMU data collected from the real-world falls and in-laboratory assessment items were processed as described in [14]. In summary, each real-world fall event and in-laboratory assessment item was labeled with an event ID, fall status (Fall or Non-Fall), fall specification (activity of daily living (ADL), side, anterior/posterior (AP)), and a fall description (e.g. "subject lost balance standing, hip or rear impact"). The raw data was band-pass Butterworth filtered (0.1-50 Hz) before generating three moving windows (100 ms duration with 50% overlap), starting 300 ms before the impact, as this would allow at least 100 ms for the device to deploy the airbags. The impact time was defined as the peak acceleration of the fall event. For non-falls, the three windows were selected that lead up to the maximum acceleration magnitude of the event. On each window, twelve features were calculated for both the accelerometer and gyroscope in each direction (x, y, and z). These features included minimum, maximum, absolute minimum, absolute maximum, root mean

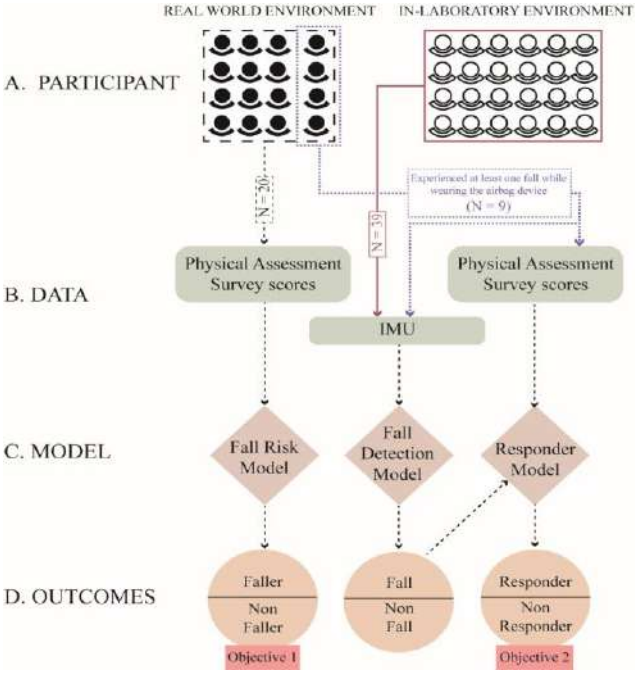

Fig. 3. The overall flowchart of data collection, processing, and machine learning models. (A) shows the data collection environment and number of participants for each model. (B) Specific features from each data were calculated and (C) trained in separate machine learning models. (D) These models were able to predict the risk of falling, pre-impact fall patterns, and responder status.

squared, median, standard deviation, skewness, kurtosis, velocity, jerk, and interquartile range. The calculated features were used as input to develop a machine learning classifier for pre-impact fall detection algorithms (Figure 2B).

2) Clinical Data:

The correlation among physical assessment subcategories and survey's sub-scores recorded at the initial visit in the community deployment pilot study were evaluated using a Pearson correlation matrix. Principal component analysis (PCA) was then applied to combine highly correlated standardized scores and surveys into single-dimensional principal component variables. To ensure maximal preservation of variability among baseline measures, only principal components explaining over 85% of the variance were included in subsequent analysis. All principal components were positively correlated with their variables and listed in Table III.

E. Machine Learning Models

To achieve both objectives of this study, three binary classification machine learning algorithms were trained to evaluate 1) the falling risk, 2) performance of the fall detection algorithm and 3) responder status of participants (Figure 2C). Four outcomes of F1 score, precision, recall and accuracy were reported separately for each logistic regression model.

1) Fall Risk Machine Learning Model:

The first machine-learning model, called the "Fall Risk Model" aimed to predict the risk of future falls over a six-month period. Of the recruited participants, those who did not complete the full duration of the study (N = 2) were excluded from this model. Participants who experienced at least one fall during the study were labeled as 'fallers' (N = 14; PD = 8, stroke = 6), while those with no experienced falls were labeled as 'non-fallers' (N = 6; PD = 2, Stroke = 4). A logistic regression model, with 1,000 iterations and L2 regularization, was trained using only the data from the clinical data from the first visit, including physical assessment, survey scores and their principal components, to predict the participants' faller status (Faller/ Non-faller; Figure 2D). To maintain balanced training, the dataset was limited to all unique combinations of six fallers paired with the six non-fallers. The model was validated using a leave-one-out cross-validation approach with the average F1 score, recall, and precision reported as measures of performance. In this model, recall is the average measure of the proportion of actual "fallers" or "non-fallers" that were correctly identified by the model. It reflects how well the model captures each class, whether it is "fallers" or "non-fallers." Precision measures the ratio of correctly predicted "fallers" or "non-fallers" to all instances predicted as that class. The F1 score and accuracy are measures that evaluate the model's performance across both "fallers" and "non-fallers." F1 score is more elaborated in (1) and accuracy is the total number of correct predictions over the total number of predictions made in the model.

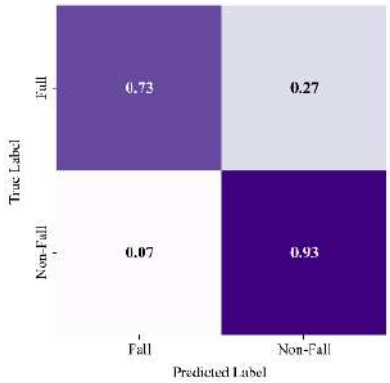

Fig. 2. Confusion matrix demonstrating the prediction performance of the fall detection algorithm (Table IV, model 2) on detecting fall and non-fall windows. Values in the top row represent the proportions of correctly and incorrectly predicted fall incidents, while values in the bottom row represent the proportions for correctly and incorrectly predicted non-fall incidents.

$$F1\ Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (1)$$

2) Fall Detection Machine Learning Model:

The second machine learning model called the "Fall Detection Model" was developed to evaluate the performance of the pre-impact fall detection algorithm for each participant (Figure 2D). IMU features were calculated from 2436 fall windows and 3004 non-fall windows in the in-laboratory dataset [14]. These features were then used to train a logistic regression classification model with class weighting, a 70%-30% train-test split, and 10-fold stratified cross-validation grouped by participants. This trained model was then tested on data from community deployment participants who

experienced real-world falls while wearing the airbag device (N = 9; PD = 5, stroke = 4), with IMU features calculated from 96 fall windows and 48 non-fall windows. To address the low number of reported real-world non-fall ADLs and maintain label balance in the test dataset, non-fall ADLs from participants' first in-lab visit (1231 samples) were incorporated into the test data. These non-fall samples were randomly under-sampled across participants to reach the 96 non-fall ADL samples and combined with their real-world fall samples in the test set. The predicted labels of the model were grouped by participants and recall and precision rate for each participant were calculated separately. In this model, recall is the average measure of the proportion of actual "fall" or "non-fall" windows that were correctly identified and precision measures the ratio of correctly predicted "fall" or "non-fall" windows to all instances predicted as that class.

3) Responder Machine Learning Model:

The third machine learning model, called the "Responder Model" was developed to predict if the fall Detection Model would work well for each individual participant. To begin, we used the F1 scores calculated for each participant to categorize them into responder and non-responder groups (Figure 2D). This score is a measure of how accurately the fall detection algorithm performed for each individual. To set a classification threshold for responder and non-responder status, we used the median performance (F1 score = 0.90) across all participants, with those scoring above or equal the median labeled as responders (N = 5) and those below as non-responders (N = 4). The third logistic regression model was trained on the physical assessments, survey scores (Table II), and their principal component variables to predict the responder status of each participant. A leave-one-out cross-validation approach was used to validate the results, with the F1 score, recall and precision metrics reported as performance measures of the model. All IMU features, machine learning and PCA analyses were developed and processed in Python (3.10.11).

III. Results

Twenty of our participants successfully finished the study period and were included in the fall risk prediction model. Nine of our participants experienced at least one fall while wearing the wearable airbag device and were included in the responder prediction model.

A. Fall Risk Prediction

A total of 3003 logistic regression models were run, each using a unique combination of four fallers and all three non-faller participants. Performance metrics and the most important predictors were averaged across these iterations. The logistic regression algorithm achieved a high performance in distinguishing fallers from non-fallers (Table IV). The four most significant predictors of faller status were 1) a lower PCA 1 score (Table III; non-faller: 0.42 ± 1.07, faller: -0.12 ± 1.03; values represent average ± standard deviation), 2) higher FGA scores in the stairs task (non-faller: 1.2 ± 0.7, faller: 1.6 ± 0.6), 3) lower scores in postural control domain of the Balance Evaluation System assessment (non-faller: 3.0 ± 2.4, faller: 1.9 ± 2.1), and 4) higher scores in sensory orientation domain of the Balance Evaluation System assessment (non-faller: 3.2 ± 1.8, faller: 3.9 ± 2.3).

B. Fall Detection Prediction

The calculated features from 192 real-world fall and non-fall windows were tested in a pre-trained logistic regression model on the in-laboratory collected data from [14]. The model effectively distinguished fall event windows from non-fall event windows (Table IV). The confusion matrix of all 196 windows is demonstrated in Figure 3. We calculated F1 scores for each participant separately based on the proportion of true and false predictions.

C. Responder Prediction

Using the median performance threshold (F1 score = 0.90), we grouped F1 score of individuals into four participants as non-responders (F1 score < 0.90; PD = 2, stroke = 2) and five as responders (F1 score ≥ 0.90; PD = 3, stroke = 2). A logistic regression model was trained on clinical features including physical assessments, survey scores (Table II), and their principal component variables (Table III) to distinguish responder from non-responder participants. This model achieved a high performance in distinguishing responders from non-responders (Table IV) and four key predictors: 1) lower PCA 2 scores (responders = -0.27 ± 1.03, non-responders = 0.33 ± 0.98), 2) higher scores in gait and pivoting as assessed by the FGA (responders = 1.6 ± 1.5, non-responders = 0.5 ± 0.6), 3) higher PCA 5 scores (responders = 0.36 ± 0.95, non-responders = -0.46 ± 0.98), and 4) higher PCA 3 scores (responders = 0.3 ± 1.3, non-responders = -0.4 ± 0.2).

IV. Discussion

The objective of this pilot study was to enhance the effectiveness of pre-impact fall detection wearable airbag devices in patients with neurological diseases by identifying individuals with high risk of falling and predicting the likelihood they will respond well to the fall detection algorithm. Our results show that baseline clinical measures and survey scores can predict the future fall risk and differentiate those who may receive the greatest benefit from various wearable devices in patients with Parkinson's disease and stroke. This approach allows for selecting responders–

TABLE IV. Performance Outcomes of the Machine Learning Algorithms

Model	Target labels	F1 Score	Precision	Recall	Accuracy
Fall Risk	"Faller" - "Non-faller"	0.76 ± 0.13[a]	0.75 ± 0.15[a]	0.79 ± 0.14[a]	0.77 ± 0.12[a]
Fall Detection	"Fall" - "Non-fall"	0.83	0.83	0.84	0.83
Responder	"Responder" - "Non-responder"	0.75	1.00	0.60	0.78

[a.] Data represent average ± standard deviation

those who have higher fall risk and benefit most from the device–and maximizing hip injury mitigation.

A. Fall Risk Prediction

Our pilot results indicate subtle differences in baseline physical assessments and clinical survey scores that can help identify individuals with a high risk of falling. Consistent with the previous studies, our findings show gait and balance outcomes as key predictors of fall risk [25], [26]. Our results showed that patients with Parkinson's disease or chronic stroke who exhibit less impairment in gait and balance abilities appear to have higher fall risk, possibly due to increased level of physical activity and greater chance of experiencing falls. This idea was also supported by two of our non-faller participants who showed a greater step count in the 10-meter walking tasks and a much lower daily step count, suggesting low balance confidence and a possible tendency to adopt a more cautious gait and sedentary lifestyle.

B. Responder Prediction

Further analysis of high fall risk patients with Parkinson's disease or stroke showed distinct differences in fall and non-fall patterns as captured by the IMU. Our fall detection algorithm was trained on in-laboratory fall data and tested on real-world fall data and could distinguish fall and non-fall patterns with a F1 score $\geq$ 0.90 for almost half of our participants. Based on the previous findings on variations in fall patterns among stroke patients with different impairment sides and severities [19], we suggested that different fall detection algorithms on wearable devices should be prescribed for different users to maximize their effectiveness. Our developed responder identification algorithm identified users for whom the fall detection algorithm performs above 0.90 with an F1 score of 0.75 and accuracy of 0.78. Participants with PD or stroke were distributed almost equally within each group. The average walking velocities for responders and non-responders are 0.6 m/s and 0.7 m/s, respectively, categorizing stroke patients as limited community ambulators in both groups [27]. Although walking speed fluctuates over time in PD, these responder and non-responder velocities are often categorized as below the threshold for community ambulation in the PD population as well [28].

The responder group reported less impairment in gait and balance scores (measured by FGA scores). Despite showing less impairment in gait and balance, they showed lower quality of life scores (WHOQOL) across four out of five life domains. This finding may show an increased awareness of one's own risk of falling, which could affect quality of life [29]. It also aligns with the previous fall risk prediction model, where less impairment correlated with a higher fall risk, likely due to increase physical activity and associated fall risks. In general, we expect that the more typical fall patterns experience by the responder group allowed the pre-trained fall detection algorithm to better distinguish falls from non-fall incidents.

This pilot study has some limitations. First, all three models presented in Table IV were developed using a limited sample size, due to both a small number of participants, and the fact we were only able to record data from real falls that were detected by the wearable system. These limitations create bias in the system, as the models were only validated on the data available from our subjects. It is important to note that the relations between important predictors of the models may not be linear and depend on the sample size. To enhance fall risk prediction and optimize wearable device prescriptions for specific neurological conditions, future studies should include larger and more diverse participant groups with varying collected data from demographics, impairment levels, physical, and cognitive abilities, and may consider a specialized detection algorithm with a very high recall rate (even at the cost of lowered precision). Second, due to the small sample size and the range of expected falls and near-fall incidents among participants in the real-world environment, we had to combine some in-laboratory ADL data with real-world non-fall incidents. It is unclear to what extent ADLs (such as walking or sit to stand) differ across laboratory and real-world settings [30], [31], and therefore future studies should aim to collect more near-fall or non-fall ADL data in a real-world environment for better representation. We believe that the results shown here demonstrate the potential for this technique to predict both fallers and responders, making us optimistic that addressing the limitations above will help to create a more generalizable model.

As a further limitation, recording falls in the real-world is challenging. To increase the chance of recording falls, we recruited subjects with an increased risk of falls by using at least one self-reported fall in the past six months as an inclusion criteria. This study primarily focused on demonstrating the approach of classifying wearable airbag users based on future fall likelihood and response rate. In addition to optimizing user classification, it is also important to consider how consistently individuals will use the device (compliance). While we believe the increased performance of the fall detection algorithm will increase the compliance rates of users, compliance will still be a challenge with any wearable device. Therefore, it is crucial that future studies work to address this issue to capture and protect from as many falls as possible. Lastly, both the responder classification and fall risk prediction algorithms were trained using six months of participant collected data and treat all outcomes as binary. Future studies should aim to explore these categorizations as continuous spectrum–ranging from very low to very high fall risk–and evaluate the device's responsiveness across varying fall types and risk levels to better adjust interventions.

V. Conclusion

By integrating physical, cognitive, and social factors prior to utilizing the fall detection algorithms, we could identify users who are likely to fall, and for whom the fall detection algorithm may perform better than others. This approach allows for designing neurological-specific algorithms, and maximizing the benefits of wearable airbag devices by focusing on 'responders' whose fall patterns can easily be detected and utilizing alternative fall detection algorithms on 'non-responders'. This strategic identification not only enhances device effectiveness but also supports more targeted fall detection algorithms and efficient fall prevention strategies.

ACKNOWLEDGMENT

We would like to greatly appreciate Kavya Sudhir, Jonathan Mendley, and Olivia K. Botonis for helping us through this project, the Wolk Company for their hardware and firmware support and all our participants for their time and help.

MyoBack: A Musculoskeletal Model of the Human Back with Integrated Exoskeleton

Rohan Walia*[1], Morgane Billot*[1], Kevin Garzon-Aguirre*[1],
Swathika Subramanian[2], Huiyi Wang[1,3], Mohamed Irfan Refai[2], Guillaume Durandau[1,3]

***Abstract*— Given the challenges of real-life experimentation, musculoskeletal simulation models could become essential in biomedical research. This is especially critical for the human back, a key structure involved in daily movements, where modeling and simulation could streamline design and support the development of treatments and robotic rehabilitation techniques, such as exoskeletons. However, musculoskeletal simulation engines are computationally demanding and lack contact dynamics, restricting current models' use in studying prolonged behaviors or optimizing system design while maintaining physiological accuracy. To overcome this limitation, this work proposes MyoBack, a human back model part of the MyoSuite framework relying on the physics engine MuJoCo. This model is derived from a physiologically accurate model built in the state-of-the-art musculoskeletal simulation software OpenSim and replicates the latter's kinematic properties accurately, with some discrepancies regarding muscle dynamics stemming from engine differences. The MyoBack model was also validated empirically by integrating a passive back exoskeleton in simulation and comparing forces exerted on the back with values from experimental trials. Over different tasks, the model reproduced measured force progressions well, resulting in RMSE = 11% for a stoop and RMSE = 16% for a squat motion pattern relative to peak forces. The MyoBack model can be accessed here: https://github.com/rohwalia/MyoBack**

I. INTRODUCTION

Human biomechanics is a rapidly growing field that attempts to understand the intricate interplay between biology and mechanics in human movement, structure, and function. In particular, modeling the back presents significant challenges due to its complex anatomy and the delicate balance required to maintain posture and mobility. The back contributes to everyday movements such as running or lifting objects [1], [2], [3], [4]. Exactly these kinds of common tasks are affected by musculoskeletal disorders (MSDs) prevalent in around 20% of the global population [5], much of it work-related [6], [7] and occurring primarily in the lower back [8]. These issues, in turn, can lead to other complications such as gait disorders, particularly in the elderly [9], limiting quality of life notably.

To alleviate these problems, assistance systems such as exoskeletons are becoming increasingly widespread and hold significant potential to enhance human mobility [10]. However, their development is human resource-intensive and time-consuming [11], [12], [10]. Integrating design and testing environments through modeling and simulation can significantly enhance efficiency, reducing time and hardware costs [13], [14]. Simulation also enables diverse and repeatable testing for optimal system performance. Hence, reliable human body models are essential to better understand musculoskeletal dynamics, identify the causes of MSDs, assess risks of repetitive or prolonged actions, and aid in the customization of medical devices for patient-specific treatment solutions.

Currently, a wide variety of human models are available. For instance, a relatively simple representation of the human body is the Human Dynamic Model [15] which simulates movements based on motion capture data. This model incorporates sufficient degrees of freedom to reproduce complex movements and approximate mechanical energy expenditure during tasks. On the other hand, there are physics-based musculoskeletal simulation engines such as OpenSim [16], AnyBody [17], and SIMM [18] which focus on making detailed and physiologically accurate models of the musculoskeletal system. These tools are extensively used in human neuromechanical control, human-robot interaction, and rehabilitation. Several of these human body models already include the back and have been used in a variety of research projects, for example, to study the effect of unilateral knee extension restriction on the back during gait [19] or to analyze the biomechanical effects of different bag-carrying styles on the back region [20], among others [21], [22], [23].

These musculoskeletal simulation engines are computationally intensive and offer limited support for complex contact interactions. Consequently, most current human body models are impractical for long-term simulations or high-frequency task repetitions while maintaining physiological accuracy. As a result, they are unsuitable for studying long-term behavior or for optimization purposes in system design. Notably, the proprietary software Hyfydy [24] provides a valid approach to this problem. Still, since it is not open-source, using it for custom use cases (e.g., testing personal exoskeleton) in different settings, such as research and industrial, might be difficult. To meet the needs of physiological accuracy, contact dynamics, speed, and accessibility, the use of MuJoCo (Multi-Joint dynamics with Contact) [25] is particularly relevant. MuJoCo is a state-of-the-art open-source physics engine designed for model-based control, offering efficient computational capabilities for multi-joint dynamics and contact mechanics. Importantly,

[3]CRIR, Jewish Rehabilitation Hospital, Canada

it has the capacity to simulate muscle dynamics while supporting contact-rich interactions. In particular, MyoSuite [26], a software framework based on MuJoCo, is more than two orders of magnitude faster than state-of-the-art musculoskeletal models. This advantage is particularly crucial for highly detailed musculoskeletal models, including our model which features a tenfold increase in muscle patterning and joint degrees of freedom complexity with 210 actuators [27]. To date, various models have been implemented (e.g., arm, leg) but not yet a model of the back. Integrating a back model into MyoSuite would, therefore, enable complex human movements involving the back to be simulated quickly and accurately. This has huge potential in the testing and development of exoskeletons and could be beneficial in rehabilitation, ergonomic design, and personalized healthcare solutions.

Therefore, we developed MyoBack, a back model part of the MyoSuite framework based on an existing OpenSim model [28]. Section II details how the MyoBack model is created and validated by comparing the OpenSim and the derived MuJoCo model with respect to kinematics and dynamics. Furthermore, a passive exoskeleton was developed within the simulation to validate the back model against empirical data. Section III explores the impact of the passive exoskeleton on various back-involved movements by integrating it with the back model and comparing the simulation outputs to experimental results.

II. METHODS

This section first describes the musculoskeletal model conversion tool [27], MyoConverter, that was used to convert the back model from Opensim to MuJoCo. Then, the manual tuning performed with the output of the conversion tool to complete the final MyoSuite back model is explained. Finally, it is outlined how a passive exoskeleton is added to the back model. This is the basis for experimental validation following the setup and protocol developed in section III.

A. MyoConverter

We derive our MyoSuite back model (.xml) from an OpenSim model (.osim) [28] using MyoConverter. This conversion tool optimizes muscle kinematics and kinetics and has been tested extensively on other musculoskeletal models such as neck, lower limb and arm [27]. The OpenSim model contains 210 muscle-tendon units (MTUs) and 18 joints. The model can be controlled by 3 "virtual" DoFs that map to the real joints: flexion extension, lateral bending and axial rotation. It has also been incorporated into a full-body lumbar spine model [29] with a general validation regarding model parameters and muscle output. In addition, a slightly adapted model [30] was explicitly validated for lifting motions, demonstrating its suitability to evaluate changes in lumbar loading during lifting. Given its extensive validation, particularly in terms of muscle activation and joint moments, the OpenSim model is regarded as the state-of-the-art reference, and the goal of MyoConverter is to align the MuJoCo model to it as closely as possible.

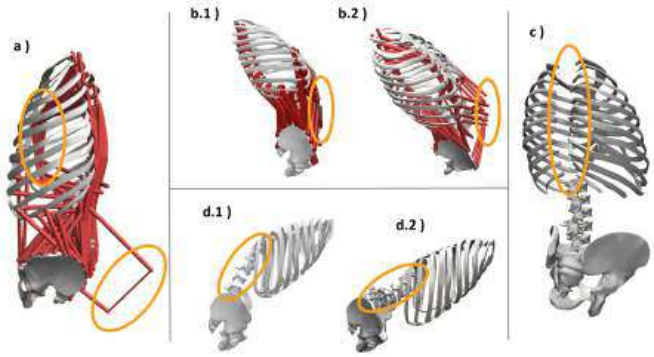
The conversion tool consists of three steps:

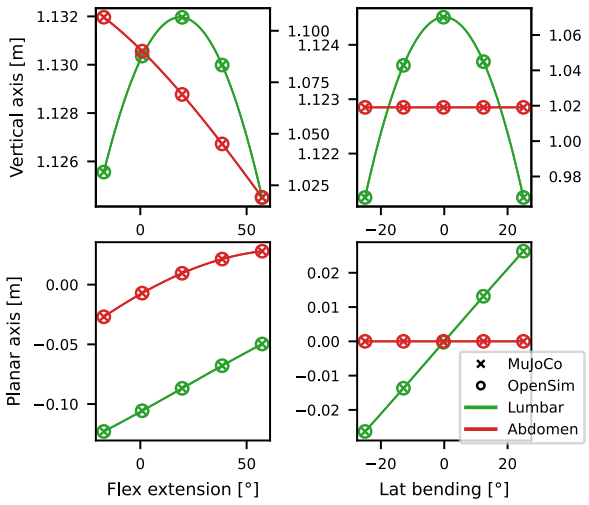
- Step 1 – Geometry Conversion: parse multi-body kinematic tree containing the fundamental elements of musculoskeletal models (body segments, joints, muscles, wrapping bodies, etc.) from OpenSim into MuJoCo.
- Step 2 – Wrapping optimization: optimize wrapping constraints to guarantee that the muscle pathways in MuJoCo are physiologically reasonable like in OpenSim while accounting for the fact that MuJoCo's wrapping surfaces are simple geometric objects (e.g., spheres, cylinders), which prevents an exact replication of OpenSim muscle pathways but enhances computational efficiency, and check the resulting moment arms exerted by each muscle.
- Step 3 – Force property optimization: optimize muscle force parameters in MuJoCo to approximate the OpenSim model's force curves and check the force-length-activation.

The conversion tool needed to be modified to convert the back model. Mainly, the handling of edge cases occurring in the OpenSim model that had not been implemented in MyoConverter, e.g., coupled constraints of the *PiecewiseLinearFunction* type, was added.

B. MuJoCo: MyoBack

The output model from MyoConverter had a few issues. The wrapping pathways of some muscles around a geometric body for specific joint configurations were discontinuous, leading to discrete jumps in muscle-tendon length (Fig.1a). Also, MyoConverter did not parse some geometries correctly from the OpenSim model (Fig.1c). The mapping of the 3 "virtual" DoFs to the real joints of the model had to be fixed as well (Fig.1b,d) by changing the equality constraints [31].





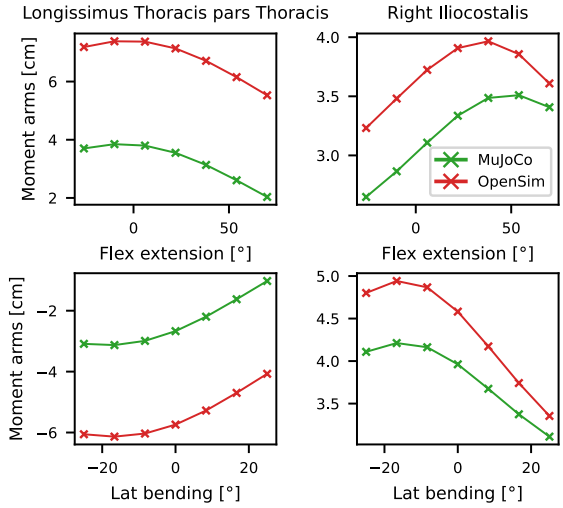


Fig. 1: Model problems after conversion a) Jumping muscles b) Immobile abdomen 1) Opensim 2) MuJoCo c) Non-curved spine 1) Opensim 2) MuJoCo d) Absent thoracic vertebrae.

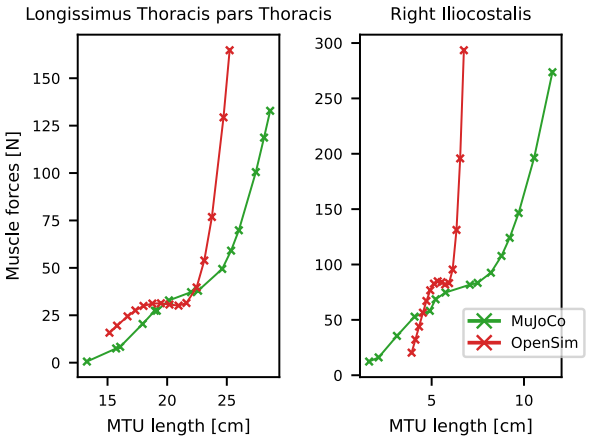

This back model was compared to the OpenSim model with respect to kinematics by observing end point positions (Fig.2a), moment arms exerted by muscles on joints (Fig.2b) and force-length-activation (Fig.2c). The results of this comparison are shown for relevant geometric bodies in the kinematic chain for the former and representative back muscles for the latter two.

(c) Observing force-length activation curves for the Longissimus Thoracis pars Thoracis and Right Iliocostalis.

Fig. 2: Comparative analysis of the MyoSuite back model and the reference OpenSim model.

C. MuJoCo: MyoBack + exoskeleton

We validated the MyoBack model by conducting trials with a passive exoskeleton. The aim was to compare the forces exerted by the exoskeleton in simulation and experiments for lifting tasks. We modeled the passive exoskeleton, the Auxivo Liftsuit 1.0 (Auxivo, Schwerzenbach, Switzerland) [32], in MuJoCo. A simple model of the passive exoskeleton was implemented respecting the mass distribution and elastic properties of the exoskeleton. For the latter, the two main elastic bands on the back were considered. The elastic bands of the passive exoskeleton were modeled as tendons [33] attached at the level of the 5th thoracic rib and the posterior superior iliac spine (see Figure 3), corresponding to the actual Auxivo elastic band positions. The tendons' stiffness was calculated to produce an equivalent force to that of the elastic bands. The Auxivo Liftsuit has previously been experimentally benchmarked, where the stiffness of its elastic bands was measured. Nonlinear relationships were identified between the force exerted by the elastic bands and their elongation during lifting and lowering [34]. However, in MuJoCo, only a constant stiffness can be implemented. The nonlinear functions were thus approximated to a unique linear function with stiffness $K_{Auxivo} = F/\Delta L$ determined to be $K_{Auxivo} = 1527.5N/m$. Due to the different resting lengths of the elastic band in the Auxivo Liftsuit and the tendons in the back model, the value for K_{Auxivo} had to be scaled accordingly and the stiffness obtained for the tendons is $K_{MuJoCo} = 526.4N/m$.

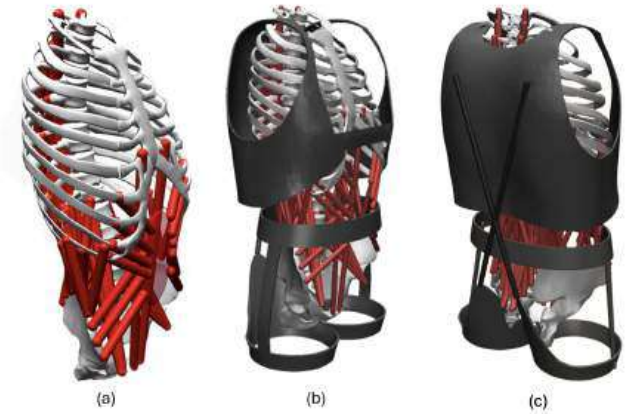

Fig. 3: (a) Back model in OpenSim. (b) MyoBack model with exosuit in MuJoCo. (c) Backward view of MyoBack model with exosuit.

The visual meshes of the exoskeleton were built using 3D modeling software separately and then added to the model. The complete MyoBack model is shown in Figure 3. For wider application, a separate version of the MyoBack model is available, with legs incorporated from the MyoLegs model of the MyoSuite framework [35], [36].

III. EXPERIMENTS

The Auxivo Liftsuit [32] was used to validate the back model. This device, designed to support lifting tasks by

reducing strain on the back and hip muscles, helps users handle loads between 5 and 20 kg with less physical stress. Users reported noticeable reductions in muscle strain and an overall improvement in lifting ease while wearing the LiftSuit [37]. Although not unique in the market—other devices like the Darwing Hakobelude (Daiya Industry Co., Ltd., Okayama, Japan) [38] offer similar support—the LiftSuit has been studied in several research contexts. User reports remain promising for its effectiveness, among other settings, in industrial applications [39], [40], [41].

A. Sensoring the exosuit

First, load cells were integrated into the elastic bands of the Auxivo to measure the actual forces applied by the exosuit onto the user, as shown in Figure 4. One end of the load cell was attached to the metal part of the elastic band and the other to the straps.

Fig. 4: a) Load cell attached in series to one end of the elastic band situated in Auxivo b) Auxivo exosuit with 2 load cells attached to each of the elastic bands. The red arrows on the elastic bands indicate the line of action of stretch force and the red dots indicate the positions of markers at the anchoring points of the elastic bands on the exosuits.

The load cells, placed in series with the elastic bands, measured the deformation of these bands as voltages. These were amplified and digitized before being processed by an Arduino microcontroller. A mapping between the forces exerted and the amplified voltages was known through prior calibration.

B. Participants

A sample of 9 participants (height in cm: 173.8 ± 11.1, weight in kg: 73.4 ± 16.5, age in years: 23.5 ± 1.4) with no previous experience with exosuits and with no history of back injuries were recruited for the study. All participants provided informed consent. The study was approved by the University of Twente's ethical review board (Ref. number: 240424).

C. Apparatus

For this study, data from load cells, reflective markers (Qualisys Medical AB, Gothenburg, Sweden), and IMUs (Movella, Enschede, Netherlands) were used. 63 optical markers were placed on the participant. 56 markers on bony landmarks and body segments and 7 on the exosuit as in [34]. 17 full-body IMU sensors were placed on the subject. Data from IMUs was visualized to examine flexion extension and knee joint angles during static hold trials. Marker data was sampled at 128 Hz and load cell data at 80 Hz. The data from markers was synchronized with the Qualisys Track Manager. This was then manually synchronized with the load cells using a switch during the trials.

D. Experimental protocol

First, the subjects performed a maximum voluntary contraction (MVC) trial to establish a baseline measurement of each muscle strength. To acquire the MVC for back muscles, the participants were asked to lie on their stomachs and perform reverse crunches against resistance, and vocal motivation was used to ask the participants to contract their muscles as much as possible. Following this, exosuits were worn by the participants and adjusted according to individual user specifications. The participants were asked to perform the following tasks commonly linked with industrial tasks [42].

1) *Static hold trials:* Participants were asked to maintain stoop posture at predefined flexion extension angles of 40°, 60°, and 80° for 3 seconds before returning to an upright posture. Then, participants were asked to perform squats at predefined knee flexion angles of 70°, 90°, and 110°, holding the position for 3 seconds before returning to the initial upright position. Both squatting and stooping movements were repeated three times each. The participants used data from IMUs as visual feedback to maintain the required joint angles.
2) *Dynamic trials*: Participants were instructed to stoop by flexing their trunk to lift an empty box from a table in front of them, then return to an upright posture. They then stooped again to place the box back on the table. Both the squatting and stooping movements were performed at a pace of 40 beats per minute using a metronome, with five repetitions for each movement.

E. Data analysis

The load cell data was filtered by a zero-lag second-order Butterworth low pass filter of 6Hz. Forces from load cells on both sides of the exosuits were averaged across all 9 participants. To obtain the resultant force acting on the trunk of the user, the measured interaction forces of the right and left elastic bands were summed.

Raw marker data was filtered by a zero-lag second-order Butterworth low pass filter of 6Hz. Marker data was used to compute the stretch forces of elastic bands and joint angles of flexion extension and knee. The previous approach described in [34] for the estimation of forces using markers on the exosuits, as shown in Figure 4, was implemented. In doing so, the change in distance between the markers placed on either end of each elastic band from when the participant was upright was considered band elongation. This value was fed to two polynomial equations representing the loading (flexion) and unloading (extension) phase of a task cycle to

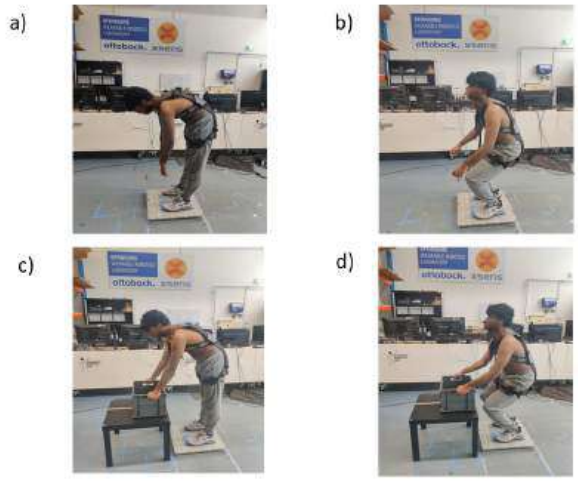

Fig. 5: a) Static stoop: Subject performing forward bend with minimal knee flexion b) Static squat: Subject performing squat with minimal trunk flexion. c) Dynamic stoop: Subject performing stoop lifting technique with a box d) Dynamic squat: Subject performing squat lifting technique with a box.

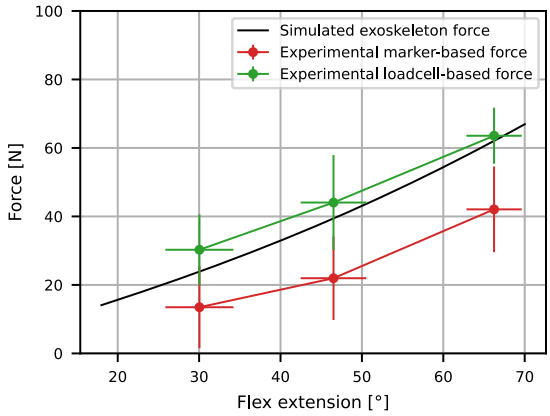
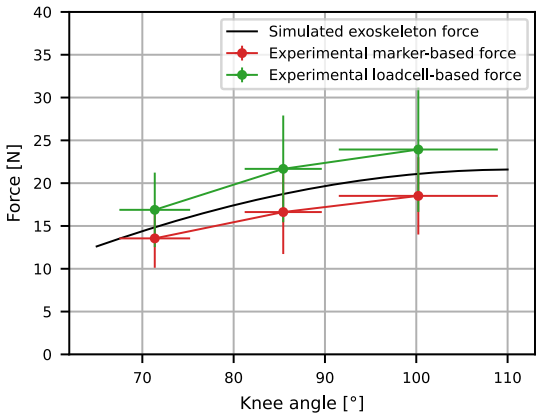
estimate forces for each exosuit. The estimated forces from the two elastic bands were summed and averaged across all participants for both exosuits. This conventional marker-based method for determining stretch forces was employed alongside the original sensor-based approach of integrating load cells into an exosuit for verification.

The flexion extension and knee joint angles were computed using marker trajectories in the 2-D sagittal plane. For flexion extension, the angle between the vector joining the markers C7 vertebra and right posterior superior iliac and an arbitrary vector perpendicular to the ground was measured. Similarly, knee flexion angles were computed using the two vectors joining right anterior superior iliac-right lateral femoral epicondyl and right lateral femoral epicondyl-right lateral malleolus.



F. Simulation

The motion patterns of the experimental trials were replicated in simulation using the MyoBack model with the exoskeleton. For the static hold trials, a sweep was done over the two relevant parameters: flexion extension angle and knee flexion angle. The latter needs to be mapped to the appropriate model joints using marker data to achieve a realistic squat position with the subject leaning forward. For the dynamic trials, marker data was again employed to obtain the joint angles and simulate the complete motion cycle of the stoop/squat.

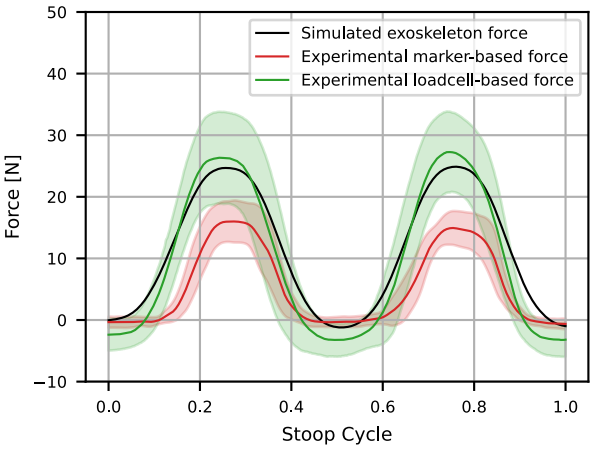


IV. Results

A. Static hold trials

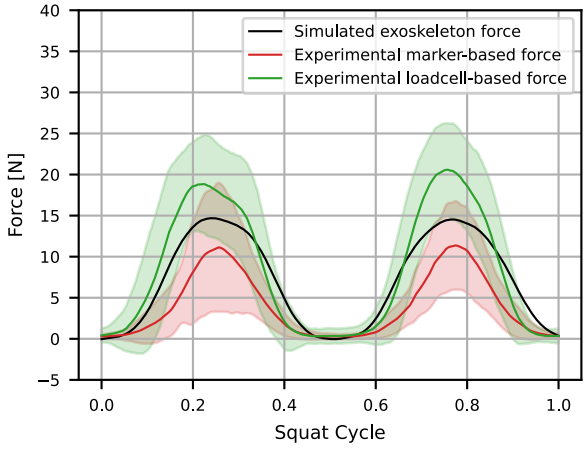
In the static stoop results (Fig.6a), the flexion extension angles executed by participants ($\overline{\mathrm{SD}} = 3.9°$) were consistently lower than the predefined values. The MyoBack model with the exoskeleton shows a good reproduction of exoskeleton forces exerted on the human body, notably better with force data derived directly from the load cell sensors ($\mathrm{RMSE_{lc}} = 4.7\mathrm{N}$ with $\overline{\mathrm{SD}}_{\mathrm{lc}} = 10.8\mathrm{N}$) than the marker data ($\mathrm{RMSE_m} = 16.4\mathrm{N}$ with $\overline{\mathrm{SD}}_{\mathrm{m}} = 12.2\mathrm{N}$). In the case of static squat (Fig.6b), the knee flexion angles match more accurately with the intended ones. However, the uncertainty increases for a deeper squat regarding the knee flexion angle ($\widehat{\mathrm{SD}} = 8.7°$) and the measured forces ($\widehat{\mathrm{SD}}_{\mathrm{lc}} = 7.3\mathrm{N}$, $\widehat{\mathrm{SD}}_{\mathrm{m}} = 4.9\mathrm{N}$). Also, here the simulated exoskeleton forces follow the experimental trend well ($\mathrm{RMSE_{lc}} = 2.6\mathrm{N}$, $\mathrm{RMSE_m} = 2.1\mathrm{N}$).

(a) Static stoop.



(b) Static squat.

Fig. 6: Comparison of experimental static trial exoskeleton force data for stoop and squat motion patterns, derived from load cells and indirectly from markers, with simulation data.



B. Dynamic trials

To allow for a better comparison, the data was normalized to the percentage of a stoop/squat cycle. For the stoop cycle (Fig.7a), the force data derived from the load cells ($\overline{\mathrm{SD}}_{\mathrm{lc}} = 5.6\mathrm{N}$) and the markers ($\overline{\mathrm{SD}}_{\mathrm{m}} = 2.3\mathrm{N}$) shows similar behavior to the static trials with the latter being consistently lower than the former and the simulated exoskeleton forces matching the former better ($\mathrm{RMSE_{lc}} = 2.8\mathrm{N}$, $\mathrm{RMSE_m} = 7.2\mathrm{N}$). Resembling the static trials, the squat cycle (Fig.7b) shows high uncertainties ($\overline{\mathrm{SD}}_{\mathrm{lc}} = 4.2\mathrm{N}$, $\overline{\mathrm{SD}}_{\mathrm{m}} = 2.7\mathrm{N}$). When the squat cycle is simulated using the MyoBack model with the exoskeleton, the reproduced force progressions correlate

well with the experimental ones ($RMSE_{lc} = 2.9N$, $RMSE_{m} = 3.8N$).

V. Discussion and Conclusions

This study introduced the MyoBack model, a human back model part of the MyoSuite framework, derived from a physiologically accurate OpenSim model. The two models were compared with respect to kinematics, moment arms exerted by the muscles depending directly on the muscle pathways and the force-length-activation of muscles to ensure the accuracy of the derived model. No discrepancies were observed for the former, suggesting that the geometries and joint relations have been transferred successfully to the MyoBack model. However, regarding the latter two deviations can be seen. This is consistent with OpenSim models of other body parts with similar complexity (number of muscles and DoFs) converted using the MyoConverter, such as the neck model (72 MTUs and 6 joints) [27].

The observed differences stem from the fundamental disparities in how MuJoCo and OpenSim handle physical constraints, such as wrapping surfaces and geometry. OpenSim provides a detailed approach to muscle pathway constraints through specialized wrapping surfaces, while MuJoCo is limited to simple geometries and constraint handling methods. Hence, although MyoConverter facilitated the model conversion, it reached its optimization limit for muscle pathways, leaving some differences unaddressed. Importantly, the direction and trend of the moment arms match well between the two models and the fact that there are no discrete jumps. Also, the muscles themselves are modeled differently in MuJoCo and OpenSim. The possible MTU length may vary for the force-length activation, given that the muscle pathways are different in the two models. But notably, the force exerted at the relative length of the muscle is the same, and the maximum muscle force matches well. This allows for simulation with the MyoBack model with reasonably accurate results.

For empirical validation, the Auxivo Liftsuit, a passive exoskeleton, was modeled in MuJoCo and added to the MyoBack model. Force data derived from load cells and marker information were successfully compared with simulated exoskeleton forces acting on the human body in the context of stoop/squat movements. However, the study's major weaknesses include a small sample size of nine participants and the use of a standard-sized exosuit, which did not account for individual differences in body size. This led to variable exosuit forces across participants. Additionally, variations in measured flexion-extension angles could be attributed to potential misplacement or slippage of IMU sensors on the lumbar region during repeated or maximum forward bending. Furthermore, the placement of pelvis markers on the exosuit rather than on bony landmarks could have contributed to inaccuracies in computed angles.

Variations in knee flexion angles might also result from offsets in the IMUs placed on the thigh and shank. The significant discrepancies between forces derived from load cells and markers requires further investigation. Notably, load cell data, which directly measures force within the system, is likely to be more reliable. In contrast, markers are prone to slippage over the duration of trials and may be placed inconsistently among participants with varying anatomies.

Future work involves the analysis of EMG data collected from experimental trials, which will enable a more comprehensive validation of muscle activation levels within the MyoBack model. Currently, the validation considers only kinematics and muscle pathways. Still, exploring whether a reinforcement learning (RL) agent trained to perform specific static and dynamic tasks will exhibit activation patterns similar to those observed in human trials will be informative. The MyoBack model has the potential to extend its applications to various aspects of human locomotion and agility, including object lifting, balancing, and running, which remain unexplored in the current study. Additionally, integrating this model with both active and passive exoskeletons across the full body could further be used for rehabilitation and industrial design purposes and benefit populations such as the elderly and workers.

***Abstract*—Bipedal gait is inherently unstable, requiring a complex interplay between foot placement and centre of mass (CoM) movement to maintain balance. While various factors are known to impact walking balance, few studies have explored the specific effects of functional asymmetry on lateral stability. This study investigates how step length, step width, and CoM adaptations impact lateral gait stability in healthy young adults walking with and without a functional asymmetry induced by fully extending the left knee. The results show that step length remains unaffected by functional asymmetry regardless of speed, while step width increases under the constraint. This adjustment increases the base of support; however, the concurrent increase in lateral CoM movement reduces overall lateral stability. These findings offer valuable insights into fundamental gait adaptation and stability mechanisms, with potential implications for designing rehabilitation strategies for individuals with gait asymmetry.**

***Index Terms*—functional gait asymmetry, margin of stability, step length, step width, centre of mass.**

I. Introduction

The ability to maintain stability (i.e., avoid falling) is fundamental to human walking. This requires humans to keep their centre of mass (CoM) within a stable base of support (BoS) formed by the contact with the ground. Due to our CoM being located high above a relatively narrow BoS, bipedal gait is inherently unstable, necessitating multiple strategies to control balance during walking [1].

Precise foot placement has been identified as the primary mechanism for maintaining bipedal stability [2]. Foot placement control uses different mechanisms in the sagittal and frontal planes, but operates simultaneously and seemingly with a degree of interaction [2]–[4]. In the sagittal plane, anterior-posterior (AP) foot placement (i.e., step length, SL) primarily drives forward progression and contributes less directly to stability [4]. In contrast, medio-lateral (ML) stability in the frontal plane requires active control [3], which can be achieved either by modulating lateral foot placement (i.e., step width, SW) during the swing phase to adjust the next step's BoS [5], [6] or by managing CoM during the stance phase [7].

This work was supported by the Australian Research Council's Discovery Project scheme (DP190100916).

While often studied separately, SW modulation and CoM movement are closely linked. Variations in CoM kinematics influence variations in SW [8], and the CoM trajectory during stance reliably predicts the next foot position variance [9]. This intricate interaction extends beyond lateral balance, as increased balance control – such as through enforced gait patterns – was shown to impose its own metabolic penalty [10], independent of costs associated with non-preferred SWs [11] or fluctuations in CoM energy [12]. Furthermore, the *bow-tie* CoM trajectory, characteristic of healthy walking, changes uniformly with walking speed [13]. In contrast, SW changes with speed have shown conflicting trends: decreasing [14], remaining unchanged [15], following a U-shape [16], or exhibiting a reverse J-curve [17] as speed increases.

The interplay between SW and CoM dynamics becomes particularly relevant in the presence of functional asymmetry, which is common in neurologically impaired populations. Functional asymmetry often results in a disrupted *bow-tie* CoM trajectory [18] and consistently wider SW across speeds [19]–[21], with falls, common during walking, often attributed to poor balance control [22]. However, studies in patient populations make it difficult to isolate the underlying biomechanical adaptations due to varying levels of impairment and individual-specific constraints. Comparing patients to healthy controls matched by speed or age provides only partial insights, as inherent biomechanical and dynamic differences persist irrespective of these factors. A notable attempt to address this gap is McCain et al. [23], who induced asymmetry in healthy individuals using knee and ankle bracing. However, the study was limited to walking only at 0.8 m/s, leaving functional asymmetry's broader implications unexplored.

This study addresses these gaps by investigating gait adaptations under functional asymmetry in healthy young adults across three speeds, focusing on the interplay between SL, SW, and CoM dynamics. A unilateral knee constraint was used to emulate biomechanical challenges faced by individuals with impaired gait, such as stroke survivors, while allowing isolation of specific gait adaptations. Stability was quantified using Hof et al.'s concept of the extrapolated CoM (xCoM) [24] and

the margin of stability (MoS). We hypothesised that functional asymmetry would lead to significant adjustments in lateral and fore-aft foot placement to counter altered CoM dynamics. We also hypothesised that walking with a knee constraint would increase MoS to compensate for the heightened demands imposed by the asymmetry. This within-subject design provides new insights into biomechanical and stability strategies under functional asymmetry, with implications for both clinical and robotic gait interventions.

II. Methodology

A. Walking dataset

We used human gait dataset published by Baček et al. [25]. The dataset contains data of 21 neurotypical young adults who walked on a dual-belt instrumented treadmill over two sessions (days). In this study, data of only 17 participants are used since two dropped out after the first session (*Sub7* and *Sub12* in [25]) and two have poor lateral-medial ground reaction force (GRF) data (*Sub9* and *Sub10* in [25]). The 17 participants analysed herein include 5 females, with the following anthropometry: age 31±8 years, body mass 72.8±13.2 kg, height 1.71±0.09 m (mean ± standard deviation).

All participants were free of any lower-extremity injury. Walking trials took five minutes each and include walking at three speeds (0.4, 0.8, and 1.1 m/s) and five cadences per speed (preferred, as well as two lower and two higher than preferred). All speed-cadence combinations were repeated twice: without constraints (i.e., *free*) and with a left knee joint extended using a passive knee brace (i.e., *constrained*), emulating hemiparetic compensatory gait. In this analysis, only tests at the participants' preferred cadence from [25] are used: *T3*, *T8*, and *T13* for free walking, and *T18*, *T23*, and *28* for constrained walking at 0.4, 0.8, and 1.1 m/s, respectively.

B. Gait variables

All gait variables were extracted and calculated in Matlab 2024a using custom-written scripts. GRF data were collected at 1 kHz and filtered using low-pass Butterworth filter with a 6 Hz cut-off frequency [26]. The vertical GRF component was used to segment walking data into gait cycles (time between two subsequent heel strikes of the same leg), with 5% of the peak amplitude used as a threshold (i.e., for a 70 kg person, the threshold is 70×9.81×0.05 = 34 N). All data represent the last 60-second average of a 5-minute trial, as gait variables of interest stabilise within 4 minutes before the analysis [27].

We define step length (SL) as the fore-aft and step width (SW) as the medio-lateral distance between the two calcaneous (heel) markers at the time of the leading leg's heel strike. Margin of stability (MoS) is calculated using the concept of extrapolated centre of mass (xCoM) [24]. Centre of mass (CoM) was calculated using the double integration method [28]; to calculate xCoM (1), CoM's medio-lateral position ($pCoM_{ml}$) was summed up with its corresponding velocity ($vCoM_{ml}$) times a factor $\sqrt{l/g}$, where l is the person's leg length and g gravity acceleration. Medio-lateral MoS (2) was calculated as the smallest lateral distance between the centre of pressure's (CoP's) measured lateral position ($pCoP_{ml}$) and the lateral xCoM position ($xCoM_{ml}$) during the stance phase. Leg length was measured as the distance between the anterior superior iliac spine (ASIS) and the ipsilateral medial malleolus in a standing position during static calibration (see [25] for details). Positive MoS values indicate laterally stable gait (the higher the value, the more stable the gait is).

$$xCoM_{ml} = pCoM_{ml} + vCoM_{ml} \cdot \sqrt{l/g}, \quad (1)$$

$$MoS_{ml} = min(pCoP_{ml} - xCoM_{ml}). \quad (2)$$

The medio-lateral CoM range of motion (ROM) is the distance between two furthest CoM positions in the lateral direction (frontal plane) during a gait cycle. A projection of the 3D CoM movement onto a transverse plane, i.e., the movement in the medio-lateral (ML) and anterior-posterior (AP) directions, makes a well-known shape resembling number eight [29]. We define the area enclosed by each of the number eight's halves (*ellipses*) as CoM Area, and CoM Area Symmetry as a ratio between the left CoM Area divided by the sum of the left and right CoM Area (50% = symmetric).

C. Statistical analysis

Statistical data analysis has been carried out in Python 3.10.10 using *scipy* package. The effects of speed and condition (free vs. constrained) on gait variables per leg were analysed using a two-way repeated measures ANOVA (RMANOVA) and a significance level of $p = 0.05$. Where statistically significant differences were found, Tukey's Honestly Significant Difference (HSD) tests were conducted for pairwise post-hoc analysis, with Bonferroni corrections applied to account for multiple comparisons. Tukey's HSD tests were also used to compare the difference between the two legs where applicable (Left vs. Right) for each speed-condition combination (e.g., free walking at 0.8 m/s). We define three levels of statistical significance: weak ($0.01<p\leq0.05$), moderate ($0.001<p\leq0.01$), and strong ($p\leq0.001$).

III. Results

In all boxplot graphs, three walking speeds are separated by vertical dashed lines, and two conditions labeled with *F* for free and *C* for constrained walking. In boxplots, box represents interquartile range (IQR, 25th to 75th percentile), middle line is median, whiskers are 1.5IQR, and (red) crosses are outliers. Data are average across all 17 participants, with full bars representing mean and error bars standard deviation of the population data.

A. Foot placement – step length (SL) and width (SW)

Increasing gait speed increases SL on both legs (Fig. 1, top row), with significant effect of speed (strong effect, $p<0.001$) during both free (blue bars) and constrained (red bars) walking. SL symmetry (not visualised), calculated as the ratio of the left SL to the sum of the two SLs (50%=symmetric), remains consistent and strongly symmetric – free vs. constrained, on average: 50.2% vs. 49.3% at 0.4 m/s, 50.1% vs. 51.1% at 0.8

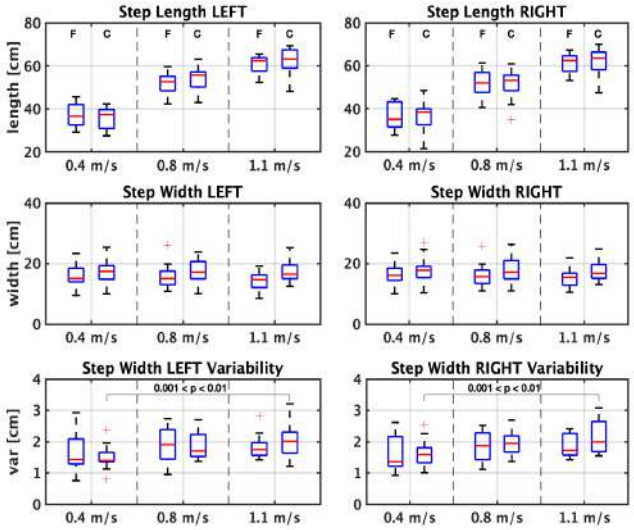

Figure 1. Step length (SL), Step width (SW), and SW variability. Note the same y-axis in each row. SW variability is calculated by averaging individual variability across participants. *F* is free, and *C* is constrained walking.

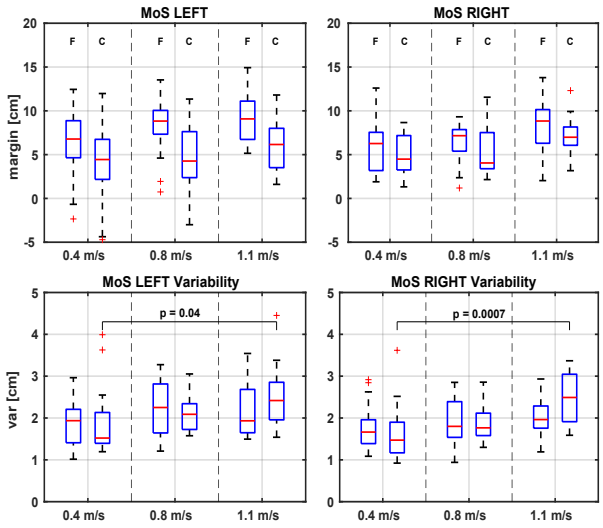

Figure 2. Medio-lateral margin of stability (MoS) and its variability across conditions. Note the same y-axis limits in each row. Positive values indicate stable gait. *F* is free, and *C* is constrained walking.

m/s, and 49.9% vs. 50.4% at 1.1 m/s. Consequently, across all speeds and conditions, there are no significant differences in SL symmetry, or in free vs. constrained SL (p>0.85).

Increasing walking speed has little effect on SW irrespective of the walking condition (Fig. 1, middle row); on both legs and in both conditions (free, constrained), the effect of speed is insignificant (p>0.95). Adding a passive knee brace increases SW by about 2 cm (≈12%) on both legs, but the increase is not significant (p>0.12). Similarly, there are no differences in SW between Left and Right legs in any of the speed-constraint combinations (p>0.99).

A different trend is observed in SW variability (Fig. 1, bottom row). During free walking, there is no significant effect of speed (p>0.49) or side (Left vs. Right; p>0.99) on repeatability of lateral foot positioning. When a knee constraint it added, walking speed only has a significant effect when comparing 1.1 to 0.4 m/s on both legs (moderate effect, 0.001<p<0.01). SW variability remains similar across the two legs (p>0.93), and added constraint does not significantly change it on either leg.

Overall, knee constraint does not affect SL or SL asymmetry, indicating a disassociation from SW modulation. SW is unaffected by the speed but increases during constrained walking, suggesting SW was used to control lateral stability.

B. Margin of stability (MoS)

Increasing walking speed increases lateral MoS in both free (Fig. 2, top row, blue bars) and constrained walking (Fig. 2, top row, red bars), albeit without statistical significance (p>0.21). Similarly, no statistically significant differences exist when comparing MoS between the two legs at any of the six speed-constraint combinations (p>0.59). Adding a knee brace on the left leg reduces average MoS on both legs and across all three speeds (Fig. 2, top row, blue vs. red) albeit with no significance (p>0.17). The exception is the left leg at 0.8 m/s, which exhibited a decrease as big as 35% (or 3 cm; p=0.07). Note that, on average, participants always walk with a stable gait (MoS>0); individually, two participants had MoS<0 on their left leg during free walking at 0.4 m/s; during constrained walking, the same two participants had MoS<0 on their left leg at 0.4 and 0.8 m/s, and one more participant at 0.4 m/s.

MoS variability remained fairly consistent across speeds, conditions, and legs (Fig. 2, bottom row). There is no significant effect of speed in either leg during free walking (p>0.28); during constrained walking, speed only significantly changes MoS variability when comparing 1.1 to 0.4 m/s on the left (weak effect, p=0.04) and right leg (strong effect, p=0.0007). There are no Left vs. Right differences in either constrained or free walking (p>0.54), and adding constraint to the left knee introduces no significant changes to MoS variability in either leg (p>0.42; notably, p=0.06 on the right leg at 1.1 m/s).

Overall, MoS slightly increased with speed but decreased on both legs under knee constraint, though without statistical significance. Trends in MoS variability suggest that participants found it more challenging to control MoS during constrained walking only at 1.1 m/s, and equally so on both legs.

C. Centre of Mass (CoM) movement

As walking speed increases, lateral CoM movement tends to decrease significantly in both free and constrained walking (strong effect, p<0.001; Fig. 3, top left). Notably, despite an increase in the lateral CoM movement when walking with constraints, the change is not significant at any speed compared to free walking (p>0.67). In contrast, CoM Area Symmetry notably changes (Fig. 3, top right). During free walking (blue bars), participants maintained near-perfect symmetry across speeds (p>0.98), as illustrated by the CoM path in the transverse plane (Fig. 3, bottom, full lines). Under constraints,

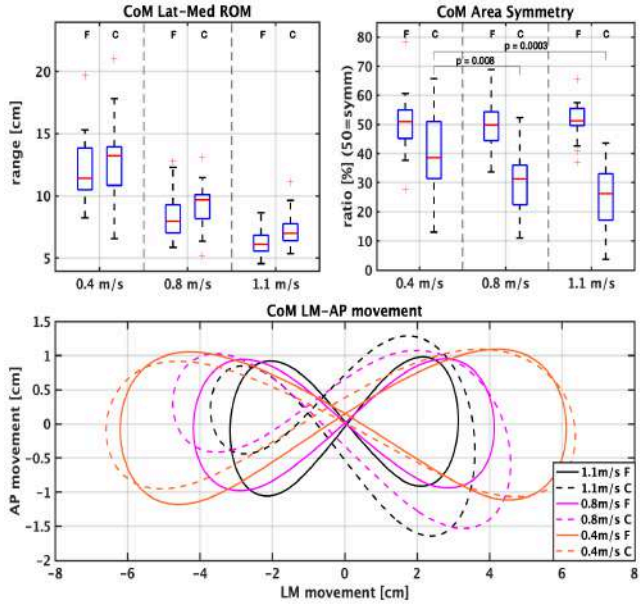

Figure 3. Centre of mass (CoM) movement in the frontal plane (ROM) and projected onto the transverse plane (Area Ratio, LM-AP movement). Top row: *F* is free, and *C* constrained walking. Bottom row: walking speeds are colour-coded and the two conditions visualised using full (free; F) and dashed (constrained; C) lines.

CoM Area Symmetry dropped below 50%, indicating greater reliance on the right (unconstrained) leg. The effect of speed on CoM Area Symmetry during constrained walking leads to significant difference between 0.4 and 1.1 m/s (strong effect, p=0.0003), and 0.4 and 0.8 m/s (moderate effect, p=0.008), and between free and constrained walking at 0.8 and 1.1 m/s (strong effect, p<0.001).

Dashed lines in Fig. 3 (bottom) illustrate the impact of a knee brace on CoM. At 0.8 and 1.1 m/s, functional asymmetry increases both lateral and fore-aft movement of the CoM on the right side, while only lateral movement increases on the left side. At 0.4 m/s, lateral CoM movement increases slightly on the right side, with reduced fore-aft and increased lateral movement on the left side. The constraint-induced changes are less pronounced at 0.4 m/s, explaining the smaller free vs. constrained CoM Area Symmetry difference at this speed compared to the two faster speeds (Fig 3, top right).

Overall, lateral CoM movement decreases with speed during both free and constrained walking, with the constraint having the greatest impact in the fore-aft direction. Constrained walking also results in marked asymmetry in the CoM Area Symmetry, reflecting a compensatory reliance on the right (unconstrained) leg to control lateral stability.

IV. Discussion

This study investigated human gait adaptations under functional asymmetry across a range of speeds relevant to healthy young adults (1.1 m/s, [30]) and hemiparetic patients (0.8 and 0.4 m/s, [31]). By having participants serve as their own control, we isolated these adaptations from other factors often present in patients or between-group comparisons. The primary focus was on the interplay between step length (SL), step width (SW), and centre of mass (CoM) movement and their combined effects on lateral gait stability. Our first hypothesis was partially confirmed: participants modulated SW but not SL to counteract CoM impacts on lateral stability. Conversely, our second hypothesis was rejected, as MoS decreased, rather than increased, during constrained walking.

A. Walking dataset

Human gait adaptations are often studied by comparing different groups, such as through speed- or age-matching designs [32], [33]. However, these approaches cannot fully account for biomechanical differences that are independent of speed or age, especially in patient populations [34]. The within-subject design of the walking study used herein [25], where participants act as their own control, offers a unique advantage by isolating gait adaptations solely due to functional asymmetry, free from other factors (e.g., muscle weakness). In the study, participants wore a passive knee brace that restricted left knee flexion, limiting ankle plantarflexion during push-off and inducing propulsive asymmetry [35] as well as compensatory gait adjustments [36]. As gait speed increased, propulsive asymmetry did too [35], reflecting the natural demands of higher speeds on joint mobility [37]. Despite a metronome guidance, participants were free to make slight adjustments to their step length and step time (and their symmetries) as long as the resulting gait speed (i.e., *stride* length / *stride* time) matched that imposed by the treadmill.

B. Fore-aft foot placement

During free walking, participants increased their SL with speed (Fig.1, top row, blue bars), consistent with the well-documented positive correlation between gait speed and SL [38]. This adaptation was observed symmetrically across both legs, resulting in strong SL symmetry at all three speeds, concurrent with the speed-agnostic propulsive symmetry reported by [35]. These findings reinforce the critical role of SL in forward progression and its assumed influence on the mechanical and metabolic costs of walking [11], [39].

Interestingly, introducing a left knee constraint had no measurable effect on SL or its symmetry (Fig.1, top row, red bars), even in the presence of pronounced propulsive asymmetries at 0.8 and 1.1 m/s [35] (similar to those observed in stroke patients classified as having *mild* to *moderate* impairments [40]). These results align with findings by McCain et al. [23], who similarly used knee brace to externally induce propulsive asymmetry and reported minimal impact on SL symmetry (and metabolic cost) during walking at 0.8 m/s. Importantly, this consistency holds despite differences in our experimental protocols, as McCain et al. did not employ metronome guidance.

A notable observation is that their participants prioritised SL over step time (ST) symmetry during constrained walking. Although ST symmetry is beyond the scope of this paper, we note that our participants exhibited similar adaptations. This behavior contrasts with findings from free walking, where ST,

rather than SL asymmetry, has been shown to significantly influence the metabolic cost of walking [12], [41]. The underlying mechanisms driving this prioritisation during constrained walking remain unclear and warrant further investigation.

C. Lateral foot placement and medio-lateral stability

In the walking study used herein [25], participants on average maintained a consistent SW and SW variability across different speeds during free walking, with similar values observed for both legs (Fig. 1, middle and bottom rows, blue bars). This stability in SW across speeds aligns with findings from [6] and [15], though it contrasts with studies like [14], [16], [17], likely due to differences in experimental designs and speed ranges tested. Additionally, our results support the finding in [4] of an independent SW-SL control at self-selected speeds, extending it across a wider range of speeds.

Generally, higher walking speeds during free walking result in reduced CoM movement in 3D space [29], as there is less time to execute step-to-step transitions. When this decrease is decoupled from SW modulations, as was the case here – SW remained consistent across speeds (Fig. 1, middle row, blue bars) – lateral stability, as defined by MoS, would be expected to increase. As shown in Fig. 2, this was indeed the case. Using MoS at 1.1 m/s, a speed close to the preferred metabolically efficient gait speed for healthy young adults, as a reference for stability, the reduction in MoS at 0.4 m/s, despite participants reporting feeling *less stable* and disliking the speed, suggests that lateral stability may not be prioritised at slower speeds.

This is likely due to the metabolic penalty associated with wider steps. While taking wider steps at a given speed enhances lateral stability in both healthy individuals and hemiparetic patients [32], [33], [42], it also increases metabolic cost [11]. Furthermore, wider steps are typically more constrained at higher speeds, where longer steps are preferred [42], suggesting that participants could have taken wider steps at lower speeds to increase their MoS. The fact that they didn't – in fact, quite the opposite – suggests that a combination of having more time to correct for potential disturbances at slower speeds and the intrinsic metabolic penalty of walking slowly takes precedence over maximising lateral stability, which is instead maintained at a *sufficient* level during free walking.

Adding a knee constraint impacted SW, MoS, and CoM, but to different degrees. Walking with propulsive asymmetry, particularly at 0.8 and 1.1 m/s [35], led to significant asymmetry in CoM Area (Fig. 3, top right), indicating increased reliance on the right (unconstrained) leg. The fully extended left knee prevented participants from performing *natural* weight acceptance following heel strike or push-off after toe-off, resulting in reduced CoM movement in the AP and increased in the LM directions (Fig. 3). The apparent effect of increased lateral CoM movement at a given speed is comparable to reducing speed, which typically allows more time to manage potential disturbances. This increased need for lateral stabilisation was accompanied by an increase in SW across speeds, as expected, and is consistent with the literature [7], [33], [43].

The increase in SW during constrained walking was consistent across speeds, mirroring the trend observed during free walking. This could be specific to our group of participants, whose preference for a consistent SW across conditions may not have been significantly challenged by the constraint or the range of tested speeds. As a result, they may have defaulted to habitual motor patterns developed during free walking, potentially trading MoS at slower walking speeds. However, this does not fully explain why participants walked with decreased MoS across all speeds compared to free walking.

At 1.1 m/s, it's conceivable that their SW was near its max value, making it mechanically difficult to walk wider. This hypothesis is supported by the increased variability in SW and MoS compared to other conditions (Fig. 1 and 2). At 0.8 and 0.4 m/s, however, this explanation seems unlikely. Instead, altered CoM dynamics during constrained walking (Fig. 3), also common in neurologically-impaired patients [18], combined with the metabolic penalties associated with increased SW and lateral stabilisation, suggests that the trade-off landscape between lateral stability and metabolic cost was shifted by the constraint. If true, participants may still have been minimising their metabolic cost, even at the expense of reducing their stability margin. This hypothesis, though, is beyond the scope of this paper and warrants further investigation.

D. Limitations

This study has several limitations. First, the participant pool of young, healthy adults limits the generalisability of the findings to broader populations. Second, it focused on SL, SW, and CoM dynamics, excluding variables like step time symmetry and metabolic cost. Lastly, using MoS as the sole metric for lateral stability, while valuable, may not fully capture the complexity of dynamic balance recovery strategies.

V. Conclusion

This paper examines gait adaptations in young, healthy adults walking with and without propulsive asymmetry, focusing on how step length, step width, and lateral centre of mass (CoM) movement interact to influence lateral margin of stability. Results indicate that humans prioritise step length symmetry even under propulsive asymmetry, while maintaining consistent step width across speeds. This results in a slight increase in lateral stability with higher speeds, suggesting humans prioritise a trade-off that ensures *sufficient* gait stability. Functional asymmetry significantly changes gait dynamics, including CoM movement and stability margins. These adaptations highlight a complex interplay between lateral balance, preferred motor patterns, and potentially metabolic efficiency. Overall, this underscores the importance of targeting propulsive asymmetry and CoM dynamics in correcting gait, rather than focusing on, e.g. reducing step length asymmetry.

Acknowledgment

The authors would like to thank Mr. Yufan Xu and his supervisor, Dr. Liuhua Peng of The University of Melbourne's Faculty of Science, for providing their expertise in running statistical analysis and preparing results.

Independent Donning and Doffing Robotic Hand System: An Innovative Solution for Stroke Home-Rehabilitation

Garam Lee, Hyun-Ji Kim, Won Kee Chang, Nam-Jong Paik*

***Abstract*—Stroke often results in spastic or clenched hands, which presents a considerable obstacle to the independent donning of robotic hand systems. To address these issues, we developed a novel robotic hand system comprising a Hand Setup Station and a Pneumatic Robotic Hand. The system was designed with the objective of facilitating efficient and independent donning and doffing. The Hand Setup Station incorporates a finger extension mechanism to safely extend clenched fingers during the process, ensuring secure and comfortable attachment. The user-friendly controls allow for precise adjustments tailored to individual needs. In a randomized evaluation involving five participants wearing a glove to simulate stroke-like hand rigidity, the system-assisted donning significantly reduced task completion time compared to manual donning (Manual 98.68 $\pm$ 7.68 sec vs. Proposed 68.89 $\pm$ 7.33 sec, $p < 0.05$). Participants reported higher ratings for ease of use (Manual 4.4 vs. Proposed 2) and experienced lower pain levels (2.2 vs. 3.8) compared to the manual process, which was noted for its physical strain and inefficiency. These findings demonstrate the system's potential to enhance usability and accessibility for stroke rehabilitation, particularly in remote or home-based settings. Future work will focus on optimizing actuator positioning, personalized control, and compatibility with various robotic hand designs for broader application.**

I. INTRODUCTION

Stroke is a leading cause of long-term disability worldwide and the second leading cause of death globally [1]. It occurs when a cerebral blood vessel is either obstructed or ruptured, resulting in localized brain cell damage [2]. This damage manifests in various neurological deficits, including hemiparesis, impaired consciousness, and speech disorders [3]. Among these, post-stroke upper limb dysfunction represents a significant challenge, as it significantly impairs patients' ability to independently perform essential activities of daily living (ADLs), including eating, dressing, and personal hygiene [4]. Consequently, restoring hand functionality is recognized as a pivotal objective in the rehabilitation process for stroke survivors [5]–[7].

The manual facilitation of hand joint movements by physical therapists is beset with significant challenges, largely due to the hand's complex biomechanical structure and the extensive range of motion it exhibits. These factors demand considerable time and effort to address [8]. To overcome these limitations, a variety of robotic systems have been developed to deliver precise and repetitive hand rehabilitation training. Compared to conventional manual therapy, robot-assisted rehabilitation offers more intensive and repetitive training within a constrained time frame, demonstrating substantial efficacy in promoting motor function recovery [9]–[12]. Furthermore, these systems are designed to incorporate the patient's motor intentions, enabling natural and intuitive interaction [13], [14]. This not only increases patient engagement but also enhances the overall rehabilitation outcome.

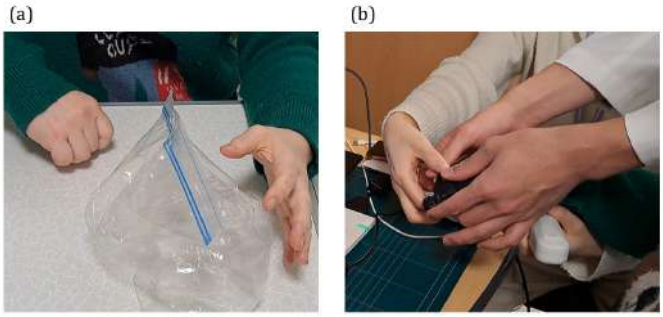

Fig. 1. The appearance of a stroke patient and the preparation process for robotic hand rehabilitation. (a) The spastic hand of a stroke patient. (b) Pretreatment to prepare the patient's hand for robotic hand donning.

However, for chronic stroke patients, spasticity or paralysis causes the hand remaining in a clenched position, as illustrated in Fig. 1. This presents a significant challenge in the direct application of a robotic hand device. For the hand extension, a therapist is required to manually extend the patient's hand, a process that is both labor-intensive and time-consuming [8], [15], [16]. This dependency precludes patients from utilizing robotic hand systems independently, thereby imposing a significant constraint on their practical application. Consequently, many patients are excluded from the benefits of such devices due to the difficulty in donning and doffing them without external assistance. To address this issue, there is a growing demand for a novel robotic hand system that enables patients to independently wear and remove the device without requiring manual intervention.

Recently, the COVID-19 pandemic has highlighted the

critical need for remote rehabilitation, as hospital visits were often restricted or entirely unfeasible. Furthermore, the shortage of physical therapists and caregivers, combined with the geographical isolation of many patients in areas with limited healthcare access, exacerbates the difficulties in providing adequate rehabilitation therapy [17], [18]. These limitations underscore the necessity for innovative solutions to address the growing demand for accessible rehabilitation. A robotic hand system that stroke survivors can independently don and operate offers a promising approach to enhance accessibility. In particular, a system optimized for remote use could provide continuous and effective rehabilitation opportunities, significantly improving outcomes for patients unable to attend conventional therapy sessions.

Against this backdrop, this study aims to develop a robotic hand system that stroke patients can use independently, without external assistance. The proposed system is designed to enhance patient autonomy, improve accessibility to rehabilitation, and enable effective utilization in remote rehabilitation environments. By addressing these challenges, the system has the potential to significantly improve the quality of life for chronic stroke patients and establish a new paradigm in rehabilitation therapy.

The following sections of this paper provides an overview of the proposed system, followed by details on the development and operating principles of the proposed robotic hand system in Section II. Section III presents the experiments of the proposed system. Section IV provides the experimental results, and discussions are drawn in Section V.

II. PROPOSED ROBOTIC HAND SYSTEM

The proposed robotic hand system is designed to enable stroke patients to independently don and doff the device without external assistance. As shown in Fig. 2, the system comprises two main components: the Hand Setup Station and the Pneumatic Robotic Hand.

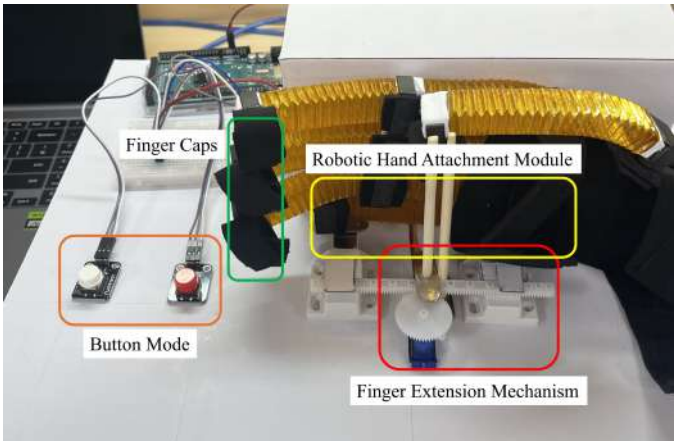

Fig. 2. A robotic hand system for independent donning and doffing of robotic hands by patients. This system is designed to allow the unaffected hand to fully assist in donning the robotic hand onto the affected hand. The station is operated simply by pressing buttons. After doffing, the system returns to its initial state, enabling the same conditions for the next donning process.

A. Hand Setup Station

The Hand Setup Station is designed to gently open the stiff, spastic hands of chronic stroke patients, preparing them for the application of the robotic hand system [19]. Chronic stroke patients, particularly those with prolonged symptoms, often exhibit persistent hand clenching, which complicates the donning of the robotic hand and limits finger mobility. To address this, the station securely stabilizes the patient's hand in a comfortable position while facilitating finger extension through the following components:

1) The Finger Extension Mechanism utilizes two thin actuators, which facilitate the gradual extension of clenched fingers. This design is inspired by findings from the BeBiTT test [20]. This test was conducted with six chronic stroke patients (3F/3M; average age 48.5 $\pm$ 16 years; average onset 3.8 $\pm$ 2.1 years). During the test, patients performed ADL tasks using common household objects, and the activity scores for the affected hand were evaluated. All procedures related to the experiment were approved by the Institutional Review Board of Seoul National University Bundang Hospital (IRB No. B-2205-756-003). Results showed that ADL tasks involving thin cylindrical objects, such as holding a toothpaste tube, had the highest activity scores as shown in Table I.

TABLE I
RESULTS OF THE BEBITT TEST FOR STROKE PATIENTS PERFORMED BY 6 PARTICIPANTS (3F/3M, AVERAGE AGE: 48.5 ± 16 YRS, ONSET: 3.8 ± 2.1 YRS) USING POWER GRASP, CYLINDRICAL GRASP, LATERAL PINCH, AND PRECISION PINCH FOR DAILY LIVING TASKS (2 REPETITIONS EACH, 5-POINT SCALE).

Participant	Spherical Grasp	Cylindrical Grasp	Lateral Pinch	Precision Pinch
1	2	3	0	0
2	1.5	3	1.5	2
3	3.5	4	1.5	2
4	1	3	0	0.5
5	2.5	5	2	2.5
6	2	4.5	3	3

Building on this, the mechanism leverages the paretic hand's adaptability to cylindrical shapes, allowing controlled finger extension through a motor-driven rack-and-pinion system. The second actuator operates the robotic hand attachment module, enabling vertical displacement for secure locking and unlocking. This dual-actuator design ensures precise, adjustable extension tailored to each patient's needs while maintaining safety and comfort.

2) The Button Mode provides an intuitive interface for controlling the Finger Extension Mechanism, featuring two distinct buttons for precise and user-friendly operation. The red button controls the actuator's vertical movement, enabling the system to position the hand in a ready posture for extension or to facilitate the safe and comfortable removal of the hand from the system. The white button allows for linear extension and retraction of the fingers, ensuring precise adjustments during the flexion or extension process based on the patient's needs.

B. Pneumatic Robotic Hand

The Pneumatic Robotic Hand utilizes Pneumatic Origami Muscle Actuators (POMA) to achieve controlled and adaptive finger movements [21]. This design enables seamless integration after the hand preparation phase, allowing patients to perform rehabilitation exercises with improved comfort and natural motion. The robotic hand comprises the following components:

1) The Robotic Hand Attachment Module enables stable attachment of the robotic hand to the Hand Setup Station during the donning process. A latch system secures the robotic hand in place, preventing unwanted movement and ensuring precise alignment during application.

2) The Finger Caps are soft, thimble-like covers placed at the ends of the robotic hand to ensure a secure and comfortable fit for each finger [22]. These caps are designed to minimize discomfort and provide stability during rehabilitation tasks, accommodating varying finger shapes and sizes.

C. Control Design

The control system of the proposed robotic hand optimizes finger extension through kinematic calculations. The cylindrical actuator extends and stabilizes the fingers while considering hand biomechanics. In stroke patients, paralysis affects the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints, making sudden extension risky [23]. Finger kinematics show that MCP movement initiates hand opening or closing, followed by PIP and DIP motion [24]. To prevent strain, the system restricts extension to the MCP joint while stabilizing the PIP and DIP joints, as illustrated in Fig. 3. The cylindrical actuator is fixed at the PIP joint, keeping the middle and distal phalanges immobile during extension.

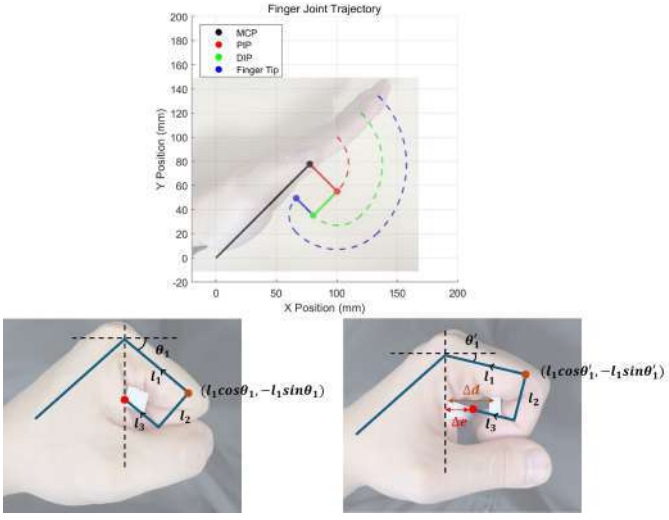

Fig. 3. Finger kinematics during hand flexion and extension.

The finger kinematic analysis is crucial to determining the minimum movement range required for the MCP joint to allow the robotic hand to be securely attached at the fingertips. Initially, the hand posture follows Eq. (1) while in a clenched state, and once the hand is extended, it follows Eq. (2).

$$l_1 cos\theta_1 - l_2 sin\theta_2 - l_3 cos\theta_3 = 0 \quad (1)$$

$$l_1 cos\theta_1' - l_2 sin\theta_2' - l_3 cos\theta_3' = \Delta e \quad (2)$$

where l_1, l_2, and l_3 represent the lengths of the Proximal Phalanx, Middle Phalanx, and Distal Phalanx. θ_1, θ_2, and θ_3 denote the flexion angles of the MCP, PIP, and DIP joints. θ_1', θ_2', and θ_3' represent the angles of the joints after the hand is extended. After finger flexion, Δe indicates the distance traveled by the fingertip from the initial pose.

The minimum linear displacement of the cylindrical actuator Δe, which is powered by the rack-and-pinion system introduced in the Finger Extension Mechanism, is set to 35 mm to accommodate fingertip attachment. Using Eq. (1) and Eq. (2), once θ_1' is determined, the desired displacement Δd can be calculated as follows Eq. (3).

$$\sqrt{(l_1 cos\theta_1' - l_1 cos\theta_1)^2 + (l_1 sin\theta_1 - l_1 sin\theta_1')^2} = \Delta d \quad (3)$$

D. General Operating Procedure

The donning process follows the sequence in Fig. 4. The user presses the red button to lock the cylindrical actuator (Fig. 4a). Using their non-affected hand, the stroke patient slightly opens the affected fingers, grasps the actuator, and wraps the wrist strap (Fig. 4b, 4c). Pressing the white button extends the actuator (Fig. 4d), guiding the clenched hand to a position where the robotic hand can attach at the fingertips (Fig. 4e). Finally, the robotic hand is secured, and pressing the red button again releases the hand from the system (Fig. 4f).

III. EXPERIMENTS

An experimental evaluation was conducted to comprehensively assess the efficiency and usability of the proposed robotic hand system during the donning process. The evaluation aimed to achieve two primary objectives: (1) to compare the time required for donning the robotic hand system with that of manual donning performed without assistance, and (2) to evaluate the level of comfort experienced by participants throughout the donning process.

The study involved five healthy participants (3 males, 2 females), each simulating the spasticity typically observed in stroke patients by wearing a custom-designed finger rigidity control glove, as illustrated in Fig. 5. The glove's adjustable cable stiffness was calibrated based on previous studies on stroke-related hand rigidity [25], [26]. As stroke severity increases, hand rigidity also intensifies, with stiffness values ranging from 0.4 to 0.9 N/mm depending on the level of spasticity. To replicate severe spasticity, the glove incorporated a spring with an average stiffness coefficient of 0.8 N/mm, ensuring that the resistance closely matched that of stroke patients with moderate to severe rigidity. By replacing the spring, the resolution of rigidity simulation can be refined,

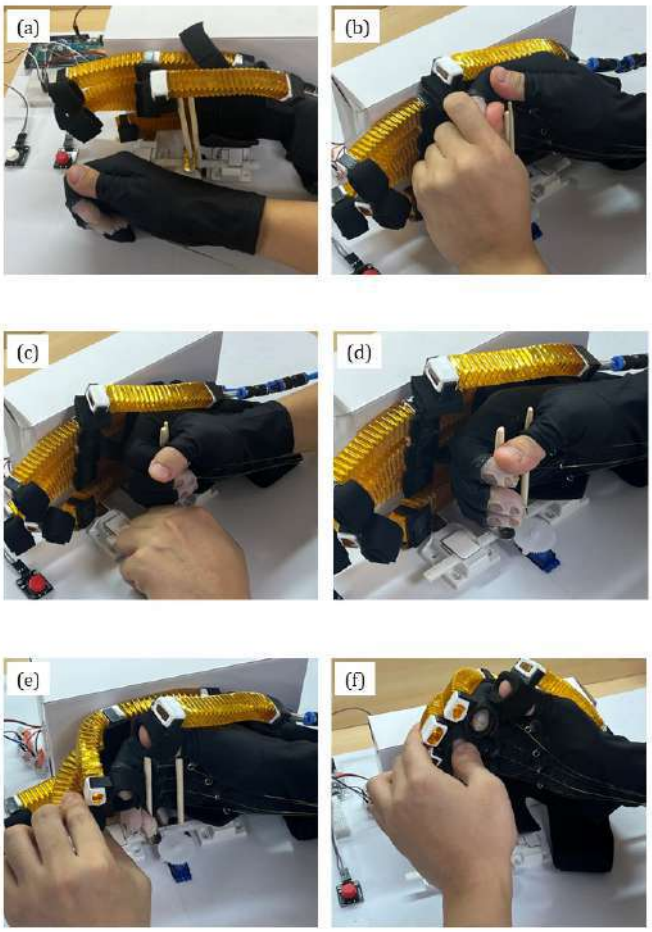

Fig. 4. Donning process of the robotic hand using the robotic hand system.

allowing for a more precise replication of varying spasticity levels.

The experiment was conducted with two conditions:

1) **Manual Donning:** Participants donned the robotic hand manually without any robotic assistance.
2) **System-Assisted Donning:** Participants donned the robotic hand using the proposed robotic system.

In both conditions, the time required to fully wear the robotic hand on the simulated affected hand was recorded. For Manual Donning, the recorded time refers to the duration required to wear the robotic hand completely. In contrast, for proposed System-Assisted Donning, the recorded time includes both the time to don the robotic hand using the system and the time required to detach the system afterward. Participants were instructed to minimize any voluntary finger movements in the simulated affected hand to replicate the limited mobility characteristic of spastic hands. To ensure reliability, participants were given sufficient time to familiarize themselves with the robotic system and the donning procedure prior to the trials. After completing the experiments, participants evaluated their perceived pain and convenience for each condition using a Likert-scale [27].

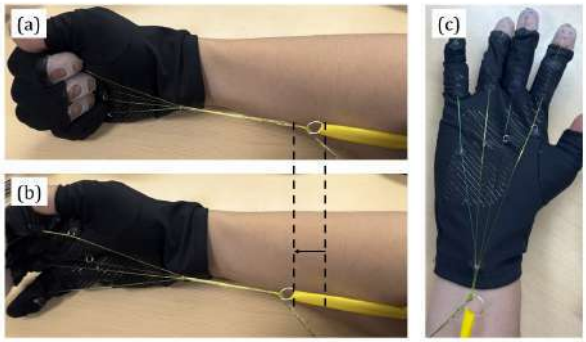

Fig. 5. A glove simulating the spasticity of a stroke patient's hand. Each finger joint is connected to a tensioner via wiring, with the tensioner stiffness adjustable to mimic varying levels of spasticity.

IV. RESULTS

A. Task Completion Time

All participants successfully completed the tasks in two randomized conditions, Manual Donning and System-Assisted Donning. For Manual Donning, the time required to fully attach the robotic hand was recorded. For System-Assisted Donning, the time to complete each step was measured according to Table II. In this setup, the timer continuously ran from the beginning, and lap times were recorded at the completion of each step.

TABLE II
SYSTEM-ASSISTED DONNING TASK ORDER AND DESCRIPTIONS

Task Step	Description
1	Extend the paralyzed hand fingers and grasp the cylindrical actuator.
2	Attach the wrist strap of the robotic hand.
3	Press the button to expand the hand.
4	Attach the robotic hand's fingertip caps to the fingers of the paralyzed hand.
5	Press the button and detach the hand wearing the robotic hand from the system.

Manual Donning required an average time of 98.68 ± 7.68 seconds. For System-Assisted Donning, the average completion times for each step were as follows: Step 1: $11.61 \pm 2.31s$, Step 2: $13.37 \pm 3.69s$, Step 3: $4.68 \pm 0.37s$, Step 4: $27.77 \pm 4.12s$, and Step 5: $9.45 \pm 0.63s$, with an overall completion time of $68.89 \pm 7.33s$ (Fig. 6). The difference in total completion time between the two conditions was an average of $98.68 \pm 7.68s$, demonstrating that System-Assisted Donning is more efficient than Manual Donning as shown in Fig. 7. A paired t-test was conducted between the two conditions (N=5, df=4), yielding a $p-value < 0.05, (T-statistic = 14.307)$, indicating a statistically significant difference between the conditions.

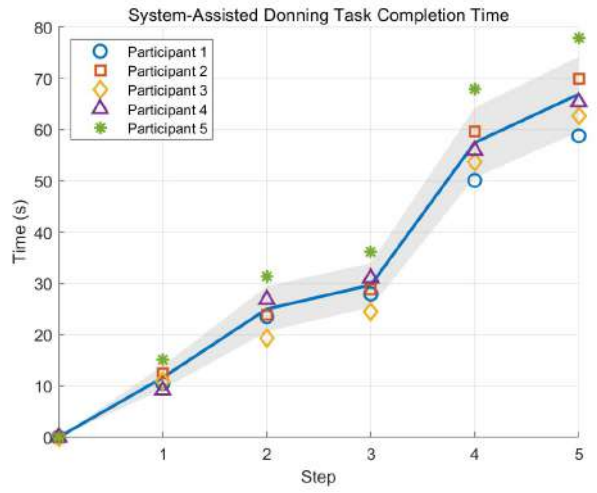

Fig. 6. Measured step-by-step task completion times for participants during System-Assisted Donning.

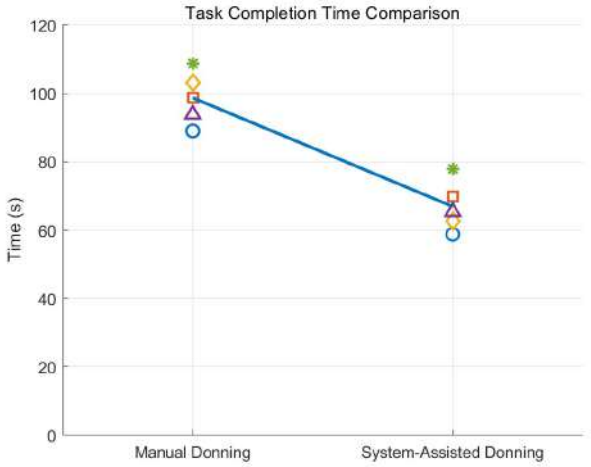

Fig. 7. Comparison of task completion times between Manual Donning and System-Assisted Donning. System-Assisted Donning significantly reduced overall task completion time compared to Manual Donning, as supported by statistical analysis ($p < 0.05$).

B. Usability Evaluation

After completing both conditions, participants evaluated the usability and pain level of the robotic hand donning process using a Likert scale questionnaire (Table. III).

For Manual Donning, the usability was rated at an average of 2 points, while the pain level was rated at 3.8 points. Participants reported difficulties due to the lack of a fixed mechanism to stabilize the robotic hand, which made it challenging to attach the hand to the participant's wrist. Furthermore, even when the fingers were extended, they tended to flex again, resulting in prolonged time and effort to insert the fingers into the robotic hand.

In contrast, for System-Assisted Donning, the usability was rated at an average of 4.4 points, with all participants providing scores of 4 or higher, and the pain level was rated at 2.2 points.

TABLE III
AVERAGE RATINGS FROM PARTICIPANTS (BLUE: MANUAL DONNING, RED: SYSTEM-ASSISTED DONNING) ON THEIR PERCEPTION OF THE ROBOTIC HAND DONNING PROCESS (PARTICIPANTS N = 5).

	1	2	3	4	5	
Difficult		2			4.4	Easy
No pain		2.2	3.8			Extreme pain

Participants highlighted that the system-assisted process was significantly easier and more comfortable compared to the manual method. They also noted that the automated assistance reduced physical strain on the wrist and fingers, making the process more effortless and less painful.

V. CONCLUSION AND DISCUSSION

This paper presents the effectiveness of the proposed system-assisted donning and doffing approach for a robotic hand. Statistical analysis revealed a significant reduction in task completion time ($p < 0.05$) for system-assisted donning compared to manual methods. A detailed analysis of Fig. 6 reveals that Task 3 in the system-assisted donning process required the shortest completion time. This suggests that the system effectively facilitates the extension and maintenance of clenched fingers, which is the most time-consuming step in manual donning. Conversely, Tasks 2 and 4 required the longest completion times. These steps involved securing the wrist strap and fitting the finger caps. This indicates potential areas for improvement, where modifications to the materials or the structural design of the robotic hand could further reduce task completion times and enhance overall efficiency. Additionally, The automated alignment during the doffing process ensures optimal positioning for subsequent use, thereby enhancing operational efficiency in iterative donning sessions. This improvement is particularly salient for users with impaired hand function, such as stroke survivors, where prolonged or complex donning procedures may induce fatigue or discomfort. User evaluation data indicated higher scores for ease of use (mean difference = 2.4) and lower reported pain levels (mean difference = -1.6) with the system-assisted approach. These findings suggest that the proposed system not only accelerates the donning process but also enhances user experience, presenting a viable solution for rehabilitation applications.

The proposed system has the potential to address critical challenges in the rehabilitation of stroke patients. By enabling independent donning of robotic devices, it reduces the need for caregiver assistance, thereby increasing accessibility and usability in home settings. A simple and straightforward donning process minimizes the need for patient training and external assistance, enabling immediate and independent use of the robotic system. This is especially valuable in remote or resource-limited areas where access to professional therapists may be restricted. Additionally, the reduction in physical strain and improved user satisfaction observed in this study suggest

that the system could alleviate some of the psychological and physical barriers associated with rehabilitation, encouraging patients to engage more consistently in therapy.

While this study showed promising results, the small sample size (N=5) included only healthy participants simulating stroke conditions, with occasional unintended muscle use potentially affecting results. Despite instructions to avoid using the muscles of the simulated paretic hand, participants occasionally relied on it for assistance, potentially influencing the results. Testing with real stroke survivors may pose challenges such as spasticity variability, cognitive impairments, and difficulties in independent donning. Addressing these factors is crucial for real-world usability. Additionally, the system's impact on long-term functional rehabilitation remains unassessed, requiring further investigation.

Future research should focus on integrating the system with advanced robotic functionalities, such as adaptive control mechanisms tailored to individual needs. Currently, the finger extension mechanism is fixed in a single position. To accommodate the variability in patients' affected hands—whether left or right—and their specific positioning, the actuator will be redesigned to adapt dynamically, ensuring optimal alignment for donning. Additionally, the extension speed and range of motion will be customized through user feedback, enabling personalized control for each patient.

Exploring the system's use in conjunction with task-specific training protocols could further enhance its rehabilitation outcomes. Longitudinal studies focusing on motor recovery and quality of life over extended periods are essential to comprehensively evaluate the system's therapeutic potential. Finally, efforts will be made to generalize the system beyond the POMA glove, creating a modular design compatible with a wide range of robotic hands. This integration will expand the system's applicability, allowing it to support diverse rehabilitation devices and scenarios effectively.

***Abstract*—Despite advances in gait-assist wearable robots, application in real-world scenarios remains limited, largely due to challenges in developing an effective user intention recognition algorithm. These algorithms are crucial as they enable the robot to move harmoniously with the user by predicting their intent during various locomotion activities such as level walking, stair ascent, stair descent, and sit-to-stand. It is essential to not only identify these locomotion modes but also their phases and progression for real-time assistance. Traditional classification methods often require extensive manual feature extraction from signals like those from inertial measurement units (IMU), electromyography, and plantar force sensors. Recent machine learning, particularly deep learning approaches, have simplified this process through automatic feature extraction. However, no existing method simultaneously predicts locomotion modes, phases, and phase progression, which is significant for personalized assistance. This study introduces a deep learning framework that classifies locomotion modes and phases and estimates the phase progressions using IMU data from sensors placed on the sternum and limbs. Results from five participants show that our model effectively classifies the locomotion phase and well estimates the phase progression percentage. The model was evaluated using a leave-one-subject-out approach, ensuring generalizability across different users.**

Keywords—Gait intention recognition, gait, deep learning, biomechanics, human computer interface

I. INTRODUCTION

Despite promising research, seldom are gait-assist wearable robots observed in real-world environments. One of the main challenges is identified to be the development of well-working user intention recognition algorithms. In order to appropriately assist the user, the robot must work in accordance with user's movements during locomotion which requires the prediction of the user's intent. Level walking (LW), stair ascent (SA), stair descent (SD), and sit-to-stand (StS), are composed of a series of biomechanically distinct phases that must be successfully executed in order to properly complete the task. Thus, the robots' control system must be able to accurately recognize not only the locomotion mode but also its phases and progression in order to generate optimal real-time assistance.

The classification of locomotion modes and estimation of gait cycle percentages, crucial for developing effective gait assistive technologies, have been extensively researched [1]–[8]. Numerous studies have introduced innovative classifiers tailored to various environments, focusing on distinguishing locomotion modes and phases. Traditional approaches often rely on feature extraction from signals obtained via sensors like inertial measurement units (IMUs), electromyography (EMG), and plantar force (PF) sensors [9]–[12]. These methods typically estimate joint trajectories and heel contacts but require significant manual intervention, making the process labor-intensive. Recent advancements in machine learning, particularly deep learning, have transformed this field. These models automatically extract relevant features, which simplifies the classification process. For instance, Huang et al. developed a support vector machine (SVM) model using EMG, PF, and IMU signals to classify five distinct locomotion modes: LW, SA, SD, ramp ascent, and ramp descent [3]. Studies by Kang and Zhu also explored classification using fewer signal modalities, such as only IMU data or a combination of IMU and encoder signals within CNN frameworks [2], [5]. These methods reduce system complexity and enhance practicality. Additionally, Wang et al. utilized long short-term memory (LSTM) models to StS

This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number: RS-2022-KH129263).

activities and divide the gait cycle into distinct phases [13]–[15]. Despite these advancements, no current approach simultaneously predicts locomotion modes, phases, and phase progression percentages. Predicting phase percentage progression is significant because phase duration can vary due to individual differences, aging, and gait abnormalities, which can impact safety due to assistance that is not in phase with the user [16]–[20].

In this study, we introduce a deep learning model capable of classifying locomotion modes (LW, SA, SD, and StS) and their respective phases while also predicting phase progression. Our model utilizes data from five IMU sensors placed on the sternum and both thighs and shanks. The algorithm was evaluated on two fronts: the classification of locomotion modes and their phases, as well as phase progression regression. Results from five participants demonstrated the model's effectiveness in recognizing individual phases and their progression. Our algorithm has the potential to enhance the performance of wearable gait-assistive robots, ultimately improving user safety and comfort.

II. Materials and Methods

A. Participants

five healthy males (age: 32±5.2 years, height: 178.4±4.4cm, and weight: 86.2±3.2kg) that participated in this study had no prior history of lower limb injuries (previous 6 months). All participants provided a written informed consent and research ethics of human experiments was ensured by conducting the sessions in accordance with the contents approved by the Institutional Review Board of Korea University College of Medicine (IRB No. KUIRB-2024-0206-01). All experiments adhered to the approved guidelines and complied with the Declaration of Helsinki. The raw data supporting the findings of this study are available upon request to the corresponding author.

B. Activity Dataset Collection

In this investigation, we utilized a set of five IMU sensors (Trigno™ wireless system, Delsys Inc., Natick, MA, USA), positioned on both lower limbs as well as the sternum of each participant. The sensors were affixed to the lateral mid-thigh, mid-shank, and at the lower end of the sternum. Once the sensors were secured, participants were instructed to perform a series of locomotion tasks, including LW, SA, SD, and StS activities.

During the LW trials, participants executed 50 consecutive gait bouts, which began from a stationary standing posture, progressed four steps, and concluded to a complete stop. For the SA and SD trials, participants began from the same idle standing position and approached the staircase with several LW steps, then ascended or descended a set of 12 steps based on the specific trial, followed by additional LW steps before concluding to a complete stop. This LW-(SA/SD)-LW cycle was repeated 20 times for each subject. Additionally, participants undertook 100 iterations of the StS task, which comprised of sitting in a chair for 3 seconds, standing up, holding a stationary position for another 3 seconds, and then returning to a seated posture. There were no restrictions regarding the pace at which these activities were carried out.

C. Ground Truth Labeling

To ensure accurate ground truth labels for the time-series IMU data, we incorporated five additional 3-axis orientation sensors alongside pressure-sensitive insoles (Pedar-X™, Novel GmbH, Munich, Germany) during the experiments. The phases of LW, SA, and SD were identified via analysis of the PF patterns (Fig. 1). Knee joint angles, obtained via 3-axis orientation sensors affixed to the thighs and shanks, were used to label the phases of standing, sitting, sit-down, and stand-up (Fig. 1). Both the orientation sensors and pressure-sensitive insoles recorded data at a frequency of 100 Hz.

For data segmentation, we applied a sliding window approach of 500 msec (50 frames) with a stride length of 10 msec (1 frame) to create input datasets for the proposed deep learning model. Each data segment received a phase label along with a progression percentage. Because predicting the phase progression is crucial for safe and comfortable assistance in gait assistive robot control it is imperative that we are able to properly label the phase progression percentages. For static activities such as idle standing and sitting, where progression is not applicable, a phase progression of 0% was assigned. For dynamic phases, the beginning was labeled as 0% and the conclusion as 100% with intermediate frames proportionately divided. During gait initiation and termination, the phases and progressions were tagged as either SS 50% or SW 50%, depending upon which limb was used to initiate or terminate the locomotion (Fig. 1). For instance, if the left leg was in the swing phase at termination, the segment was labeled as SS 50%, while a right leg in the swing phase was marked SW 50%. Since the right limb was defined as the ipsilateral limb, SS was indicative of the SW phase for the left limb. The 50% progression designation was based on the observation that, upon initiating gait, the limb's lifted position aligns closely with the midway point of the swing phase. This holds true at the end of the locomotion cycle as well. The ground truth label for each input segment was thus determined from the phase and progression of the final frame within the 500 msec segment. The data segments were also categorized into 16 distinct phases, which include two idle phases (standing and sitting), as well as the sit-down, stand-up, and four phases each for LW, SA, and SD. Specifically, the phases for LW, SA, and SD were designated as DS1, SS, DS2, and SW, including the right limb as the ipsilateral limb. These classifications were guided by established literature that delineates the biomechanical criteria necessary for executing each locomotion phase[13]–[15], [21]–[23].

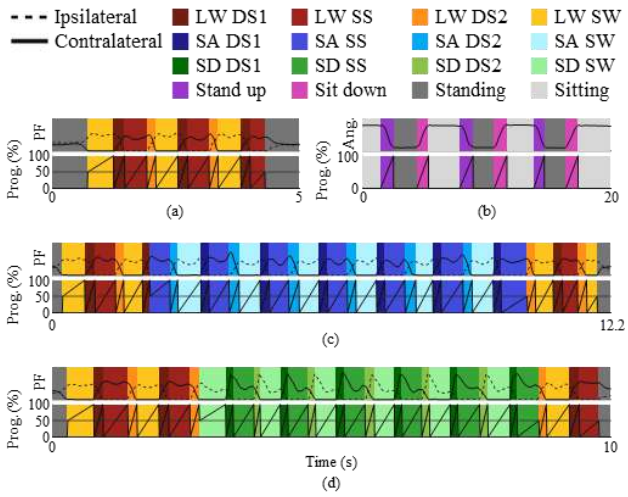

Fig. 1. Ground truth labeling. The locomotion modes, phases, and the phase progression percentages were labeled by assessing the PF for LW, SD, and SA, and the knee joint angles for StS. (a) Top row shows the PF for LW. As seen below, the gait phases are differentiated by the different shades. Also, the black line depicts the ground truth phase progression percentages. (b) The StS activity is shown. The different shaded areas depict the different phases: sitting, stand-up, standing, and sit-down. The phases were divided according to the knee angles shown in the upper row. (c) and (d) The SA and SD gait sessions are shown. For both cases, the upper rows show the PF patterns. The data shows that several LW steps were taken prior to SA or SD and a few LW steps were taken afterwards. The phases were divided according to the PF patterns, and phase progression percentages were assigned accordingly.

D. Deep Learning Model and Training

Our novel deep learning framework is designed as a two-stage sequential system, drawing inspiration from the framework previously proposed by Yu et al. [6]. In the first stage, a Bidirectional LSTM (Bi-LSTM) model is utilized to concurrently identify the locomotion type and its corresponding phases (Fig. 2a). The model processes inputs of the dimension (50, 30) and includes two Bi-LSTM layers, each with 50 units. These are followed by Dense layers with 50 and 32 units, activated via ReLU. The final layer, with 16 units, implements a softmax activation function to categorize the data into 16 distinct phases, capturing each unique combination of locomotion type and phase (Fig. 2b). Depending on which locomotion mode and phase are classified, if the locomotion mode is not idle (i.e., standing and sitting), the system selects one of 14 independent Bi-LSTM-based models to handle the input in order to perform phase percentage regression. The input is the same as the input that was fed to the model in the first stage (refer to Fig. 2c). These networks also receive inputs of size (50, 30) and are comprised of two Bi-LSTM layers, each with 50 units. The output layer is a single unit activating using a sigmoid function, while ReLU activation is applied throughout the preceding layers. Importantly, all 14 networks share consistent hyperparameters. This stage focuses on predicting the phase progression percentage using the model corresponding to the phase determined in the initial stage.

Development and training of the model were performed using TensorFlow (version 2.10.0) and Python (version 3.9.18). The Adam optimizer, with a batch size of 128 and for 50 epochs, was employed in all models. To mitigate overfitting, early stopping was implemented, and TensorFlow's hyperparameters were decided using a random search method.

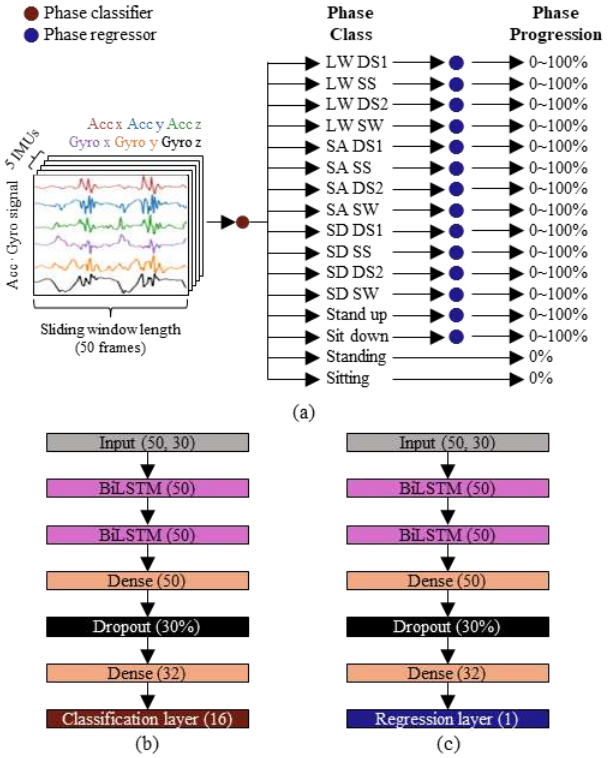

Fig. 2. Schematic of the proposed two-stage deep learning model for classifying locomotion mode and phase and predicting the phase progression percentage. (a) The input data is first fed to a phase classifier (red circle) which classifies the input data into 16 individual classes. For the 14 dynamic classes, the input data are used to estimate the phase progression percentage via a Bi-LSTM-based regressor (blue circle). (b) A Bi-LSTM-based model for phase classification. (c) A Bi-LSTM-based deep learning model for phase progression regression.

E. Evaluation Metrics

When dealing with the different nature of classification and regression outputs, it is essential to use appropriate evaluation metrics. For the classification of locomotion mode and phase, accuracy is a commonly used metric. Accuracy is the ratio of correctly predicted instances to the total number of instances. Nevertheless, relying solely on accuracy may be insufficient for assessing a model's performance. To gain deeper insights, metrics such as precision, recall, and F1-score are also employed. Precision indicates the proportion of true positive predictions among all positive predictions. Recall reflects the proportion of actual positive instances that were correctly identified by the model. The F1-score, which is the harmonic mean of precision and recall, offers a balanced evaluation of classification performance. The formulas for accuracy (A), precision (P), recall (R), and F1-score ($F1$) are as follows:

$$A = \frac{N_{tp}+N_{tn}}{N_{tp}+N_{tn}+N_{fp}+N_{fn}} \quad (1)$$

$$P = \frac{N_{tp}}{N_{tp}+N_{fp}} \quad (2)$$

$$R = \frac{N_{tp}}{N_{tp}+N_{fn}} \quad (3)$$

$$F1 = \frac{2PR}{P+R} \quad (4)$$

where N_{tp}, N_{tn}, N_{fp}, and N_{fn} are the number true positives, false positives, and false negatives, respectively.

Unlike binary classification problems, multiclassification problems require the use of macro-precision (P_{macro}), macro-recall (R_{macro}), and macro-F1 ($F1_{macro}$) metrics because there are multiple true positives. This also circumvents any biases that can occur due to data imbalances. The indices are calculated as shown below:

$$P_{macro} = \frac{1}{n}\sum_{1}^{n}\frac{N_{tp}}{N_{tp}+N_{fp}} \quad (5)$$

$$R_{macro} = \frac{1}{n}\sum_{1}^{n}\frac{N_{tp}}{N_{tp}+N_{fn}} \quad (6)$$

$$F1_{macro} = \frac{2P_{macro}R_{macro}}{P_{macro}+R_{macro}} \quad (7)$$

Where n is the number of classes. We additionally present the normalized confusion matrix, in which the columns correspond to predicted labels and the rows to actual labels. Consequently, the diagonal elements illustrate the probabilities of true positives, while the off-diagonal elements indicate the probabilities of misclassification. Furthermore, we evaluate the model's ability to identify transitions between phases of locomotion modes. This is measured using $\Delta t_{transition}$, as defined in Eq. 8, which denotes the average of the absolute time delays between the estimated and actual phase transition points. Various types of misclassifications such as negative delay, positive delay, and non-adjacent errors are illustrated in Fig. 3.

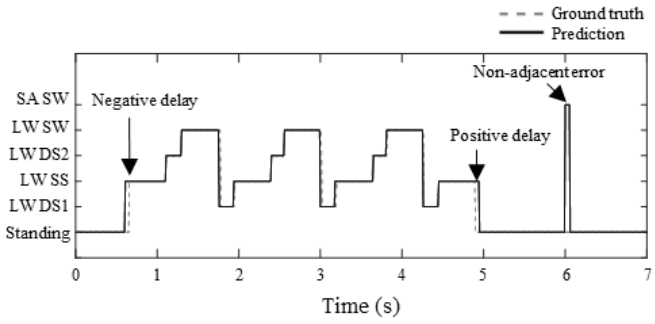

Fig. 3. Transient depiction of ground truth phases and predicted phases. The solid and dashed lines represent the predicted and ground truth phases, respectively. A negative delay is defined as instances where the subsequent phase is estimated in the current input, such that the prediction leads to the ground truth. Positive delays are the opposite, where the estimated class corresponds to the previous phase.

$$\Delta t_{transition} = \frac{1}{N_{transition}}\sum_{i=1}^{N_{transition}}|\hat{t_i} - t_i| \quad (8)$$

Where, $N_{transition}$ denotes the total number of phase transitions, and $\hat{t_i}$ and t_i represent the time of the estimated and ground truth transition, respectively. Also, phase percentage regressor was evaluated via root mean square error ($RMSE_{phase}$).

The evaluation techniques outlined above are suitable for analyzing individual subjects. To evaluate the model's performance across the entire group, we utilized a leave-one-subject-out strategy. This method allows for the assessment of the model's effectiveness on previously unseen subjects by setting aside one subject as the test sample while using data from the other subjects for training the model. This process was repeated for each of the 10 participants. Subsequently, median and quartile values were calculated to provide a comprehensive summary of the model's performance across all subjects.

III. Result

A. Classification Results

A total of 1,967,176 input data samples were evaluated in this study with 117,210 misclassifications leading to a median accuracy of 94.01%. The median P_{macro}, R_{macro}, and $F1_{macro}$ of the entire group was 88.19%, 90.96%, and 89.38%, respectively. The median $\Delta t_{transition}$ was 0.11 seconds and the confusion matrix for subject 1 is shown in Fig. 4. When we analyze the confusion matrix, we can observe that most of the misclassifications are adjacent to the diagonal line, which suggests that most misclassifications were due to negative or positive delays. This observation is further supported by the infrequent occurrence of non-adjacent errors that which were noted in less than 0.15% of instances (Fig. 5).

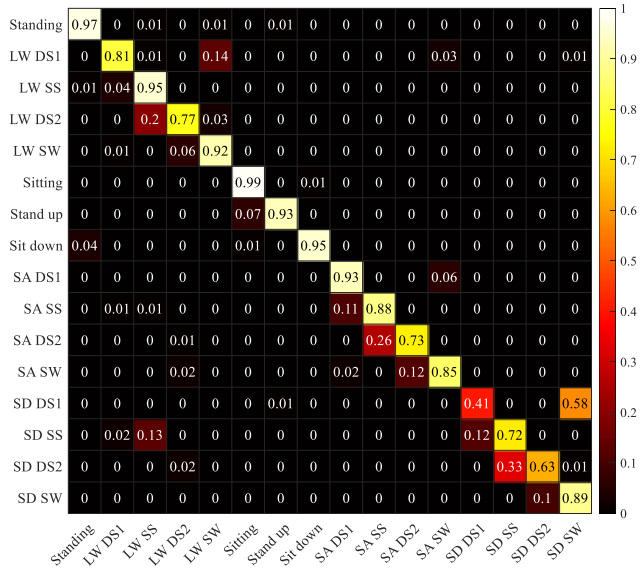

Fig. 4. Confusion matrix for all 16 activity phases for subject 1. The diagonal elements represent the probability of true positives.

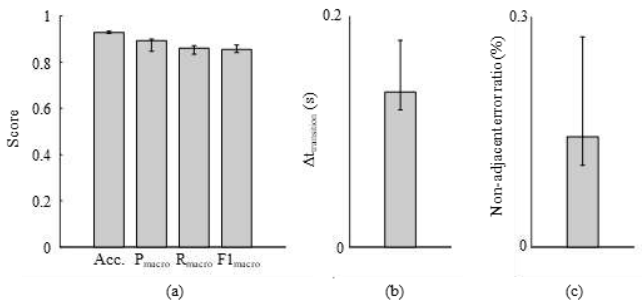

Fig. 5. Group analysis for activity phase classification. The accuracy, P_{macro}, R_{macro}, and $F1_{macro}$ are shown in (a), the $\Delta t_{transition}$ and non-adjacent error ratio are shown in (b) and (c), respectively. The data are represented as median and quartiles.

B. *Phase progression regression results*

To assess the performance of our model in predicting phase progression, we compared the regression trajectories against the ground truth, represented as red and black lines in Fig. 6, respectively. The trajectories for both the predicted and actual phases of LW, StS, SA, and SD are illustrated in Fig. 6a-d. It is evident that the red lines closely follow the black lines, indicating a strong regressor model. For a more quantitative evaluation, we computed the $RMSE_{phase}$ between our predictions and the ground truth values. The results indicated a median $RMSE_{phase}$ of 9.6% across all samples and 7.6% for only those that were correctly classified (Fig. 7). Although our model demonstrated reasonably good performance, we noted that the $RMSE_{phase}$ values for the DS phases of LW, SA, and SD were higher when compared to other phases. We previously categorized the phase progression for gait initiation and termination as either SW 50% or SS 50%, based on which limb initiated or concluded the locomotion mode. The findings presented in Fig. 6 and Fig. 7 suggest that our model effectively estimates phase progression in line with this classification.

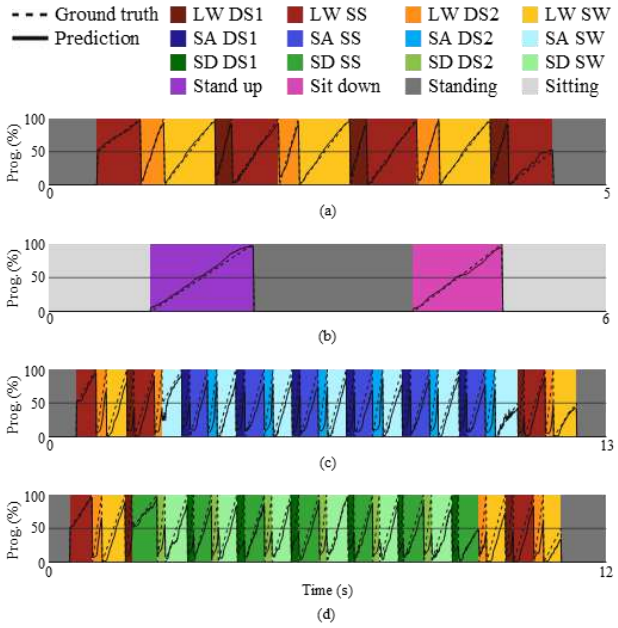

Fig. 6. Phase progression percentage regression results for subject 1. The solid and dashed lines represent the estimated phase progression percentage and ground truth, respectively. The results are shown from top to bottom for LW, StS, SA, and SD.

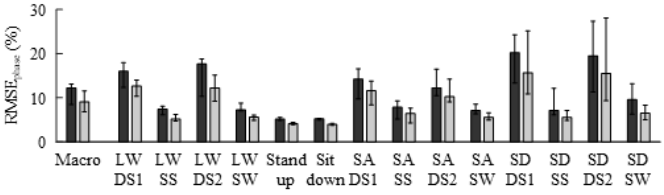

Fig. 7. Group analysis for phase progression percentage regression. The median $RMSE_{phase}$ all 14 dynamic locomotion mode phases for all sample data and only the correctly classified data are shown as black and grey bars, respectively. The error bars represent the quartiles.

IV. Discussion

In this study, we present a novel two-stage deep learning framework that employs a Bi-LSTM architecture for classifying locomotion phases, specifically focusing on locomotion with LW, SA, SD, StS actions. Additionally, we incorporate a 1-D CNN model to estimate phase progression percentages. The system processes kinematic data obtained from IMU sensors strategically placed on the thighs, shanks, and sternum of participants. Our experimental results, drawn from a study involving five subjects, indicate that our approach effectively classifies 16 distinct phases across the four locomotion modes while predicting their progression percentages. This assessment is supported by various performance metrics such as accuracy, P_{macro}, R_{macro}, $F1_{macro}$, and $RMSE_{phase}$. Notably, the model demonstrates low $\Delta t_{transition}$, highlighting its potential for integration into gait-assistive robotics, which require prompt actuator responses.

To elaborate, our phase classification algorithm achieved commendable median performance ratings, recording an accuracy of 94.01%, P_{macro} of 88.19%, R_{macro} of 90.96%, $F1_{macro}$ of 89.38%, along with a $\Delta t_{transition}$ of just 0.11 seconds. A thorough examination of the confusion matrix revealed patterns in classification errors; for instance, while phases involving sitting, standing, sit-down, and stand-up movements were predominantly accurate, certain dynamic segments (DS phases) occasionally faced misclassification into adjacent phases. This suggests that while our classification model operates effectively, transitional errors primarily emerge during phase transitions. In addition, our regression model for phase progression displayed robust performance, underscored by a low $RMSE_{phase}$ value of 7.6%.

However, our study has its set of limitations. The participant pool was restricted to five healthy individuals, excluding those requiring assistive support for gait tasks or individuals with gait abnormalities, who represent the intended audience for our model. Moreover, the locomotion mode classification and phase progression models have yet to undergo real-time testing. For future application in practical settings, the system must efficiently process input from five IMU sensors with data dimensions of (50, 30) on a mobile platform. Furthermore, although the model is intended for gait intention recognition in wearable robotics, it has not yet been deployed on actual robotic systems. Additionally, it may be pointed out that our deep learning model may not be optimal, considered that it has not been compared to state-of-the-art deep learning models such as attention mechanisms and transformers. Finally, to suit gait assistive robots, the system should operate free of positive delays, fostering timely assistance prior to robotic actuation. We propose that a possible solution lies in adjusting label shifts in the dataset to reflect predictive outcomes rather than exact ground truths.

Future investigations will aim to assess the model's efficacy across a broader demographic, including the elderly and individuals with anomalous gait patterns or disabilities. Additional focus will be placed on expanding the dataset to encapsulate a wider array of activities and corresponding

phases. For certain intricate movements, the deployment of five IMU sensors may prove inadequate, thus requiring supplementary sensors or a multimodal approach encompassing varied sensor technologies. Moreover, we will explore the model's real-time operational capabilities using IMUs in conjunction with single-board computers, paving the way for applications in health monitoring, diagnostic procedures, and the enhancement of gait-assistive robotic technologies.

Introducing V-Soft Pro: a Modular Platform for a Transhumeral Prosthesis with Controllable Stiffness

Giuseppe Milazzo, Giorgio Grioli, Antonio Bicchi, and Manuel G. Catalano

***Abstract*— Current upper limb prostheses aim to enhance user independence in daily activities by incorporating basic motor functions. However, they fall short of replicating the natural movement and interaction capabilities of the human arm. In contrast, human limbs leverage intrinsic compliance and actively modulate joint stiffness, enabling adaptive responses to varying tasks, impact absorption, and efficient energy transfer during dynamic actions. Inspired by this adaptability, we developed a transhumeral prosthesis with Variable Stiffness Actuators (VSAs) to replicate the controllable compliance found in biological joints. The proposed prosthesis features a modular design, allowing customization for different residual limb shapes and accommodating a range of independent control signals derived from users' biological cues. Integrated elastic elements passively support more natural movements, facilitate safe interactions with the environment, and adapt to diverse task requirements. This paper presents a comprehensive overview of the platform and its functionalities, highlighting its potential applications in the field of prosthetics.**

I. Introduction

Limb loss brings profound challenges to individuals, affecting not only their motor capabilities but also their emotional well-being and social lives. Prosthetic devices help bridge this gap by restoring the natural appearance of the human body and some functional capabilities of human limbs. However, current prostheses fall short of replicating the complex functionality of natural limbs, focusing mainly on enabling users to achieve a basic level of self-sufficiency with essential motor functions.

Myoelectric upper-limb prostheses represent the current frontier in human-like limb restoration and natural motor control. However, robotic prostheses often rely on rigid joints, which lack the fluid, adaptive behavior that human limbs exhibit in motion and interaction with the environment. Humans voluntarily adjust the impedance of their limbs by coactivating antagonistic muscles. This adaptive strategy provides flexible and responsive limb behavior: a compliant approach reduces applied force during constrained tasks and allows safe exploration in unfamiliar environments, while high stiffness enables precision tasks and counters external forces effectively [1]–[4]. Inspired by this capability, it is clear that upper-limb prosthetic devices should incorporate mechanisms for users to actively control impedance, which would enhance both versatility and task performance [4], [5]. Unlike human limbs, rigid joints lack the adaptability provided by passive compliance and controllable stiffness. Rigid devices are also less suitable for safe interaction in unstructured and dynamic environments, where humans frequently face unpredictable conditions in daily life. Unable to absorb shocks, these devices increase the risk of harm to people and objects during unintended collisions, which are common due to a lack of proprioceptive feedback. Furthermore, rigid prostheses are limited in their ability to apply low interaction forces, making delicate interactions with fragile objects challenging.

Fig. 1. Two configurations of the V-Soft Pro transhumeral prosthesis, customized to meet diverse user needs. Panel (a) illustrates a V-Soft Pro configuration designed to achieve a human-like weight distribution for proximal transhumeral amputations. Panel (b) shows a version of the V-Soft Pro platform adapted for users with longer residual limbs.

Impedance control has revolutionized robotic applications that require physical interaction with the environment and cooperation with humans [6]–[9], enabling robots to follow planned paths during free motion and supervise interaction forces when encountering obstacles along the path. Impedance control can be implemented in standard torque-controlled robots simply via software. However, it relies on high-performance sensors, actuators, and computing, making it well-suited for most industrial applications but difficult to integrate into portable robotic devices with limited battery life and performance, such as prostheses [10]. An alternative approach is to embed variable impedance characteristics directly into the robot hardware design [11]–[13]. On one hand, Variable Impedance Actuators (VIAs) involve complex hardware implementations, as they require dedicated mechanisms to alter the physical properties of the joint. On the other hand, they often rely on simple software control

and are intrinsically robust and versatile, as joint impedance is dictated passively by the physical properties of the joint. Among VIAs, VSAs integrate redundant actuation and non-linear elastic transmissions into their mechanical design, allowing them to adjust output stiffness by controlling the active deflection of elastic elements, akin to antagonistic muscle coactivation.

This paper introduces V-Soft Pro (V-SP), a modular platform for an active transhumeral prosthesis with user-controllable stiffness. The platform consists of two elbow modules, three wrist modules, and two hand modules, which can be combined to create a transhumeral prosthesis tailored to the user's limb morphology and the available biosignals for control. While some of the V-SP modules have been previously presented and characterized in our past works [14], [15], this paper focuses on their integration into a customizable transhumeral prosthesis with variable stiffness (VS). Section II provides an overview of the state of the art in transhumeral prostheses and VS prosthetic joints. Section III details the V-SP hardware design and the implementation of its submodules. Section IV presents the hardware integration of two different configurations of the V-SP platform and demonstrates the functionality of the VS transhumeral prostheses. Section V discusses potential applications and limitations of the system, and conclusions are provided in Section VI.

II. Related Work

Robotic upper limb prostheses typically feature rigid actuation and fixed impedance properties. However, some elbow and wrist prostheses offer a transition between two discrete stiffness levels (locked or unlocked) by activating a locking mechanism through electromyographic (EMG) control or with the contralateral arm. For instance, elbow prostheses[1,2] can be locked to support external weights or unlocked to swing freely during walking [16]. Similarly, spring-loaded flexion wrists[3] can be unlocked to exploit environmental constraints during grasping or locked to resist perturbations [17]. While these locking mechanisms provide some degree of task adaptability, they lack the natural ability to smoothly and accurately control joint stiffness. VSAs have recently been applied in prosthetics due to their similarity to the human musculoskeletal system in terms of interaction and joint stiffness regulation. Recent studies report applications of VSAs in standalone VS prosthetic joints, including ankle-foot [18]–[20], hand [21], wrist [15], and elbow [14], [22] prostheses. However, multiple VS joints have never been integrated into a single transhumeral prosthesis.

Wrist prostheses are often significantly streamlined to reduce overall complexity. These prosthetic wrists are typically passive and usually feature a limited number of degrees of freedom (DoFs), prioritizing wrist pronation/supination (wPS), occasionally implementing wrist flexion/extension (wFE), and rarely incorporating radial/ulnar deviation (RUD) [23]–[25].

Developing human-like bionic hands has been a longstanding challenge in upper limb prosthetics research. Due to the remarkable complexity and versatility of human hands, artificial hands inevitably require a trade-off between functionality and complexity. Polyarticulated hand prostheses are sophisticated devices that typically include a set of pre-installed standard grips, each designed for a specific task [26]–[29]. However, these dexterous devices are often abandoned due to their increased weight, cognitive load, and the frustration of selecting the desired grasping strategy [30], [31]. In contrast, soft hands are easier to use, as their compliant designs allow passive adaptation to object shapes. Additionally, some can modulate stiffness to enhance precision and grasp strength, utilizing technologies such as pneumatic actuators, shape memory alloys, or cable-driven actuation [32].

Bionic limb replacement becomes more challenging as the level of amputation grows, and prosthetic devices must implement a higher number of motor functions while respecting strict morphological (i.e., size and weight) and functional (i.e., range of motion, torque, speed, and battery life) requirements [14], [15], [33], [34]. Consequently, transhumeral prostheses often omit some biological DoFs and leave small space for user-centered customizations due to restrictive design constraints [16], [35]–[38].

III. The V-Soft Pro Platform

The V-SP platform features a modular design, outlined in Fig. 2, allowing users to select the most suitable configuration based on their individual residual limb morphology, number of independent control channels, and daily needs. The platform includes the VS-Elbow, presented in [14], which offers two different layouts designed to optimize ergonomics and biomimicry for both distal and proximal transhumeral amputations. Additionally, users can choose from three prosthetic wrists, depending on their ability to control numerous DoFs. The V-SP platform includes the VS-Wrist [15], a prosthetic wrist with 3 active DoFs and controllable stiffness, along with two commercial wrists: the Ottobock Wrist Rotator[4] and the Ottobock Quick Disconnect Wrist[5]. Additionally, the V-SP platform is compatible with two prosthetic hands: the SoftHand Pro and SoftHand 2. This flexibility allows the user to choose from terminal devices with varying levels of dexterity, depending on their myoelectric control skills and daily needs.

A. Elbow Module

The VS-Elbow is a prosthetic elbow featuring redundant actuation and non-linear elastic transmission, which allows for decoupled control of elbow stiffness and position. The VS-Elbow features a single kinematic DoF that actuates elbow flexion/extension (eFE). However, the device incorporates two DC motors, which drive the elbow shaft through an open timing belt. Belt tension is adjusted via a lever arm

mechanism that affects the active deflection of extension springs. By leveraging redundant actuation, the VS-Elbow adjusts the active length of the transmission belts, thereby modifying the preload on the elastic transmission and regulating elbow stiffness. This mechanism of stiffness regulation is analogous to the coactivation of agonist-antagonist (AA) muscle groups, such as the biceps and triceps brachii. Each DC motor is equipped with a planetary gearbox and a worm gear to amplify output torque, ensuring sufficient performance for standard activities of daily living, such as actively lifting payloads of up to 3 kg. The motor transmission is designed to be non-backdrivable, enabling the VS-Elbow to support payloads and maintain high stiffness passively, which in turn improves battery efficiency. The output joint is decoupled from the motor shaft, ensuring compliant behavior and maintaining the imposed stiffness even when the system is powered off.

The VS-Elbow is available in two different layouts to accommodate the diverse morphologies of residual limbs. The VS-Elbow AA adopts a VSA with an AA configuration, where one elastic actuator represents the triceps brachii and the other represents the biceps brachii. Thus, the net torque generated by one branch relative to the other produces elbow flexion or extension, while their magnitudes determine the joint stiffness. The AA design results in a compact form factor that can be fully contained within the forearm segment of the bionic limb. Due to this feature, the VS-Elbow can be adapted to fit proximal transhumeral amputations while meeting the restrictive functional and morphological requirements of upper limb prostheses, and it can achieve symmetry with the contralateral elbow axis of rotation. However, since the weight of the elbow prosthesis is concentrated in the forearm, the VS-Elbow AA may not offer optimal comfort for individuals with distal transhumeral amputations, as it leaves unused space in the upper limb segment.

Addressing individuals with short residual limbs, V-Soft Pro features the VS-Elbow D2, a prosthetic elbow that evenly distributes its mass and volume between the upper limb and forearm. This unique design ensures a human-like mass distribution, enhancing ergonomics and promoting natural movement for distal transhumeral amputees [14]. The VS-Elbow D2 is a VSA with an Explicit Stiffness Variation layout, where the two DC motors operate independently to control either the position or the stiffness of the joint. The stiffness motor is located in the upper limb segment and modulates joint stiffness by adjusting the preload of two elastic transmission mechanisms. These non-linear springs are configured to function as an AA system, ensuring symmetry of joint stiffness during both flexion and extension. Conversely, the position motor is located in the forearm segment and drives eFE by rotating the forearm around the fixed elbow shaft.

B. Wrist Module

The wrist module of V-Soft Pro can be customized to accommodate the final user's available control channels and daily needs. The VS-Wrist is the most advanced wrist module in the platform, featuring 3 active DoFs and user-controllable stiffness. It is the first prosthetic wrist designed to actively restore all human wrist DoFs while providing decoupled stiffness control across a continuous range through modulation of non-linear spring preload. Typically, a 3-DoF VSA requires 6 motors, resulting in significant bulk and weight that would hinder prosthetic applications. However, the VS-Wrist utilizes a hybrid parallel-serial architecture to achieve 3 kinematic DoFs and user-controllable stiffness within a compact design, requiring only 4 motors. The parallel manipulator (PM) offers a hemispherical range of motion, enabling wrist flexion/extension (wFE) and radial/ulnar deviation (RUD). Although it has two DoFs, the PM is redundantly actuated by three DC motors through a non-linear elastic transmission. This architecture allows modulation of internal forces to the PM, thereby adjusting the preload on the non-linear springs without affecting the wrist equilibrium position, and enabling decoupled stiffness and position control. Similar to the VS-Elbow, each motor transmission incorporates a planetary gearbox and a worm drive, achieving non-backdrivability to maintain static loads without power consumption. Furthermore, the VS-Wrist includes a dedicated motor unit that actuates wrist pronation/supination (wPS) through two opposed universal joints, positioned at the center of the PM.

V-Soft Pro is also compatible with two simpler commercial prosthetic wrists, offering options for users with fewer control inputs or those preferring a lighter device, although at the expense of some functionalities. The Ottobock Wrist Rotator is a commercial myoelectric wrist that supports EMG control of wPS, while wFE and RUD are blocked. The Ottobock Quick Disconnect Wrist is more compact but allows only passive wPS, which the user can actuate using the contralateral arm.

C. Hand Module

The SoftHand Pro [39] uses a single motor to actuate 19 DoFs, replicating the kinematics and morphology of a human hand. Each finger consists of three rigid modules, similar to phalanges, with the thumb comprising only two segments. These phalange modules are 3D-printed and available in various sizes. Elastic joints connect consecutive phalanges, ensuring robust and safe interaction with the environment. In this way, rigid links, representing bones, are connected by elastic bands that function like ligaments. A differential transmission evenly distributes contact forces across all fingers, enabling the hand to grasp objects of various shapes. Thanks to the mechanical intelligence inherent in its design, the SoftHand Pro is intuitive to use, allowing users to execute a variety of grasping strategies that passively adapt to different shapes with a single closing command. For users with advanced EMG control skills, the SoftHand 2 introduces an additional synergistic actuator, expanding the range of grasping, manipulation, and fine gesture capabilities [40]. The SoftHand also features a silicone glove or rubber pads, enhancing grasp stability and offering a customizable cosmetic appearance.

IV. Experiments

We present the integration of the V-SP platform in two distinct configurations. The first configuration includes the VS-Elbow D2, the VS-Wrist, and the SoftHand Pro, providing a total of 5 DoFs for kinematics and 2 DoFs for stiffness control. The second configuration utilizes the VS-Elbow AA, the Ottobock Wrist Rotator, and the SoftHand 2, offering 4 kinematic DoFs and 1 DoF to control elbow stiffness.

Each motor position is regulated by a dedicated PID controller operating at 200 Hz, which modulates the duty cycle of a 20 kHz PWM signal. The system is powered by a single 24 V commercial battery. An external laptop, running a Matlab Simulink graphic user interface, enables the user to set position and stiffness references for each prosthetic joint, as well as to monitor encoder and EMG signals in real-time.

We report preliminary lab tests demonstrating the varying degrees of prosthesis functionality achievable through customization of the modular V-SP platform. A comprehensive technical characterization of the V-SP platform submodules can be found in [14], [15], [39], [40]. Fig. 3 presents photo sequences extracted from the multimedia material accompanying this paper. Fig. 3a illustrates the first configuration of the V-SP system during coordinated active motion of all prosthetic joints, highlighting its high wrist mobility. Fig. 3b depicts the second configuration of the V-SP system, where the prosthesis adjusts its elbow stiffness to adapt to different tasks. This adaptability suggests the enhanced versatility of V-SP prostheses in unstructured environments. The V-SP transhumeral prosthesis can reduce elbow stiffness to accommodate obstacles along its path and comply with external forces, enabling gentle interactions. Conversely, it increases elbow stiffness to reject disturbances and support precision tasks.

V. Discussion

Current robotic prostheses significantly enhance the quality of life for upper limb amputees. However, they typically incorporate simplified motor functions and lack the natural compliance of human limbs. Replicating the controllable stiffness of the human musculoskeletal system in a prosthetic device would enable more human-like interactions, thus increasing acceptance and social integration. Moreover, compliant bionic limbs improve safety by absorbing unintended impacts that can arise from the absence of proprioceptive feedback or from errors in the operation of the prosthetic limb. Furthermore, VS prostheses can adapt their behavior to various tasks encountered in daily life. As shown in Fig. 3b, soft joints enable the exploitation of environmental constraints, ensuring safe interactions in cluttered environments by adapting to obstacles and preventing damage. Meanwhile, high elbow stiffness is crucial for rejecting disturbances during precision tasks. While this preliminary experiment suggests that VS prosthetic limbs may improve users' quality

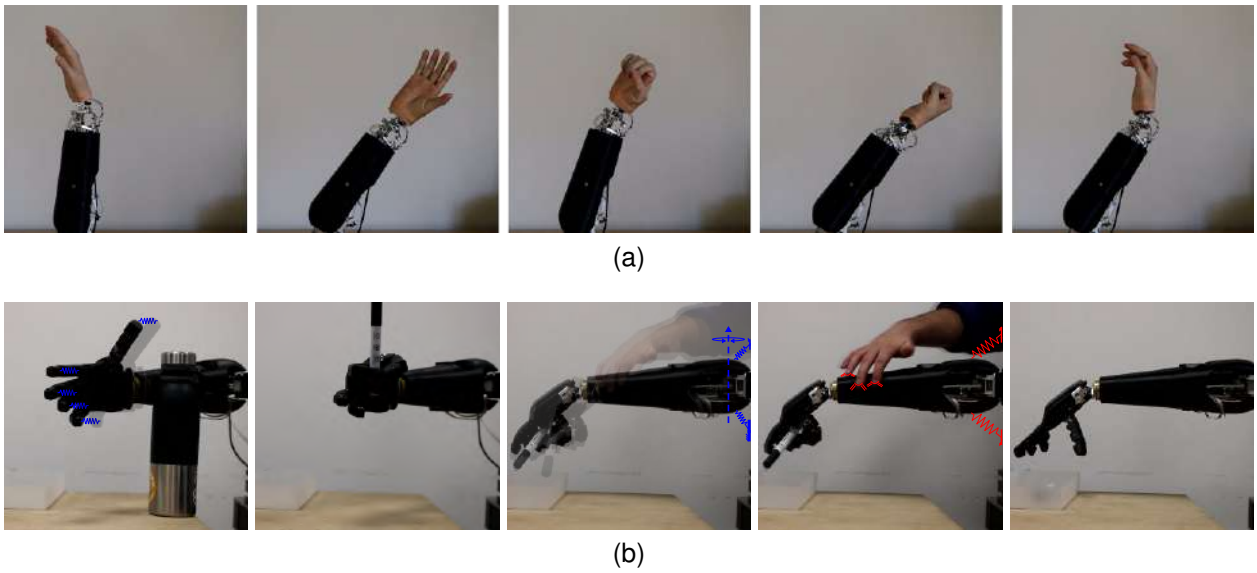

Fig. 3. Functional demonstration of two configurations of the V-Soft Pro system. Sequence (a) shows the V-SP platform performing active, simultaneous motion across all its submodules. Sequence (b) demonstrates the benefits of variable stiffness actuation within the transhumeral prosthesis. In the first scene, the prosthesis uses low joint stiffness to navigate an unstructured environment, allowing gentle contact with nearby objects without knocking them over. It then performs a tripod grasp (second scene) followed by wrist pronation. With low elbow stiffness, the prosthesis adapts to external forces without resisting (third scene). However, the V-SP system can increase its stiffness to counter external disturbances (fourth scene) and perform precision tasks (fifth scene).

of life, further testing with prosthesis users is necessary to evaluate their real-world functionality.

The V-SP platform offers a customizable transhumeral prosthesis that meets diverse user specifications, considering both ergonomics and the number of controllable motions. Future work will focus on tailoring the EMG control of the V-SP system to the individual user. One possibility is to adopt existing EMG-based VS controllers from the literature, which regulate the stiffness and position of single-DoF joints [41]–[43], and extend these approaches to sequential control, commonly used in multi-DoF prostheses. In this scenario, the user utilizes a switching signal to toggle control between different prosthetic joints, such as rapid coactivations, signals from auxiliary EMG recording sites, or even a physical switch activated by the contralateral arm. While sequential control is easy to implement, it may result in unnatural motion and unintuitive control as the number of DoFs increases, limiting the usability of advanced prostheses. Key enablers of this technology may include surgical procedures that increase the number of independent biosignals (e.g., Targeted Muscle Reinnervation and Regenerative Peripheral Nerve Interfaces), cutting-edge EMG recording technologies (such as high-density EMG and implantable electrodes), and advanced neural decoding algorithms [26], [44]–[46].

VI. Conclusion

Current robotic prostheses lack the innate compliance and variable stiffness of human limbs, leading to unnatural interactions with people and objects, while compromising versatility and social engagement. To address these issues, this paper presents V-Soft Pro, a modular platform for a transhumeral prosthesis with user-controllable stiffness. V-Soft Pro features a user-centered design, enabling customization of its components based on the user's level of amputation, daily needs, and myoelectric control skills. Recognizing the diversity among users, the modular design offers various configurations to optimize comfort and usability for each individual. The prosthetic joints integrate VSAs to replicate the adaptive behavior of human limbs, providing human-like dynamics and continuous joint stiffness regulation. The V-Soft Pro system has the potential to significantly enhance the user experience by improving the natural feel of bionic limbs and offering customized prosthetic solutions to individual needs. However, further research is necessary to accurately decode user intent, enabling more natural operation of the prosthesis and maximizing its capabilities. Clinical trials with prosthesis users are needed to assess the functionality of user-controllable stiffness in prosthetic devices during ADLs and social interactions.

***Abstract*—Upper extremity (UE) impairments resulting from non-communicable diseases continue to rise annually across the globe. Robotic devices offer promising solutions for mitigating the long-term logistical challenges and limited recovery outcomes associated with short-term, one-to-one rehabilitation sessions. This study presents a repeatability analysis of CLEVERArm (compact, lightweight, ergonomic, VR/AR-enhanced rehabilitation arm), an eight-degrees-of-freedom (DOF) robotic exoskeleton for treating patients with UE impairments, focusing on validating both single-DOF (sDOF) and multi-DOF (mDOF) trajectories produced by the device. Eighteen healthy subjects performed tasks ranging from simple to complex UE movements associated with activities of daily living. The device then autonomously repeated the movements made by the participants. Across all tasks, CLEVERArm demonstrated low root mean square deviation ($< 3.42^{\circ}$), and high correlations (> 0.99) between reference and repetition trajectories recorded by absolute encoders. High intra-class coefficient values (> 0.9) further constitute the system's consistency and accuracy in UE movement over time. These results suggest that CLEVERArm can reliably replicate input trajectories, providing consistent and positive outcomes in rehabilitation settings. Future work will utilize the device's ability to accurately replicate trajectories for designing personalized rehabilitation regimens, monitoring patient progress, and tailoring exercises to individual needs, ultimately enhancing long-term recovery for patients with UE impairments.**

I. Introduction

The prevalence of neurological and neurodegenerative disorders, including spinal cord injury (SCI), traumatic brain injuries (TBI), Parkinson's Disease (PD), Multiple Sclerosis (MS), and stroke, is now affecting a billion people in the world [1]. Projected increases in the incidence of each disorder will lead to higher rehabilitation costs and treatment of each condition. However, the projected growth of professionals with the appropriate training is considerably lower than the incidence rate [2]. Consequently, these conditions pressure healthcare providers for treatment, rehabilitation, and support services. Thus, an autonomous intervention can mitigate the effects of logistical constraints and provide intensive, repetitive, and task-oriented rehabilitation that is needed for effective recovery in the long term [3].

The inherent capabilities of robotic systems in producing high-intensity, repeatable, and precisely controllable motions make them a desirable candidate for upper extremity (UE) rehabilitation [4]. Two types of robotic systems exist: end-effectors and exoskeletons. End-effector robots tend to focus rehabilitation on the distal part of the UE. In contrast, exoskeletons focus heavily on the entire UE by aligning them with the anatomical axes of the patient [5]. Due to the limitations of end-effector control of the proximal aspects of the UE, researchers have focused on exoskeletons, as they enable patients to perform movements that typically span a broader range of the UE workspace. These movements range from single-degree-of-freedom (sDOF) to multi-degree-of-freedom (mDOF) tasks, assessing the patient's ability to perform activities of daily living (ADL) movements that replicate those commonly performed in everyday life [6]. Despite this advantage, achieving kinematic compatibility between the exoskeleton and the human arm remains a challenge, making trajectory assessment and control difficult across a wide range of movements [2], [7].

With the use of robotic exoskeletons, robotic devices can provide more reliable quantifiable metrics that can track patient improvement in trajectories compared to existing clinical measures such as the Fugl-Meyer Assesment (FMA) and Modified Ashworth Scale (MAS) that rely on ordinal scales to track rehabilitation progress [8]. Previous forms of robotic assessments have relied on metrics quantifying trajectory tracking and speed in point-to-point reaching tasks [9], [10] while ADL tasks limited to a singular aspect of the UE workspace [11]. However, while the metrics for each trajectory are validated, the motions themselves are not complex enough to transfer to real-life situations where patient improvement

would be noticeable [12], [13]. Additionally, many of the assessment methods rely on trajectory characteristics [14], [15] and patient capability [16], depending on control measures to account for errors when trajectories are repeated [17], [18]. They do not consider the consistency of robotic controllability when trajectories are reproduced on multiple attempts based on the reference path lines.

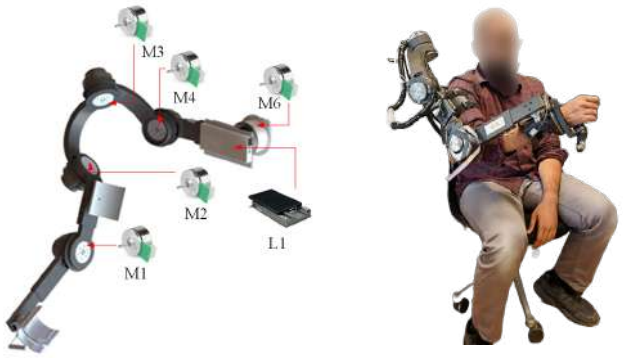
This study aims to validate the CLEVERArm (compact, lightweight, ergonomic, VR/AR-enhanced rehabilitation arm) exoskeleton, developed by our research team [2], [19], in accurately reproducing various movements. The device is designed to automatically provide repetitive rehabilitation and offer 0-100% weighted support during various UE motions. A large cohort of subjects was used to statistically validate the device's repeatability (i.e. carrying out a trajectory multiple times) and reliability (i.e. consistency in replicating the inputted trajectory) across tasks of varying complexity. The validation process includes visual inspection, quantitative measurements, and statistical analysis, ensuring the system's robustness and performance.

II. Materials and Methods

The following subsections detail the CLEVERArm specifications and validation methodology employed in this study.

A. CLEVERArm Exoskeleton System

The CLEVERArm (see Fig. 1) has eight DOFs supporting the motion of the shoulder girdle, glenohumeral (GH) joint, elbow, and wrist. Out of the eight DOFs, six DOFs are active (Maxon EC brushless motors), while the other two are passive. An active DOF is used to assist in flexion/extension of the elbow joint, while three active DOFs are used to support shoulder motion. Two additional active DOFs, one prismatic and one revolute, are used to account for scapulohumeral rhythms during shoulder motion. Robotic configuration is determined using joint angle measurements from absolute rotary encoders (AksIM™ Off-Axis Rotary Absolute Magnetic Encoder) situated at each of the revolute joints.



The overall control architecture of the CLEVERArm involves baseline gravitational compensation with the appropriate inertial parameters calculated by the CAD model in SolidWorks [2].The exoskeleton currently operates within a user-friendly interface on LabVIEW. For the passive therapy module, the subject performs the motion while the pathline is recorded. The recorded pathline is interpolated into 100 equally spaced points, appended with its reverse to form a complete movement, and repeated as required by the desired number of iterations for the robotic trajectory. A uniform PID controller (K_p = 1.5, K_i = 0.03, K_d = 0.002) is applied to each actuator at every point, with baseline controllers running concurrently. The passive therapy module has been optimized using parallelization strategies to minimize delays in the long-term during execution of the desired trajectories.

TABLE I: Rehabilitation Tasks

Name	DOF	Task Description	Configuration
Task 1	Single	Elbow Flexion-Extension	0-140°
Task 2	Single	Shoulder Abduction-Adduction	0-90°
Task 3	Single	Shoulder Flexion-Extension	0-90°
Task 4	Multiple	Reaching to Head	As needed
Task 5	Multiple	Eating Activity	As needed
Task 6	Multiple	Combing Activity	As needed

B. Experimental Protocol

The Institutional Review Board (IRB) granted ethical approval (IRB2018-0016DQ, QU-IRB 1884-EA/23, MRC-02-22-164), ensuring adherence to established research standards. We recruited 18 healthy subjects (age range 18-35) to determine the repeatability of the CLEVERArm device. All participants had no history of UE injuries or musculoskeletal disorders. All tasks were exclusively performed using their right limbs. Each subject executed a set of six tasks, repeating each task five times, resulting in a total of 30 experiments per participant. Upon wearing the exoskeleton, subjects initially executed each task themselves, constituting the reference data for subsequent evaluations. The CLEVERArm device then replicated the motion for each task five times, denoted as repetitions. The arm's starting position was fully extended for all task scenarios. Joint angle data for actuators 1 to 4, where actuator 1 corresponds to the elbow and 2 to 4 to the shoulder, were measured using the built-in absolute encoders (Fig. 1a). The sampling rate was 100 Hz. Subjects engaged in three sDOF and three ADL, referred to as mDOF, including reaching towards the head, combing, and eating (Table I). This comprehensive study design ensures a thorough exploration of the CLEVERArm's repeatability across various simple to complex activities, providing valuable insights for future developments and applications.

C. Repeatability Analysis

The repeatability assessment of CLEVERArm was carried out employing a comprehensive array of methodologies, each aimed at providing an in-depth understanding of its performance characteristics. These methodologies included visual inspection, correlation analysis, computation of root mean square deviation (RMSD) between reference and repetition signals, analysis of variance (ANOVA), and computation of intraclass correlation coefficients (ICCs).

1) Visual Inspection and Quantitative Measurement: Both the reference and repetition tasks were plotted for each actuator to qualitatively assess the similarity and consistency between the two signals, allowing for the identification of any observable discrepancies or patterns. To quantify the differences, the RMSD was computed for each task:

$$d_t = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}, \tag{1}$$

where y_i and $\hat{y}_i$ denote the i-th sample of the reference and repetition signals, respectively, n represents the total number of samples and d_t represents the RMSD for the *t*-th task. Additionally, the Pearson correlation coefficient (r) was computed to quantitatively evaluate the relationship between the reference and repetition signals as follows:

$$r = \frac{\sum_{i=1}^{n}(y_i - \bar{y})\left]\hat{y}_i - \bar{\hat{y}}\right)}{\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2 \sum_{i=1}^{n}\left]\hat{y}_i - \bar{\hat{y}}\right)^2}}, \tag{2}$$

where n is the total number of samples, y_i and $\hat{y}_i$ are the reference and repetition signals for the i-th sample, and $\bar{y}$ and $\bar{\hat{y}}$ are the mean values of the reference and repetition signals, respectively.

2) Analysis of Variance (ANOVA): A two-way within-within repeated measure ANOVA was conducted to assess differences across tasks, repetitions, and their interactions. In this design, subjects were considered random effects to account for individual variability, while tasks and repetitions were analyzed as fixed effects to explore their impact on RMSD values. The generalized eta squared (η^2) was used to calculate effect sizes, providing insight into the practical significance of the findings. The effect size can be interpreted as negligible when $\eta^2 < 0.01$, small $0.01 <= \eta^2 < 0.06$, medium $0.06 <= \eta^2 < 0.14$, and large $\eta^2 >= 0.14$ [20]. This approach enabled a comprehensive investigation, shedding light on the performance and repeatability of the CLEVERArm exoskeleton system.

3) Intraclass Correlation Coefficient (ICC): ICCs were computed to assess the test-retest reliability of the CLEVERArm exoskeleton system across tasks and repetitions. ICC(3,1), a two-way mixed effect for consistency, was chosen for its ability to capture systematic differences and random errors within each repetition, making it suitable for evaluating the device's reliability. The test-retest reliability value can be interpreted as follows: <0.5 = poor reliability, 0.5-0.75 = moderate reliability, 0.75-0.9 = good reliability, and >0.90 = excellent reliability [21].

III. Results and Discussion

The repeatability of CLEVERArm was analyzed using a multifaceted approach, including visual inspection, quantitative analysis, and statistical analysis. As shown in Fig. 2, the alignment between repetition and reference signals across various tasks showcased a clear consistency in the system performance. Complementing this qualitative assessment, Table II presents quantitative measurements, including RMSD and correlation values between reference and repetition signals for all tasks. The results consistently demonstrate values below 3.42° and above 0.99 for RMSD and correlations, respectively, underscoring the system's remarkable stability and fidelity in executing synchronous movements across tasks. The RMSD values across actuators show generally low deviation, with most tasks demonstrating less than 1° of variation for sDOF and less than 2° for mDOF tasks. Only in shoulder flexion-extension did actuator 4 exceed 3° (3.41°), while actuator 2, the key responsible actuator, showed less than 1° of deviation. This discrepancy is likely due to external forces from subject movement or slight posture changes. The mDOF movements showed a slight increase in variation compared to sDOF, as expected, due to their inherent complexity. Overall, the system's performance remains stable, with deviations within acceptable limits, confirming its robustness for rehabilitation applications.

Despite minor fluctuations, the average RMSD remained consistently below 2° (Fig. 3), indicating high repeatability across tasks and trials. It should be noted that the marginally moved actuators produced minimal variations (see Fig. 3), which resulted in low correlations, although both signals aligned. This occurs because the small differences between data points and the mean reduce the numerator in the correlation coefficient calculation. In essence, even though the signals visually align, the lack of significant movement variation limits the extent of their linear relationship, resulting in lower correlation values. Nevertheless, both of these qualitative and quantitative analyses provide a holistic understanding of CLEVERArm's repeatability.

The two-way repeated measure ANOVA revealed significant effects for both task ($F(5, 85) = 9.262, p < 0.01$) and repetition ($F(4, 68) = 8.321, p < 0.01$). Effect sizes, represented by generalized eta squared (η^2), indicated that the task had a relatively large effect size ($\eta^2 = 0.340$), suggesting that differences between tasks accounted for a substantial proportion of the variability in the data. This outcome was anticipated due to the higher complexity of tasks involving mDOF compared to those with sDOF, where multiple actuators move simultaneously, resulting in significant differences. This reaffirms the effectiveness of the task complexity design in evaluating CLEVERArm's repeatability. In contrast, repetition had a smaller effect size ($\eta^2 = 0.007$), indicating a lesser and negligible impact on the outcomes and consistent performance irrespective of repetition. While the first repetition consistently yielded lower RMSD values compared to other repetitions, the difference was less than 0.2°, as reflected in the effect size

TABLE II: CLEVERArm's Repeatability Analysis

Metric	Actuator	Elbow Flexion-Extension		Shoulder Abduction-Adduction		Shoulder Flexion-Extension		Reaching to Head		Eating Activity		Combing Activity	
		Mean	STD	Mean	STD	Mean	STD	Mean	STD	Mean	STD	Mean	STD
RMSD	Actuator 1	2.03	1.14	0.54	0.54	0.18	0.39	0.69	0.53	2.51	0.86	2.27	0.84
	Actuator 2	0.89	0.40	2.64	0.74	0.87	0.78	2.77	0.90	1.78	0.62	2.07	0.82
	Actuator 3	0.51	0.30	1.81	0.85	0.93	0.81	1.96	0.65	1.29	0.42	1.38	0.51
	Actuator 4	0.61	0.48	1.54	0.72	3.41	1.11	1.49	0.98	0.98	0.51	1.20	0.58
Correlations	Actuator 1	1.00	0.00	0.37	0.48	0.09	0.32	0.61	0.46	1.00	0.00	1.00	0.00
	Actuator 2	0.76	0.42	1.00	0.00	0.53	0.50	1.00	0.00	0.99	0.00	1.00	0.00
	Actuator 3	0.39	0.54	0.98	0.02	0.27	0.66	0.99	0.02	0.66	0.01	0.97	0.11
	Actuator 4	0.38	0.44	0.78	0.40	0.99	0.00	0.78	0.36	0.54	0.46	0.73	0.48

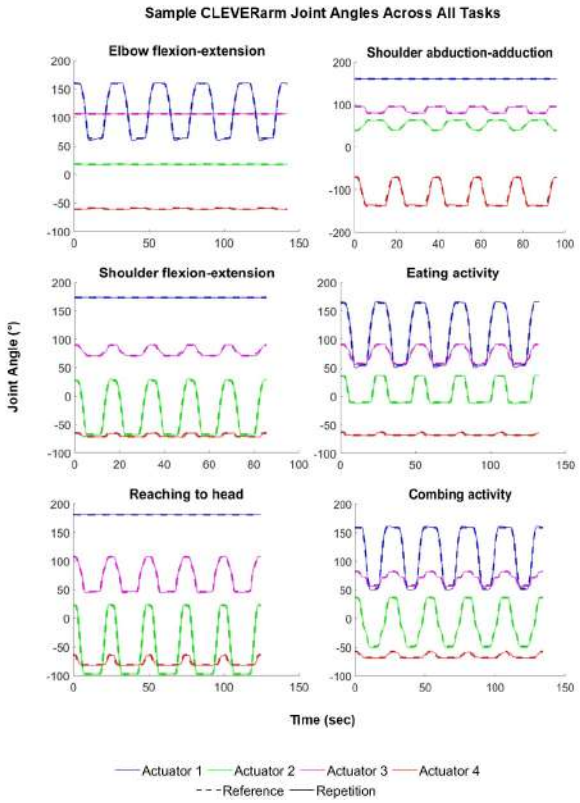

Fig. 2: Illustration of CLEVERArm joint angles across all tasks for all actuators, with dashed lines representing reference signals and solid lines indicating repetitions. Plots depict data for one subject.

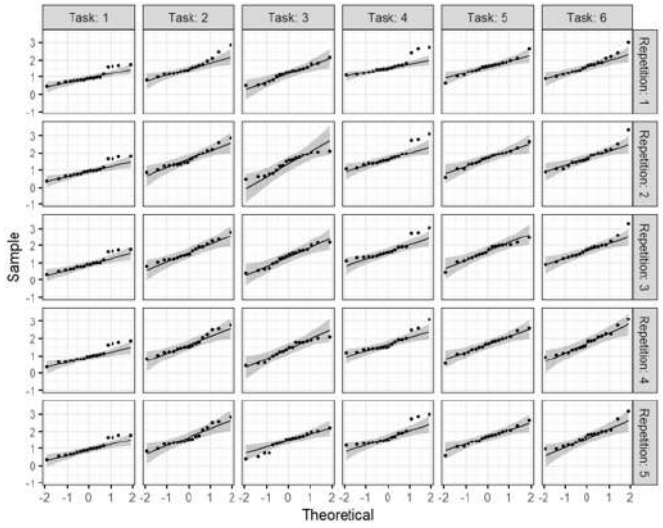

Fig. 4: Q-Q plots for the two-way repeated measure ANOVA

calculation of 0.007, indicating negligible significance.

These findings collectively affirm the robust repeatability of the CLEVERArm system, demonstrating its ability to replicate movements across various repetitions consistently. Moreover, adherence to statistical assumptions of homogeneity, independence, and sphericity ensures the validity and reliability of the ANOVA results. While normality tests using the Shapiro-Wilk test indicated that the residuals from the ANOVA were not normally distributed ($W = 0.971$, $p < 0.001$), the Quantile-Quantile (Q-Q) plot (Fig. 4), which compares sample quantiles with theoretical normal distribution, visually affirms that the deviation is marginal. In the Q-Q plot, if the points fall along a straight 45-degree line, it indicates that the sample follows the theoretical distribution; however, deviations from this line suggest departures from normality, such as skewness or the presence of outliers. As shown in the figure, since the residual errors were not highly skewed, the reliability of the ANOVA results can be considered acceptable, as suggested by [22].

Table III presents the ICC values for each task, ranging from 0.93 to 0.99, along with corresponding 95% confidence intervals. The high ICC values indicate excellent test-retest reliability of the CLEVERArm exoskeleton device across different tasks. The consistency and stability of measurements across repetitions underscore the device's ability to produce consistent outcomes, which is essential for its clinical utility.

TABLE III: Intra-class correlation coefficient for various tasks performed by CLEVERArm

Task	ICC	95% CI	
		Lower	Upper
1	0.99	0.97	0.99
2	0.97	0.94	0.99
3	0.93	0.87	0.97
4	0.96	0.93	0.98
5	0.97	0.95	0.99
6	0.97	0.94	0.99

These findings suggest that clinicians and researchers can depend on the CLEVERArm exoskeleton to reliably and accurately assess UE movement parameters across diverse tasks.

The robust repeatability demonstrated by the CLEVERArm exoskeleton system holds significant clinical implications for rehabilitation practices and patient care. The system's ability to consistently replicate movements across various tasks and repetitions underscores its potential as a reliable tool for therapeutic interventions targeting UE impairments. Clinicians can leverage the system's precision and stability to design personalized rehabilitation protocols tailored to individual patient needs. By incorporating the CLEVERArm into rehabilitation regimens, therapists can track patients' progress accurately, monitor movement patterns, and adjust treatment strategies accordingly. In future work, we aim to integrate electromyography (EMG) signals into CLEVERArm's controller algorithm to enhance assistance, as EMG signals reflect muscle activation and provide critical insights into patient participation. We have developed machine learning algorithms to classify movement types [23] and predict joint angles [24] based on EMG data, which will be incorporated into the control system. This approach aligns with previous recommendations to combine muscular activity analysis with kinematic measures for developing more effective, patient-specific neurorehabilitation paradigms [25].

IV. Conclusion

The analyses of the repeatability and efficacy demonstrated that the CLEVERArm is a valuable exoskeleton system in UE rehabilitation. We verified the system's robust performance and reliability across various tasks and repetitions comprehensively through visual inspection, quantitative measurements, and statistical analysis. The consistently high intraclass correlation coefficients (ICCs) ($>$0.9) obtained for each task further reinforce the system's ability to produce consistent outcomes and accurately capture changes in UE movement over time. Additionally, the low RMSD values ($< 3.42°$) and high correlations ($>$0.99) between reference and repetition signals attest to the system's ability to reproduce desired movements accurately, which was further supported by the two-way repeated measures ANOVA analysis. This study lays the groundwork for further exploration into optimizing the system's functionality, expanding its clinical applications, and enhancing rehabilitation outcomes for individuals with UE impairments. The device's consistent performance across tasks of varying complexity highlights its versatility, addressing rehabilitation goals ranging from basic range-of-motion exercises to intricate functional movements mimicking ADL. By leveraging the insights gained from this investigation, future endeavors can continue to propel the field of exoskeleton-assisted rehabilitation forward, ultimately benefiting patients and clinicians alike.

Unsupervised robot-assisted therapy at home after stroke: a pilot feasibility study

Giada Devittori[1], Daria Dinacci[2], Claudio Petrillo[2], Paolo Rossi[2], Roger Gassert[1,3] and Olivier Lambercy[1,3]

***Abstract*— Unsupervised robot-assisted therapy could allow increasing upper limb therapy dose for stroke survivors with minimal additional burden on the healthcare system. Thanks to the ability to actively assist movement and dynamically adapt the assistance level, actuated devices can support individuals with a wide range of deficits. However, these devices are often complex to use, and their application in a fully unsupervised setting has rarely been explored. Here, we present a pilot study investigating the feasibility of unsupervised therapy with ReHandyBot, an actuated device for upper limb rehabilitation. The increase in therapy dose achieved during unsupervised training, device usability and user experience were evaluated. Stroke inpatients of a rehabilitation clinic learned how to use the device for two weeks with progressively decreasing levels of supervision. After discharge, they could take it home for two weeks of unsupervised therapy. Four of the five recruited participants learned how to use the device without supervision, and three completed the protocol. During the two weeks at home, on average they performed 518.3 minutes of therapy with ReHandyBot. Usability and user experience ratings show that the device was well accepted. These positive results support larger studies investigating unsupervised home therapy with ReHandyBot and suggest that active devices can be used by patients with no to mild cognitive impairments at home without the supervision of external persons.**

I. INTRODUCTION

Stroke is one of the leading causes of disability, and many stroke survivors are left with chronic upper limb impairments [1], which negatively affect quality of life. Giving stroke patients the opportunity to perform more upper limb therapy than offered during standard care may improve their functional outcomes and overall well-being [2]. However, increasing the dose of therapy (e.g., therapy time) for stroke patients, either during their stay in the clinic or at home after discharge, presents many challenges, mainly related to the high costs of rehabilitation and the limited number of available therapists for an increasing number of patients [3].

Unsupervised therapy is one approach holding the promise of giving stroke patients access to a higher dose of therapy with minimal additional burden on the healthcare system. In this setting, patients perform exercises without the supervision of any external person, ideally directly at their homes. Several tools for unsupervised therapy have been explored, e.g., exergames and sensor-based devices [4], [5]. Thanks to the ability to actively support movements, dynamically adapt the assistance level, and provide engaging exercises, active (i.e., actuated) robotic devices might be the most comprehensive solution to support a broad range of stroke patients during unsupervised upper limb therapy. However, most active robotic devices do not meet the requirements for fully unsupervised training. For instance, they are often difficult to use or do not have the ability to automatically tailor the difficulty of therapy to the evolving level of impairment. Therefore, some form of supervision is often still required also when deployed at home (e.g., remote by a therapist, onsite by caregivers [6]) and the fully unsupervised use of active robotic devices has rarely been explored.

Our group developed the ReHapticKnob, an active end-effector device for hand rehabilitation, focusing on its clinical benefit, usability, and adaptability [7], [8]. Recently, a clinical trial with 13 subacute stroke patients showed that unsupervised therapy with the ReHapticKnob in a clinical setting is feasible and can increase therapy dose compared to standard care [9]. Building on these promising results, we propose to evaluate a similar unsupervised rehabilitation concept in patients' homes, as outpatients have access to significantly fewer therapy sessions than inpatients and may benefit most from an increase in therapy dose. A portable version of the ReHapticKnob, named ReHandyBot, was thus developed. Despite the smaller dimensions, ReHandyBot has the same functionalities and therapy exercises as its previous version.

Here, we present a pilot study evaluating unsupervised therapy at home with ReHandyBot. The main goals of this pilot study are to investigate (i) the feasibility of unsupervised therapy with ReHandyBot within stroke patients' homes, (ii) the effect of unsupervised therapy with the device on therapy dose after discharge from the clinic, and (iii) the usability of ReHandyBot and user experience when training with it outside of clinical settings. This work will help define whether ReHandyBot, and potentially other similar active devices, can be used at home in a fully unsupervised way to provide novel solutions for increasing therapy dose for neurological patients without increasing therapists' workload.

II. METHODS

A. ReHandyBot

ReHandyBot (Fig. 1) is an actuated end-effector haptic device for hand sensorimotor therapy with two degrees of freedom [10]. Its exercises focus on grasping (i.e., finger flexion and extension) and forearm pronosupination movements and follow the neurocognitive therapy approach, which trains motor, sensory, and cognitive functions [11]. The therapy

[3]Future Health Technologies program, Singapore-ETH Centre, Campus for Research Excellence and Technological Enterprise (CREATE), Singapore

Fig. 1. A stroke patient training with ReHandyBot at home. The hand is fixed to the handles with Velcro straps, and a hand cover hides the hand as the exercises require patients to focus on the somatosensory feedback from the impaired hand and not on the visual feedback [11]. The virtual environment of the exercises is shown on the monitor of the laptop and patients use a color-coded pushbutton keyboard to interact with it.

tasks mainly involve interacting with the objects rendered by the device and displayed in the virtual environment to identify their different mechanical properties (e.g., stiffness, length) based on the somatosensory feedback from the affected upper limb.

Therapy with ReHandyBot is tailored to each patient according to the following procedure. Before the first session with the device, therapists select therapy settings specific to the patients, such as which exercises suit them. During the first two sessions, patients perform assessments of hand function implemented in the device. ReHandyBot then combines therapy settings, assessment results, and patient's performance during the exercises (constantly monitored by the device) to automatically adapt therapy difficulty throughout the following sessions [8]. This ensures that, after the first session, no external intervention is needed to further tailor therapy difficulty.

To increase motivation to train, a simple gaming environment was integrated, where patients earn coins based on their training time. The coins can then be used in the context of a virtual traveling theme where patients can explore and get to know some interesting facts about different cities around the world. These facts (i.e., information and related picture) are presented at the end of each session only if the patient has trained for more than 15 minutes.

B. Study protocol

This study was approved by the Swiss authorities supervising clinical trials with medical devices (CE TI 4371, Swissmedic 102706281). The study protocol is adapted from [12], but with an unsupervised part at the patient's home.

To summarize, a target sample of 5 participants was selected, as it was considered sufficient for a pilot feasibility study. Participants were stroke inpatients of the Clinica Hildebrand Centro di Riabilitazione Brissago. Inclusion criteria were age between 18 and 90 years old, recruitment within 12 weeks from stroke onset, pre-stroke modified Rankin score [13] $\leq$ 1, National Institutes of Health Stroke Scale [14] $\geq$ 1 in at least one of the items regarding motor or

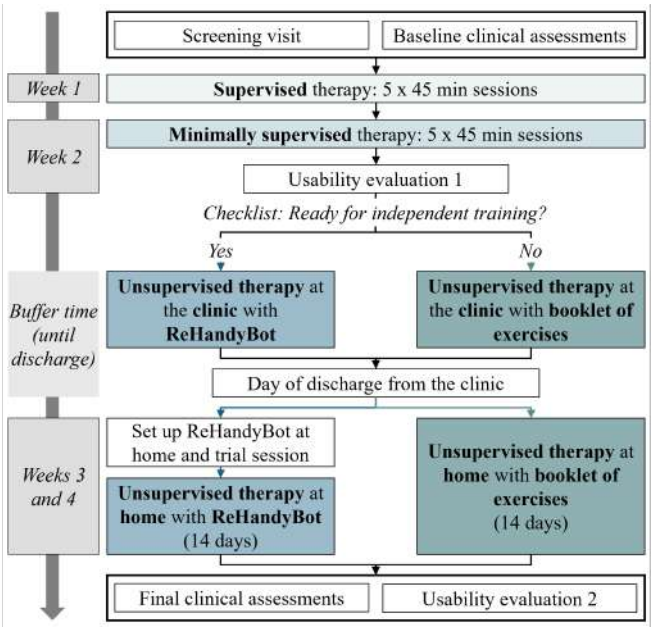

Fig. 2. Study protocol followed during this pilot feasibility study investigating the use of ReHandyBot in the home setting.

sensory function and ataxia, possibility (e.g., enough space) to set up the ReHandyBot at home, and signed informed consent form. Exclusion criteria were moderate to severe aphasia (Goodglass-Kaplan's scale [15] $<$ 3), moderate to severe cognitive deficits (levels of cognitive functioning-revised [16] $<$ 9), functional impairment of the upper limb due to other pathologies, severe pain in the affected arm (visual analogue scale for pain $\geq$ 5), other pathologies possibly interfering with the study, pacemakers and other active implants, discharge to an assisted living facility (e.g., care home), and modified Ashworth Scale (mAS) [17] $>$ 2 for one or more muscles of the impaired upper limb.

To enable patients to safely and comfortably learn how to use ReHandyBot, a progressive transition from supervised to unsupervised use of the device was implemented [12]. For each participant, the study protocol lasted around five to six weeks (Fig. 2). The first two weeks of the study, namely the familiarization phase, took place at the clinic. The first week included five sessions of 45 minutes of supervised therapy with ReHandyBot (one session per day, weekends excluded), where a supervisor (i.e., a therapist or an investigator) was present to explain how to use the device. The second week (five sessions of 45 minutes) was minimally supervised, i.e., participants tried to perform therapy with ReHandyBot by themselves. The supervisor was still present but helped only upon request.

At the end of the familiarization phase, the supervisor used a checklist to determine if the participant correctly learned how to use ReHandyBot and was ready to safely use it without supervision. If the participant was ready for independent therapy with ReHandyBot, they could take it home and continue to train with it unsupervised for two weeks, with the recommendation of performing at least one

therapy session per day (i.e., around 45 minutes). For ethical reasons, if the participants were not ready for independent therapy with the device, they were given the possibility to continue training at home unsupervised with a booklet of conventional exercises, which were explained by the therapist before discharge.

Ideally, the minimally supervised phase would have ended the day before discharge from the clinic so that the unsupervised phase could have directly started when the participant was back at home. However, estimating the exact day when a participant was discharged was difficult. Therefore, a buffer time was considered. The buffer time lasted from the first day after the minimally supervised phase to the day before discharge and was, thus, variable according to the different participants' schedules. During this buffer phase, the participant performed unsupervised therapy at the clinic, again with the recommendation of performing at least one therapy session per day. For participants who brought ReHandyBot home, one to three days after discharge, one of the investigators installed the device at their home and performed a minimally supervised session with the patient to ensure that everything was correctly set up and the patient felt comfortable with the new setting. The two weeks of unsupervised therapy at home started the day after.

At the beginning of the study, participants underwent a screening visit with a physician, where the eligibility criteria were checked and the Montreal Cognitive Assessment (MoCA) [18] was performed. At the beginning and at the end of the study, clinical assessments (e.g., the Fugl-Meyer Assessment of Upper Extremities (FMA-UE) [19]) were also performed. At the end of the minimally supervised phase, participants had to rate the usability of ReHandyBot and user experience when training with it (Usability 1). This evaluation was repeated at the end of the protocol (Usability 2).

During the unsupervised phase at home, therapists and investigators did not contact the participants to remind them to train or to adjust therapy parameters (i.e., fully unsupervised therapy). Any contacts made by participants to request assistance were recorded, together with the actions taken to address the issues.

C. Outcome measures

The feasibility of unsupervised therapy at home with ReHandyBot was measured as the number of subjects who could proceed to the unsupervised phase with the device, safety of use (i.e., number of adverse events and device deficiencies), and attendance during the unsupervised phase. Attendance is defined as the percentage of days the participant trained at least once with ReHandyBot (detected through the device data) out of the total number of offered days for unsupervised therapy at home. Parameters (e.g., age, cognitive deficit) possibly influencing the ability to train unsupervised were also evaluated.

The dose of unsupervised therapy at home with ReHandyBot was measured as therapy duration in minutes per day and total minutes over the two weeks of unsupervised therapy, number of task repetitions, and percentage increase in physical therapy time due to therapy with the device with respect to the conventional physical therapy time (i.e., upper limb and lower limb physio- and occupational therapy) performed as outpatients. When possible, conventional physical therapy time was precisely calculated for each participant based on their conventional therapy plan provided by the administration of the outpatient centers. Participants, however, were instructed to note in a journal the duration and type of conventional therapy performed during the unsupervised phase, and this data was used in the absence of more precise one.

The change in usability and user experience between the evaluations given during Usability 1 and Usability 2 was analyzed to define whether training at home without supervision negatively impacted usability and user experience. Usability questionnaires comprised the System Usability Scale (SUS) [20] and the Post-Study System Usability Questionnaire (PSSUQ) [21]. User experience was assessed with the net promoter score (NPS) [22], the customer satisfaction score (CSAT), the "interest/enjoyment" subscale of the intrinsic motivation inventory (IMI), and custom questions (e.g., relative to the gaming environment). The NPS reflected the probability on a scale ranging from 0 to 10 that a participant would recommend therapy with the ReHandyBot to another patient. The CSAT corresponded to the participant's level of satisfaction with the therapy with ReHandyBot on a 5-point scale ranging from "very unsatisfied" (i.e., 1) to "very satisfied." A semi-structured interview about ReHandyBot and unsupervised therapy was performed during the Usability 2 session.

The difference in the content of the therapy sessions performed with ReHandyBot in the three phases was evaluated to determine whether participants engaged in the exercises during the unsupervised phase. Therapy content was assessed by calculating intensity (i.e., number of task repetitions per minute), task performance (i.e., correct trials out of the total number of repetitions), and the ratio of effective therapy time (i.e., net therapy time without breaks) to total duration of a therapy session. For all three phases, we expected no significant difference in therapy content.

The changes in clinical assessment scores (i.e., functional recovery) were not analyzed as part of this pilot study focusing on feasibility.

D. Data analysis

Descriptive statistics (mean and range (min-max)) were used to characterize study population, attendance, therapy dose, user experience, device usability, and therapy content. The total dose of unsupervised therapy achieved in the unsupervised phase at home was calculated only for participants who completed the two weeks at home. The other dose-related metrics included data for all participants training without supervision.

The difference in the scores collected during Usability 1 and Usability 2 was computed to evaluate the impact of unsupervised therapy on the metrics related to usability

and user experience. Participants who did not perform the Usability 2 session were excluded from this analysis.

Given the low sample size, no statistical analysis was performed, and parameters possibly affecting the ability to train unsupervised with ReHandyBot were qualitatively analyzed.

III. RESULTS

Five participants were recruited for this feasibility study. Of these, three completed the entire protocol, one (P3) dropped out at the end of the minimally supervised phase without providing a specific reason, and one dropped out after 9 days of unsupervised therapy at home due to a second stroke. Participant's characteristics are reported in Table I.

TABLE I

CHARACTERISTICS OF THE STUDY PARTICIPANTS.

	Mean (range)	**Ratio**
Age (years)	67.2 (59.0-75.0)	
Gender (Female:Male)		0:5
Time after stroke onset (days)	16.2 (6.0-46.0)	
Stroke type (Ischemic:Hemorrhagic)		5:0
Impaired side (Left:Right)		1:4
MoCA (30 = minimum impairment)	23.8 (15.0-27.0)	
FMA-UE (66 = minimum impairment)	59.8 (52.0-64.0)	

A. Feasibility of unsupervised therapy with ReHandyBot

Four participants met the requirements defined by the checklist and could bring ReHandyBot home. For them, mean attendance during the unsupervised phase at home was 83.9% (57.1-100.0%). The participant who could not proceed to independent training at home with the device (i.e., P3) dropped out before starting the unsupervised phase. No adverse events related to the study protocol or device deficiencies were reported.

Age and level of impairment did not seem to affect the ability to train without supervision, as the oldest participant and the one with the lowest baseline FMA-UE score could train with ReHandyBot at home. In contrast, cognitive ability may be a relevant factor, as P3 had a lower MoCA score (i.e., 15) than the participants who could train without supervision with the device (MoCA $\geq$25).

During the unsupervised phase at home, one participant contacted one of the investigators once, as he could no longer turn on the device. After going to the participant's home, the investigator could solve the issue as it was not a technical problem, but the participant got confused and set the power switch to the wrong position.

B. Dose of unsupervised therapy and content of the therapy sessions performed with ReHandyBot

Over the two weeks of unsupervised therapy at home, on average, participants trained for a total of 518.3 (399.9-582.2) minutes with ReHandyBot. Considering only the days when the participants used the device, the mean daily therapy dose was 41.4 (36.4-46.8) minutes and the mean number of daily task repetitions was 146.3 (117.5-166.4). The increase in physical therapy time achieved by the participants thanks to training with ReHandyBot (compared to conventional therapy) was 177.5% (117.6-293.7%).

The content of the therapy sessions performed with ReHandyBot during the three phases of the study is reported in Table II.

TABLE II

CONTENT (MEAN (RANGE)) OF THE THERAPY SESSIONS PERFORMED WITH REHANDYBOT DURING THE SUPERVISED (SUP), MINIMALLY SUPERVISED (MIN), AND UNSUPERVISED (UNS) PHASES.

	SUP	**MIN**	**UNS**
Intensity (repetitions/minute)	2.0 (1.8-2.4)	3.3 (2.9-3.5)	3.5 (3.0-4.1)
Task performance (%)	59.3 (48.6-65.2)	69.0 (62.9-71.7)	67.4 (63.2-71.1)
Effective/total therapy time	0.6 (0.5-0.7)	0.8 (0.8-0.9)	0.8 (0.7-0.9)

C. Usability and user experience

The results of the usability and user experience questionnaires for participants who completed both usability evaluations (n=3) are reported in Table III and Table IV.

TABLE III

RESULTS (MEAN (RANGE)) FOR THE OUTCOME MEASURES RELATED TO THE USABILITY OF REHANDYBOT AND USER EXPERIENCE.

	Usability 1	**Usability 2**	**Difference**
SUS (0-**100**)	85.0 (80.0-95.0)	94.2 (90.0-97.5)	9.2 (2.5-15.0)
PSSUQ (**1**-7)	1.7 (1.2-2.1)	1.6 (1.0-1.9)	-0.1 (-0.3-0.2)
NPS (1-**10**)	9.0 (7.0-10.0)	9.0 (8.0-10.0)	0.0 (-2.0-3.0)
CSAT (1-**5**)	4.0 (4.0-4.0)	4.3 (4.0-5.0)	0.3 (0.0-1.0)
IMI (1-**7**)	6.0 (4.7-6.7)	6.2 (4.6-7.0)	0.2 (-0.1-0.4)

For each scale, the range of possible answers is indicated in brackets. The value corresponding to the best rating in terms of high usability and user experience is given in bold.

During the semi-structured interview, two participants mentioned that 45 minutes of therapy with ReHandyBot were very intense and tiring, and the break time between exercises should be increased or the overall session duration decreased.

When asked whether unsupervised therapy at home is helpful, participants agreed and said that they appreciated the possibility of training more. Furthermore, one stated that unsupervised therapy is a valid option only if persons are motivated to train and convinced that they are doing something beneficial for them. Another participant said, "A good occupational therapist is better than a robot. The combination of outpatient sessions with a therapist and the robot at home is good. Only having the robot is not."

Participants were also asked if they would consider paying to rent ReHandyBot, and they all answered that they probably would. Two participants mentioned that having evidence that a tool helps recover hand function is a crucial factor that would influence their decision on whether to pay for it or not.

TABLE IV

RESULTS (MEAN (RANGE)) FOR THE CUSTOM QUESTIONS (Q1-Q5) RELATED TO REHANDYBOT AND THE GAMING ENVIRONMENT.

		Usability 1	**Usability 2**	**Difference**
Q1.	The gaming environment motivated me to train more.	3.7 (1.0-7.0)	4.0 (2.0-5.0)	0.3 (-2.0-2.0)
Q2.	The gaming environment prevented me from focusing on the therapy exercises.	7.0 (7.0-7.0)	7.0 (7.0-7.0)	0.0 (0.0-0.0)
Q3.	If I could choose, I would remove the gaming environment from the therapy sessions.	7.0 (7.0-7.0)	7.0 (7.0-7.0)	0.0 (0.0-0.0)
Q4.	If I could choose, I would keep training with ReHandyBot at home.	N/A	2.7 (1.0-5.0)	N/A
Q5.	Reminders to do the unsupervised therapy sessions would have helped me to train more.	N/A	6.7 (6.0-7.0)	N/A

Possible answers ranged from 1 (i.e., completely agree) to 7 (i.e., strongly disagree). Q4-5 were only asked during Usability 2. N/A: not applicable.

Furthermore, one participant stated that if he could, he would have kept the device. Two others stated that their hand already recovered well. Therefore, they would have kept the device past the two weeks to continue training, but they mentioned that they would have likely not continued using it daily.

IV. DISCUSSION

The main goal of this pilot feasibility study was to determine whether people after a stroke could learn to independently use the active rehabilitation robot ReHandyBot while they were hospitalized in a rehabilitation clinic and then, once discharged, take it home to continue training without the supervision of any external person. Further goals were to investigate the increase in therapy dose achievable by training with the rehabilitation device at home compared to conventional care, as well as the usability of ReHandyBot and the user experience when training with it. The results presented here suggest that unsupervised therapy at home with ReHandyBot is feasible and can lead to an important increase in the dose of upper limb therapy performed by the patients. Furthermore, our study is one of the first to show the feasibility for stroke patients with mild to no cognitive impairments to use active, end-effector robotic devices for fully unsupervised home therapy.

A. Unsupervised therapy at home with ReHandyBot was feasible and allowed to increase therapy dose

The majority of the study participants were able to learn to operate the device independently, although they were part of one of the age groups that is expected to be less familiar with technology [23]. Participants who performed unsupervised therapy with ReHandyBot trained for more than 8 hours during the two weeks at home. The daily dose of unsupervised therapy achieved in this pilot study was higher than that reported in other studies evaluating the minimally supervised or unsupervised use of rehabilitation technologies by stroke patients or older adults. For example, the average daily use in [24] and [25] was 21 minutes over 4 weeks and 29 minutes over 8 weeks, respectively. Attendance (83.9%) and therapy dose (518 minutes) achieved here were also higher than the mean ones registered by patients training unsupervised at the clinic with the non-portable version of the ReHandyBot (i.e., ReHapticKnob) [9], which were 77% and 360 minutes, respectively. Since the protocol of the two studies was similar, this difference could be partly explained by the fact that, in the previous study, participants were inpatients already undergoing many conventional therapies, and we did not give precise recommendations on how much to train with the device.

As expected, the mean percentage increase in physical therapy time achieved in this pilot study thanks to unsupervised therapy with ReHandyBot is higher (around 4x) than that reported in [9], where the participants undergoing unsupervised robot-assisted therapy were inpatients of a rehabilitation clinic. This is mainly due to the drastic decrease in the dose of conventional therapy accessible to outpatients. These findings emphasize how unsupervised therapy with active devices at home is even more necessary than in a clinical setting when aiming to increase the therapy dose.

Although the increase in therapy dose achieved in this pilot study is important, the amount of additional upper limb therapy performed by the participants with ReHandyBot was still not as high as what seems necessary to lead to significant benefits (e.g., 25-30 hours per week [26], [2]). This suggests that, in the future, we should increase the recommended number of daily therapy sessions or recommend a number tailored to the individual patient's level of impairment. Another possibility would be to implement additional motivational strategies to encourage patients to train more. Indeed, although patients would not remove the gaming environment from the therapy sessions with ReHandyBot (Q3), its ability to boost motivation varies greatly between individuals (Q1).

Also worth noting is that the absence of the therapist did not negatively impact the therapy content, and consequently the therapy quality, between the different phases of the study. Indeed, intensity, task performance, and the ratio of effective to total therapy time during the unsupervised phase were similar to the minimally supervised phase and greater than during the supervised phase. Lower values for the supervised sessions can be explained by the fact that in this phase patients were unfamiliar with the device and the exercises, and more time was dedicated to instructions.

B. ReHandyBot showed good usability and user experience

The metrics tested in Usability 1 and Usability 2 remained stable or improved between the two time points, indicating that the home setting and the absence of the therapist did not negatively affect the perceived usability of ReHandyBot and the user experience.

The NPS, CSAT, and IMI ratings suggest that participants were satisfied, enjoyed training with the device, and would

recommend it to other patients. According to the mean SUS results ($\geq$85), the usability of ReHandyBot is good to excellent [27]. The mean SUS scores obtained here are higher than those obtained by other devices tested with minimal or no supervision. For example, the SUS score for the MERLIN (i.e., a passive device for the upper limbs) was 77 [28].

C. Limitations and future work

The number of participants included in this pilot feasibility study was low, and the unsupervised phase at home lasted only two weeks. Therefore, the results must be interpreted carefully, and more data is needed to draw conclusions, specifically with respect to the potential clinical benefits of this approach. Moreover, the patients enrolled in this study had mild upper limb impairment. While we know from previous work that our device can also be used by more severely impaired patients, it would still need to be verified how these preliminary results translate to this population. In fact, moderately and severely impaired patients are the ones who should benefit most from training with ReHandyBot and might be more motivated to increase their therapy dose.

However, the preliminary findings of this study are encouraging and support testing unsupervised training with ReHandyBot with more subjects and for a longer time (i.e., 6 weeks of unsupervised therapy at home) to verify if the increase in therapy dose and high attendance can be maintained.

ACKNOWLEDGMENT

The authors would like to thank the study participants and all the therapists and physicians of the Clinica Hildebrand Centro di riabilitazione Brissago who contributed to this study.

***Abstract*—To secure the amount of rehabilitation in motor function recovery training after stroke, it is important to realize a rehabilitation robot for the upper limb to guide the reaching motion of patients in the acute and convalescent phases of rehabilitation in hospitals and in the maintenance phase of rehabilitation at home without a therapist. Therefore, in this study, the escort-type rehabilitation robot, which has been proposed as a structure to guide the user's hand position and arm posture, is shown to have a motion range for the user's reaching motion including arm posture. In addition, it is shown that the escort-type rehabilitation robot can guide reaching motion for the arm posture as well as the hand position and can also guide functional reach in collaboration with the user's trunk motion, proven by simulation and experiment.**

I. Introduction

Many studies have suggested the effectiveness of robot-assisted therapy using upper limb rehabilitation robots for training the recovery of upper limb motor function after stroke [1] [2]. This robot-assisted therapy is based on brain plasticity [3], and assists repetitive motion and task-oriented training [1]. The upper limb rehabilitation robot are classified into end-effector type rehabilitation robots that hold the upper limb near the hand and exoskeleton type rehabilitation robots with a similar structure to the upper limb [4] [5].

Examples of endeffector-type rehabilitation robot development include MIT-MANUS which guides arm motions while supporting the hand and forearm with a planar arm [6], InMotion ARM which was developed as its successor [7], GENTLE/s which guides arm reaching motions with a 3-DOF arm [8] and Gentle/G which is also equipped with a mechanism to guide hand motions [9], and NeReBot which guides the arm by suspending it with wires [10] [11] which is guided by suspending the arm with a wire. Examples of exoskeletal rehabilitation robots include the T-WREX [12] [13], the ARMin-II [14], and the Harmony [15]. Comparing these two forms, endeffector-type robots are easier to precisely control the hand position, while exoskeleton robots are easier to support the arm posture [4]. The basic issue in the mechanical design of these rehabilitation robots is how to provide an upper limb motion guidance function.

Reaching motion of stroke patients targeted by such robots has been reported to produce characteristics that differ from those of healthy subjects [16]. In addition, it has been shown that the reaching motion of stroke patients is more dependent on compensatory movements than that of healthy subjects [17]. Based on the above, it would be desirable that the robot's reaching motion guidance of the upper limb described above suppress compensatory movements and provide a more natural motion pattern for the entire upper limb, including the hand position and arm posture.

On the other hand, for exoskeletal robots, to address the problem of misalignment between the robot's shoulder joint position and the patient's vulnerable shoulder joint position, the introduction of compliant actuation [18] and the automatic adjustment to decrease the misalignment [19] have been reported. However, considering that the trunk plays an important role in reaching motion, it is desirable to be able to perform a functional reach [20] that collaborates the upper limb motion and the shoulder position motion by the trunk.

To address this problem, the authors' research team has shown the usefulness of employing the rehabilitation robot structure that we call the escort-type [21]. This escort-type robot, like the end-effector type, is designed to be attached to the forearm of the patient's upper limb to guide the reaching motion. However, (1) it can provide arm posture guidance as well as hand position guidance, and (2) it does not constrain the shoulder joint position, thus allowing functional reach. In addition, a new escort-type rehabilitation robot structure has been proposed [22] [23], but the research is limited to basic kinematic analysis concerning the validity of the structure.

Therefore, the objective of this study is set to clarify that this escort-type rehabilitation robot is suitable for guiding reaching motion. The research subjects are set to clarify the motion range required for reaching motion in consideration of safety [24], and to clarify that this robot can guide reaching motion including arm posture and that it can tolerate functional reach.

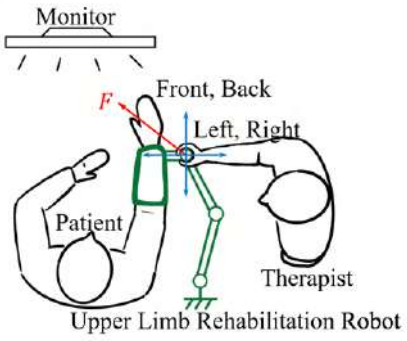

Fig. 1: Robot intervening in rehabilitation

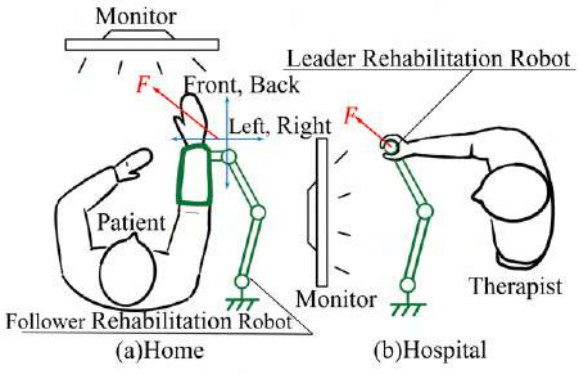

Fig. 2: Teleoperated rehabilitation robot

This paper is organized as follows. Section 2 describes the basic concept of the escort-type rehabilitation robot, the robot under discussion, and the problem statement. Section 3 clarifies how to calculate the motion range of the robot when it is attached to an upper limb dummy robot. In Section 4, simulation results show that the robot is capable of both hand position guidance and arm posture guidance, and that it can tolerate functional reach. In Section 5, experiments are described to examine the validity of the robot. In the concluding section, the findings of this study are presented.

II. Proposed Escort-type Rehabilitation Robot

A. Concept on Upper Limb Rehabilitation Robot

Fig.1 shows a conceptual diagram of a rehabilitation robot for upper limb that is used in the acute/convalescent phase of rehabilitation in hospitals for training the recovery of upper limb motor function. Here, the therapist applies manipulative force to the rehabilitation robot attached to the patient's forearm to guide the reaching motion of the patient whose upper limb has been paralyzed due to stroke. With this configuration, the rehabilitation robot can record changes in the position and posture of the patient's hand on the upper limb, changes in the force applied by the robot to the patient, and changes in the force applied by the therapist to the robot, if any. The recorded information could be used to assess the patient's recovery.

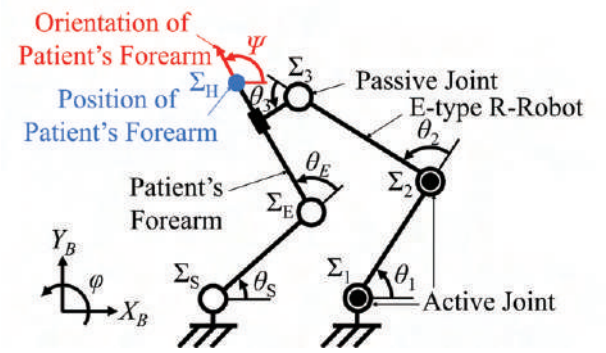

Fig. 3: Conceptual diagram of escort-type rehabilitation robot

Fig.2 shows a conceptual diagram of a teleoperated rehabilitation robot base on a leader-follower type rehabilitation robot for upper limbs to be used in convalescent phase rehabilitation in hospitals after acute phase rehabilitation and in maintenance phase rehabilitation at home. By using such a leader-follower type robot, not only can record changes in position and force as in the acute/convalescent phase rehabilitation, but also can guide the patient's reaching motion during the maintenance phase rehabilitation at home, where therapists are not present. Combined with the information recorded during the acute/convalescent phase of rehabilitation, this information can be used to assess the patient's level of recovery in a series of rehabilitation. The use of this rehabilitation robot in the hospital before the patient is discharged from the hospital will provide practice for the maintenance phase rehabilitation at home.

To design the robots shown in Fig.1 and Fig.2 so that they can be regarded as the same robot by patients and therapists is a useful way to secure the amount of rehabilitation in a series of acute, convalescent, and maintenance phases. For this reason, this idea can be stated as the design concept of this rehabilitation robot.

Fig.3 is a conceptual diagram of an escort-type upper limb rehabilitation robot that is attached to a patient's forearm to guide the reaching motion of the upper limb. The robot includes both active and passive joints. The active joints control the movement, while the passive joint allows flexibility when attached to the patient' s forearm. This setup ensures that both the patient's and the robot' s arm postures remain fixed during movement. However, the passive joint does not constrain the patient' s shoulder position. In the three-dimensional version of this robot described below, the robot can also guide the patient' s arm posture while assisting reaching motion.

B. Escort-Type Rehabilitation Robot

Fig.4 describes the structure for the escort-type upper limb rehabilitation robot attached to a dummy robot. The dummy robot acts as patient in upper-limb rehabilitation and the escort-type robot is attached at the patient forearm at the point O_A. This figure indicates the arm posture at the initial position, where the escort-type robot's joint angles θ_1 to θ_3 are set to 90° and θ_4 to θ_5 are set to 0°, while the dummy

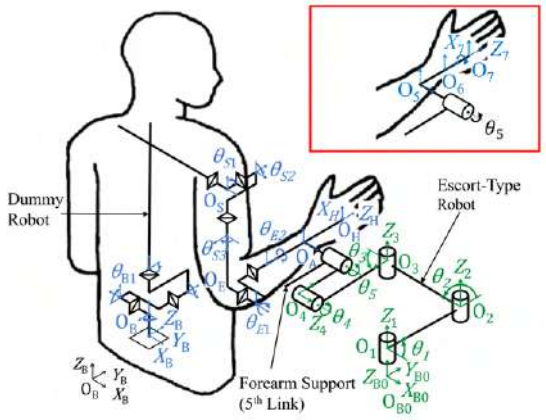

Fig. 4: Proposed escort-type rehabilitation robot [22] [23]

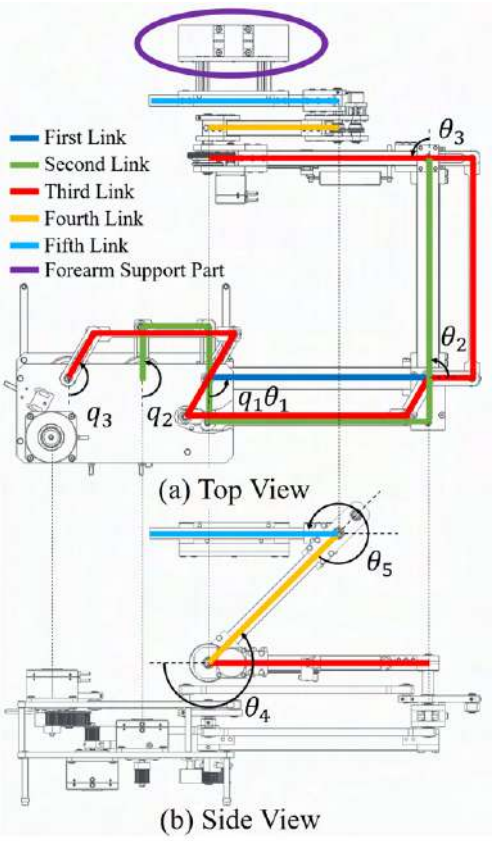

Fig. 5: Escort-type rehabilitation robot kinematic model

robot's arm adopts an L-shaped posture. This configuration is chosen because it provides a clear and structured reference pose, making it easier to analyze joint movements. When the escort-type robot attached to the dummy robot, inverse kinematics can be determined that will be explained clearly in the next subsection. The escort-type robot shown in Fig.5 has four active joints (joints 1 to 4) and a passive joint (joint 5), and a forearm support to be attached to the patient's forearm. These four active joints are used to guide the translational position x, y, z of the hand and the yaw angle ψ, which is

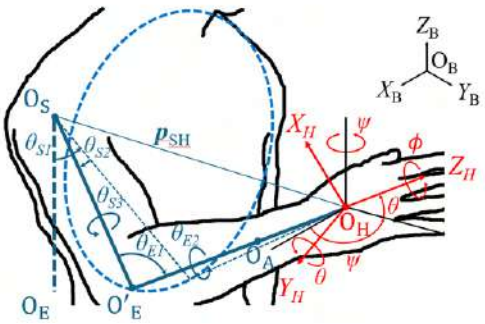

Fig. 6: Orientation of hand and arm posture

a part of the arm posture. The DH parameters of the escort-type upper limb rehabilitation robot and the dummy robot are described in the appendix.

C. Problem Statement

In this study, the following two problem statements are made in accordance with the research subject.

1) To clarify the method of deriving the motion range of the escort-type rehabilitation robot for the upper limb.
2) To clarify that the escort-type rehabilitation robot for the upper limb has a structure that (a) enables arm posture guidance as well as hand position guidance in guiding reaching motion, and (b) allows functional reach.

In 1), it should be noted that in the case of escort-type rehabilitation robots with passive joints, the arm posture of both the patient and the robot are determined when the robot is attached to the patient's arm (in this study, to the arm of the dummy robot). Therefore, when using inverse kinematics to derive the motion range, the arm posture of the robot is derived after the arm posture of the patient is derived for the condition in which the robot is attached to the patient's arm.

On the other hand, note that in 2) (a), different arm postures can be taken for the same hand position guidance in reaching motion. Also, in 2) (b), it is to be shown that the shoulder position can be shifted for functional reach while the escort-type rehabilitation robot is guiding the reaching motion.

III. Motion Range

A. Inverse Kinematics

To determine the motion range of an escort-type rehabilitation robot, we assume that the robot is attached to the forearm of the upper limb dummy robot described above. The position and posture of the hand are then given as grid points in the hand space, and each joint angle obtained by inverse kinematics is examined to judge whether it is within the range of each feasible joint angle.

Fig.6 shows that the hand posture can be represented by the roll angle ϕ, the pitch angle θ, and the yaw angle ψ. However, in the escort-type upper limb rehabilitation robot, ϕ is excluded from the target to be guided. Additionally, θ and ψ are not independent when the dummy robot's forearm is attached to the escort robot' s 5-th link at point $\mathrm{O_A}$, as no free motion

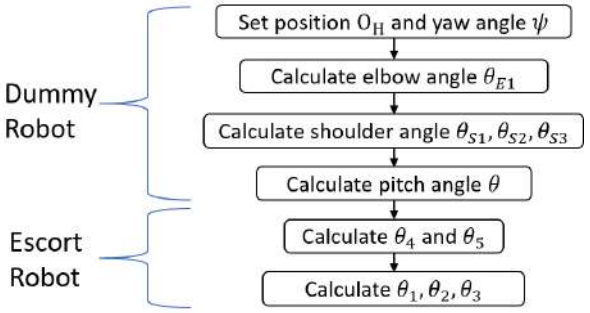

Fig. 7: Flow chart of inverse kinematics

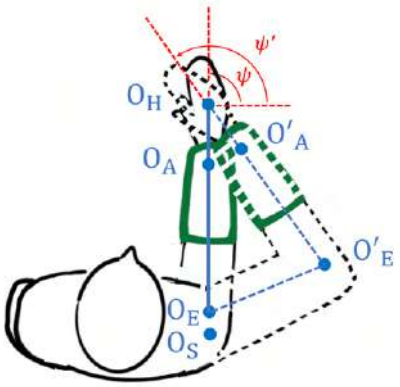

Fig. 8: Relation between yaw angle ψ and arm posture

remains. Once the yaw angle, ψ is set and the shoulder position O_S is fixed, the arm posture is reduced to a single degree of freedom (1-DOF). Therefore, in the inverse kinematics, the hand position and orientation are given by the total four components of x, y, z of the point O_H on the hand, and the yaw angle ψ. In the inverse kinematics explained below, the pitch angle θ is first obtained for the given hand position and posture based on the geometric relationship among the patient's shoulder position O_S, elbow position O_E and hand position O_H.

As shown in Fig.7, the procedure to calculate inverse kinematic for the attached escort and dummy robots begins by determining the dummy robot's angles based on the target hand position O_H and yaw angle ψ, followed by the escort robot's angles. The forearm twist angle θ_{E2} is set to $0°$ because torsional roll angle ϕ at hand shown at Fig.6 is not subject to induction as we assume no bending occurs at wrist since dummy robot is used instead of patient's hand. Next, we set shoulder position O_S as reference point to calculate elbow angle θ_{E1} in order to determine the elbow position at O_E. From all positions of O_H, O_E, and O_S, the shoulder angles θ_{S1}, θ_{S2}, and θ_{S3} are calculated to ensure the angles are within the constraints.

Next, the fourth joint angle θ_4 is calculated by focusing on the O_A and O_4 positions. Then, the fifth joint angle θ_5 is calculated from the obtained pitch angle θ and the fourth joint angle θ_4. The position of O_3 can be obtained from the positional relationship with O_4 because the third link L_3 is oriented toward the yaw angle ψ. L_1, L_2 are first obtained for the second joint angle θ_2, and then for the first joint angle θ_1. Finally, the third joint angle θ_3 is obtained from ψ, θ_1 and θ_2. By determining that these angles are within the constraints of the escort robot and dummy robot, it is possible to determine the range of motion. The described inverse kinematics is essential for using it both simulation and experiment.

B. Analysis of Motion Range

Motion range can be determined by constraints of escort robot and dummy robot which is can lead to define the forearm motion and the range that escort robot can be reach to guide patient's hand.

The folowing describes the robot's constraint ranges:

a) Joint constraints for escort robot
$\frac{\pi}{6} \leq \theta_1 \leq \frac{5\pi}{6}, \frac{\pi}{6} \leq \theta_2 \leq \frac{5\pi}{6}, \frac{\pi}{6} \leq \theta_3 \leq \frac{5\pi}{6}$
$\pi \leq \theta_4 \leq \frac{3\pi}{2}, -\frac{2\pi}{3} \leq \theta_5 \leq \frac{2\pi}{3}$

b) Joint constraints for dummy robot
$\frac{5\pi}{18} \leq \theta_{S1} \leq \frac{4\pi}{3}, 0 \leq \theta_{S2} \leq \pi, \frac{\pi}{6} \leq \theta_{S3} \leq \frac{8\pi}{9}$
$0 \leq \theta_{E1} \leq \frac{29\pi}{36}$

c) Rehabilitation-specific joints constrain
$\frac{\pi}{6} \leq \theta_1 \leq \frac{5\pi}{6}, \frac{\pi}{6} \leq \theta_2 \leq \frac{5\pi}{6}, \frac{\pi}{6} \leq \theta_3 \leq \frac{5\pi}{6}$
$\frac{17\pi}{18} \leq \theta_4 \leq \frac{3\pi}{2}, \frac{7\pi}{4} \leq \theta_5 \leq 2\pi$
$\frac{5\pi}{18} \leq \theta_{S1} \leq \pi, 0 \leq \theta_{S2} \leq \frac{\pi}{2}, \frac{\pi}{6} \leq \theta_{S3} \leq \frac{8\pi}{9}$
$0 \leq \theta_{E1} \leq \frac{29\pi}{36}$

The rehabilitation-specific joint constraints for the escort and dummy robots are designed to ensure safety and prevent strain to the patient, especially at the shoulder. For the escort robot, θ_4 is limited to at least $170°$ as the forearm starts from an initial position of π and may drop around $10°$ due to gravity, and θ_5 is restricted between $0°$ and $45°$ to prevent the elbow from moving above shoulder level. For the dummy robot, the shoulder's angles θ_{S1}, θ_{S2} are restricted to prevent hand movements above the shoulder and to accommodate the escort robot's link lengths. These constraints will determine the range of motion described in Fig.9 so that the motion range will be included in the safe range to avoid injury to the patient. The joint ranges also have been modified for inverse kinematics, ensuring the range boundaries remain within these real constraints to ensure safety during rehabilitation.

Fig.8 shows a topview image of the arm postures corresponding to the yaw angles ψ and ψ', when the shoulder position O_S and the hand position O_H are constant. The arm posture can be obtained using the inverse kinematics described above by specifying ψ or ψ'. This figure indicates the arm posture at initial position will be change according to the maximum value of yaw angle within robot constrain.

Fig.9 shows positions O_H are set with increments of 0.15 meters in the X or Y axis and 0.1 meters in the Z axis, allowing for a detailed analysis of forearm motion. The motion is calculated from the minimum of yaw angle ψ, from $\frac{\pi}{2}$ to the

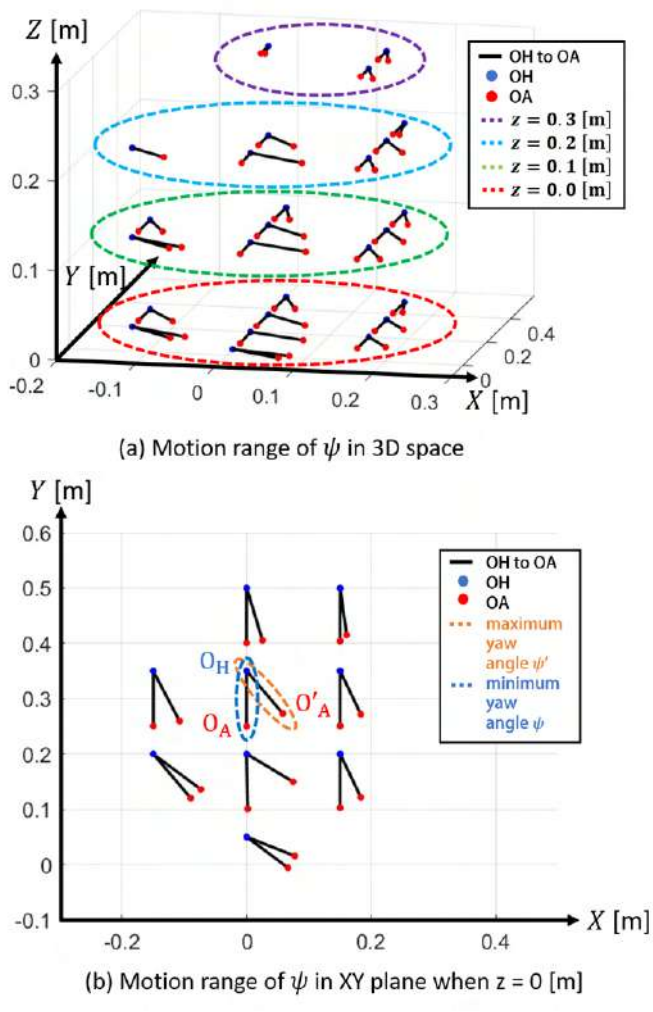

Fig. 9: Motion range of ψ at each translational position

maximum yaw angle. The initial position $\boldsymbol{p}_S = [0\ 0.35\ 0]^{\mathrm{T}}[\mathrm{m}]$ indicate at the Fig.8 and Fig.9(b) shows arm posture change reaching the maximum value of yaw angle 127°. This motion range of ψ can be determined by constrains of escort robot and dummy robot.

In order to ensure that the robot's motion range includes the motion range required for reaching motion and that the robot's footprint is small, it is necessary to design the mechanism using not only the setting of the robot's base position but also the setting of constraints on link lengths and joint angles.

IV. Simulation

A. Design Parameters

This subsection defines the design parameters for constructing the real escort-type upper limb rehabilitation robot and its simulation model. Despite having a parallel link mechanism, it is treated as a serial link robot, excluding the auxiliary link in discussions of hand characteristics.

The link lengths from the root of each i-th link to its center of mass are given by $L_{Ci} = [L_{C1}\, L_{C2}\, L_{C3}\, L_{C4}\, L_{C5}]^{\mathrm{T}} = \left[\frac{L_1}{2}\ \frac{L_2}{2}\ \frac{L_3}{2}\ \frac{L_4}{2}\ \frac{L_5}{2}\right]^{\mathrm{T}}$[mm]. The material density is defined as $\rho = 2.69 \times 10^{-3}$ [g/mm^3], while the mass of each link is computed using $m_i = \rho A_i B_i L_i$, where A_i and B_i represent the link height and width, respectively, with values $A_i = B_i = [30\ 30\ 30\ 20\ 15]^{\mathrm{T}}$ mm.

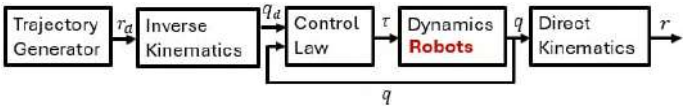

Fig. 10: Control system of escort-type rehabilitation robot

B. Control System and Issues for Investigation

This section simulates motion control for guiding the dummy robot' s reaching motion with the escort-type rehabilitation robot. The effectiveness of this guidance is shown from two perspectives.

1) Escort-type rehabilitation robot can provide arm posture guidance as well as hand position guidance.
2) Escort-type rehabilitation robots allow trunk movements to perform Functional Reach.

Fig.10 is the control system for guiding the reaching motion of the upper limb dummy robot by the escort-type rehabilitation robot. In this case, the handling of the hand position and posture is the same as in the motion range analysis in the previous section. That is, the target hand position $\boldsymbol{r}_d$ of the upper limb dummy robot is represented by four components: three components of the target hand translational position $\boldsymbol{p}_d$ and one component of the target hand posture angle ψ_d. The time function is used as the target hand trajectory. Inverse kinematics calculates the target value $\boldsymbol{\theta}_d$ of the joint angles $\boldsymbol{\theta}$ of the four active joints defined by the DH notation, and further calculates the target value $\boldsymbol{q}_d$ of the joint angle $\boldsymbol{q}$ defined according to the mechanical structure. The control input is determined using a PD control law, expressed as $\tau = K_p(q_d - q) - K_d(\dot{q}_d - \dot{q})$, where the proportional and derivative gains are set to $K_p = 1.2$ and $K_d = 0.8$. The dynamics of the escort-type rehabilitation robot used in the simulation is obtained by Simscape Multibody in MATLAB/Simulink. The monitoring of the hand position $\boldsymbol{r}$ in the simulation is calculated by applying forward kinematics to the joint angle $\boldsymbol{q}$.

C. Guiding Reaching Motion in Different arm Postures

The reaching motion was conducted to investigate whether the escort-type upper limb rehabilitation robot can assist the dummy robot in reaching its desired position, not only when the yaw angle remains constant throughout the rehabilitation but also while accommodating various yaw angles to adjust the arm posture. Fig.11 shows the arm postures of the dummy robot as the escort-type upper limb rehabilitation robot assists it in reaching $\boldsymbol{p}_{OH2} = [0\ 0.48\ 0]^{\mathrm{T}}[\mathrm{m}]$. Escort-type upper limb rehabilitation robot is being attached to the forearm of dummy robot on point $\mathrm{O_{A1}}$. Dummy robot's shoulder is fixed throughout the entire simulation on $\boldsymbol{p}_{OS} = [0\ 0\ 0.3]^{\mathrm{T}}[\mathrm{m}]$, and

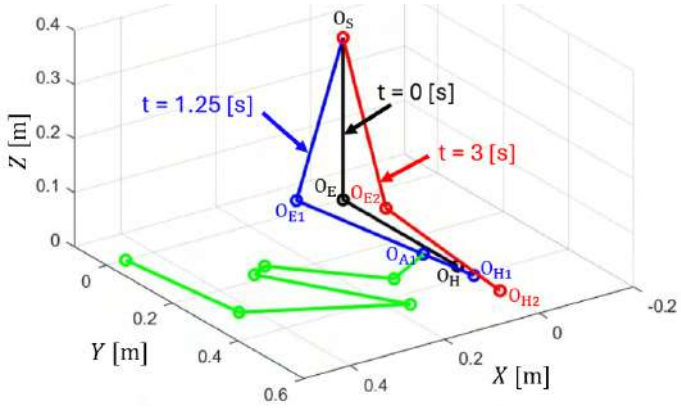

Fig. 11: Dummy robot arm posture when t = 0, 1.25 and 3[s]

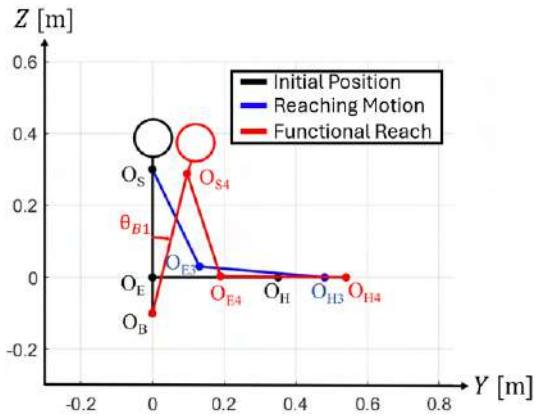

Fig. 13: Reaching motion (RM) and functional reach (FR)

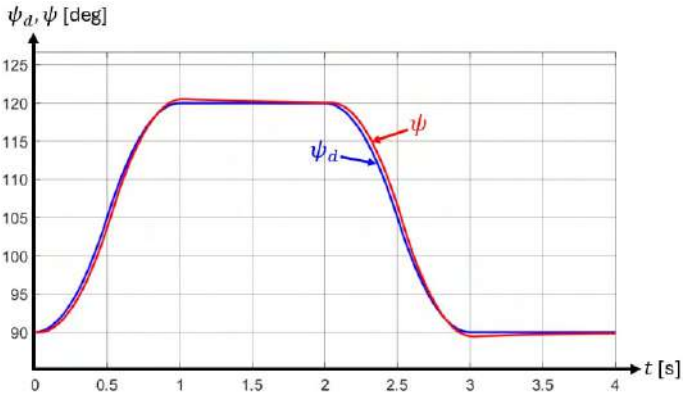

Fig. 12: Desired yaw angle ψ_d and its response ψ

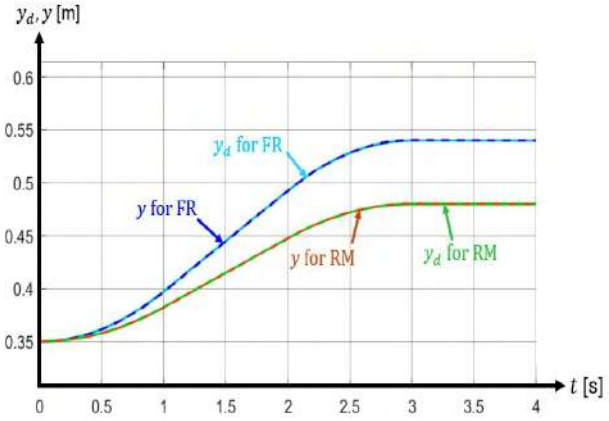

Fig. 14: Desired y position y_d and response y in RM and FR

the initial position of its hand is $\boldsymbol{p}_{OH} = [0\ 0.35\ 0]^{\mathrm{T}}[\mathrm{m}]$ on yaw angle 90° when t = 0 [s]. Then, the dummy robot will be assisted to reach $\boldsymbol{p}_{OH1} = [0\ 0.4\ 0]^{\mathrm{T}}[\mathrm{m}]$ when t = 1.25 [s] while changing the yaw angle from 90° to 120°. Lastly, the dummy robot will reach the desired position when t = 3 [s] and the yaw angle will be guided back from 120° to 90°. The proposed robot is able to guide the arm posture to achieve the desired yaw angles as shown in Fig.12. This tells that the escort-type upperlimb rehabiliation robot can help the patients to improve their arms mobility across all axes and not just on fixed yaw angle.

D. Allowing Trunk Movements for Functional Reach

This section describes the simulation of escort-type upper limb rehabilitation robot assisting dummy robot in two conditions which are reaching motion, RM (shoulder position is fixed) and functional reach, FR (shoulder position is not fixed). Fig.13 shows both conditions as the desired position for reaching motion is $\boldsymbol{p}_{OH3} = [0\ 0.48\ 0]^{\mathrm{T}}[\mathrm{m}]$ and functional reach is $\boldsymbol{p}_{OH4} = [0\ 0.54\ 0]^{\mathrm{T}}[\mathrm{m}]$. Both simulation using constant yaw angle throughout the simulation which is 90°. For functional reach, the proposed robot can be set to guide the dummy robot to reach a further position within the safe range as bending motion is allowed. In this case, the dummy robot's body will be assist to bend 14° to reach $\boldsymbol{p}_{OH4} = [0\ 0.54\ 0]^{\mathrm{T}}[\mathrm{m}]$. The actual trajectory for both conditions obtained from the simulation is close to the desired trajetoryas shown in Fig.14, which tells that the escort-type upper limb rehabilitation robot can also guide the body of dummy robot within safe range.

The above simulation results show that the proposed escort-type rehabilitation robot can simultaneously guide the arm posture while guiding the hand position for reaching motion, without fixing the shoulder joint position as an exoskeleton-type rehabilitation robot does.

When the proposed escort-type robot is deployed in actual clinical practice, we believe it will function effectively in a series of rehabilitation as described in Section 2.

V. Experiment

Fig.15 and Fig.16 show a photograph of the Escort-Type upper limb rehabilitation robot prototype attached to the forearm of an upper limb dummy robot, when we confirmed that the robot could take an arm posture to guide the reaching motion of the upper limb dummy robot. Torque control is used for this experiment same as simulation and input is determined the same way as simulation where the proportional and derivative gains are set to $K_p = 2.0$ and $K_d = 0.05$. In this prototype, a 70W DD motor is used as the drive motor for the first, second, and third joints, and is installed on the base. A pulley and a

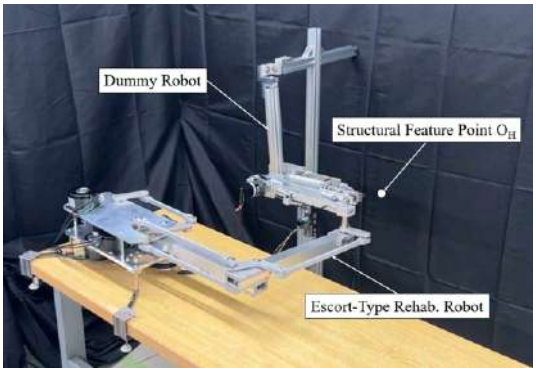

Fig. 15: Photo of escort-type robot during initial position

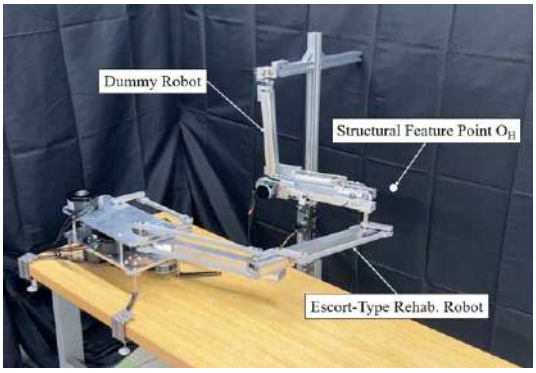

Fig. 16: Photo of escort-type robot during reaching motion

timing belt constitute the drive unit with the reduction ratio of 3. A 40W DD motor is used as the drive motor for the fourth joint, installed at the tip of the third link, and a gear is used to configure the drive unit with the reduction ratio of 5. Since the weight of the arm is added to the fourth joint, a gravity compensation mechanism using a spring is installed to generate the necessary driving force.

On the other hand, the upper limb dummy robot has a joint structure that resembles a human upper limb and upper body, all of which are non-driven joints, as described above. In addition, the shoulder position of the upper limb dummy robot is fixed by three joints in the waist that generate forward and backward tilting of the upper body, right and left tilting, and torsion.

In order to correspond to the aforementioned simulation, this prototype is planned to adopt a different arm posture when guiding the reaching motion of the upper limb dummy robot. The real-time control system for this prototype is based on Simulink Desktop Real-Time, which runs on a PC.

Fig.17 and Fig.18 show the experimental results of guiding hand with the same desired trajectory of hand position and yaw angle as described in the simulation section. During functional reach, the dummy robot's body bends because the shouder is not fixed, causing the shoulder position in the Y axis to increase as it moves forward, reaching a maximum at $\boldsymbol{p}_{OS} = [0\ 0.11\ 0.28]^{\mathrm{T}}[\mathrm{m}]$. Hence, the result shows that arm posture and hand can be guide when shoulder is fixed or not proven

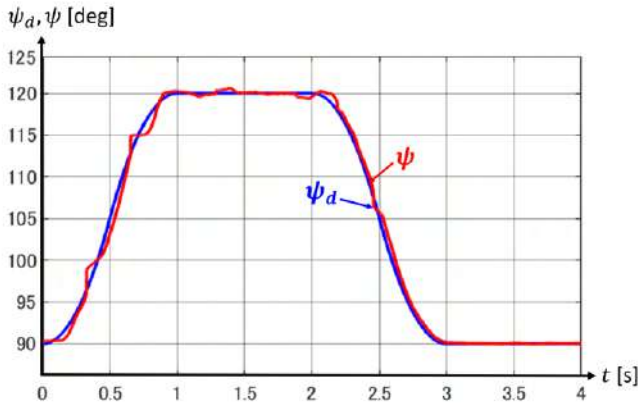

Fig. 17: Desire yaw angle ψ_d and its response ψ

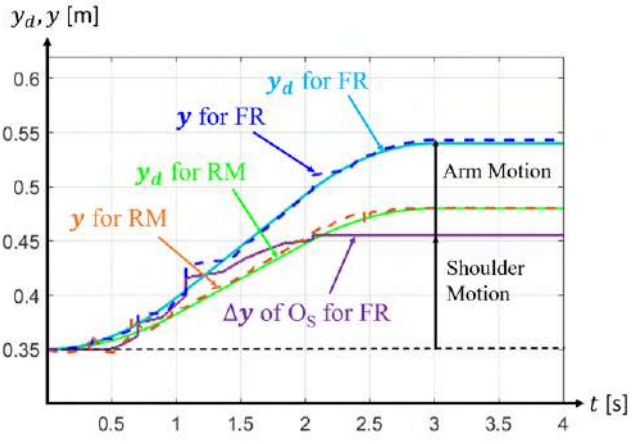

Fig. 18: y position and shoulder position in RM and FR.

by experiment as well as simulation.

VI. Conclusion

The findings obtained in this study are as follows.

1) The method for deriving the motion range of an escort-type rehabilitation robot for the upper limb was clarified. In the escort-type rehabilitation robot with passive joints, the arm postures of both the patient and the robot will be determined when the robot is attached to the patient's arm (or to the arm of a dummy robot in this study). Therefore, the inverse kinematics of the robot for deriving the range of motion is performed on the patient's arm, and the arm posture of the robot is derived after the arm posture of the patient is derived.
2) The escort-type rehabilitation robot for upper limbs was found to have the following two features: (1) The structure enables simultaneous hand position guidance and arm posture guidance in reaching motion, and (2) The structure allows functional reach because the shoulder position is not restrained during the reaching motion.

These features are unique and novel contributions of this research on rehabilitation robots for upper limbs.

Future research topics for the practical use of the escort-type upper limb rehabilitation robot include the measurement of not only the hand position and posture but also the force applied from the escort-type upper limb rehabilitation robot to the upper limb dummy robot during the guided reaching motion, and the establishment of an evaluation method for the degree of recovery during the rehabilitation process.

A Therapist-Inspired Approach to Stiffness Modulation in Rehabilitation Exoskeletons

Beatrice Luciani[1,2,*], Alessandra Pedrocchi[1,2], Francesco Braghin[1,2] and Marta Gandolla[1,2]

***Abstract*—In rehabilitation robotics, adapting exoskeleton behaviour to align with therapists' approach -where they intuitively vary their arm stiffness to provide tailored assistance to patients- is key for effective treatment and technology acceptance. Advanced robotic platforms have multiple setting parameters, but these often fail to precisely reflect therapists' desires. This work presents a novel framework to quantify and replicate therapists' stiffness when guiding arm movements, enabling its transfer to exoskeleton control. Using surface electromyography and torque sensors, we analyzed the relationship between muscle activity and joint torque to estimate stiffness, specifically focusing on the elbow joint. We tested our framework on the AGREE exoskeleton with three healthy participants simulating therapist roles and interacting with the robot under different conditions. Participants' activity was recorded and their elbow stiffness was then converted to robotic stiffness to control the elbow flexion-extension joint. Results show that our framework effectively captured participants' behavioural nuances and translated them into human-like robotic behaviours. When applied to AGREE, therapist-derived stiffness values generated trajectory-tracking errors similar to those observed when participants manually guided the robot. By mirroring therapists' adaptive support, this approach could enhance patient recovery and bridge the gap between human and robotic therapy in clinical settings.**

***Index Terms*—rehabilitation exoskeletons, stiffness modulation, therapist, learning from humans**

I. Introduction

When performing complex tasks, people naturally adapt the rigidity, or stiffness, of their arms to match the varying resistance of the environment. This adaptation aids in more effective interaction with the surroundings [1]. In robotics, this behaviour is implemented through the *variable impedance control* (VIC) [2]. VIC allows the mechanical behaviour of a robot to be altered by adjusting stiffness, damping and inertia. These alterations make the robot more suited to the demands of a task, especially when the external environment is unpredictable or not well known.

Taking a look at a classic therapy session of post-stroke rehabilitation, we would see a therapist manipulating the arm of the patient. This allows the therapist to perceive and understand the needs and level of motor capacity of the patient they are treating. At this point, the therapist can tune his/her support to the execution of the therapy exercise, on the basis of his/her experience, regulating the rigidity of his/her hand and arm. The rigidity of rehabilitation robots can also be tuned, specifically by acting on their joint-level stiffness parameters. The best values can be selected empirically by sampling the parameter space that guarantees stable robotic behaviour [3], or by acting mechanically on the joint if provided with a variable stiffness actuator [4]. This shapes the interaction between the robot and the user, ranging from full guidance to varying levels of assistance, to simple gravity support for the user's free movement[5]. Patient performances are evaluated by the therapist or through the use of sensors and a modality is chosen for the execution of the exercises, providing the desired level of assistance [3].

The above method, however, does not ensure that the different contributions provided by the robotic device correspond to the amount of support a therapist would apply for a specific patient condition, nor do they necessarily meet the therapist's expectations for the rehabilitation session. As a result, this can decrease the overall effectiveness of therapy, potentially causing "slacking" [6] and reducing clinicians' acceptance of rehabilitation robotics. To address this lack of correspondence, studies in the literature have investigated possibilities for rehabilitation robots to mimic therapists' support to be provided to the arm of the patient, focusing on the transfer of force profiles [7], [8]. To extrapolate force contributions from the therapist's actions, researchers have employed specific force sensors. Not every robotic device, anyway, is provided with the same sensors and literature approaches might not always be applicable. To overcome literature limitations concerning both the correspondence of robot and therapist behaviours and hardware availability, our project aims to develop a framework that records the therapist's support directly from a portable sensor to be positioned on the therapist's arm and extract stiffness values to be then transferred to the robot.

II. Related projects: translating human stiffness to robots

In the literature, various approaches to extracting the human arm's stiffness have been explored [9]. Traditional methods include **active evaluation** of end-point stiffness, where controlled perturbations are applied to the human hand, followed by measurements of resulting displacements and forces [10]. While precise, this technique can be challenging for real-time implementation in dynamic therapy settings [11]. Alternatively, **musculoskeletal models** of the arm [12] can be exploited to evaluate stiffness at different limb levels. Such models can provide detailed representations of joint

stiffness but are often computationally expensive, limiting their practicality for adaptive robotic applications. **Surface electromyography (sEMG)** based methods, on the other hand, have gained significant traction due to their ability to provide real-time tracking of muscle activity in an effective and non-invasive way. In particular, they can be used to evaluate the co-contraction activity of antagonist pairs of muscles, which is directly linked to joint torque profiles [13] and to the stiffness of the limb [14], [15].

In the industrial sector, EMG-based frameworks have been used for human-robot collaboration applications. In this context, real-time stiffness modulation can optimise the robotic response to human movements, enhancing both safety and efficiency in tasks that require precise manual control [11], while also improving robot performances. For example, Liang *et al.* [13] developed an electromyography-based stiffness evaluation framework designed to real-time adjust the tracking capabilities of an industrial robot, thus reducing the impact of external disturbances. They linked sEMG data from the biceps and triceps to the force exerted at the elbow level by a user, to then estimate custom parameters for the electromyography-stiffness transformation. In another work, Wu and colleagues [16] presented a framework for endpoint stiffness extraction for teleoperation and optimisation of industrial interactive tasks. sEMG signals are recorded with an armband and forearm angles are evaluated via an optical-marker system. From the collected data, their system evaluates the operator's stiffness and adjusts the corresponding stiffness of an industrial manipulator.

Stiffness estimation from EMG signals has also been exploited in the field of surgical robotics. The work presented by Arduini *et al.*[17], for instance, describes a Learning from Demonstrations framework that leverages electromyography and motion tracking to determine the endpoint stiffness of a surgeon while performing surgical blunt dissection tasks.

In rehabilitation, sEMG is a leading method for creating a natural interaction between humans and rehabilitation devices and is normally used for intention-detection purposes. Therefore, its use can be easily extended to stiffness estimation purposes. In their work, Ma *et al.* [18] proposed a neural-network-based framework to extract the endpoint stiffness of post-stroke patients from EMG data and elbow angle, and consequently adjust the control of the rehabilitation robot. Castellini and colleagues [19] implemented a hand-stiffness extraction framework to intuitively control the stiffness of a rehabilitation robot or prosthesis. They integrated it with force feedback, to create a rehabilitation system that regulates robotic contribution to patients' capacities and provides them with realistic feelings of natural control over the robotic device.

Although the applications developed thus far for rehabilitation have shown effective results, they primarily focus on adjusting robotic stiffness to match the patient's remaining abilities. To our knowledge, none have aimed at translating a therapist's stiffness into robotic behaviour.

III. Therapist's stiffness extraction framework

The framework we developed to extract arm stiffness values from therapists' demonstrations, similar to what Liang *et al.*[13] did for industrial applications, analyses the correlation between sEMG signals and joint torque. In fact, according to the literature, we can quasi-linearly correlate torques (τ) and muscular activity of antagonist pairs of muscles ($p_{agonist}$ and $p_{antagonist}$), according to the following general equation:

$$\tau_{joint} \approx A * p_{agonist} + B * p_{antagonist} \quad (1)$$

and then use A and B to extract stiffness values from co-contraction signals, as we will explain later. We specifically focused on the evaluation of the therapist's arm stiffness at the elbow-joint level.

A. Experimental setup

To extract the therapist's muscular activity and torque produced at the elbow joint, we decided to employ two main devices:

1) AGREE: AGREE [3] is an upper limb exoskeleton designed for arm neuro-rehabilitation. It is composed of four robotic joints and each joint actuation unit has a brushless motor, an incremental encoder for position information and a reaction torsional loadcell (TRT-50/200, Transducer Techniques, CA, USA) to provide torque data. Sensor data are recorded at 1 kHz.

2) Myo Armband: The Myo armband by Thalamic Labs is a wearable device equipped with eight electromyographic (EMG) electrodes and a 9-axis inertial measurement unit (IMU). The recording frequency for the EMG sensors is $f_{samp} = 200Hz$. The Myo armband transmits these signals via Bluetooth to possible connected devices, such as prosthetics or computers [20]. Even if we decided to use it for the analysis of the biceps-triceps complex, it can be worn both on the upper arm and forearm, according to the groups of muscles one wants to record.

B. Framework

The stiffness-extraction framework we developed can be divided into two subsequent phases: *Calibration* and *Stiffness extraction* (see Fig.1). At the start of the procedure (*Calibration* phase), the participant wears the Myo Armband on his/her upper arm, verifying that it adheres to the skin and is placed at the level of the midpoint of the bicep belly. The Armband needs to be left in position along all the steps.

1) Calibration:

Phase 1 - EMG peaks extraction: The participant is asked to execute three consecutive isometric contractions of the biceps, followed by three consecutive isometric contractions of the triceps, using a table as support and stopper. The Armband records the EMG signal coming from the eight channels and includes a 50 Hz notch filter to eliminate power-line noise. We elaborate the data through the following **EMG-analysis** steps:

- **Envelope extraction**: the sEMG signals are elaborated to extract the general muscle activation pattern. The magnitude of the analytic recorded signal is computed

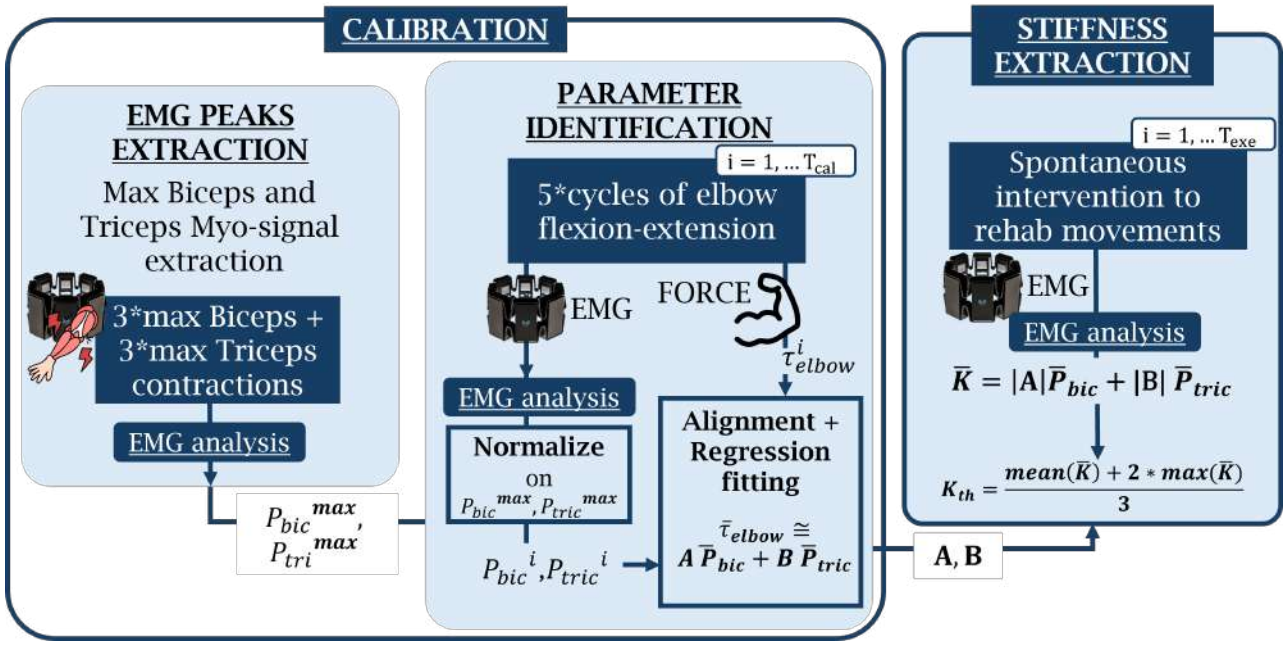

Fig. 1. Scheme of the therapist-stiffness extraction framework. With the calibration phase, we can extract the maximum values for Biceps and Triceps contraction, use them to normalise EMG data recorded while the therapist freely moves the arm wearing the Myo, and define the regression parameters that link the therapist's muscular activity and force exerted at the level of the elbow. We can then use such parameters, during therapist-patient interactions, to transform recorded EMG data into corresponding stiffness values to describe therapist's support.

via the *hilbert* MATLAB function and provides the envelope of the EMG.

- **Filtering**: the resulting signals are low-pass filtered ($f_{cut} = 2.5Hz$ - set experimentally to align with literature values [21]).
- **Main signals extraction**: since users can wear the bracelet without precise muscle alignment, the readings from each channel of the Myo reflect activity across multiple muscles. The sensors capture a mix of signals from various motor units, including those of both the muscles of interest. To address this, we apply Principal Component Analysis (PCA) to the data from all eight channels. PCA identifies and extracts two summarising signals (the two first principal components coming from the analysis) that represent the contraction activity of the biceps and triceps.

We then evaluate the maximum for the two resulting biceps and triceps components along the calibration signals, obtaining the sEMG values for the maximal contractions (p_{bic}^{max}, p_{tri}^{max}).

Phase 2 - Parameters identification: To estimate the parameters A and B presented in Eq.1, we need to study the correlation between the sEMG biceps and triceps signals and the torque produced at the elbow joint. To build such correlation, the participant (i.e. the therapist) is asked to wear the AGREE exoskeleton, always with the Myo Armband placed on the upper arm, and perform 5 full-range repetitions of an elbow flexion-extension movement. To minimise external forces and characterize the elbow parameters for the therapist, the movement is carried out with AGREE set in a gravity-compensating modality, allowing the participant to move without resisting gravity. Having to support the weight of the robotic arm when wearing it would, in fact, overload the patient's muscles and potentially alter stiffness results. The exoskeleton is adjusted so that the shoulder is elevated and the elbow flexion extensions are performed on a horizontal plane. During the movement execution, we record sEMG data and elaborate them as previously described, to extract their two main components. Biceps and triceps activities are then normalized with respect to, respectively, p_{bic}^{max} and p_{tri}^{max}. We obtain p_{bic}^{i} and p_{tri}^{i}, where $i = 1, ..., T_{cal}$ and T_{cal} is the time-length of the recording. EMG normalised data are then synchronized with torque data coming from the sensor of AGREE elbow joint (τ_{elbow}^{i}, with $i = 1, ..., T_{cal}$).
Adapting Eq.1 to our specific case, we obtain:

$$\overline{\tau}_{elbow} \approx A \cdot \overline{p}_{bic} + B \cdot \overline{p}_{tri} \tag{2}$$

where:

- $\overline{\tau}_{elbow} = (\tau_{1,elbow}, \tau_{2,elbow}, ..., \tau_{T_{cal},elbow})^T$,
- $\overline{p}_{bic} = (p_{bic,1}, p_{bic,2}, ..., p_{bic,T_{cal}})^T$,
- $\overline{p}_{tri} = (p_{tri,1}, p_{tri,2}, ..., p_{tri,T_{cal}})^T$.

we can perform a least squares fitting to define A and B parameters.

2) Stiffness extraction: Having modelled the stiffness behaviour of the participant's arm, we can now ask them to perform any desired movement, with only the Armband on to record their sEMG activity (as depicted in Fig.2). According to the aforementioned literature work by Liang *et al.*[13], we can exploit the parameters extracted during Calibration to

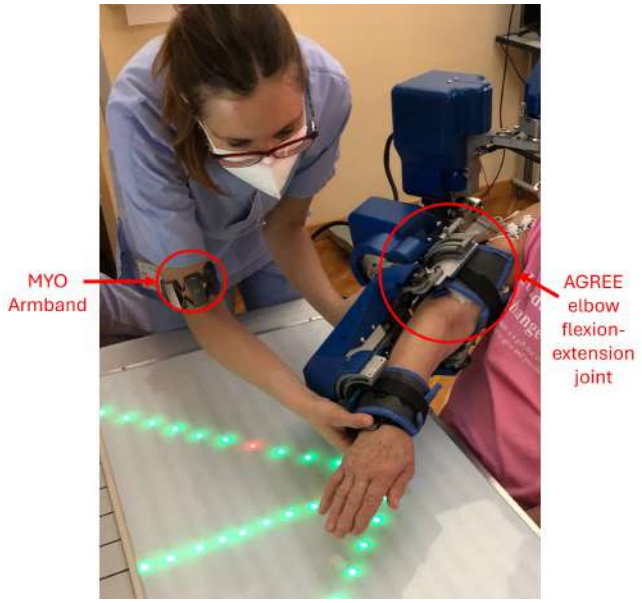

Fig. 2. The therapist can wear the Myo Armband on the upper arm while manipulating the robot along the desired movements. In this way, the co-contraction activity of the biceps and triceps are evaluated and can be used to obtain the therapist's stiffness values thanks to the A and B parameters previously extracted during the calibration.

transform the EMG data recorded in this phase into punctual elbow stiffness values:

$$\overline{K} = |A| \cdot \overline{p}_{bic} + |B| \cdot \overline{p}_{tri} \tag{3}$$

where $\overline{K} = (k_1, k_2, ..., k_{T_{exp}})^T$ and $|A|$ and $|B|$ are the absolute values of A and B. This time, $i = 1, ..., T_{exp}$, where T_{exp} is the time duration of the participant's movements. After the recording, we estimate a global stiffness value

$$K_{th} = \frac{mean(\overline{K}) + 2 \cdot max(\overline{K})}{3} \tag{4}$$

to describe the therapist's behaviour. The idea is that, according to the specific condition of interaction with the patient and to the therapist's approach towards the therapy execution, his/her EMG activity will change, and so will the corresponding stiffness. Eq.4 is defined experimentally to balance the mean and maximum stiffness, ensuring that transient peaks do not overly dominate the result while still capturing significant variations.

Conversion to AGREE stiffness values: The stiffness values estimated so far do not actually have a real measurement unit and are just meant to describe variations in human behaviour. To tune AGREE behaviour according to such variations, we rescale human stiffness values in AGREE joint stiffness value. Specifically, we know that K_{AGREE}, at the elbow joint, goes from $5\frac{Nm}{rad}$ to $60\frac{Nm}{rad}$ [3]. Given that K_{th}^{max} can be estimated from p_{bic}^{max} and p_{tri}^{max}, and that we evaluated K_{th}^{min} to be approximately zero, we can compute:

$$K_{AGREE} = (60 - 5)\frac{Nm}{rad} \cdot \frac{K_{th}}{K_{th}^{max}} + 5\frac{Nm}{rad} \tag{5}$$

By rescaling stiffness within AGREE's operational range, we ensure that variations in therapist stiffness are transferred to AGREE while maintaining system stability. Since AGREE has physical limitations, we need to avoid excessive stiffness that could induce vibrations or excessive compliance that could result in instability. This transformation is therefore necessary to ensure safe operation.

C. Testing

To prove the efficacy of our framework, we involved healthy volunteers in testing our system from the therapist's point of view, with two different experiments. Participants were required to have no history of neurological diseases and to have full upper-limb function. Tests were approved by the Ethical Committee of Politecnico di Milano (Application No. 8/2022 - 16.02.2022).

Experiment 1: For the first experiment, three volunteers were recruited and were asked to wear the Myo Armband on their upper arm and keep it in place throughout the entire experiment. First, they completed the two first steps of the framework, allowing us to identify their personal parameters. Then, we asked them to interact with AGREE in two different tests, manipulating the exoskeleton in the execution of an elbow flexion-extension exercise, and repeating the movement five times per test. During the **Test 1**, AGREE was set in a modality defined as *null-gravity*, where it does not compensate for its own weight and should, for our experiment, represent a patient who is unable to actively move or lift the arm. In **Test 2**, AGREE was set in *gravity-compensation* mode, where it does not actively move but compensates for its weight. In this case, it should represent the behaviour of a less-impaired patient.

The variable behaviours of AGREE should produce different behaviours in the subjects playing the therapist part, who are led to approach the exoskeleton with variable contributions for the execution of the same task. Specifically, we expect the arm stiffness obtainable from **Test 1** (i.e. severely-impaired patient) to be higher than the arm stiffness evaluated during **Test 2** (i.e. mildly-impaired patient).

Experiment 2: As an additional validation to our framework, we asked one of the three volunteers to manipulate AGREE. He physically supported it in the execution of a predefined trajectory (i.e., a reaching task from one point to another) and repeated the movement five times. During the manipulation, AGREE was set to a low-assistive modality (namely **A3** in [3]), and we measured the kinematic error at each joint, with respect to the desired trajectory. After assessing the stiffness of the therapist's arm along the manipulation, it was translated into AGREE stiffness values. Then, using the calculated robotic stiffness, AGREE independently executed the same trajectory, without any external intervention. We finally compared the kinematic error produced at the elbow joint when the participant assisted the trajectory with the error generated by AGREE's flexion-extension joint during its independent execution. AGREE kinematic performances, depending on the choice of stiffness and damping for each of its joints, can also be retrieved from its control-system analysis, presented in [3]. This experiment was repeated twice (Trial 1 and Trial 2).

IV. Results and Discussions

Experiment 1: Our framework was tested with three healthy participants acting as therapists, each performing stiffness modulation under different robotic assistance conditions. Table I summarizes the individual parameters and stiffness values derived from the two test conditions described in the previous paragraphs. In **Test 1**, where AGREE simulates a fully impaired patient, we observed notably higher arm stiffness values. This indicates high effort and rigidity from the participant to stabilize and guide the robot. In contrast, **Test 2** resulted in lower stiffness values, reflecting a more flexible approach from the participants. This reduction, which is coherent with our expectations, confirms that the framework can successfully modulate stiffness in response to varying conditions of therapist-patient interactions, thus mimicking therapist-driven adaptations during therapy sessions.

TABLE I
RESULTS OF THE TESTS PERFORMED WITH THE THREE PARTICIPANTS: A, B PARAMETERS OBTAINED THROUGH OUR FRAMEWORK, STIFFNESS VALUES IN THE DIFFERENT TESTING CONDITIONS, BOTH IN "MYO-SCALE " AND AGREE SCALE.

	A	B	Stiff Max	Stiff 1	Stiff 2
S1	2.80	1.41	1.65 (60 $\frac{Nm}{rad}$)	0.85 (33 $\frac{Nm}{rad}$)	0.49 (22 $\frac{Nm}{rad}$)
S2	1.73	2.17	1.27 (60 $\frac{Nm}{rad}$)	0.96 (46 $\frac{Nm}{rad}$)	0.63 (32 $\frac{Nm}{rad}$)
S3	1.57	4.00	1.29 (60 $\frac{Nm}{rad}$)	0.97 (46 $\frac{Nm}{rad}$)	0.67 (33 $\frac{Nm}{rad}$)

The stiffness values we extract can vary based on several factors. The therapist's decisions, such as how much support to provide or whether to grasp the patient's arm more proximally or distally, are part of the rehabilitation strategy and directly affect the recorded stiffness. External factors like the therapist's positioning or the physical distance between the patient and therapist, on the other side, can lead to variations in stiffness that are not directly tied to the clinician's intentions for executing the task. However, even if these factors do not explicitly define a rehabilitation strategy, they still influence the haptic interaction between the therapist and the patient's arm in a conventional therapy session. As a result, it is reasonable to replicate their effects in our framework, as they naturally shape the physical dynamics of therapist-guided movements.

Experiment 2: As previously described, in the second experiment we compared the kinematic error produced by the therapist's intervention to that produced by the robot while working with the corresponding stiffness parameter, to assess the fidelity of the system in transforming human behaviour into robotic. As shown in Fig.3 **A3** parameters would produce, without external interventions, a mean tracking error at elbow level of around 11 degrees.

With subject guidance to the movement of the robot, instead, we evaluated a mean error over the execution of the trajectory of 4.5 degrees for the first trial, and 5.9 degrees for the second. The extracted elbow stiffness values were converted, for the two trials, to AGREE stiffness values and coupled with the damping associated with the **A3** modality

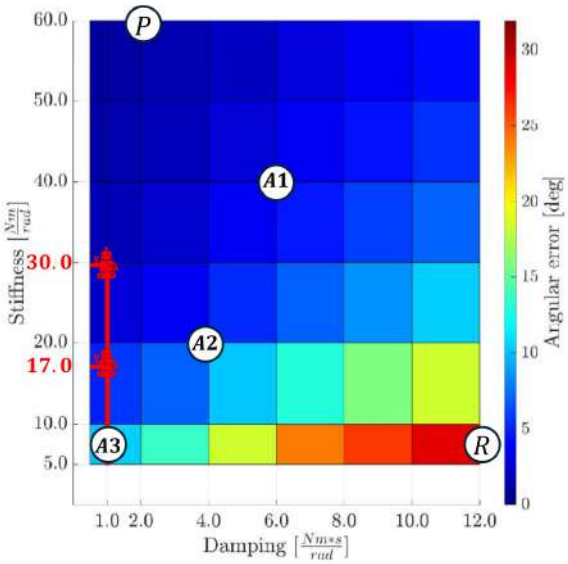

Fig. 3. Colour map of the kinematic error made by the robot, at the elbow joint, given the combination of all the possible values of stiffness and damping included in the stability range for the joint itself. We highlighted the pairs of parameters identified in our second experiment, with the indication of the corresponding errors. The references to the **P, A1, A2, A3** and **R** indicate the couples of parameters selected for the different working modalities presented in [3]. In those modalities, parameters were selected sampling the space of stable parameters.

($D = 1.0Nm * sec/rad$). Tab.II summarizes the results for the two trials of this second experiment. The mean trajectory-tracking errors for the AGREE elbow flexion-extension joint, as shown in Table II, are 4.0 degrees and 6.1 degrees, respectively. Considering the range of potential errors caused by varying the AGREE elbow joint parameters, we can conclude that both values are comparable to their corresponding manipulation errors. This finding confirms the reliability of the method in accurately replicating the therapist's approach to executing exercises.

TABLE II
RESULTS OF THE TWO TRIALS OF THE SECOND EXPERIMENT, INCLUDING THE HUMAN STIFFNESS EVALUATED AT ELBOW LEVEL, WITH THE ERROR PRODUCED BY HUMAN MANIPULATION, AND THE CORRESPONDING ROBOTIC STIFFNESS WITH THE ERROR AGREE ELBOW JOINT WOULD PRODUCE WITH SUCH A STIFFNESS.

	Therapist		AGREE	
	Stiffness	Error [deg]	Stiffness [Nm/rad]	Error [deg]
Trial 1	0.50	4.5	30	4.0
Trial 2	0.09	5.9	12	6.1

V. Conclusions and Future Perspectives

In this work, for the first time, we have developed a framework to translate therapist behaviours in terms of stiffness to a rehabilitation robot, overcoming the problem of defining the assistance through parameters. The results of the experiments we conducted demonstrate the potential of the framework to capture the individualised nature of therapist-patient interaction and translate it into robotic action.

The punctual stiffness values extracted during the teaching phase are then summarised with a single value to capture the "global" therapist's behaviour. The global stiffness is then transformed into robotic parameters to be applied during a whole rehabilitation session or, at the very least, during a specific exercise. Even if punctual stiffness values are surely more representative of the variations in the therapist's approach along with the execution of the therapy exercise, employing them at the current stage of this research would have strongly limited the applicability of the results, forcing us to re-apply the recorded stiffness along with the execution of the single recorded trajectory. By overcoming the strict link between a specific stiffness profile and its corresponding trajectory, and generalising the relationship between stiffness variations and kinematics through techniques like machine learning approaches, we can broaden the applicability of our system. We could, for instance, reproduce the vector-search-based approach we employed for force-based mimicking in one of our previous studies [7].

A fundamental future step for this research is presenting our framework to therapists and other clinicians in neurorehabilitation. Their feedback on the utility of this approach, related to its ability to accurately represent therapists' behaviours and intentions, along with an evaluation of usability, would add important insight. The involvement of clinicians would also help us understand how the extracted stiffness values change according to the individual approach therapists adopt when manipulating patients' arms.

On the Impact of Proprioception in EEG Representations and Decoding during Human-Hand Exoskeleton Interaction

Qiang Sun, Eva Calvo Merino, Liuyin Yang, Axel Faes, and Marc M. Van Hulle

***Abstract*—Controlling a hand exoskeleton based on electroencephalogram (EEG)-based brain-computer interfacing (BCI) holds promise for human motor augmentation and neurorehabilitation. To achieve natural control, a critical step is to understand the impact of proprioception provided by the exoskeleton during interaction. In this study, we aim to approach the goal by quantifying EEG representations and BCI performance. We monitored 25 healthy subjects' full-scalp EEG while performing different finger movement tasks with a cable-driven hand exoskeleton. Each task involves three movement modalities, i.e., imagined (IM), passive (PM), and congruent imagined and passive (IPM) finger flexion. We found that alpha (8 - 13 Hz) and beta (13 - 30 Hz) band desynchronization in the sensorimotor area was significantly stronger for PM and IPM tasks compared to IM, with no significant difference between PM and IPM. Using machine learning models, we achieved a high accuracy in classifying exoskeleton-assisted movements from the rest condition (IPM vs. REST: 0.80 ± 0.07, PM vs. REST: 0.72 ± 0.10), with the IPM modality returning the highest accuracy. However, distinguishing between IPM and PM yielded only 0.61 ± 0.09, significantly lower than the condition of intention detection without the exoskeleton (IM vs. REST: 0.73 ± 0.08). Our findings suggest that sensorimotor EEG activity can track proprioceptive feedback induced by the hand exoskeleton. While this feedback is pronounced and distinguishable, detecting motor intention during exoskeleton movement remains highly challenging. This highlights the need for advanced decoders and control strategies for the future development of continuous BCI-actuated hand exoskeletons.**

***Index Terms*—brain-computer interfaces (BCIs), electroencephalogram (EEG), hand exoskeleton, motor intention, proprioception.**

I. Introduction

Brain-computer interfaces (BCIs) build a direct connection between the human brain and effectors, bypassing the normal neuromuscular pathway [1]. A promising field for BCI systems is human motor augmentation and neurorehabilitation, where the end users can rely on a brain-actuated exoskeleton to accomplish daily activities. For practical considerations, electroencephalogram (EEG) is recommended for recording brain activities as it is non-invasive, affordable, and offers relatively high temporal and spatial resolution compared to other non-invasive recording techniques. A successful demonstration has been realized by Soekadar *et al.* [2], where an individual with impaired hand function could accomplish different daily hand tasks with an EEG-controlled exoskeleton.

Exoskeletons are widely used in neurorehabilitation to encourage the patient's engagement which in turn promotes motor recovery [3]. A BCI-controlled exoskeleton is particularly useful in this case as the patient's active motor intentions can be decoded and translated into exoskeleton commands. For patients with limited motor control functions, their intentions are conveyed through imagined movement, a type of movement that motor-disabled individuals can do by imagining a given movement without actually performing it [2], [4]. Such a closed-loop active robot-assisted mode has been shown to improve post-stroke rehabilitation outcomes [4]. In this study, we focused on BCI-actuated hand exoskeletons, as they hold promise for restoring intuitive finger control in people with hand motor impairments.

A major feature of human-exoskeleton interaction, compared to human-robotic arm or avatar interaction, is the strong proprioceptive feedback provided by the device. Once the exoskeleton is activated, the user can sense body posture and limb movements during physical interaction, leading to the excitation of the sensorimotor cortex [5]–[7]. From ongoing EEG, this excitatory activity is characterized by a power decrease or increase in particular frequency bands, termed event-related desynchronization (ERD) and event-related synchronization (ERS), respectively [8]. Specifically, robot-assisted passive movement can elicit bilaterally distributed alpha (8 - 13 Hz) and beta (13 - 30 Hz) ERD during the movement, albeit stronger on the contralateral side [5], [7]. Once the movement is terminated, ERS in the beta band occurs centrally, partially reflecting an active inhibition of the motor cortex by somatosensory afferents [9].

From a control perspective, it is pivotal to develop asynchronous and, ideally, continuous BCI, as it attributes to the autonomy of the user and provides more natural control capabilities. An asynchronous BCI system allows the user to voluntarily decide when to initiate or terminate a task. In contrast, a continuous BCI system provides ongoing, real-time outputs that continuously map the user's brain activity

to control parameters, such as movement or speed, reflecting their dynamic motor intentions. Both types of BCIs rely on real-time monitoring and decoding of the user's motor intentions. However, as the exoskeleton will produce proprioceptive afferents during interaction, the difficulty of motor intention decoding from EEG needs to be addressed. Indeed, a recent study reported that motor intention detection is more challenging during lower-limb exoskeleton interaction compared to a static case [10]. However, whether this phenomenon pertains to hand exoskeletons remains unexplored.

In this study, we designed an experimental paradigm combining a cable-driven hand exoskeleton and full-scalp EEG recordings. Our first objective is to compare the EEG representations of different movement modalities, including imagined (IM), passive (PM), and congruent imagined and passive (IPM) finger flexions, with a particular interest in comparing IPM and PM. The second objective is to assess motor intention detection performance in situations with and without exoskeleton assistance. Based on our findings, we highlight the key challenges of EEG decoding during human-hand exoskeleton interaction.

II. Materials and Methods

A. Subjects

We recruited 25 right-handed subjects (12 males and 13 females, 24.20 ± 3.29 years old). Each subject's handedness was evaluated using the Edinburgh Handedness Inventory[1]. All subjects participated in a single-session EEG experiment. This study was approved by the Ethical Committee of the University Hospital of KU Leuven (UZ Leuven) under reference number S6254. Before the experiment, all subjects were informed about the study details and gave their written consent.

B. Experimental setup and paradigm details

The experiment was conducted in a quiet recording room. Subjects sat on a comfortable chair wearing the EEG cap and a right-hand exoskeleton, as illustrated in Fig. 1a. We configured 62 EEG active electrodes (Easycap GmbH, Germany) covering the full scalp following the 10%-System. Additional reference and ground electrodes were placed at FCz and AFz, respectively. When preparing the electrodes, we kept the impedance below 5kΩ. For EEG recording, we used the Neuroscan SynAmps RT device (Compumedics, Australia) operating at 1000 Hz sampling rate. As for the exoskeleton, we used the Gloreha Sinfonia (renamed R-TOUCH by BTL Industries). This device enables one degree-of-freedom for each finger and controls its flexion and extension by an electric actuator-driven steel cable (Fig. 1b).

The paradigm instructions were shown on the screen (ViewPixx, Canada) in front of the subjects (Fig. 1a). We designed three movement modalities, namely, IM, PM, and IPM. Each modality had three finger tasks including thumb, index, and middle-ring-little finger flexion. The timing of an exemplary imagined thumb trial is shown in Fig. 1c. At the beginning of the trial, a cross was shown on the screen for 1.5s instructing the subject to stay focused. Later, a circle and tick marks, were shown, centered on the cross, as well as a word cue indicating the finger task to be performed. Upon the disappearance of the word cue (1s later), the circle started to shrink at a constant speed. Once the circle touched the tick marks(2s later), the subject performed the finger task, either by imaging finger flexion (IM and IPM conditions) or by refraining from any mental tasks but by undergoing (and feeling) the exoskeleton movement (PM condition). After 2.5s, the subject could relax for 2-3s. There was a homing-back action from the exoskeleton in the PM and IPM conditions. For IM and IPM, we asked our subjects to perform kinesthetic imagination, i.e., imagine they were moving their right-hand fingers at the same speed as the shrinking circle. For PM, we asked our subjects to avoid any mental tasks. The exoskeleton moved the fingers at the same speed. The experiment had 30-40 rounds with each round randomizing three modalities each one comprising three randomized finger tasks. The subjects could relax between rounds and were given a form to report the trials they did wrong in the past round. All subjects practiced the paradigm prior to the real experiment. A camera monitored the behavior of each subject's right hand during the entire experiment.

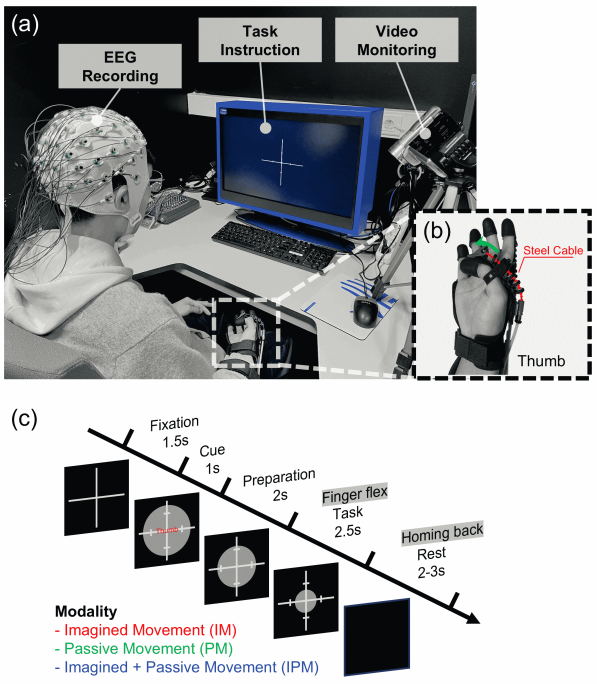

Fig. 1. Experimental paradigm. (a) Experimental setup. The subject wore a hand exoskeleton and performed the instructed tasks while the full-scalp EEG signals were recorded. (b) The exoskeleton made the thumb of the subject flex via a steel cable. (c) Timing of an exemplary imagined thumb movement trial.

C. EEG data preprocessing

Data preprocessing was done based on customized MATLAB code and scripts from the FieldTrip toolbox [11]. The recorded raw EEG data were downsampled to 250 Hz for ease

[1]https://www.brainmapping.org/shared/Edinburgh.php

of computation after applying an antialiasing filter. Then, two notch filters were applied to remove power line noise at 50 Hz and 100 Hz. Next, we filtered the continuous signals into 0.1 - 120 Hz. The mentioned filters were all 3-order Butterworth IIR filters. Before removing eye movement artifacts, we visually inspected and removed faulty channels noted during the recording. Then, we used independent component analysis (*runica* implemention in FieldTrip) to detect vertical and horizontal eye movement-related components and removed them. Common average referencing was implemented. Finally, we imputed the excluded noisy channel EEGs based on those of neighboring electrodes.

The cleaned EEGs were segmented into 9-s epochs according to trial markers, starting from trial onset (Fig. 1c). For each epoch, we detected the noisy channels based on features: kurtosis, mean value, and variance. Specifically, a channel was detected as noisy if any of its features exceeded three times the standard deviation of the mean for all channels. The noisy channels were interpolated. We also removed bad epochs when a third of the channels had an amplitude over ±100 μV.

D. EEG representations

We looked into event-related spectrum perturbation (ERSP) of the EEG signals, which reflects the spectra power changes relative to a baseline. The group-averaged ERSP for a given finger task at channel *c*, frequency *f*, and time *t* is calculated as:

$$ERSP(c,f,t) = \frac{1}{S}\sum_{s=1}^{S}\frac{1}{N}\sum_{n=1}^{N}\Big]F_{s,n,c}(f,t) - F_{s,n,c}^{baseline}(f)\Big) \tag{1}$$

where *S* and *N* represent the number of subjects and the number of trials in the current task, respectively. $F_{s,n,c}$ indicates the time-frequency representation (TFR) of the *c*-th channel and *n*-th trial from subject *s*. We calculated the averaged power from 0.5 to 1.5s with respect to the appearance of the cross during the fixation phase (Fig. 1c) as the baseline $F_{s,n,c}^{baseline}$. The TFRs were calculated based on Short-Time Fourier Transform (STFT) with a window of 1s and overlap of 1 sample. We took the logarithm for ERSP calculation.

EEG oscillatory activities in the alpha (8 - 13 Hz) and beta (13 - 30 Hz) bands were specifically analyzed, as these rhythms are characteristic of both active and passive finger movements [6], [12]. We first visualized the topographical distribution of alpha and beta ERSP on the scalp. Then, we looked into the TFR of the representative EEG channels.

E. Decoding models

We built four binary classification models based on the Fisher Geodesic Minimal Distance to Mean (FgMDM) classifier [13]. FgMDM works in the Riemannian space and shows exceptional decoding performance in many BCI tasks [14]. In the first model, we classified IM versus the resting state (IM vs. REST), representing motor intention detection without exoskeleton movement. The second and third models classified PM versus REST and IPM versus REST, respectively, to assess whether the exoskeleton induces distinguishable features. The final model classified IPM versus PM (IPM vs. PM), simulating a scenario to determine the presence of motor intention during exoskeleton interaction. We pooled all three finger tasks' epochs together for IM, PM, and IPM. The cleaned epochs were further bandpassed into 4 - 40 Hz. Considering the shorter displacement of thumb flexion and future online BCI applications, we opted for a 1-s data length to test decoding performance. Therefore, we extracted the first 1-second segment (time window: 4.5 – 5.5 s) from the task period for IM, PM, and IPM, respectively (Fig. 1c). For the resting state, a 1-second segment (time window: 0.5 – 1.5 s) was obtained from the fixation phase (Fig. 1c), which also served as the baseline for ERSP calculation. In the end, we obtained 105.25 ± 13.57, 105.08 ± 12.08, and 106.67 ± 11.94 segments for IM, PM, and IPM, respectively. The resting state contained the same number of segments as IM, PM, and IPM, respectively.

The FgMDM classifier was implemented using the Covariance toolbox[2] with the Riemannian mean and distance as model parameters. All models were trained and tested following a 10×5-fold (stratified) cross-validation procedure. The average accuracy (correct predictions out of all samples) is reported.

F. Statistical analysis

We compared the alpha and beta rhythm power changes at channels C3 and C4 via the Wilcoxon rank sum test. We used repeated measures Analysis of Variance (ANOVA) to test the difference of alpha and beta rhythm for different modalities. Once a significant effect was found, we performed multiple comparisons with Bonferroni correction. The classification accuracies from different models were tested in the same way. The normality of variable observations was examined based on the Shapiro-Wilk test. All statistical analyses used a significant level of 0.05.

III. Results

A. Exoskeleton-assisted finger movements induce strong EEG desynchronization in sensorimotor area

Figure 2 illustrates the evolution of EEG activities within the alpha and beta bands for three movement modalities. Each topoplot represents the averaged ERSP across all finger tasks, subjects, and the selected time window. During the preparation stage, IM and IPM exhibited relatively stronger power decreases (i.e., desynchronization or ERD) compared to PM in the contralateral central region, with IPM showing more widespread activation. Upon exoskeleton activation, stronger ERD occurred in the sensorimotor area, as observed in PM and IPM modalities during the task and rest stages. The proprioceptive feedback-induced ERD was bilaterally distributed, with the strongest effects observed contralaterally. It is worth noting that for PM and IPM in the rest stage, the exoskeleton is

[2]https://github.com/alexandrebarachant/covariancetoolbox/tree/master

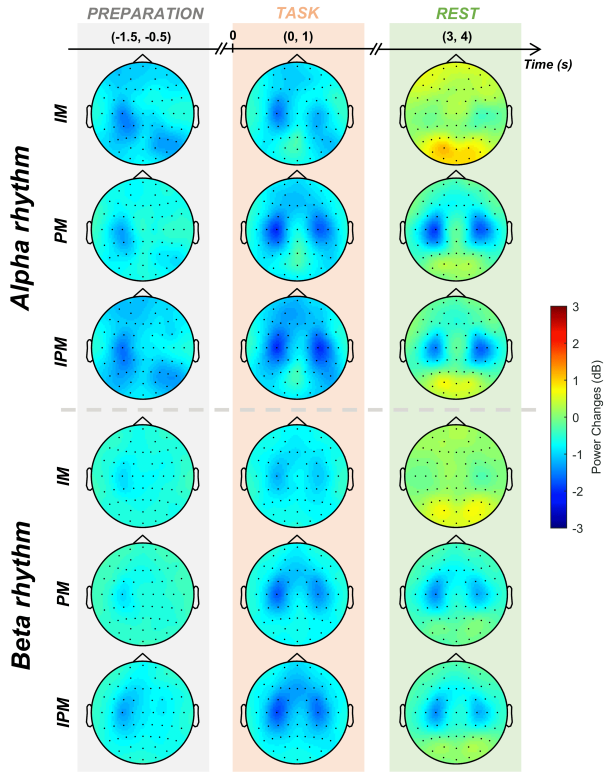

Fig. 2. Changes in alpha and beta rhythm power distribution over time for different movement modalities across three interaction stages: Preparation, Task, and Rest. Each column represents a distinct stage, with time = 0 s indicating the onset of the task. The color scale shows power changes in dB. EEG electrode locations were marked in black dots.

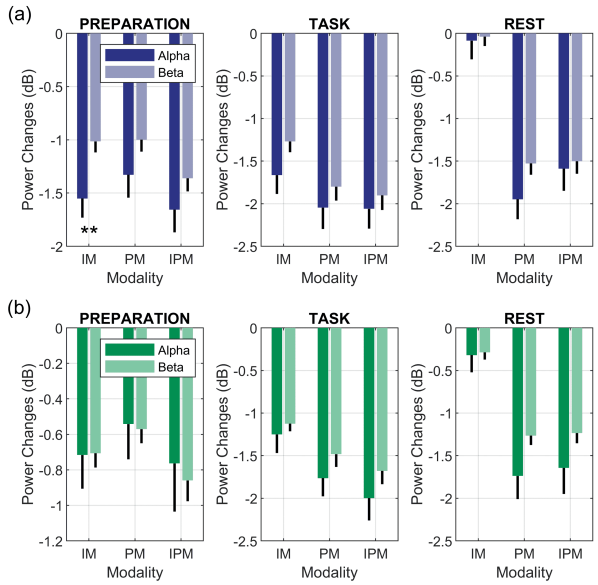

Fig. 3. Comparison between alpha and beta band power changes at channel (a) C3 and (b) C4. From left to right, each subfigure represents a different interaction stage similar to Fig. 2. The whisker on each bar corresponds to the standard error of the mean (SEM) power changes across subjects. The asterisk indicates a significant difference between alpha and beta was found via the Wilcoxon rank sum test (**: $p < 0.01$).

homing back at a faster speed, which partly explains why rest-stage ERD patterns differ from those of the task stage. Additionally, a strong ERS was observed in the occipital region for the IM modality during REST when the subject ceased motor imagery, with a similar but less pronounced effect for IPM and minimal occurrence in PM. For the distribution differences between alpha and beta rhythms, more brain regions engaged in alpha ERD, particularly for the preparation and task stages. The strength of each rhythm at the C3 (contralateral) and C4 (ipsilateral) EEG channel was statistically compared in Fig. 3. Generally, alpha rhythm showed stronger ERD compared to the beta rhythm for the EEG channels of both hemispheres, with the exception of the preparation stage in C4. However, a significant difference between alpha and beta was only found in C3 during the preparation stage of the IM modality (Fig. 3a).

B. Comparable alpha and beta ERD in exoskeleton-assisted movements regardless of motor intentions

Figure 4 presents the time-frequency representation of the C3 and C4 channels for three movement modalities. The 8-30 Hz frequency band activity was most pronounced in each modality, particularly when exoskeleton movement was involved (Fig. 4a and d). During exoskeleton-assisted movement (PM and IPM), stronger ERD was observed compared to

TABLE I
COMPARISON BETWEEN MOVEMENT MODALITIES IN ALPHA AND BETA BAND POWER CHANGES AT CHANNEL C3 AND C4. N.S. INDICATES NOT SIGNIFICANT

Channel	Rhythm	Comparison	P-value
C3	alpha	PM vs. IM	0.00044218
		IPM vs. IM	0.00086206
		IPM vs. PM	n.s.
	beta	PM vs. IM	3.234e-05
		IPM vs. IM	4.5419e-06
		IPM vs. PM	n.s.
C4	alpha	PM vs. IM	0.003176
		IPM vs. IM	5.6824e-05
		IPM vs. PM	n.s.
	beta	PM vs. IM	0.00098239
		IPM vs. IM	9.517e-06
		IPM vs. PM	n.s.

IM. A pronounced ERS was observed in the IM condition after the end of the task, whereas the exoskeleton-induced ERD persisted because of the device homing back. During the task, alpha and beta rhythms showed distinct behaviors, as illustrated in Fig. 4b-c and e-f. Notably, a steep decrease in alpha power was observed upon exoskeleton activation (Fig. 4b and e). In terms of modality differences, PM and IPM showed similar alpha and beta band desynchronization, with minimal variation during the pre- and post-task stages. Table I compares power changes across modalities in the alpha and beta bands during the task stage (time window: 5 - 6s), revealing significant differences for both PM and IPM compared to IM, while no significant difference was detected between PM and IPM.

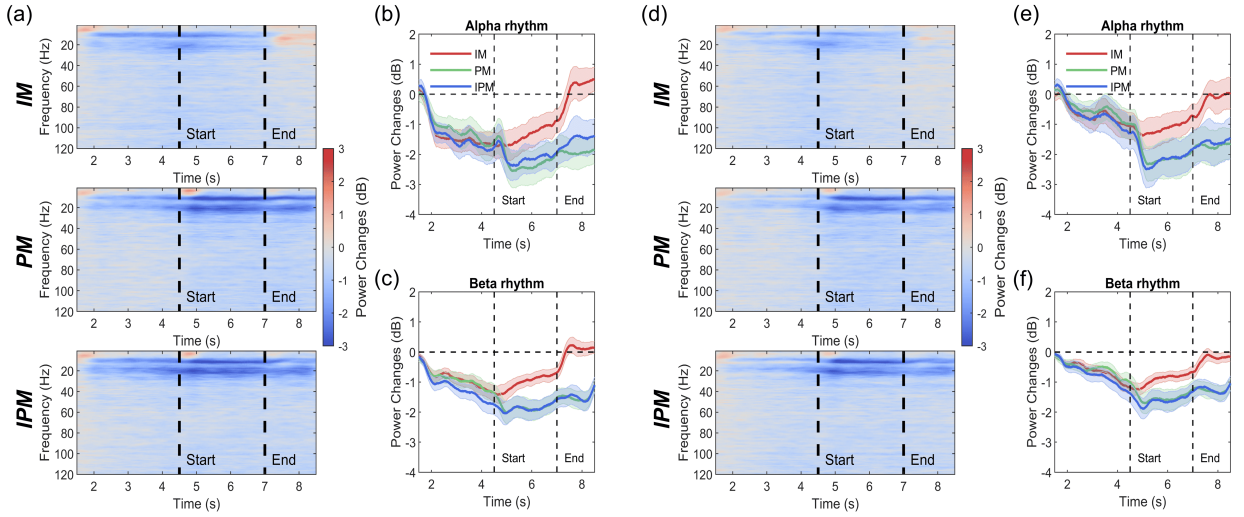

Fig. 4. Time-frequency representation of EEG activity in the C3 (a-c) and C4 (d-f) channels for different movement modalities. (a, d) Time-frequency spectra for IM, PM, and IPM modalities, illustrating power changes in dB over time. (b-c, e-f) Comparison of alpha (8-13 Hz) and beta (13-30 Hz) band power changes across movement modalities. 'Start' and 'End' denote the onset and offset of the task, respectively. Thick lines in (b-c) and (e-f) correspond to the average across trials, shaded regions to the 95% confidence interval.

C. Motor intention detection is more challenging with proprioceptive feedback

Figure 5 presents the binary classification results from four models. In general, distinguishing different movement modalities from the resting state is relatively easy, with the highest accuracy achieved 0.80 ± 0.07 (IPM vs. REST). The worst condition was IPM vs. PM, which obtained an accuracy of 0.61 ± 0.09, thus slightly above the chance level. It is interesting that the models IM vs. REST and PM vs. REST showed no significant difference, and a larger accuracy variation was found for PM vs. REST.

IV. Discussion

As growing attention is being dedicated to BCI-controlled hand exoskeletons, the challenges for advancing this BCI application should be addressed. In this study, we focused on a critical component, namely, motor intention decoding from brain activities during human-hand exoskeleton interaction. From continuous EEG recordings, we observed that exoskeleton-assisted passive movement introduced prominent bilateral ERD in alpha and beta bands, which is similar in frequency range but stronger in amplitude compared to imagined movement-induced neural correlates (Fig. 2 and Fig. 4). When the exoskeleton's movement was involved, it became difficult to discern motor intention-related EEG responses, as reflected by the statistical comparisons between PM and IPM modalities (Table I). This could partially explain why motor intention detection was quite difficult for IPM vs. PM (Fig. 5).

It is worth noting that our study focused specifically on the interaction between humans and a cable-driven hand exoskeleton. EEG correlates may vary across different exoskeleton systems. Our findings align with those reported in [6], where the same hand exoskeleton model was used,

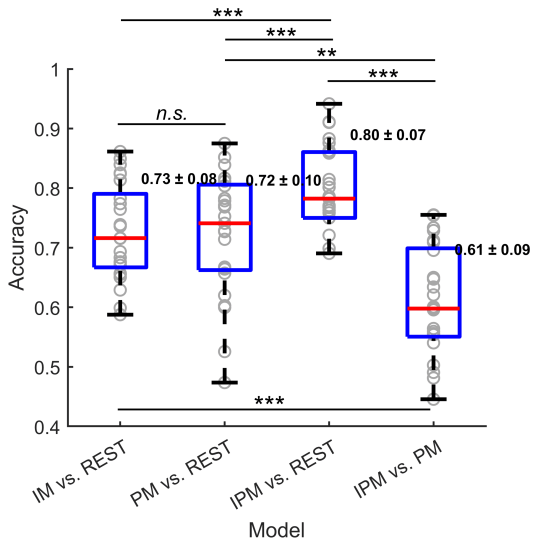

Fig. 5. Comparison between different binary classification models. Each box shows the distribution of each subject's accuracy (n = 25), with the middle red line representing the median. The whiskers correspond to 1.5 × IQR. The average accuracy and standard deviation are shown next to each box. P-values from post-hoc multiple comparisons are marked on the figure (***: $p < 0.001$, **: $p < 0.01$, n.s.: not significant)

and ERD patterns were observed in similar frequency ranges. Although the proprioceptive representation of the hand differs from that of proximal limb counterparts [15], similarities in EEG correlates are evident across the hand (our study and [6]), wrist [5], forearm [16], and lower limb [7]. Generally, passive movement elicits bilateral alpha and beta ERD, with a predominance on the contralateral side. On the other hand, factors such as movement speed and the type of exoskeleton motor will also impact EEG correlates. For example, Iwane

et al. reported that passive movement speed was correlated with the contralateral beta rebound and ipsilateral alpha ERD [16]. Mitra *et al.* observed a strong broadband synchronization coinciding with the robot movement [17], suggesting some exoskeletons (Harmony Exoskeleton used in their study) will likely introduce instrumental noise.

When comparing alpha and beta ERD, we found alpha rhythm had stronger desynchronization than beta rhythm (Fig. 3), particularly on the contralateral side, which is in line with observations in [5], [7], [18]. This supports earlier observations that alpha and beta rhythms would be related to different functional properties, i.e. somatosensory- and somatomotor cortical function, respectively [19]. Another finding in our study is that passive movement produced clear-cut modification of alpha band oscillations compared to beta band upon exoskeleton activation, as depicted in Fig. 4b-c. This could be partially explained by the sensitivity of alpha rhythm to attention and cognitive engagement [20]. During exoskeleton-assisted movements, the subject might pay more attention to the sensation of movement or the mechanical action of the exoskeleton.

We found a significant difference in motor intention detection with and without exoskeleton movement in Fig. 5. With exoskeleton movement, intention detection becomes more challenging (IPM vs. PM compared to IM vs. REST). This phenomenon was also reflected in Ferrero *et al.*'s study [10], where the authors found that it was more challenging to detect 'stop' intention when the lower-limb exoskeleton was activated compared to detecting 'start' intention without robot activation. Our experiment revealed that when the exoskeleton is activated, brain activations are similar regardless of whether the subject imagines a movement (IPM modality) or not (PM modality). In contrast, when the exoskeleton is not involved, the ERD induced by motor imagery (IM modality) can be clearly distinguished from REST. Therefore, extracting motor intention-related EEG features becomes more challenging in situations with exoskeleton activation. An interesting finding is that although both IPM and PM showed significantly different power changes compared to IM (Table I), PM vs. REST did not show as high accuracy as IPM vs. REST, nor IM vs. REST. One explanation is that we were classifying the covariance feature on the manifold space, not the power feature.

Although BCI-actuated hand exoskeletons hold great promise for neurorehabilitation, their current control strategies remain limited. Typically, a BCI decoder detects the user's motor intention and triggers the exoskeleton accordingly. However, once the exoskeleton is activated, the decoder struggles to function effectively, restricting the system to discrete control [21]. This means users can initiate movement but cannot continuously modulate or stop it. A key challenge for the next generation of BCI-exoskeleton systems is enabling continuous control, where motor intentions are dynamically monitored and executed in real-time. Our findings highlight this challenge: during exoskeleton interaction, the brain generates ERD patterns that are similar but stronger than those observed during motor imagery (Fig. 2, Fig. 4). Moreover, our decoding results suggest that detecting motor intention becomes significantly more difficult when the exoskeleton is moving (IPM vs. PM), with a classification accuracy only marginally above chance level. There is a trade-off between system stability and subject engagement. For stable control and better task completion, one may consider using a shared-control strategy [22] as it relies more on robot intelligence. For natural control and more subject engagement, we believe subject learning and advanced decoders are required. Indeed, although we asked the subject to avoid performing any movement imagination during PM, they reported that it was quite hard to finish the task. This suggested that subject learning is necessary in order to obtain task-differentiable data [23]. Our previous studies have shown the possibility of regressing fine finger movements from intracranial brain activity [24], [25], those explainable models can be particularly useful for continuous motor intention decoding during human-hand exoskeleton interaction.

V. Conclusion

We designed an experiment to investigate the impact of proprioception in EEG representations and decoding when interacting with a hand exoskeleton. We found when the exoskeleton was activated, strong alpha and beta ERDs were elicited due to proprioceptive afferents. However, EEG correlates were similar in situations with and without imagined motor intention upon the exoskeleton activation. Those findings explain why poor motor intention detection accuracy was observed when involving the exoskeleton. For future development of continuous BCI-actuated hand exoskeletons, we suggest using advanced decoders or control strategies considering the trade-off between system stability and subject engagement.

***Abstract*—Stroke is a common healthcare problem, leading to disability and significantly impacting individuals' quality of life. A customised device was suggested to be used for robotic-assisted therapy to meet different stroke survivors' needs. However, most existing upper limb rehabilitation robots only offer a generic handgrip, which fails to meet the various needs of stroke survivors with different spastic patterns and levels of upper limb weakness. This study investigates the technical and clinical feasibility of customised handgrips to meet stroke survivors' needs through an online questionnaire with 25 therapists and parametric handgrip designs. One wrist support and two different handgrips were designed, and their size (e.g., length and width) can be adapted based on the individual anthropology data. By using the additive manufacturing method, the manufacturing cost of bespoke handgrip is reduced by up to 15%. Additionally, more than 90% of professionals (n=23) stated the positive impact of customised handgrip on rehabilitation outcomes and 72% (n=18) would like to use it with stroke survivors due to its high accessibility and variability. The results indicate that a customised handgrip has the potential to benefit the stroke rehabilitation from both technical and clinical perspectives.**

Keywords—customisation, stroke, rehabilitation, bespoke, additive manufacturing

I. INTRODUCTION

During the last few decades, the ability of robotics-assisted therapy to promote high intensity, high repetition, task-oriented exercise and quantifiable neurorehabilitation was identified, which is considered one of the most effective methods to restore upper limb function [1]. Evidence shows that post-stroke upper limb robotic-assisted therapy can significantly improve motor control ($P<0.05$) [2]. The majority of existing end-effector upper limb rehabilitation robots are limited in that they provide only a generic handgrip. The handgrip in this research is defined as the passive handle attached to an end-effector rehabilitation robot. However, a generic handgrip cannot meet the needs of all stroke survivors due to the various spastic patterns and upper limb weakness levels. The common spasticity patterns of the upper limb after a stroke are 'Flexed elbow', 'Bent wrist', 'Pronated forearm', 'Clenched fist', and 'Thumb in palm', and these different patterns limit their ability to grip a generic handgrip. From the designers' perspective, providing a customised upper limb rehabilitation handgrip (e.g., handgrip size, shape, and type) could be an effective solution to enhance access to rehabilitation and improve outcomes. Based on this, one research question was raised '*Would customised handgrip be beneficial for stroke rehabilitation?*'

Fu in 2019 [3] identified the four most frequent grip types that people use in activities of daily living: grasp grip (usage frequency 33.3%), pinch/key grip (66.7%), pencil grip (14.3%) and hook grip (4.8%). He conducted a review of 120 upper limb rehabilitation robots found that 52.5% (63/120) included handgrip, while only 8.7% (11/120) provided pinch grip. This indicated that the current rehabilitation robot cannot provide sufficient grip types to meet Activities in Daily Living (ADLs).

According to professionals' recommendations in the United Kingdom *National Clinical Guideline for Stroke* [4], customised rehabilitation devices such as individually fitted orthosis were suggested for use to meet different users' needs. However, most of the commercialised rehabilitation robots are developed for using in hospitals, often at a high cost [5]. Additive manufacturing (AM) is an ideal technology for customisation at a relatively low cost and has been widely used in bioengineering and medical devices in the last several decades such as implants, orthoses and rehabilitation robot [6]. With minimal design restrictions, AM enables medical institutions to produce customised, cost-effective, durable, and lightweight products with low labour input [7].

Customised rehabilitation devices can increase users' satisfaction and allow more users to receive better rehabilitation results. Chen et al in 2016 identified that the bespoken rehabilitation devices can meet specific requirements of prostheses and orthoses, which improve the satisfaction of both healthcare professionals and stroke survivors [8]. In 2019, Sarwar et al [9] highlighted that bespoken hand exoskeleton systems can be provided at a relatively low cost by using AM. In 2021, Ibrahim and Faller designed and developed a customised hand rehabilitation glove by using AM that can fit different individuals to avoid the secondary injury caused by misalignment [10]. However, the measurement method they used to obtain anthropology data was 3D scanning, which is not simple or convenient enough for both therapists and stroke survivors. Additionally, the rehabilitation glove requires stroke survivors can grasp, which limits the type and number of stroke survivors who can use the customised rehabilitation glove. However, most

customised upper limb rehabilitation robots limit the types of users due to complex structures and requirements for users' movement ability. Therefore, the customised handgrip for an upper limb rehabilitation robot which is easy to use and fit for more stroke survivors' needs is required. Although some research emphasises the importance and potential of customisation in stroke rehabilitation, most of them focus on the control algorithms or human-computer interaction, no relevant study focuses on design customisation and its feasibility [11].

To answer the research question, this research aims to identify the technical and clinical feasibility of a customised handgrip for a rehabilitation robot and how if they could benefit stroke survivors, therapists, and manufacturers. A two-stage research approach was undertaken. During the first stage, we determined and designed customised handgrips for the upper limb rehabilitation robot using parametric design. In the second stage, the clinical feasibility of customised handgrip was identified through an online questionnaire with healthcare professionals.

II. Methodology

A. Design and optimisation of customised rehabilitation robot handgrip

1) Identification of customisation rehabilitation robot handgrip type

We conducted a consultation with physiotherapists (PTs) and an online questionnaire with 11 PTs and 4 occupational therapists (OTs) to determine customised rehabilitation robot handgrip types and their priority for stroke survivors. Participants were asked to rank the four grip types (grasp, pinch, pencil and hook grip) according to the importance level for upper limb rehabilitation from high to low (1 to 4).

2) Conceptual design and parameters determination

Parameter determination: A consultation with an experienced therapist led to categorizing handgrip sizes into small, medium, large, and extra-large, based solely on anthropometric data (e.g., palm width, hand length, wrist circumference). The measurement method is introduced in Table I which was inspired by the Saebo glove selection method. If measurements were difficult to obtain, then the unaffected hand could be used or estimated from observation.
Conceptual design: CAD software (SolidWorks) as used for parametric 3D design and cost estimation. The SolidWorks costing tool was utilised automatically calculate the manufacturing cost according to the manufacturing geometry, manufacturing method, materials and labour setting [12]. The default setting in the SolidWorks costing was used including the material information and labour rate that was set as the UK average labour cost of manufacturing.

TABLE I. Method to determine the handgrip size

Anthropological data (mm)	Handgrip parameter (mm)
Palm width between the 1st and 5th metacarpophalangeal joints	Height (H) of vertical handgrip
Hand length (tip of the 3rd finger to the 1st wrist crease)	Diameter (D) of vertical/hemispheric handgrip
Wrist circumference	Width (W) of the wrist support is the 1/2 of wrist circumference

B. Questionnaire to determine professionals' view of customised rehabilitation robot handgrip

1) Design and distribution of the questionnaire

To identify the professionals' views on the customised upper limb rehabilitation robot handgrip, an online questionnaire was devised by our research team and piloted with 25 healthcare professionals in our clinical stroke research network. The first part was about the participants' background including work experience and experience using rehabilitation robots. The second section was professionals' views of the customised handgrip for upper limb rehabilitation robots. The questionnaire was distributed by email, through relevant research networks of our research team, and social media to professionals with previous or current experience in stroke rehabilitation in any clinical setting. Participants were provided the Participant Information Sheet (PIS) before starting the formal online questionnaire. They were free to opt for this online questionnaire anytime. Only the response with 100% completion was included in the final data analysis.

2) Questionnaire data analysis

Mann-Whitney test and descriptive statistics in IBM SPSS v25.0 was used to compare and describe quantitative data. The groups were categorised based on participants' experience of using rehabilitation robots. A general thematic analysis and was conducted to determine professionals' views of the customised handgrip for upper limb rehabilitation robots for qualitative data analysis. Participant statements were downloaded into Excel and categorised using a coding matrix. Descriptive statistics, including frequency counts and percentage distributions, were used to summarise key themes and the prevalence of specific responses. All questionnaire responses and collected data were anonymised and did not contain any sensitive data.

According to the ethical requirement of the University of Manchester and NHS Health Research Authority, this research does not require ethical approval.

III. Results

A. Design and optimisation of customised handgrip

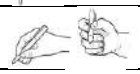
1) Conceptual design of customised rehabilitation robot handgrip

Of the 15 therapists involved in the first stage of this study, 73% had more than 10 years' working experience. Table II illustrates the usage and importance level of four grips in daily living (grab grip, pinch grip, pencil grip and hook grip). The pinch grip was found to be the most commonly used (66.7%, 14/21 activities), followed by the grab grip (33.3%, 7/21 activities) [3]. However, according to the questionnaire results, the grasp grip was reported as the most important followed by the pinch grip.

According to the questionnaire results, the concept should be developed as a parametric modular handgrip. This design should guarantee the integration of essential sensors and allows the model to automatically adapt to the needs of different stroke survivors. This should ensure economic feasibility whilst also bespoke rehab. Thus, based on the therapists' suggestions and the postures of the four main grip types, hemispherical and vertical handgrips were selected for design. The hemispherical design was chosen for its ergonomics, stability, and manufacturability, while the vertical handgrip was selected for its widespread use. Both designs support four grip types and accommodate stroke survivors by allowing size adjustments. As shown in Table III, the wrist support was designed for stroke survivors having

mild-moderate, severe-very severe weakness or inability to grasp at all. The wrist support can work with either a hemispherical handgrip or a vertical handgrip as an extra support for the forearm. The hemispherical handgrip would be suitable for stroke survivors with mild to moderate weakness, finger stiffness, or the ability to perform hook or grasp grips. The vertical handgrip was designed for stroke survivors with mild to moderate weakness or those able to perform grasp, pinch, or hook grips. All handgrips featured Velcro for secure user attachment and a modular connector for an upper limb rehabilitation robot. Their size (length and width) was adjustable based on individual anthropometric data. Additionally, an optional force sensor was integrated to monitor grip strength, with a dedicated space ensuring sensor stability regardless of size or shape modifications. A two-step guideline was created to help therapists determine customised handgrips: 1) selecting the handgrip type based on the patient's condition (e.g. weakness level, hand characteristics), and 2) determining the size using anthropometric data (e.g., hand length, palm width) measured by therapists.

TABLE II. THE FREQUENCY OF HUMAN GRIPS IN ACTIVITES OF DAILY LIVING AND THE IMPORTANCE LEVEL OF REHABILITATION



Type of grip	Illustration of grip	Frequency in daily life (%) [3]	Importance level[1]
Grasp grip		7 (33.3%)	1
Pinch grip		14 (66.7%)	2
Pencil grip		3 (14.3%)	3
Hook grip		1 (4.8%)	4
(***Note*** [1]: Results were obtained from the online questionnaire with 15 therapists; the importance level from high to low is from 1 to 4).			

TABLE III. CONCEPTUAL DESIGN OF CUSTOMISED HANDGRIPS FOR A REHABILITATION ROBOT

	Wrist support	Hemispherical handgrip	Vertical handgrip
Conceptual Design			
Target users	**1.** Severe or very severe weakness **2.** Wrist stiffness **3.** Cannot grasp at all	**1.** Mild to Moderate weakness **2.** Finger stiffness **3.** Can do some hook or grasp grip	**1.** Mild to Moderate weakness **2.** Can do some grasp, pinch, pencil or hook grip

2) Technical feasibility of customised rehabilitation handgrip

The SolidWorks 2020 costing tool was used to estimate manufacturing costs and assess the feasibility of a customised handgrip. All the parameters such as labour cost and materials were set to guarantee data consistency in different manufacturing methods. Fig.1 indicates the estimated cost of customised handgrips for various manufacturing methods when the total manufacturing quantity was 100. At 60% infill rate, the AM reduced cost by 5-15% across all handgrip types compared to traditional manufacturing at a low small manufacturing quantity.

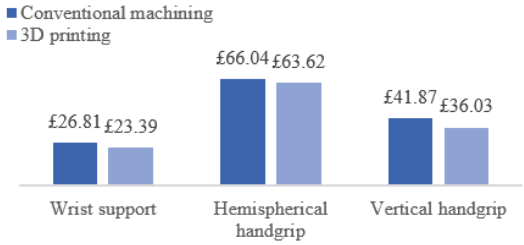


Fig. 1. Manufacturing cost estimation of per customised handgrip according to different manufacturing methods

B. The clinical feasibility and potential benefit of the customised handgrip

In total, 25 professionals participated in the online questionnaire, most from the UK (n=21, 84%) (Table IV). More than half were PTs (n=14, 56%); one-third were OTs (n=8, 32%). Most (n=19, 76%) had more than five years' work experience and worked in the local public health system—National Health Service (n=15, 60%). In-patient rehabilitation unit was the most common (n=18, 72%) work setting. Almost half (n=11, 44%) had the experience of using rehabilitation robots, all based in clinical settings.

In terms of the rehabilitation robot used by professionals in this research, most of them (10 of 11) provided a combination rehabilitation for both arm and hand, while only 5 of them provided customisation which was 'MIT-Manus', 'Re-o-Go', 'MyoPro', Motus Nove' and 'Amadeo'. While the professionals reported that these rehabilitation robots provided customised handgrips, most achieved customisation by adjusting the Velcro fixation or control system (e.g. resistance level), except the ReoGO and MyPro which provided multiple handgrip or support options. Although the features can be adjusted for these robots including the resistance of glove, different types of handgrips and finger position, professionals reported *"The glove is fiddly to fit the handgrips/gloves"*. Although the effectiveness of robotic-assisted therapy has been demonstrated, the adaptation rate is low which is compared with other common intervention, especially for the complexed hand rehabilitation. Table V indicates the current intervention for hand rehabilitation after a stroke. The repetitive task training / functional task practice mentioned frequency (MF) =17.02%) was the most used intervention followed by exercise (MF=20%) and splints or orthoses (MF=13.48%).

More than 90% of professionals (n=23) stated the positive impact of customised handgrip on rehabilitation outcomes and 72% (n=18) would like to use a customised handgrip with stroke survivors due to its high accessibility and variability. 'Accessibility' here is defined as the opportunity for stroke survivors to use rehabilitation robots. Few professionals (n=4, 16%) were reluctant to use customised handgrip due to the high cost, limited clinical evidence and required extra training. Stroke survivors with moderate upper limb weakness were regarded as the most suitable people (34%) to use customised handgrip, with approximately equal proportions of stroke survivors with mild or severe upper limb weakness (Table VI). Professionals with and without experience using rehabilitation robots had similar opinions on the type of stroke survivors who were suitable to use customised ($P>0.05$). Although some suggested using customised handgrip for stroke survivors having severe weakness, they also pointed out that more intense training and therapists' supervision may be required.

TABLE IV. DEMOGRAPHICS OF QUESTIONNAIRE PROFESSIONAL PARTICIPANTS

Characteristic		Number (%) of participants
Country United Kingdom		21 (84%)
	United States	2 (8%)
	United Arab Emirates	1 (4%)
	Prefer not to say	1 (4%)
Profession	Occupation therapists	8 (32%)
	Physiotherapists	14 (56%)
	Doctors	2 (8%)
	Others (Research associate)	1 (4%)
Work organization*	Local public health system/ NHS	15 (60%)
	Private practice	5 (20%)
	Other (University or rehabilitation product institution)	6 (24%)
Work setting*	Acute care	15 (60%)
	In-patient rehabilitation Unit	18 (72%)
	Long-term care	5 (20%)
	Outpatient Clinic	14 (56%)
	Community-based care	15 (60%)
	Other	4 (16%)
Career stage	< 1 year experience	1 (4%)
	1—5 year's experience	5 (20%)
	6—10 year's experience	5 (20%)
	> 10 year's experience	14 (56%)
Experience in using rehabilitation robots Have experience		11 (44%)
	Have no experience	14 (56%)
*(**Note**: * participants indicated all the areas in which they had experience, so totals exceed 100%)*		

TABLE V. THE RESULTS OF THE PREVALENCE OF HAND REHABILITATION INTERVENTIONS AFTER STROKE

Current intervention for hand rehabilitation	Frequency (%)
Repetitive task training / functional task practice	24 (17.02%)
Exercise	20 (14.8%)
Splints or orthoses	19 (13.48%)
Electrical stimulation	17 (12.06%)
Mental practice	15 (10.64%)
Mirror therapy	13 (9.22%)
Constraint-induced movement therapy (CIMT)	13 (9.22%)
Bobath	7 (4.96%)
Virtual reality	5 (3.55%)
Other (e.g. robotics, hydrotherapy or spasticity management)	8 (5.67%)

TABLE VI. SUITABILITY OF CUSTOMISED HANDGRIPS FOR DIFFERENT LEVELS OF UPPER LIMB WEAKNESS FROM QUESTIONNAIRE

Upper limb weakness level	Suitability (%)
Mild weakness (movement in all joints against gravity but limited range, strength, and dexterity).	13 (24.53%)
Moderate weakness (some movements in all joints but limited range against gravity and only a basic, weak grip grasp, little dexterity. Can use the arm as a 'helping hand').	18 (33.96%)
Severe weakness (can make movements in some joints but not against gravity, no functional grip).	11 (20.75%)
Very severe (complete paresis, no functional movement).	5 (9.43%)
Others	6 (11.32%)
*(**Note:** Participants can select multiple options, so suitability is calculated as the selection count for each option over the total selections)*	

IV. DISCUSSION

The results of this research identified the potential feasibility of a customised upper limb rehabilitation robot handgrip for stroke rehabilitation from both a manufacturing and rehabilitation perspective. The parametric design allows engineers to adapt the 3D design quickly according to stroke survivors' data (e.g., palm width and length). By using the AM method, users will be provided with more customised features such as the material, colour, and texture. The texture of a handgrip plays a crucial role in user preference and usability, as it directly affects comfort, grip stability, and tactile feedback. A well-designed texture can enhance user confidence, reduce fatigue, and improve overall interaction, particularly for individuals with limited hand function. The rehabilitation feasibility of a customised handgrip was identified by an online questionnaire with 25 professionals. Due to the variety of stroke survivors' weakness levels, the standard handgrip is always insufficient or uncomfortable to use. Professionals highlighted the potential of customised handgrips to increase the accessibility of upper limb rehabilitation robots and stroke survivors' motivation.

A. Technical feasibility of customised upper limb rehabilitation robot handgrip

The goals of the medical device industry are reducing costs, waste, energy use, and labour. AM has been recognised as a cost and labour-effective method for prototyping and manufacturing [13]. AM is not yet cost-competitive for high-volume manufacturing but is viable for small-scale or personalised medical devices, where traditional tooling is costly. For a production volume of 100, AM costs 85-95% of traditional methods, with cost reduction varying by design complexity. It enables affordable customization without additional tooling, tailoring products to stroke survivors' needs while reducing production cycles by eliminating machine changeovers and labour shifts [13].

Despite its benefits, AM adoption faces challenges, such as surface quality [14]. For medical devices like prostheses and orthoses, a key challenge, as highlighted by Ngo et al., is layer delamination and internal stress from non-uniform phase changes [15]. High AM usage increases plastic waste, which is difficult to recycle. Additionally, the lack of standards limits adoption. While AM shows promise for customised rehabilitation robots, most research remains in early stages due to technological barriers and concerns [10]. The concerns of using customised handgrip will be discussed in the next section.

B. Clinical feasibility of customised home-based rehabilitation robot handgrip

1) Benefits of customised home-based rehabilitation robot handgrip

Analysis of ADLs showed the most prevalent grip was the pinch grip, but rehabilitation robots also needed to accommodate a grasp grip. This indicates that a generic (grasp) handgrip cannot meet the needs of stroke survivors who need to facilitate more ADLs-based practice or who are unable to grip. Pencil and hook grips were a lower priority. This shows that single-grip robots (which are currently the norm) are not fit-for-purpose and limit access for those with severe disabilities. Most professionals showed positive attitudes toward using the customised rehabilitation robot grips due to the higher accessibility, and higher variability in patients.

Potential improvement in rehabilitation outcomes

Promoting improved clinical outcomes of rehabilitation has been reported as the biggest benefit of rehabilitation robots/technology (Fig. 2). To improve the normal pattern of

movement, the handgrip needs to be based on the individual for stroke survivors. Additionally, the individualised presentation of the stroke survivors and impairment levels makes customisation relevant to the rehabilitation of the individual. According to professionals' experience, high tone makes conventional grip (grasp grip) often difficult to achieve and changes in sensation and pain also make standard equipment difficult to use. Moreover, different grip functions are important for function transfer. A suitable handgrip allows progression and enables the rehabilitation robot to be used with a wide range of patient capabilities. Moreover, customised handgrips bring more practice variation to stroke survivors which may help them stay interested and practice more.

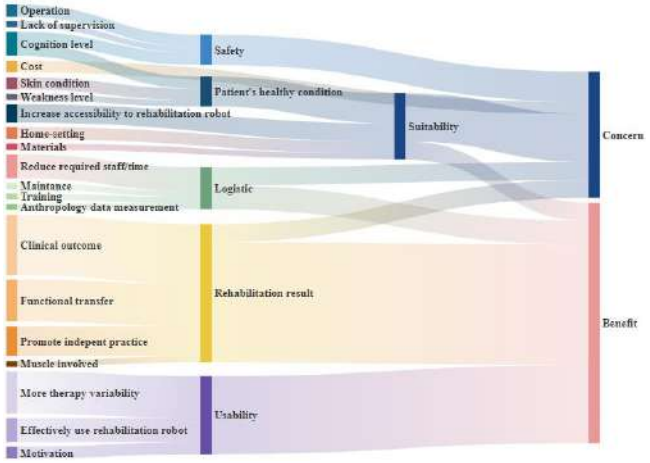

Fig. 2. Thematic analysis results: Sankey diagram illustrating the benefits and concerns of using a customised upper limb rehabilitation robot handgrip. The width of each theme represents its relative weight

Improve the usability and accessibility

Professionals raised that the rehabilitation robot handgrip in the current market is fiddly to fit for both therapists and stroke survivors. Ease of donning and doffing is a requirement for customised handgrip and upper limb rehabilitation robots. Compared to standard one-size-fits-all grips, the customised design offers better adaptability to individual hand shapes and impairments, as supported by insights from our questionnaire. While initial adaptation may require brief familiarization, both therapists and patients can easily adjust with minimal training. Apart from this, stroke survivors with poor grip strength or increased tone are difficult to maintain. Providing the adjustable Velcro tape can help to easily and safely fix stroke survivors' hands. As highlighted by professionals, every individual is unique in their grip and functioning pre- and post-condition events. A generic grip may fit a majority of service users, however, those who arguably need the support most would not be catered for without it. The customised handgrip provides more options of shapes, sizes, and materials for stakeholders (stroke survivors and therapists), which also increases the accessibility of rehabilitation robots for stroke survivors. Additionally, a parametric modular design supports sensor integration in a handgrip by offering flexibility and adaptability.

In addition to function-related characteristics such as shape and size, personal preference-related characteristics such as colour and texture were suggested as customisation options to appeal to stroke survivors by professionals. The personal preference has been emphasised for chronic disease rehabilitation and medical technology assessment [16]. In 2013, Centre for Devices and Radiological Health (CDRH) in the United States (US) conducted a project that identified the patient-centric assessment for medical technology has the potential to lead a better decision-making in healthcare [17]. Lewis et al emphasised that users' preference testing provided valuable information that can help to improve the design and development of a medical device, and users' acceptance in 2022 [18]. However, it still requires more standards to help put the personal preference in medical device design loop. In addition, AM customised handgrips presents several challenges, including ensuring biocompatibility and durability of materials to meet medical standards (e.g., ISO 13485 and IEC 60601). Regulatory approval for patient-specific designs can be complex, requiring thorough validation and compliance with medical device certification processes. Additionally, achieving consistent mechanical properties and surface finishes while maintaining cost-effectiveness remains a key hurdle for widespread clinical adoption. In addition, professionals want to use customised handgrip for an upper limb rehabilitation robot not only in clinical settings but also for users at home, a win-win strategy for therapists and stroke survivors. For the therapists, they are able to diagnose or supervise more patients; for the stroke survivors, they could reduce the time and cost of travelling between their homes and rehabilitation centres. Additionally, usability trials should be conducted to gather qualitative insights on user experience, ease of adaptation, and comfort. Additionally, feedback from healthcare professionals should be incorporated to refine the design and optimise its application. Further investigation into material preferences and grip textures will help improve user satisfaction and increase the likelihood of adoption. Future work should focus on refining personalisation methods based on patient-specific grip strength and dexterity levels to enhance functional outcomes.

2) Concerns and requirements of customised home-based rehabilitation robot handgrip

Although benefits and desire of using customised handgrip have been identified in this study, few professionals (n=4, 16%) raised concerns regarding the safety, suitability (e.g., upper limb weakness level), and logistics "*Not sure if the customised handgrip can be benefit to all users*". These concerns are highly consistent with our previous study *'Professionals' Views and Experiences of Using Rehabilitation Robotics With Stroke Survivors: A Mixed Methods Survey'[19]*, which indicates that similar concerns are raised by professionals when adopting new technology. As with other medical devices, safety is a paramount consideration for adopting a customised handgrip, which is often raised by professionals. Stroke survivors with cognitive or open wounds are not suitable for using customised handgrip. In addition, considering the degree of upper limb weakness and spasticity pattern to determine the handgrip can avoid secondary injury during the training. The potential extra training for device operation and the maintenance of handgrips were also raised as main concerns. The same concern was raised for rehabilitation robot adoption [19]. Staff shortages and heavy workloads in public healthcare may be a factor. The WHO reports a current shortage of 7.2 million healthcare workers, projected to reach 12.9 million by 2035

[20]. The easy-to-use and easy-to-maintain customised handgrips are desired to avoid extra training and workload.

Placement of fingers, especially for the thumb is helpful, but it is often difficult and not always possible with the robot. In addition to this, finger release and strength monitoring were also suggested for the customised handgrip. However, it is difficult to find the balance between the stakeholders' desires and the final function of products. More research and clinical trials are required to identify the balance between the product features and stakeholders' desires.

C. *Study limitations*

This study has some limitations. Stroke survivors were not involved in the questionnaire, and their feedback is essential to strengthen the research. Additionally, manufacturing costs varied depending on initial settings such as cost of materials and labour, requiring further detailed cost analysis in future studies.

V. CONCLUSION

Customisation of rehabilitation robots has attracted researchers' interest for its potential to improve clinical rehabilitation outcomes. However, there is no studies have specifically focused on customised handgrips. This research identified and demonstrated the clinical and technical feasibility of a customised handgrip for upper limb rehabilitation robot, demonstrating its potential to address different user needs effectively. The most significant outcome is that individuals who genuinely require rehabilitation can now access it through the use of upper limb rehabilitation robot with customised handgrip. This advancement not only enhances accessibility but also promotes user-centred rehabilitation by accommodating individual preferences and physical conditions. Moreover, the approach offers a substantial advantage in terms of cost-efficiency. By utilising parametric modular design and AM manufacturing, the proposed handgrip can be produced and customised economically (e.g., handgrip type, shape, size, and material customisation), making it suitable for widespread implementation. This combination of accessibility, adaptability, and affordability marks a meaningful step forward in the field of assistive robotics and rehabilitation, paving the way for improved outcomes and quality of life for users. Future research should focus on commercialization, and market adoption challenges. Additionally, refining the design based on patient feedback will enhance adaptability and accessibility in rehabilitation. More clinical research is also required to increase the new technology including the customised handgrip adoption for stroke rehabilitation.

Towards Magnetically Induced Skin Stretch for Hand Proprioceptive Feedback

Eleonora Fontana*[1], Manuel G. Catalano[2], Giorgio Grioli[1,2], Matteo Bianchi[1], and Antonio Bicchi[1,2]

***Abstract*— Skin stretch feedback is increasingly recognized in rehabilitation and prosthetics for its ability to convey proprioceptive cues. Magnetically-induced skin stretch can offer interesting perspectives, not only for non-invasive stimulation but also for integration within the body. This study presents the first step towards the development of the MISS (Magnetically Induced Skin Stretch) device, a wearable system that uses magnetic interactions to provide proprioceptive feedback through skin stretch. By manipulating two magnets attached to the skin, the device aims to convey stretch sensations for hand proprioception. After preliminary Finite Element Method Magnetics simulations (FEMM), we came to the MISS design, which consists of a C-shaped ferromagnetic core with two solenoids at its ends. When the solenoids are powered, they generate a magnetic field that interacts with the magnets, causing controlled skin displacements to produce both stretch and pinch sensations. Psychophysical tests with the device positioned on the hand dorsum were performed to evaluate the skin deformations, whose outcomes support the device's potential application in proprioceptive feedback for prosthetics and hand rehabilitation.**

I. INTRODUCTION

Proprioception is fundamental for motor control, balance, and coordination in everyday tasks as well as in complex activities. In the context of human-computer interaction, robotics-enabled prosthetics, and rehabilitation, there is a growing interest in developing systems capable of restoring or enhancing proprioceptive feedback [1], [2]. Among the various methods for delivering this sensory information, one promising approach is the use of skin stretch, which involves the mechanical deformation of the skin to convey information about movement and forces applied to the body. Specifically, skin mechanoreceptors have been shown to play a significant role in the kinesthetic perception of finger and joint positions [3], [4], eventually inducing illusory sensations of movement. In previous research, we further explored this relationship between skin stretch and finger joints [5], confirming its fundamental role in proprioception.

Several approaches for delivering skin stretch have been explored in literature, with notable success in providing naturalistic feedback. Typically, these devices use mechanical actuators to pull or push the skin, aiming to convey feedback proportional to the hand level of aperture [6], [7], [8]. For example, Colella et al. [9] proposed the Stretch-Pro, a wearable device that provides proprioceptive feedback on artificial hand aperture using fixed actuated rollers to induce skin stretch. In addition to traditional proprioceptive feedback systems, recent research has explored magnetic field-based systems as alternatives to mechanical actuators to induce skin deformation. These systems can be employed in skin-integrated feedback solutions [10] or wearable devices [11], and offer promising non-invasive options. For instance, contactless devices use time-varying magnetic fields to stimulate mechanoreceptors through obstacles [12], [13], while others, such as the device described in [14], employ magnetic interactions between two magnets to generate tactile feedback. By adjusting the magnets' position, distance, and intensity, the magnetic field can be modulated to induce different skin sensations, such as vibrations, enhancing tactile feedback and perception.

Magnetically driven interfaces are appealing not only for their non-invasive nature but also for their potential for integration within the body. One example for bionic limb control is the Myokinetic Interface described in [15], [16], where external coils are used to track implanted permanent magnets inside the muscle. This system enables the detection of muscle contractions and translates them into control signals for a myoelectric prosthesis, facilitating a more fluid and natural interface. In their latest study [17], researchers demonstrated that, after just six weeks, the participant was able to complete a series of functional tasks, achieving performance scores comparable to those obtained with myoelectric controllers while maintaining similar physical and mental workloads.

While non-invasive systems are generally preferred, it is not always clear if the additional benefits of invasive technologies justify replacing non-invasive alternatives. Non-invasive methods face limitations such as bulk, daily application, and, in some cases, restricted sensory feedback. As implanted systems improve in safety, longevity, and biocompatibility, their clinical feasibility is expected to grow [18].

In this context, our goal is to explore, for the first time, the feasibility of using magnetic forces to induce skin stretch by moving magnets placed on the skin. While the focus is currently on non-invasive methods, this work may eventually open the possibility of implanting the magnets under the skin to enhance embodiment, which could contribute to the development of a new generation of high-performance bionic limbs [19]. This paper presents an initial step toward the development of the MISS (Magnetically Induced Skin Stretch) device. Worn on the hand dorsum as reported in Fig. 1, the MISS device utilizes magnetic interactions between coils and magnets affixed to the skin to generate different stretch sensations, i.e. stretch and pinch. We provided a comprehensive overview of the design process, including the optimization of the device's components and the results of preliminary simulations. Additionally, we conducted both physical and psychophysical characterizations with 12 able-bodied participants to assess the device's effectiveness in producing skin deformations. Specifically, we calculated the Just Noticeable Difference (JND) and Point of Subjective Equality (PSE) for both skin stretch and pinch conditions. The JND results indicate that participants were more sensitive to changes in pinch feedback than in stretch. However, the PSE values were nearly identical for both conditions, indicating that participants perceived both sensations as equally intense. These results demonstrate that the MISS device can reliably generate distinct stretch and pinch sensations, with good discrimination and precision, making it a promising solution for prosthetics and rehabilitation applications.

II. THE CONCEPT

Investigating the use of magnetic fields to generate controlled skin displacement remains a novel approach to inducing proprioceptive feedback via skin stretch. In our previous study [20], we investigated the feasibility of manipulating a single magnet using three solenoids positioned beneath a layer of artificial skin. The setup presented in [20] allowed for directional control of the magnet's movement. However, various limitations emerged during testing. In that configuration, the magnet was not constrained, allowing it to slide easily over the artificial skin. When we attached the magnet to the skin (to ensure that any movement would directly translate into skin displacement), the system struggled to achieve the same degree of movement. This was due not only to the increased resistance from the skin but also to the limited magnetic field generated by the solenoids. This limitation is intrinsic to solenoids, which primarily produce a strong magnetic field within their core, while the field strength outside remains minimal [21]. As a result, the magnet aligned with only a small portion of the field lines, leading to a weak magnetic interaction and insufficient force to effectively move it when affixed to the skin.

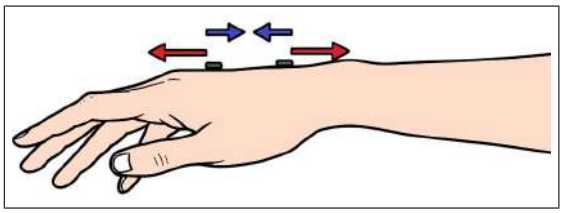

Fig. 2. Conceptual representation of the skin stretch (in red) and pinch (in blue) strategies achieved through the interaction of an external magnetic field with two magnets attached to the skin. By modulating the magnetic field, the magnets can be repelled (skin stretch) or attracted (pinch effects) to each other.

To address these challenges, we focused on optimizing the design to maximize the external magnetic field while maintaining a compact, wearable device. The core concept of this study is to apply forces at two different points on the skin to produce skin deformations, namely, *stretch* and *pinch*, along the longitudinal direction of the hand dorsum (see Fig. 2). When these points are drawn apart, the skin between them stretches, creating a stretch sensation; conversely, when the points are pushed closer together, the skin compresses, producing a pinch sensation. We selected the longitudinal direction based on prior evidence suggesting its enhanced efficacy for delivering skin stretch feedback [22]. To implement this principle, two magnets were attached to the skin at the designated points. By modulating an external magnetic field, we aimed to control the movement of these magnets along the longitudinal axis, ideally generating the desired stretch and pinch sensations. Therefore, our goal was to design a system capable of producing a sufficiently strong magnetic field in the region where the magnets were attached to the skin, ensuring they experienced enough force to achieve the desired skin displacements.

III. THE MISS DEVICE

A. Design Investigation

Starting from three different setups, we evaluated their effectiveness in enhancing the interaction between the magnets and the magnetic field generated by the coils.

All three experimental setups were designed utilizing a ferromagnetic core with a circular cross-section, having a diameter of 4 mm, around which a coil of 500 turns of 30 AWG (American Wire Gauge) frame wire was wound. The core is made of iron, selected for its favorable ferromagnetic properties, with an expected relative permeability μ_r of 2000. The core length is approximately 20 cm. The inductance L of each coil was estimated using the following equation:

$$L = \frac{\mu_0 \cdot \mu_r \cdot N^2 \cdot A}{l} \tag{1}$$

where $\mu_0 = 4\pi \times 10^{-7}$ H/m represents the permeability of free space, μ_r is the relative permeability of the iron core, $N = 500$ denotes the number of turns in the coil, $A = 1.257 \times 10^{-5}\,\mathrm{m}^2$ is the cross-sectional area of the core, and $l = 0.2\,\mathrm{m}$ is the length of the core. Based on these

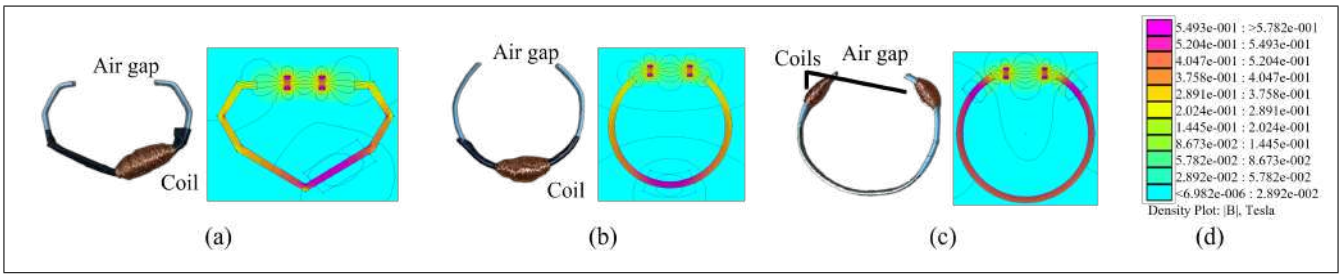

Fig. 3. Outline of the three setup configurations: (a) the initial design featuring a single coil and a ferromagnetic core, (b) a revised design with rounded core edges and a central coil, and (c) an optimized configuration with two coils positioned near the core ends. Next to each setup, the simulated magnetic field distribution is shown, computed using FEMM software with a current of 1 A through the coil windings. The color scale in (d) represents magnetic field strength, while variations in color and field line density highlight the progressively enhanced magnetic interaction.

parameters, the inductance of each coil was calculated to be approximately 39.5 mH. For the simulations, two cylindrical, axially magnetized neodymium permanent magnets (S-06-02-N, Supermagnete, Webcraft GmbH, Gottmadingen, Germany) were considered. These magnets have a diameter of 6 mm, a height of 2 mm, and a holding force of approximately 740 g. The presence of these magnets is crucial in shaping the magnetic field across the air gap, which significantly influences the overall flux and the current dynamics within the system. In simulations, we assumed that the magnets would be positioned on the skin aligned with opposite polarities at a 20 mm distance between them to avoid undesired migration due to their attractive forces, remaining above the two-point discrimination threshold for the hand dorsum [23]. Furthermore, all three setups were designed to be worn in such a way that there is a 10 mm distance between each end of the C-shaped core and the attached magnets. When the solenoid is powered, the core becomes magnetized, inducing distinct magnetic poles at its ends. The magnets then interact with the magnetic field in the air gap, experiencing either attraction or repulsion, depending on the direction of the current and the resulting polarity of the core.

To evaluate the effectiveness of these setups, we conducted simulations using the Finite Element Method Magnetics (FEMM) software, a widely-used open-source tool for 2-D finite element magnetic analysis and simulations [24], [25], [26]. The simulations allowed us to model the magnetic field distribution and assess the strength of the interaction between the coils, the ferromagnetic core, and the magnets placed on the skin. For the simulations, a current of 1 Ampere was assumed to flow through the coils. Fig.3 illustrates the setups and their corresponding simulations. Compared to the configuration in Fig.3(a), the device in Fig.3(b) incorporates rounded edges to reduce magnetic field dispersion caused by sharp core edges [27]. The setup in Fig.3(c) maintains the smoother core geometry while adding two coils closer to the core ends to further optimize the magnetic field distribution in the air gap. Simulations reveal that the third setup, with its dual-coil configuration and smoothed core, achieves the strongest magnetic interaction, as indicated by the darker core color. Additionally, the density of magnetic field lines between each end of the core and the magnets was notably higher in Fig. 3(c), indicating a more efficient interaction between the magnets and the coil-generated field. These results suggested that the third setup is predicted to generate the largest displacement of the magnets, which could lead to more pronounced skin stretch and pinch effects.

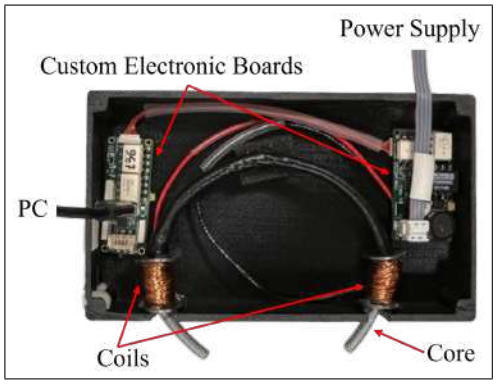

Fig. 4. Overview of the main components of the MISS device. An external case houses two custom electronic boards that control the current flowing through the coils wound around the ends of a ferromagnetic core. When powered, the device generates a magnetic field in the air gap, interacting with magnets attached to the skin to induce targeted skin deformations.

Based on these considerations, we decided to adopt the third setup to develop the MISS device for hand proprioceptive feedback.

B. Final Configuration

The final configuration of the MISS device is depicted in Fig. 4. It consists of a C-shaped ferromagnetic core with coils positioned at each end. The MISS device is worn on the hand dorsum, positioned so that two magnets on the skin are aligned within the air gap at a specified distance, as depicted in Fig. 5 and defined in previous sections. The magnets are securely attached with a skin-safe adhesive (Mastix Spirit Gum, Kryolan, Berlin, Germany). The device is controlled by two custom electronic boards based on a Cypress PSoC (Programmable System-on-Chip) microcontroller [28]. When activated, the coils magnetize the ferromagnetic core, establishing distinct north and south poles at the ends. The interaction between these poles and the magnets has the aim of producing targeted pinch and stretch sensations on the skin.

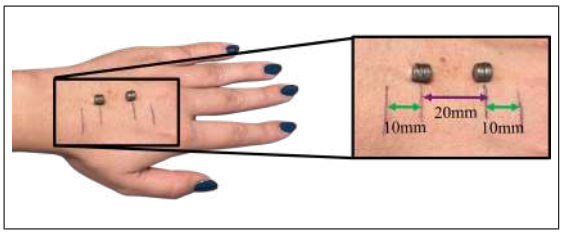

Fig. 5. Schematic representation of the magnets' position on the hand dorsum. The magnets are affixed to the skin with a mutual distance of 20 mm, each placed 10 mm from the ferromagnetic core ends of the device.

IV. DEVICE CHARACTERIZATION

The MISS device is designed to be worn on the dorsum of the user's right hand. To evaluate its functionality, we conducted both a Physical Characterization and a Psychophysical Characterization.

A. Participants

Twelve participants (4 female, 8 male; mean age 31) took part in both the physical and psychophysical experiments. Since skin displacement may be influenced by Body Mass Index (BMI), we selected individuals with BMIs within the average range for standard biometric tables (BMI range: 20–24.9) [29]. All participants were screened to ensure they had no physical limitations that could affect the experimental outcomes. They were comfortably seated in an office chair with their forearm in a neutral position (thumb facing upward) and their elbow resting on a table. To maintain this posture, each participant's hand was supported by an external support fixed to the table, allowing for a relaxed yet stable hand position. An elastic band was placed around the wrist to ensure the MISS device remained securely in position throughout the experiment. The experimenter verified that the magnets were securely attached in the correct position, ensuring the distances specified in the previous sections using a caliper. To eliminate visual and auditory distractions, they wore goggles with obscured lenses and noise-canceling headphones playing white noise. The experimental procedures were approved by the Committee on Bioethics of the University of Pisa - Review No. 68/2024, and all participants provided informed consent prior to participation.

B. Physical Characterization

To investigate the correlation between the magnetic field generated by the two coils and the resulting skin displacement produced by the interaction between the magnets and the field, we conducted a Physical Characterization of the MISS device. In this experiment, the objective was to determine the optimal voltage threshold for powering the device, balancing the maximum achievable displacement while staying within safety parameters. Starting from 0V, the voltage was incrementally increased until the displacement of the magnets reached a threshold, defined as the point at which no further significant increase in displacement was observed. To measure the displacement, we draw a marker on the skin, aligned with the center of each magnet. The movement of the marker, induced by skin stretch, was recorded with a camera, while graph paper was placed beneath the area of interest to facilitate displacement quantification throughout the characterization process.

C. Psychophysical Characterization

The Psychophysical Characterization aimed to assess the participant's ability to distinguish between varying levels of skin stretch or pinch induced by the MISS device, quantified in terms of the Just Noticeable Difference (JND). The JND represents the smallest change in a stimulus that can be detected by the participant [30]. To calculate the JND, we employed the method of constant stimuli [30], a widely used psychophysical method that involves presenting two stimuli to the participant—a reference stimulus (RS) and a comparison stimulus (CS)—and asking them to judge which stimulus feels stronger.

1) Experimental Session: During the experiment, participants received paired stimuli presented in a pseudorandom order. Each trial consisted of the presentation of the first stimulus, followed by a 1-second inter-stimulus interval, and then the second stimulus, after which participants were asked to indicate the one that felt stronger. The experiment consisted of two blocks, each corresponding to a direction of magnet displacement—pinch or stretch—with 100 trials in each block. The binary responses of the participants were recorded.

2) Data Analysis: To analyze participants' responses, we employed a Generalized Linear Mixed Model (GLMM)[31], which accounts for both the fixed effects of experimental variables and the random effects due to inter-participant variability. The GLMM framework allows for the modeling of binary response data while accommodating the hierarchical structure of repeated measures across participants. A probit link function was used to model the probability $P(Y_j = 1)$ that, in trial j, the participant judged the comparison stimulus to be more intense than the reference stimulus. The model is expressed as:

$$\phi^{-1}[P(Y_j = 1)] = \beta_0 + \beta_1 \cdot x_j \tag{2}$$

where ϕ^{-1} is the inverse of the cumulative normal distribution (probit transformation), and x_j represents the intensity of the comparison stimulus. The parameters β_0 and β_1 correspond to the intercept and slope, capturing the fixed effects.

This model was applied across all participants to estimate key psychometric parameters, including the JND and the Point of Subjective Equality (PSE), representing the comparison stimulus value at which participants were equally likely to perceive it as either stronger or weaker than the reference (corresponding to a response probability of 0.5). We derived 95% confidence intervals (CIs) for these estimates using a bootstrap method, ensuring robust estimates of precision and accuracy for each experimental condition. For further details on this analysis, please refer to [31].

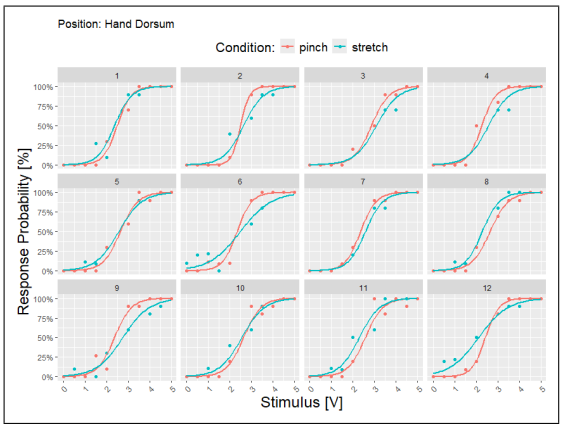

Fig. 6. Results of the psychophysical characterization, showing GLMM predictions for the stretch and pinch conditions across all subjects for the hand dorsum. The dots are data points corresponding to the individual predictions of the GLMM for each participant (labeled 1 - 12). Each box represents the model's predictions for the response probability under the stretch and pinch conditions, summarizing the trend across all subjects.

V. RESULTS

A. Physical Characterization

The maximum effective voltage identified in the first experiment was 5V. This threshold was established based on both safety and performance considerations: beyond 5V, further voltage increases did not result in significant displacement, indicating that the system had reached its effective operating capacity. Although modeling the relationship between voltage and skin stretch was not the goal of this study, we report here the skin stretch values observed at the maximum applied voltage. We plan to investigate such a relationship in depth in future work. Specifically, the mean displacement on the hand dorsum was 5.64 mm for skin stretch (standard deviation: 0.50 mm) and 6.18 mm for pinch (standard deviation: 0.75 mm). Additionally, the 5V limit is well below the threshold established by general electrical safety standards [32], ensuring that the current induced remained below levels associated with noticeable physiological effects [32]. Thus, this voltage was chosen to balance device efficacy in achieving targeted displacement with the safety and comfort of participants, minimizing any risk of discomfort or harm.

B. Psychophysical Characterization

For the JND calculation using the method of constant stimuli, we considered the range defined by the maximum voltage of 5V determined in the previous experiment. This range was divided into ten equally spaced intervals, from 0.5V to 5V, with a step size of 0.5V (0.5, 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, 5V). The reference stimulus (RS) was set at 2.5V, while the remaining nine values served as comparison stimuli (CS). The results of the GLMM applied to each participant are shown in Fig. 6. The obtained JND and PSE values, along with their respective 95% CIs, are summarized in Table I for both stretch and pinch conditions.

TABLE I

SUMMARY OF JND AND PSE VALUES FOR STRETCH AND PINCH CONDITIONS ON THE HAND DORSUM.

	JND [V]	**95% CIs [V]**	**PSE [V]**	**95% CIs [V]**
Stretch	0.63	[0.58; 0.68]	2.53	[2.43; 2.63]
Pinch	0.37	[0.33; 0.41]	2.52	[2.42; 2.61]

VI. DISCUSSION AND CONCLUSION

In this study, we developed, designed, and evaluated the MISS (Magnetically Induced Skin Stretch) device, a novel wearable system that leverages magnetic forces to induce skin stretch and provide proprioceptive feedback. Three initial configurations were tested, with the dual-coil C-shaped core design ultimately selected based on simulation results. Psychophysical testing on able-bodied participants demonstrated that the device effectively generated distinct stretch and pinch sensations on the hand dorsum. Moreover, participants were able to reliably differentiate stimulus intensities, as indicated by the calculated Just Noticeable Differences (JNDs) and Points of Subjective Equality (PSEs) for both conditions.

The results summarized in Table I show that participants were more sensitive to variations in stimulus intensity during the pinch condition, as indicated by the lower JND (0.37V) compared to the stretch condition (0.63V). One possible explanation is that in the pinch condition, the magnets experience both the repulsive force from the coils and an increasing attractive force pulling them together, leading to greater displacement. Our measurements showed that the displacement of the magnets was significantly greater in the pinch condition compared to the stretch condition, with statistical analysis (t-test, $p < 0.05$) confirming the possibility of enhanced stimulus perceptibility. Regarding the PSE, values for both conditions were similar, suggesting that participants perceived comparable stimulus levels as equal across conditions. The associated 95% confidence intervals (CIs) also provide insight into response consistency. Although the CIs for both conditions significantly overlap, the slightly narrower CIs for the pinch condition suggest that responses were more consistent among participants.

Despite these promising results, our study has some limitations. First, testing was conducted exclusively on able-bodied participants and focused only on the hand dorsum. Further research is necessary to evaluate the effectiveness of the MISS device with prosthesis users and in other relevant body areas. Additionally, our sample was limited to younger participants, whereas age-related declines in skin elasticity and proprioception may influence displacement and detection thresholds. Future studies should include a broader age range to investigate these effects. While this study focused on binary stimulation, future work will explore continuous proprioceptive feedback by refining control strategies and graded stimulation patterns. We also aim to improve the design for greater compactness and seamless integration into prosthetic sockets. Moreover, we plan to extend testing to a larger and more diverse participant group, including prosthesis users,

to assess the device's potential in conveying proprioceptive feedback during active tasks. Finally, we will explore the integration of MISS with robotic supernumerary hands for rehabilitation applications [33].

Enhancing Hand Dexterity Assessment Through Protocol Revision and Pilot Evaluation of the Virtual Eggs Test

Lucia Angelini*, *Student Member, IEEE,* Michele Piazzini*, Robinson Guachi, Francesca Toso, Marco Baccini, Francesca Cecchi† and Marco Controzzi†, *Member, IEEE*

***Abstract*— Hand function assessment enables the therapist to select the proper rehabilitation therapy as well as to monitor the recovery progress. The Virtual Eggs Test (VET) stands out from the other tests for hand dexterity evaluation since evaluates both gross and fine dexterity. This is achieved by integrating measures of accuracy and speed in transporting objects with increasing fragilities. A clinical trial to validate VET was carried out with a population of amputees and a small group of healthy participants, showing promising results. To improve the resolution of the test, here we propose a revised version of the execution protocol without extending the duration. The new version has been preliminary evaluated by seven healthy participants of different ages. The results of this pilot study support test-retest reliability for the original formulation of the Fine Dexterity Index, while suggesting for a revision of the Gross Dexterity Index.**

I. Introduction

Hand assessment is the examination process used to evaluate the performance of the hand [1]. It enables therapists to select the appropriate rehabilitation process and monitor recovery over time [2]. Different methods can be used to evaluate the hand functions, such as the measurement of the range of motion (ROM) or handgrip strength [3]. Among those, the evaluation of hand dexterity plays a key role. Hand dexterity is considered a valid indicator of the residual function of the hand [4] and "the best predictor of independence during everyday activities" [5]. Hand dexterity can be defined as the ability to coordinate voluntary movements (and thus forces) to complete a functional task with accuracy, speed and efficiency [6]. It can be classified into fine and gross dexterity according to the precision of the movement required [7][8]. Hand dexterity is a skilled behavior that entails the coordination of multiple segments of the hand [9]. Consequently, assessing hand dexterity poses a significant challenge [5][9]. Hand dexterity is typically evaluated by observing patients as they perform simple tasks or by using standardized assessment tools [10]. These last must demonstrate validity and reliability prior to their use in a clinical context [2], [5]. In other words, assessment tools should be able to measure what they intend to measure (i.e. validity) and provide similar results under the same conditions (i.e. reliability) so that therapists can trust the outcome of the test [11][12]. Tools for the evaluation of the hand dexterity have been largely reviewed [2], [5], [13]. They can be grouped based on the assessment method (i.e., self-reported or performance-based), the type of evaluated dexterity (i.e., fine, gross or both) and the target population. Self-reported tests (i.e., questionnaires) rely on the subject's perception of his/her capability in real-life environments. In contrast, performance-based tests are objective tools that evaluate subjects' performance in standardized tasks [2]. Three frequently used and validated performance-based tests [5] are the Box and Block Test (BBT), the Minnesota Rate of Manipulation Test (MRMT), and the Purdue Pegboard Test (PPT). The first two tests are employed to assess gross dexterity, while the third focuses on the evaluation of fine dexterity. In the BBT, subjects are asked to transfer the larger number of rigid wooden blocks from one compartment of a box to another, one by one, within a time limit of 60 seconds. The outcome of the test is the total number of blocks successfully transferred [7]. The MRMT consists of five subtests in which subjects are asked to turn and/or place small pegs into a board. The score is computed as the sum of the time taken to complete all subsets [14]. Similarly, the PPT is composed of 4 subtests involving the insertion of pins, collars, and washers into predefined small holes. Both hands are assessed during the test, either individually or in a coordinated fashion. The score is the sum of elements correctly positioned within a predefined amount of time (30 or 60 seconds) [8]. The previously described tests, as well as most of the other non-validated tests, are time-based [2]: they provide outcome measures related to the completion rate of the task without considering other important factors, such as in-hand manipulation or dynamic force control [10]. Quite the opposite, the Strength-Dexterity test (SD) is a test that specifically focuses on dynamic force control. The test evaluates subjects' ability to regulate the force at their fingertips to compress springs avoiding their buckling [15]. We have proposed the Virtual Eggs Test (VET) to evaluate hand dexterity by merging those two approaches. The VET outcomes combine information related to the task completion rate (i.e., the speed of the task) and dynamic force control (i.e., the accuracy of the task) [16]. The VET assesses both fine and gross dexterity evaluating the ability of subjects to transport objects with different fragilities (doubled Virtual Egg – VE) from one side to the other of a barrier, without breaking them and as fast as they can. A preliminary version of the VET was successfully exploited in various studies

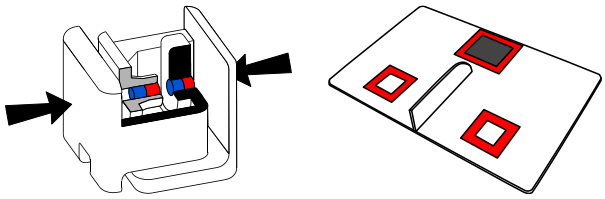
involving amputees [17], [18], [19]. The first campaign devoted to the validation of the VET was conducted with 35 healthy individuals and 30 amputees using myoelectric prostheses [16]. The results proved construct validity (i.e., the capability of discriminate different groups) and test-retest reliability for the healthy population. However, test-retest reliability was achieved after an intense familiarization phase. Healthy participants performed the VET twice in each session and only comparisons between the last performed VET of each session showed test-retest reliability. Moreover, reliability was investigated only on healthy participants aged between 21 and 45 and using their dominant hand, without accounting for age or sex that are factors proved to influence hand dexterity [20], [21]. Results variability among subjects was low, for both the outcome measures of the VET (i.e., Fine Dexterity Index and Gross Dexterity Index). This low variability could be biased by a lack of age diversity among participants or/and by the poor resolution of the VET that may not be able to perceive existing differences. These considerations led us modify the protocol with the aim of increasing the usability and the resolution of the assessment tool, without affecting the overall duration of the test [22]. So, we increased the number of VEs comprising the kit from 11 to 20 and we changed their break threshold to simulate more fragile objects. We aim to exploit the new protocol to collect normative data for healthy participants and to validate the VET with different populations. Here, the new protocol was tested within a pilot study involving seven healthy participants with ages ranging from 29 to 83 years. Test-retest reliability and variation based on age were preliminary evaluated. This paper reports the results of this pilot, and it is organized as follows: Section II presents the experimental procedure describing the new protocol of the VET, the outcome measures of the test and the statistical analysis performed on the data. Results are reported in Section III and discussed in Section IV.



II. Materials and Methods

A. Participants

Seven participants were enrolled considering the inclusion and exclusion criteria listed in Table 1. Participants were distributed among seven different groups according to their age: 18-29, 30-39, 40-49, 50-59, 60-69, 70-79, >80 (Table 2). Four participants were right-handed according to the Oldfield questionnaire (see the Experimental Procedure).

Table 1 Inclusion and exclusion criteria

Inclusion Criteria	*Exclusion Criteria*
Participants of both sexes and any ethnicity aged ⩾ 18	Severe visual and oculomotor deficits
Absence of motor impairments	Neurological or musculoskeletal pathologies that impact upper limb function, clinical instability
Willingness to participate in the study and sign the consent form	Psychiatric comorbidities
	Lack of understanding of the Italian language
	Consumption of alcohol or diuretics before tests

(a) (b)

Figure 1 Setup of the Virtual Eggs Test. (a) Virtual Egg [16]; (b) platform.

Table 2 Participants enrolled for the pilot study

Group age	*Age*	*Sex*	*Dominant hand*
18 – 29	29	Female	Right
30 – 39	39	Male	Left
40 – 49	46	Female	Left
50 – 59	59	Female	Right
60 – 69	64	Male	Left
70 – 79	79	Female	Right
> 80	83	Female	Right

Participants carried out the experiment without compensation at the premises of the Fondazione Don Carlo Gnocchi (FI). The experiment was conducted in full compliance with international legislation and its national transposition concerning clinical trials and the principles of the Declaration of Helsinki. Participants signed the informed consent and read the information sheet of the study. The study was approved by the local ethical committee of the Area Toscana Centro, Italy (Approval number: 23327_spe.).

B. Experimental procedure

Prior to the experiment procedure, the laterality of the participant was assessed according to the Oldfield questionnaire [23]. Participants performed the Virtual Eggs Test (VET) in two different trials with both hands. The distance between the two trials was at least 14 days to decrease the possibility of learning effects [24]. The dominant hand was always tested first.

C. The Virtual Eggs Test

Setup. The setup of the Virtual Eggs Test (VET) comprised 20 Virtual Eggs, a platform and a software (Figure 1). The Virtual Egg (VE) is a custom fragile device (Figure 1 (a)). It is equipped with a magnetic fuse responsible for keeping the external wall in a pre-defined "non-collapsed" position. When the VE is grasped with a grip force greater than the break threshold (T_{break}) the external walls collapse and the VE "breaks". The break threshold of the magnetic fuse can be calibrated either by changing the magnetization of the magnets or their distance. Each VE is characterized by the normalized break threshold $\Phi = T_{break}/GF_{min}$. Where $GF_{min} = W/(2*\mu)$ is the minimum grip force necessary to lift it, W is the weight of the VE and μ is the coefficient of friction between the fingers and the graspable walls. We covered these walls with sandpaper

(grit 240) to decrease the variability among participants. The coefficient of friction was experimentally derived and equal to 1.44. The range and the step of the values of Φ within the 20 VEs comprising the kit were selected after a preliminary test phase. They range from 1, which corresponds to the minimum grip force required to lift the object without breaking it, to 10.5 with increasing steps of 0.5 (Table 3).

TABLE 3 BREAK THRESHOLDS AND NORMALIZED BREAK THRESHOLDS OF THE VES.

VE#	Weight (g)	Break threshold (N)	Φ
1	90.4	0.31	1
2	89.1	0.47	1.5
3	89.2	0.62	2
4	89.6	0.77	2.5
5	90.5	0.92	3
6	90.7	1.09	3.5
7	90.6	1.23	4
8	90.8	1.37	4.5
9	90.9	1.53	5
10	90.4	1.69	5.5
11	90.5	1.86	6
12	90.6	2.02	6.5
13	90.4	2.15	7
14	89.6	2.32	7.5
15	90.9	2.46	8
16	91.0	2.61	8.5
17	90.7	2.77	9
18	90.9	2.94	9.5
19	90.8	3.08	10
20	90.7	3.23	10.5

The platform (Figure 1 (b)) is placed on the table 10 cm away from the edge and wire-connected with the PC where the software is running. The platform hosts three distinct areas: the home position and two Egg placers divided by a 6 cm high barrier. Each area is highlighted with a red frame and is equipped with a sensor to record the time of the task. During the test, the platform collects the data, which are stored and visualized by the software that also supports the examiner during the execution of the VET allowing him/her to take notes of the broken VE.

Protocol. We here exploited an adaptive protocol comprising two consecutive phases: a familiarization phase and a testing phase. Before starting, the participant washes his/her hand and sits on an adjustable chair, the position of the chair is set so that when the hand lays on the platform the forearm is parallel to the floor. During the familiarization and the testing phase, the participant performs many trials with different VE. Each trial comprises the following sequence: (i) dip the thumb and index finger into the magnesite powder; (ii) voluntarily break the VE multiple times to test its fragility; (iii) place the VE on the starting Egg placer (i.e., the one on the side of the tested hand); (iv) perform seven repetitions. The movement of the VE over the platform is defined as repetition (Figure 2). Each repetition consists of the following steps: (i) put the hand in the home position; (ii) reach and grasp the VE from the starting Egg placer exploiting a pinch grasp; (iii) transport the VE over the barrier as fast as possible and without breaking it; (iv) place the VE in the ending Egg placer; (v) replace the hand over the home position. The ending Egg placer of the first repetition becomes the starting Egg placer in the second repetition and so on: the VE is moved once from right to left and once from left to right.

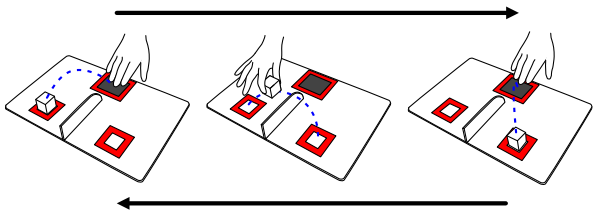


Figure 2 Repetition (movement of the VE over the platform). The movement can be performed from right to left or from left to right.

A repetition fails if the participant releases the VE in a wrong position or breaks it, while a trial fails if at least two of the seven repetitions fail. During the familiarization phase, the participant completes three trials with VE20 (the most robust one), VE10 and VE5, respectively. Instead, the testing phase comprises several trials with different VEs. The first trial is performed with VE20, then the subsequent number of the VE to be transported, and so its fragility, is chosen according to the performance of the participant following an Up/Down method [25] with a size of step down and up equal to 3 and 2 respectively (Figure 3 - left). If the subsequent VE number is less than 1 or exceeds 20, VE1 or VE20 is respectively selected. The test phase ends when the fifth reversal (i.e., a successful trial following one or more failed trials, or vice versa) occurs or if the participant has manipulated the VE20 or the VE1 for three trials consecutively.

Metrics. The VET returns as outcomes two different indexes: the Fine Dexterity Index (FDI) and the Gross Dexterity Index (GDI) [16]. The former index assesses the capability of transporting the most fragile VEs (and so the fine dexterity) while the latter describes the ability to move the most robust VEs as fast as possible but without breaking them. Together, the two indexes comprehensively described the performance of the participants considering the two trade-off factors during the task: the regulation of the grip force to not break the object and the time required to accomplish the task.

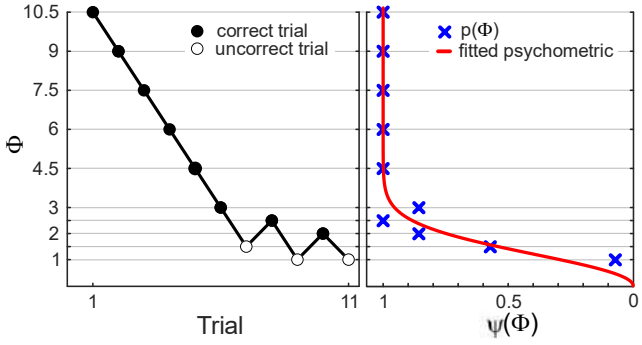

Figure 3 Example of a VET protocol following un up/down procedure (left) and the fitted psychometric curve (right).

More in detail, for each manipulated VE, the first factor is evaluated by the ratio of successful repetitions over the total ones. The collected data express the probability of correct transport of a VE with a specific normalized threshold, $p(\Phi)$. Following the high-threshold theory [25], $p(\Phi)$is fitted using

Weibull's psychometric function $\psi(\Phi)$ (1) (Figure 3 - right). The guessing rate γ was fixed to 0 since the data were derived from the performance of the participant, and the slope β was fixed to 2 based on previous experimental evaluation.

$$\psi(\Phi) = (1-\lambda)\left(1 - e^{\left(-\frac{\Phi}{\alpha}\right)^2}\right) \quad (1)$$

The outputs of the fitting are two parameters λ and α. The lapse rate λ is mostly associated with the performance of the most robust VEs. The threshold α varies according to the performance of the most fragile VEs. The lower the values of those two parameters the better the performance of the participant.

The time required to accomplish the task (b), which is the second trade-off factor, is calculated as mean of the best transport time of VE20 and VE19. Finally, by combining λ, α and b, we defined the Fine Dexterity Index FDI (2) and the Gross Dexterity Index GDI (3) as follows:

$$FDI = \alpha \quad (2)$$

$$GDI = \left(1 - \frac{b}{20}\right)(1-\lambda) \quad (3)$$

D. Statistical Analysis

Statistical analysis was performed using IBM® SPSS® and Matlab. We separately evaluated the test-retest reliability for each outcome measure (i.e., FDI and GDI) for the dominant and non-dominant hand. We followed a two-step procedure according to the CONSMIN guidelines [26][27]: (1) evaluate the stability of patients; (2) compute the Intraclass Correlation Coefficient (ICC) with the 95% Confidence Interval (CI) if data were stable. The stability of patients was evaluated by exploiting non-parametric tests since the small sample size (i.e., seven participants). We selected the T-Wilcoxon Signed Rank if the distribution of the difference between the two populations was symmetric ($|\gamma| < 1$, where γ is the skewness index), otherwise, we used the Sign test. The statistical significance of all the tests performed was defined by $p < 0.05$. The ICC coefficient was evaluated as two-way mixed effects absolute agreement single measurement [28] (also named ICC(A,1) [29]). According to Resnik et al. [13] we considered an excellent reliability when ICC ≥ 0.8, good reliability if 0.80 > ICC ≥ 0.6, and poor reliability if ICC < 0.6. In addition, we report Standard Error Measurement (SEM) (4), Minimal Detectable Change with a 95% CI (MDC_{95}) (5), and MDC95 percentage ($MDC_{\%}$) (6), where SD is the standard deviation of the score from all subjects [30] and $\bar{X}$ is the mean of the considered variable.

$$SEM = SD \times \sqrt{1 - ICC} \quad (4)$$

$$MDC_{95} = SEM \times 1.96 \times \sqrt{2} \quad (5)$$

$$MDC_{\%} = \frac{MDC_{95}}{\bar{X}} \times 100 \quad (6)$$

III. Results

The Fine Dexterity Index (FDI) and the Gross Dexterity Index of each participant are shown in Table 4 and Figure 4. FDI and GDI are reported according to the hand (dominant or non-dominant) and the sessions (test or retest). The mean distance between test and retest was 24 days (Table 4). Test-retest reliability was assessed for each Index and each hand separately. No statistical differences were found for the FDI both for the dominant and non-dominant hand (Wilcoxon signed-rank p-value = 0.237 and p-value = 0.612, respectively). For the dominant hand, the ICC was 0.95 (with 95% CI = 0.76 to 1.00), the SEM was 0.204, the MDC_{95} was 0.567 and the $MDC_{\%}$ was 28.0%. For the non-dominant hand, ICC was 0.91 (with 95% CI = 0.56 to 0.98), the SEM was 0.216, the MDC_{95} was 0.598 and the $MDC_{\%}$ was 29.5%. Regarding the GDI, no statistical differences were found for the dominant hand (Wilcoxon signed-rank p-value = 0.237) with ICC equal to 0.13 (with 95% CI = -0.39 to 0.73), SEM equal to 0.023, MDC_{95} equal to 0.064 and the $MDC_{\%}$ was 7.2 %. On the contrary, GDI shows statistical differences for the non-dominant hand (Wilcoxon signed-rank p-value = 0.018).

IV. Discussion

The VET aims to evaluate hand dexterity focusing on the capability of the participant to carry fragile objects without breaking them and as fast as possible. We improved the VET with respect to its first validation [16], by introducing a structured familiarization phase aiming to reduce the learning. In addition, we enlarged the number of the VEs (from 11 to 20) to have a finer discretization, keeping the execution time similar to the previous version by following an up/down procedure. To assess these changes and in the effort of extending the results of the previous study, we are currently running a clinical trial to collect normative data. Here we present a first evaluation of the modified protocol. The two-fold objective is to estimate test-retest reliability both for the dominant and non-dominant hand and preliminarily evaluate the influence of age on the results. Difference between performance of the dominant and non-dominant hand are not investigated in this pilot. Seven healthy participants, aged between 29 and 83 years, were involved in this pilot study. They performed the VET in two different sessions, distant no less than 14 days, with both hands. For each participant, performances were reported as Fine Dexterity Index (FDI) and Gross Dexterity Index (GDI). Test-retest reliability was statistically evaluated while the trend according to age was qualitatively assessed by looking at the trend of the data.

FDI, for both the dominant and non-dominant hand, shows excellent test-retest variability with an Intraclass Correlation Coefficient (ICC) equal to 0.95 and 0.91 respectively [13]. The new protocol proves to preserve the reliability of FDI without requiring the participant to perform the test twice [16]. However, the sample size should be increased including at least 30 participants to have more robust results [28], this is currently under investigation. The Standard Error Measurement (SEM) and Minimal Detectable Change (MDC_{95}) are similar for both hands. This suggests the VET can evaluate without bias both the dominant and non-dominant hands. The finding is coherent with the construct of the test. The VET is symmetrical, both in the setup and in the task, and

TABLE 4 OUTCOME MEASURE OF THE VIRTUAL EGGS TEST (VET) AND DISTANCE BETWEEN TEST-RETEST FOR EACH SUBJECT. THE FINE DEXTERITY INDEX (FDI) AND GROSS DEXTERITY INDEX (GDI) ARE REPORTED FOR THE DOMINANT AND NON-DOMINANT HAND FOR THE TWO DIFFERENT TRIALS (TEST AND RETEST).

	Distance between test and retest (days)	*FDI*				*GDI*			
		Dominant hand		*Non-dominant hand*		*Dominant hand*		*Non-dominant hand*	
Group age		*test*	*retest*	*test*	*retest*	*test*	*retest*	*test*	*retest*
18 – 29	42	1.67	1.41	1.75	1.41	0.92	0.91	0.89	0.91
30 – 39	15	1.63	1.41	1.68	1.42	0.91	0.90	0.90	0.91
40 – 49	24	1.34	1.47	1.71	1.26	0.85	0.89	0.86	0.88

Standard deviation	10.8	0.98	0.85	0.60	0.84	0.03	0.01	0.02	0.01

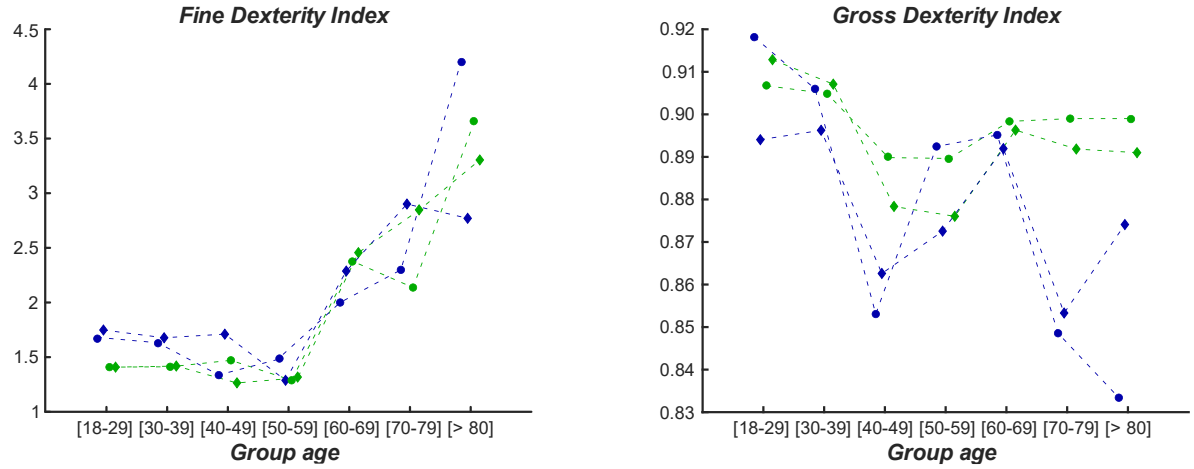

Figure 4 Outcome measure of the Virtual Eggs Test (VET), data associated with the test and retest are reported in blue and green respectively, data of the dominant and non-dominant hand are reported with circle and rhombus respectively. Fine Dexterity (FDI) (a), Gross Dexterity Index (GDI) (b).

does not change based on which hand the participant uses. By looking at the relationship between age and FDI we can observe an increase in FDI (i.e., a decreasing fine dexterity) with increasing age. This result is coherent with normative data of other hand dexterity assessment tools such as the Box and Block Test [7] or the Nine Hole Peg Test [31]. The variability of the values of FDI is higher with respect to our previous study [16]. In our opinion, this is caused by the heterogeneity of participants' ages but also by an increased resolution of the VET led by a finer discretization of the break threshold. On the contrary, GDI didn't prove test-retest reliability. In the case of the dominant hand, data didn't prove a statistical difference but showed a poor ICC. In the case of non-dominant hand, data showed a statistical difference. Usually, participants have a higher GDI (i.e., a better performance) during the retest session (Table 4). GDI is mainly affected by the performance associated with the most robust VEs. Those VEs are the first to be manipulated at the beginning of the testing phase, so the participant may be less confident in performing the test. In addition, GDI is computed considering the transport time of only two VEs (VE20 and VE19) and this could amplify the overmentioned problem. This result is in contrast with our findings in the first validation [16] where GDI proved test-retest reliability. One reason may lie in the fact that in [16] we used higher break thresholds (normalized force three times higher than the one used here). A new formulation of the GDI, an extension of the familiarization phase or an increase break threshold of the most robust VEs may be required to increase the reliability of GDI over time. We are confident that one or the combination of those possible improvements will make the GDI reliable. The variability of the GDI among participants is low, and so trends of the performance according to age are difficult to propose. As for the FDI, additional participants are needed to increase the power of the study. Results associated with SEM, MDC_{95} and $MDC_{\%}$, are reported for the sake of clarity of the procedure but not detailed discussed since the small sample size. Currently we are running an investigation involving

additional participants, and we will further analyze these values in a large population.

V. Conclusions and Future Works

The outcomes provided by this pilot study suggest that the new protocol can keep the reliability of the VET in terms of Fine Dexterity Index (FDI). On the contrary, results suggest for a revision of the Gross Dexterity Index (GDI) to increase its reliability and variability among different ages. In addition, more participants must be enrolled to increase the statistical power of the analysis and also to take into account other variables influencing the results such as the sex and the dominance of the hand [20], [21]. The new study, that is undergoing, involves both males and females for each age group and randomizes the order of the first-tested hand (i.e., dominant or non-dominant) among participants to investigate if the VET can highlight the difference between the two hands. Moreover, clinical trials involving participants with different pathologies will be carried out to continue the VET validation.

Beyond the Legs: Leveraging Trunk and Driving Muscle EMG to Improve Gait Model Predictions

Annika Guez, Sabine Baier, Nicolas Berberich, Ravi Vaidyanathan and Gordon Cheng

***Abstract*— Gait prediction models based on electromyography (EMG) have been extensively used for motion intent detection in lower-limb exoskeletons. Traditionally, gait prediction models tend to rely solely on lower-limb EMG signals. However, based on the importance of trunk muscles in clinical gait studies, we hypothesise that these could provide valuable information for the development of more accurate gait models. Furthermore, based on previous literature on muscle functionality during steady-state walking, we also hypothesise that focusing on muscle groups that are responsible for movement generation in gait (referred to as driving muscles, or "drivers") will lead to improved kinematics predictions compared to other muscle subsets. In this study, we examine the predictive value of EMG signals extracted from the trunk and driving muscles versus purely the lower-limbs in predictive gait models. We investigate prediction horizons of 0.05 ms (one time-step ahead), 100 ms, and 200 ms, and predict the angular output of the hip, knee and ankle joints, as well as the estimated gait cycle percentage. Our results show that models trained using trunk muscle EMG significantly outperform models trained only on lower-limb EMG, particularly for knee angle outputs with longer prediction horizons (p <0.05). Furthermore, training on selected driving muscles further improved model performance when predicting the knee and ankle joint kinematics, particularly with short prediction horizons (p <0.001). These findings support the hypothesis that including trunk muscles contributes significantly to the development of accurate gait models, and highlight the potential of targeting "drivers" to select more relevant EMG inputs for kinematic predictions.**

I. Introduction

In recent years, lower-limb exoskeletons (LLEs) have been gaining traction as a means for helping patients regain their independence and providing assistance through their rehabilitation process [1], [2]. Within this context, understanding the complex internal mechanisms of the user's neuromusculoskeletal function is crucial in developing effective user-centred devices [3]. Consequently, establishing reliable relationships between the user's intent and their corresponding limb movements has been a core focus in research. This effort involves in-depth gait analysis and advanced modelling techniques to generate the required kinematic information for accurate exoskeleton control [4]. Given that LLEs are robotic systems designed for human-in-the-loop control, correctly deciphering the user's motion intent is essential for the user's safety and rehabilitation effectiveness.

Electromyography (EMG) is a sensing modality that detects the electrical activity generated in muscle fibres prior to muscle contraction. In the domain of gait analysis and modelling, EMG signals have extensively been used as inputs for motion intent detection [5], and are currently the only clinically viable approach to interfacing with the subject's nervous system without surgery [3]. However, the translation of these EMG-based models to clinical environments, either within patient populations or in the development of LLEs, remains a challenge [6]; the non-stationary nature of EMG signals and their susceptibility to external factors limit their application in muscle-driven models [7], which is further exacerbated by inter-session and cross-subject inconsistencies [8]. Therefore, input optimisation is essential to ensure accurate predictions, and the reduction of redundant hardware could help improve computational efficiency and reduce cost for LLE applications.

Previous studies on EMG-driven models for lower-limb kinematics predictions have focused mainly on muscles from the lower-limbs [9], with a particular focus on the Gluteus (GT), Rectus Femoris (RF), Biceps Femoris (BF), Vastus Lateralis (VL), Tibialis Anterior (TA), and Soleus (SO) to predict the angular kinematics of the hip, knee and ankle. However, in addition to the lower-limbs, clinical gait research puts an emphasis on the role of the trunk during gait, and the relationship between trunk muscle activation and lower-limb movement [10]. Furthermore, the trunk has often been a point of focus in gait rehabilitation practices [11]. The trunk muscles play a dual role during steady-state walking, focused on both the maintenance of postural balance and the facilitation of lower-limb movement; the trunk is perceived as the centre of the functional kinematic chain during gait [12] as its muscle activation precedes those of the lower-limbs and pushes the Centre of Mass (CoM) forwards [10], therefore providing a stable basis for control and the generation of movement during gait.

Beyond the role of the trunk, this notion of task-specific muscle roles can be extended to the lower-limbs as well, as previous studies have made the distinction between muscles responsible for movement generation (also known as "drivers") and those that provide stability and balance to facilitate the motion (also known as "stabilisers") [13]. Whilst this distinction isn't yet clear for all the muscles involved in gait, the Multifidus (MF) and Erector Spinae (ES) muscles have been characterised in previous studies as "drivers" due to their clear phasic activation patterns [14], [15]. and SO have also been recognised as "drivers" in the lower-limbs [16]. Based on this information, we further hypothesise that using these "driving" muscles as inputs into our gait models would lead to better predictions, since they would have a more direct relationship with the resulting movement. In this study, we therefore investigate whether the use of trunk muscles and "driver" muscles as EMG signal inputs will improve gait model predictions, compared to using only leg muscles as previously done in literature.

II. Methods

A. Subjects

This study involved 5 able-bodied participants with no previous neurological or physiological conditions that could impact their gait (2 male, 3 female, with a mean age of 26 $\pm$ 5 years, a mean height of 171 $\pm$ 10 cm, and a mean weight of 62 $\pm$ 10 kg). The experiments used in this study were conducted in accordance with ethical guidelines approved by the Imperial College Research Ethics Committee (ICREC reference: 21IC7204).

B. Experimental procedure

To gather steady-state gait data across various walking speeds, the participants were asked to walk on a treadmill at speeds ranging from 0.40 $m{\cdot}s^{\propto l}$) to 0.80 $m{\cdot}s^{\propto l}$), with increments of 0.04 $m{\cdot}s^{\propto l}$), for a duration of 2 minutes per speed (this corresponds to an average of 75 strides per speed, so over 680 steady-state cycles per subject). Since this study focuses on the recruitment strategies of the subject's muscles to generate the cyclical movements at different speeds for efficient walking, overground walking or start-and-stop tasks were not investigated.

*1) **Delsys bipolar EMG**:* During walking, synchronous muscle activity data was collected using Delsys Avanti Trigno bipolar EMG sensors placed on 8 muscles from the trunk and the lower-limb based on the SENIAM [17] standards. Since gait is predominantly a combination of weight shifting in the transverse plane as well as movement from the lower-limbs, the trunk data was acquired bilaterally (from both sides) to capture the adjustments of the CoM [18] whilst the leg data was acquired unilaterally since we are only focusing on the joint angles of the investigated limb [9]. In particular, bilateral data were recorded from the MF and Erector Spinae Longissimus (ESL), in conjunction with lower-limb data of the dominant leg recorded from the RF, BF, TA and SO. The dominant leg was determined through a push test by selecting the leg with which the participant instinctively stepped forward.

*2) **Vicon Motion Capture**:* Using a Vicon Motion Capture system with ten 120 Hz Vicon Vero v2.2 cameras positioned around the workspace, the joint kinematics of the subjects' dominant leg were recorded as they walked. These encompass the joint angles from the hip, knee, and ankle joints, which have all previously been used for gait analysis and prediction [7]. The marker trajectory data was labelled using the Vicon Nexus software, and kinematics information was extracted using the Nexus Plug-In Gait Kinematics pipeline for lower-body modelling [19]. Since all the data acquisition was done simultaneously through the analogue-integrated version of the Delsys Avanti Trigno (EMG) and Vicon Nexus (motion capture), the two data streams were internally synchronised during recording. The motion data was then upsampled to align with the sampling frequency of the EMG signals.

C. Data preprocessing

To facilitate the analysis of the recorded EMG signals after having been standardised, these were band-pass filtered (20-400 Hz), rectified, and low-pass filtered at 10 Hz to extract the signal envelopes. Causal filtering was used to ensure that the temporal integrity of the data was maintained. To capture the sequential nature of the data, the signals were segmented into windows, with a duration of 250 ms (500 samples for a 2 kHz sampling frequency) and a step of 40 samples. To analyse the predictive power of the different muscle subsets, multiple prediction horizons (PHs) were investigated, i.e. the time between the end of the EMG input window and the predicted joint angle output. Each extracted EMG window was therefore paired with joint angle outputs corresponding to the following PHs: 0.5 ms (one time-step ahead of the window, also referred to as the "one-step-ahead" prediction), 100 ms, and 200 ms.

1) Muscle subsets: The majority of previous EMG-based gait studies focused on the RF, BF, TA and SO as inputs to their models, as they are perceived to be the main muscles responsible for the motion of the knee and ankle joints [16]. Our analysis further focuses on the inclusion of trunk muscles as inputs to gait prediction models, specifically comparing this commonly used lower-limb muscle subset with the following 2 subsets: one solely composed of trunk muscles, and one composed of a combination of trunk and leg muscles that are theorised to be the main "drivers" of motion during cyclic gait. The investigated subsets are shown in Table I, with the *Drivers* subset corresponding to muscles identified as "drivers" in literature. [14]–[16].

TABLE I: Muscle groups included in the investigated subsets. The suffix "-L" and "-R" refer to the left and right sides of the body. Trunk muscles were always included bilaterally.

	Muscle groups							
Subset	ESL-L	ESL-R	MF-L	MF-R	RF	SO	BF	TA
Trunk	✓	✓	✓	✓				
Leg					✓	✓	✓	✓
Drivers			✓	✓	✓	✓		

All the analysed muscle subsets in this study comprised of 4 muscle groups at a time to ensure that the results across the different muscle combinations weren't biased by the amount of available data.

2) The predicted outputs: Following previous studies on modelling joint kinematics in gait [9], this study employed all the lower-limb joints as outputs to the prediction, consisting of the recorded hip, knee, and ankle joints of the dominant leg. Since joint angle range of motion (RoM) is

dependent on the physiology of the subject, an additional, physiology-independent output was investigated to assess its viability; the gait cycle percentage (GC%) represents the user's progression through the gait cycle, as a percentage of the total cycle. This metric was designed using the knee angle's flexion peaks to segment the gait cycles, with the percentages linearly fitted to each extracted cycle.

D. Multi-Layer Perceptron

A regressive multi-layer perceptron (MLP) was implemented as the evaluation model, mapping the windowed EMG envelopes to the chosen predictive output (see Subsection II-C.2). The model architecture consisted of 7 fully connected layers with Rectified Linear Unit (ReLU) activation, trained using a Mean Squared Error loss function and an Adam optimizer. Although there exists more advanced architectures, MLPs are simpler and better suited for smaller datasets, whilst maintaining the ability to approximate temporal dependencies due to the use of windowed inputs [20]. To ensure that the extracted results were representative of the dataset and to minimise bias caused by the train-validation split, the models were trained using a 5-fold cross-validation scheme. The models using the muscle subsets outlined in Subsection II-C.1 were trained using a learning rate (LR) of $10^{\circ 4}$ and a weight decay of $10^{\circ 5}$ for a maximum of 100 epochs, with early stopping if the validation performance stagnated for more than 6 epochs. The reported validation performance in Section III is that of the best validation performance achieved before the model stopped training. To allow for a more meaningful comparison of the performances achieved, the recorded validation Root Mean Squared Error (RMSE) values were normalised based on the true range of the output; for the angular outputs, this corresponds to the RoM of the joint, whilst this was set to 100 for the GC%.

E. Analysis Outline

Models were trained for all the combinations of investigated muscle subsets (see Subsection II-C.1) and predicted outputs (see Subsection II-C.2), resulting in the training of 12 MLPs per subject for a given PH, and a total of 180 5-fold cross-validation models across all subjects and conditions for the 3 chosen PHs (see Subsection II-C).

To evaluate the statistical significance of the results, an independent two-sample t-test was conducted to compare the validation RMSE values (from the 5-fold cross-validation scheme) of the MLP models across the different investigated muscle subsets for all given output variables (only two models are compared at a time). Prior to conducting the statistical analysis, the normality of the RMSE distributions was assessed using a Shapiro-Wilk test. The results are reported in the performance figures using the following notations: ($* = p < 0.05$; $** = p < 0.01$; $*** = p < 0.001$; $**** = p < 0.0001$).

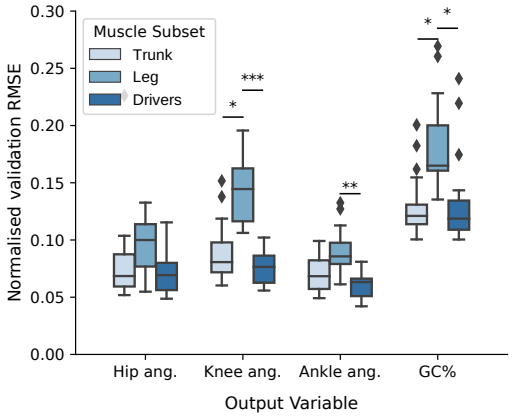
III. Results

A. Subset comparison in the one-step-ahead scheme

Figure 1 illustrates the normalised validation RMSE of the models across all subjects, trained on all combinations of muscle subsets and outputs for the one-step-ahead prediction scheme. As can be seen, for all predicted outputs, the *Trunk* subset consistently outperformed the *Leg* subset, with an average normalised RMSE decrease of 1.64% for the hip joint, 5.62% for the knee joint, 2.10% for the ankle joint, and 6.65% for the GC%. Whilst the performance of the *Trunk* and *Drivers* subsets was comparable in the case of the hip and the GC%, the *Drivers* outperformed the *Trunk* muscles when predicting the knee and ankle joints, with a normalised RMSE decrease of 6.60% and 3.10% respectively. Table II gives a more detailed description of the p-values for the individual subjects.

TABLE II: P-values comparing Trunk vs. Leg subsets (TL) and Leg vs. Combined subsets (LC) for all investigated subjects in the one-step-ahead MLP prediction scheme.

	Hip		**Knee**		**Ankle**		GC%	
Subjects	TL	LC	TL	LC	TL	LC	TL	LC
1	-	****	***	****	-	***	**	***
2	-	*	*	***	**	*	*	**
3	*	-	***	**	*	**	-	-
4	****	****	****	****	***	***	****	****
5	**	****	*	***	**	***	**	-



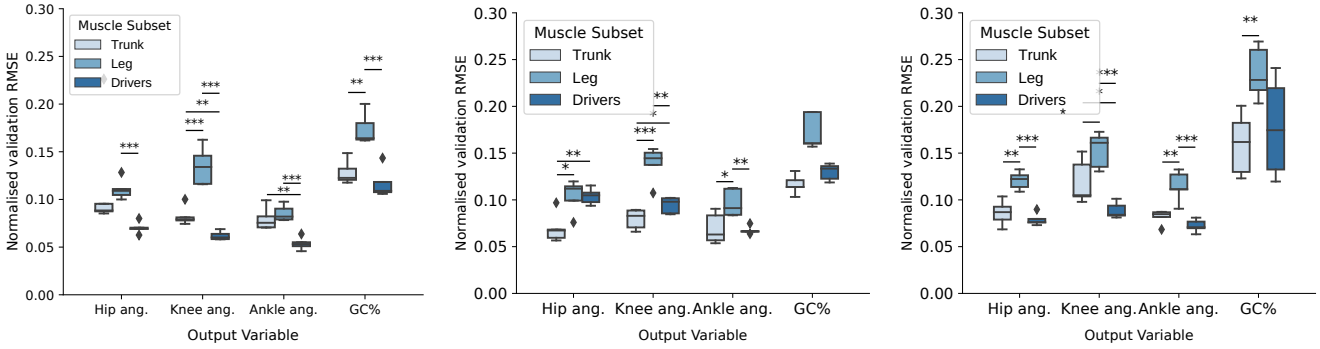


Fig. 1: Cross-subject performance of the investigated muscle subsets for the different predicted output variables in the one-step ahead scheme

At first glance, from Figure 1, the comparative performance of the *Trunk* and *Drivers* subsets could suggest that the MF is the main predictor for this joint as it is present in both subsets, and is therefore responsible for the improved model performance. However, the subject-specific visualisation in Figure 2 shows that the predictive power of these two subsets seems to alternate across subjects, thus alluding to more complex inter-subject variations in muscle recruitment strategies for hip movement. This could be related to the subjects' specific balancing strategies, as some will focus on the flexion and extension of the hip to maintain balance (known as *hip-strategy*, with an emphasis on trunk extension) while others will instead sway about their ankle joint (known as *ankle-strategy*) and therefore display less balance-focused hip movements [21].

(a) Subject 1 (b) Subject 3 (c) Subject 5

Fig. 2: The performance of the investigated muscle subsets when predicting the different outputs in a one-step-ahead scheme for 3 example subjects. Subjects 1, 3, and 5 were selected for this visualisation since they displayed a range of different significance levels during the significance analysis (see Table II).

B. The impact of prediction horizons on performance

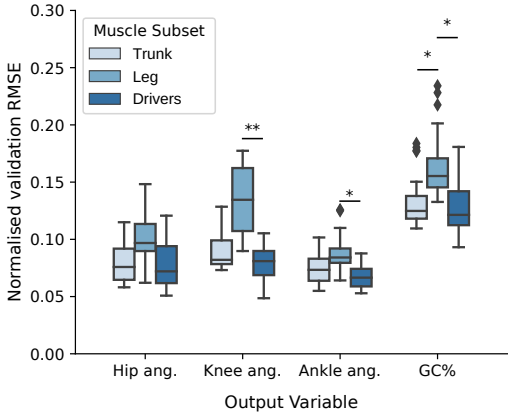

Fig. 3: Cross-subject performance of the investigated muscle subsets using a 100 ms prediction horizon.

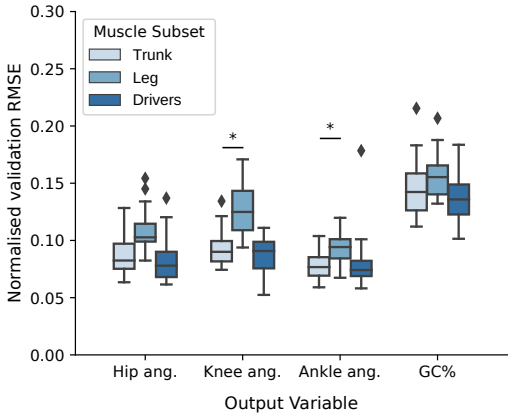

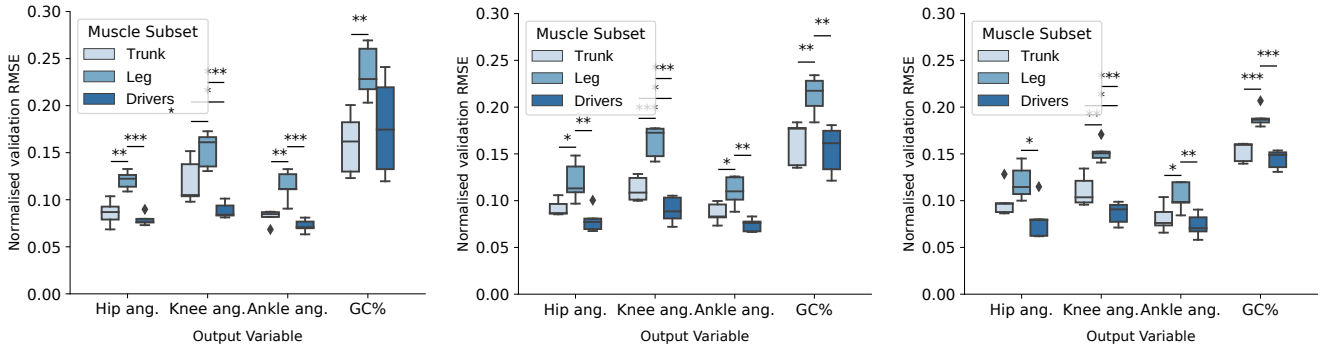

Fig. 4: Cross-subject performance of the investigated muscle subsets using a 200 ms prediction horizon.

As outlined in Subsection II-E, the prediction was repeated for PHs of 100 ms and 200 ms to assess their relationship to subset performance. Figures 3 and 4 illustrate the performance of the subsets on all investigated outputs for the 100 ms and 200 ms windows respectively. Surprisingly, the cross-subject prediction performance of the subsets remained largely unaffected by an increased PH, likely due to the cyclic nature of the motion. This suggests that differences between subsets are more influenced by signal quality than by time-based suitability. As can be seen, the *Trunk* and *Drivers* subsets consistently performed better than the *Leg* subset across all predicted outputs, with a normalised RMSE decrease of 5.63% between the *Leg* and *Drivers* subsets for the knee joint, and 2.50% for the ankle joint. However, the significance of these results decreased as the PH increased (the pairwise p-values between the *Drivers* and *Leg* subsets increased from $p < 0.001$ to $p < 0.01$ for the knee angle prediction, and $p < 0.01$ to $p < 0.05$ for the ankle angle). It should however be noted that, whilst there is a greater significance between the performances of the *Leg* and *Drivers* subsets for a 100 ms PH, the greater significance shifts to the *Leg* and *Trunk* pairs at 200 ms, suggesting that the trunk muscles' activation patterns become more important than the lower-limb's when attempting earlier predictions. This could be related to the importance of the trunk with regards to anticipatory postural adjustments, in preparation for the movement of the legs [22].

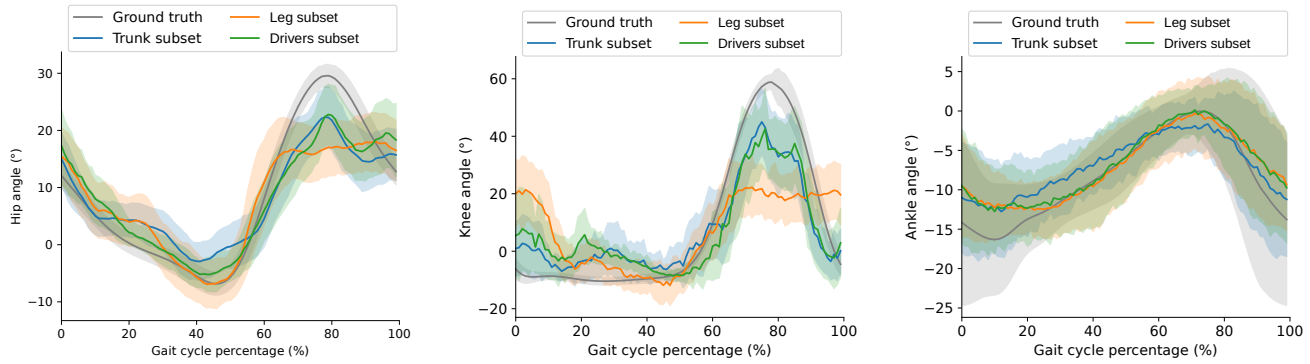
Figure 5 illustrates the change of subset performances across the investigated PHs for an example subject. Whilst the average performance values and their attributed pairwise significance varies across PHs, the trend remains the same for this subject, with the *Drivers* subset achieving the lowest validation RMSE values across all joint angles. The most noticeable change in this scenario, however, is the increasing performance for the prediction of the GC% as the PH increases, reinforcing the potential of gait cycle progression as a representative measure for gait-related outputs.

IV. Discussion

Across all subjects in the one-step-ahead prediction scheme, both the *Trunk* and *Drivers* subsets outperformed the *Leg* subset, particularly for the knee joint output. Whilst this general trend remained the same across all PHs, the *Drivers* subset displayed the strongest significance when comparing

(a) One-step-ahead (b) 100 ms horizon (c) 200 ms horizon

Fig. 5: Prediction performance of the investigated subset and output pairs for Subject 5, across different prediction horizons.



its performance to the *Leg* subset for both the knee and ankle joints when using a 100 ms PH, with p-values of $p < 0.001$ and $p < 0.01$ respectively. Despite lower p-values ($p < 0.01$ and $p < 0.05$ respectively), this suggests that "driving" muscles could provide valuable information for more accurate gait predictions relative to solely leg muscles. Interestingly, the strongest significance, when comparing against the performance of the *Leg* subset, shifted from the *Drivers* to the *Trunk* subset when employing a 200 ms PH. This could be due to the importance of the core muscles in performing anticipatory postural adjustments in preparation for lower-limb motion [22], highlighting the importance of including the trunk muscles in predictive gait modelling.

The notion that human movement results from the coordinated co-contraction of muscle synergies has been widely studied in gait analysis [23]. While gait prediction models often prioritise lower-limb muscles as inputs, other muscle groups - particularly the trunk - play a crucial role in leg mobilisation and can enhance model accuracy, as demonstrated by our results. Future EMG-based gait models should therefore incorporate trunk muscles to improve prediction performance. Furthermore, the increased performance when using "driving" muscles as inputs reveals that the understanding of task-specific muscle roles could also provide indications on which muscle groups to prioritise when selecting gait model inputs. This physiologically informed input selection is particularly relevant when analysing steady-state walking; due to the cyclical nature of gait, the central nervous system (CNS) aims to minimise cognitive effort by reducing the number of muscles that behave volitionally [24]. Therefore, whilst a large number of muscles from the trunk and lower-limbs activate during gait, only a fraction of these are responsible for the generation of movement ("drivers") whereas the others focus on providing stability and balance. The improved performance when using the *Drivers* subset in this study would suggest that the concentric contraction of these muscles provide a more reliable EMG input [25], and that their activation could be more directly linked to the kinematic outputs observed. Future research should therefore prioritise the deeper physiological understanding of the target task, including muscle recruitment strategies and functional roles, which would enable the selection of the most relevant muscles as inputs, and further enhance model performance.

Although the *Trunk* and *Drivers* subsets consistently outperformed the *Leg* subset across all subjects and PHs, Figures 1, 3, and 4 reveal noticeable cross-subject differences in the comparative performance of the *Trunk* and *Drivers* subsets, especially for the hip joint, which could stem from individual variations in balancing strategies. Figure 6 illustrates the predicted joint angles in the one-step-ahead scheme for one of the validation folds of an example subject. As can be seen, the predictions from the *Trunk* and *Drivers* subsets for the hip and knee joints are closer to the ground truth than that of the *Leg* subset. Whilst this isn't as evident for the ankle joint in this example fold, Figure 6.c does give us insights on the balancing strategy used by the subject: the noticeably higher variance of the ankle angle throughout the gait cycle would suggest the subject was heavily reliant on adapting the ankle's angular position to maintain posture (i.e. using *ankle strategy* for balance), which is further corroborated by the reduced knee flexion during the stance phase. Considering the impact of gait strategies on muscle activation patterns and joint trajectories, understanding and accounting for these inherent cross-subject variations could help group individuals with similar EMG patterns and kinematic profiles. This could facilitate the development of generalisable models and should be a focus of future research.

V. Conclusion

Due to their role in both postural balance and motion during gait, *Trunk* muscles were shown to be a reliable source of EMG inputs for gait prediction models compared to the *Leg*, with an average normalised RMSE decrease of 5.62% for the knee joint and 2.10% for the ankle joint in the one-step-ahead scheme, 4.49% and 1.31% for a 100 ms PH, and 3.40% and 1.53% for a 200 ms PH. The *Trunk*, however, exhibited a larger performance variability for the hip angle and GC%, which could be related to physiological balancing strategies that differ across subjects. On the other hand, selecting *Drivers* as inputs to the model led to consistently higher prediction performances for the knee and ankle joints, with the *Drivers* subset resulting in an average normalised RMSE decrease relative to the *Leg* subset of: 6.60% and 3.07% (one-step-ahead), 5.63% and 2.15% (100 ms horizon),

(a) Hip angle (b) Knee angle (c) Ankle angle

Fig. 6: An example prediction output for the (a) hip, (b) knee, and (c) ankle angles averaged across gait cycles. The results shown here are for Subject 4 and correspond to the validation output of one of the folds in the one-step-ahead scheme.

and 4.06% and 1.35% (200 ms horizon) for both joints respectively. This study demonstrates that incorporating trunk muscles enhances prediction performance, and highlights the importance of understanding muscle functionality (drivers vs. stabilisers) for developing accurate gait models. Such insights could facilitate the selection of more relevant EMG inputs for LLEs, improving safety and reliability while also reducing costs. Future research should therefore prioritise the inclusion of trunk muscles and the further exploration task-specific muscle roles.

Egocentric Perception of Walking Environments using an Interactive Vision-Language System

Haining Tan, Alex Mihailidis, and Brokoslaw Laschowski

Abstract – **Large language models can provide detailed contextual understanding of a scene beyond what computer vision alone can provide, which has implications for robotics and embodied intelligence. In this study, we developed a novel multimodal vision-language system for egocentric visual perception, with an initial focus on real-world walking environments. We trained a number of state-of-the-art transformer-based vision-language models that use causal language modelling on our custom dataset of 43,055 image-text pairs for few-shot image captioning. We designed a new speech synthesis model and a user interface to convert the generated image captions into speech for audio feedback to users. Our system also uniquely allows for feedforward user prompts to personalize the generated image captions by incorporating human cognition in the decision making. Our system is able to generate detailed captions with an average length of 10 words while achieving a high ROUGE-L score of 43.9% and a low word error rate of 28.1% with an end-to-end processing time of 2.2 seconds. Overall, our new multimodal vision-language system can generate accurate and detailed descriptions of scenes, which can be further augmented by user prompts. This innovative feature allows our image captions to be personalized to the individual needs and preferences of the user, thus optimizing the closed-loop interactions between the human and generative AI models for understanding and navigating of real-world environments.**

I. Introduction

Vision plays a critical role in human locomotion by providing feedback about the environment, allowing individuals to navigate obstacles, maintain balance, and adapt their behavior accordingly. Visual information helps in the coordination of motor actions, such as stepping over obstacles or adjusting walking speed [1], by allowing the brain to predict and respond to changes in the terrain. Without vision, humans often struggle to move efficiently and safely in dynamic environments, highlighting the fundamental link between visual perception and movement. Inspired by this biological vision-locomotor control, computer vision systems, powered by deep learning, have likewise been developed for robotics [2]-[7]. However, language can provide a more detailed contextual understanding of a scene beyond what computer vision alone can provide.

The use of image captions for human-robot locomotion is a relatively unexplored area of research. By translating complex visual information into natural language, image captions could provide a high-level abstraction of the real-world (e.g., terrain types and obstacles), in addition to providing an intuitive user interface for human interaction. Textual information could be used by reinforcement learning algorithms to dynamically adapt the human and robot's walking strategy, allowing for real-time optimization based on the described scene [8]-[10]. Recent advances in generative AI and vision-language models [11] have opened new opportunities for this area of research. For example, [12] and [13] recently showed that vision-language models could interpret dynamic and unpredictable environments and execute complex navigational tasks from natural language instructions for robotics. Unlike traditional computer vision systems that focus on feature extraction, vision-language models can provide a richer understanding of scenes through textual abstraction. This enables detailed, user-personalized feedback, enhancing human-robot interaction.

Here we developed a new multimodal vision-language system for egocentric visual perception of real-world walking environments. We trained several transformer-based vision-language models [14]-[16], characterized by strong few-shot performance, which were pretrained on large vision datasets with natural language supervision [17]. Our system is able to generate accurate and detailed scene descriptions and identify obstacles, changes in terrain, and other critical navigational cues. We also developed a new speech synthesis model and a user interface to convert the generated text into audio feedback to users. Our system also uniquely allows for user prompts to tailor the generated image captions to the individual needs and preferences of the human user by incorporating human cognition in the decision making. Our system addresses key limitations in previous research, including dynamic scene interpretation beyond static object recognition, personalized user feedback for diverse navigation, and real-time closed-loop human-AI interaction for improved decision-making. To our knowledge, this is the first study to explore closed-loop human-AI interactions with vision-language models for real-world locomotion.

II. Methods

A. Image Dataset with Natural Language

We used the Microsoft COCO Captions dataset to finetune our vision-language models, a widely used benchmark dataset in computer vision and natural language processing [18]. The dataset contains over 200,000 images with human-generated captions. The images were collected from a wide range of contexts, including diverse settings such as urban environments and natural landscapes. For image captioning of walking environments, we adapted and manually curated a subset of the MSCOCO Captions dataset. We collected 43,055 image-text pairs based on the appearance of keywords. The average length of the captions in our new dataset was 10-15 words per cap-

tion. Prior to model training, we standardized the images to RGB format and performed a random split, allocating 90% and 10% of the images for training and testing, respectively.

B. Vision-Language Models

Our image captioning module is used to generate detailed descriptions of the images using large vision-language models. We used an encoder-decoder framework (Fig. 1), which is common in state-of-the-art vision-language models, to translate images to text. The system extracts features from the initial input image and converts the 2D data structure into a sequence of visual tokens through a vision encoder. We then perform a sequence-to-sequence translation using our text decoder to produce contextually relevant captions corresponding to the visual environment.

This encoder-decoder framework was first proposed using a convolutional neural network as the vision encoder and a long short-term memory (LSTM) network as the text decoder [19] for real-world multimodal perception. To improve the quality of the text generation, we applied a transformer-based architecture to perform causal language modeling [20]. Causal language models can capture extensive context because they attend directly to any previous token to predict the next token through the attention mechanism. They have consistently demonstrated impressive capabilities since the inception of large language models like GPT2 [15], which can capture extensive context because they consider all previous tokens to predict the next token. The transformer architecture is designed for parallel processing of sequences and uses attention mechanism to capture relationships among tokens, leading to a more coherent and contextually relevant text generation. Given a sequence of tokens, the general loss of causal language models is computed by:

$$L_{CausalLM}(x) = \frac{1}{T}\sum_{i=1}^{T} log\ P(x_i|x_{<i})$$

We first encoded the visual information into a sequence of embeddings analogous to word embeddings in language models. We used the Vision Transformer (ViT) model, which segments the image into patches for encoding [14]. Following the visual tokens, our transformer decoder starts the image caption generation with a start-of-sentence (SOS) token. To handle the multimodal nature of our task, we used bifurcated multi-head self-attention to separately model the interactions between the word and visual embeddings and the relationships among word embeddings themselves. This dual aspect of self-attention allows our models to produce captions that are both visually congruent and linguistically coherent. To model sequentially dependent structures, we masked the self-attention such that each caption token only attends to the preceding caption tokens and the visual tokens.

As shown in Fig. 1, our model also has the inherent flexibility to integrate user prompts as additional features for our image caption generation. If a user prompt is introduced, we initialize the decoding sequence after the visual embeddings and the SOS token, directing the decoder to generate the subsequent responses based on the user prompt. This novel function enhances the performance and human interaction for our multimodal system. We used two generative vision-language models as the backbone of our image captioning module, building on recent advances in vision-language pre-training [17], including the ViT-GPT2 and the Generative Image-to-text Transformer (GIT) models.

We first experimented with the ViT model as our vision encoder and the GPT2 as our text decoder [14]-[15]. The ViT model, designed to process visual data like sentences [14], splits the input image into a series of patches. These patches are then linearly embedded, with positional encodings added to retain the locational context, resulting in a sequence of visual embeddings that serve as an input to our language model. For text generation, the GPT2 model uses a robust transformer architecture to interpret these visual embeddings and generate descriptive captions. The pre-trained GPT2 comes with an extensive understanding of language and allows for relevant text generation that is synched with the visual input when adapted through fine-tuning on our new image-text pairs of real-world walking environments.

We also experimented with the GIT model [16] for image captioning. This unified transformer-based architecture uses the CLIP vision encoder based on contrastive learning between the vision and language modalities [17], which embeds visual tokens in the same embedding space as the language tokens, leading to a more consistent decoding process. The GIT model is pre-trained on a vast dataset comprising billions of vision-language pairs and demonstrates a strong capability to interpret complex visual environments and recognize scene texts without relying on external optical character recognition systems. We optimized the GIT model to provide descriptive navigational information.

We fine-tuned both vision-language models on our new custom dataset using an NVIDIA Tesla A100 GPU for 5 epochs with a learning rate of 5e-5. To reduce the high GPU RAM requirement due to the large model size and to accelerate model training, we used 16-bit floating precision for the numerical optimization on GPU instead of the commonly used 32-bit precision.

C. Speech Synthesis Model

To convert the image captions from our vision-language models into speech for audio feedback to users, we developed a speech synthesis model building on state-of-the-art text-to-

speech models. We used the SpeechT5 transformer encoder-decoder model as our backbone network with a set of modality-specific (speech/text) pre-nets and post-nets [21]. We used the text encoder pre-net to handle text inputs and the speech decoder pre-net and post-net for speech outputs. We used the text encoder pre-net to map the word tokens of our generated captions into a sequence of embeddings as inputs to our encoder. After the encoding, our speech decoder performs a sequence-to-sequence transformation to generate a log mel spectrogram conditioned on the hidden representations from the speech decoder pre-net and refined by the speech decoder post-net. We converted the output log mel spectrogram into an audio waveform via an additional vocoder neural network.

The SpeechT5 model can also convert to diverse voices, with the speaker embeddings as decoder inputs that capture a speaker's unique voice characteristics [21]. We used X-Vector speaker embeddings, which are derived from deep neural networks and have shown to be superior in capturing contextual information from speech frames. Our speaker embeddings were sourced from the CMU ARCTIC speech synthesis database [22]. Our system provides users the ability to customize the output voice by substituting different speaker embeddings. The vocoder we used to generate the final audio waveform is an advanced generative adversarial network (GAN), which is designed to generate high-quality speech waveforms from spectrograms [23].

We designed a custom end-to-end pipeline to integrate our image captioning module with our speech synthesis module. The pipeline starts with our image captioning module, which takes visual input from the environment and extracts image features. Our vision encoder then transforms the features into visual tokens, followed by our text decoder to generate descriptive captions conditioned on an optional user prompt. This textual information is then rendered into speech waveforms by our speech synthesis model to provide users audio feedback of the outputs, allowing the user to interact bidirectionally with the generative AI models and improve system performance by incorporating human cognition in the decision making.

D. User Interface Design

To enable human interaction and real-world practical use, we deployed our new multimodal system on the Gradio platform powered by cloud compute [24]. We configured the virtual environment required to support our models and all necessary scripts to execute the system. Additionally, we embedded our system in a web app based on the Next.js framework and hosted on GitHub Pages. We developed this web app with an emphasis on human interaction and a minimalist user interface design to promote accessibility across diverse user populations. Fig. 2 shows several examples of our user interface in action.

E. Performance Evaluation

We evaluated the performance of our vision-language models using several well-established metrics for text generation, including the Recall-Oriented Understudy for Gisting Evaluation (ROUGE) score. The ROUGE score measures the similarity between the generated text and a set of reference texts, which are typically human annotated. We focused on two common variants: ROUGE-N and ROUGE-L. The ROUGE-N score evaluates the overlap of n-grams, bordering sequences of *n* words, between the generated candidate and the reference text. We also used the ROUGE-L score that measures the longest common subsequence between the candidate and the reference. A higher ROUGE score indicates a better quality of the generated caption in terms of its similarity to the reference image captions that are human annotated. We also used the Word Error Rate (WER), which measures the

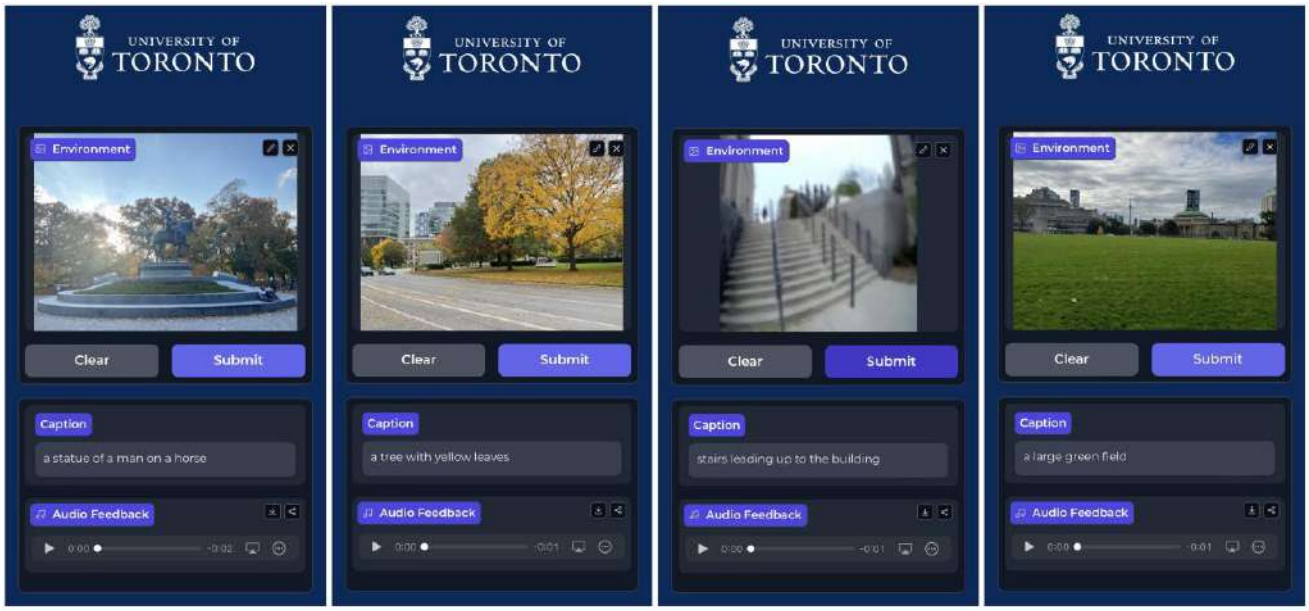

Fig. 2 Our custom-designed user interface to provide audio feedback to users describing the generated image captions by the vision-language models. Our interface also supports feedforward user prompts, allowing for closed-loop human-AI interactions and the ability to augment the decision making of the vision-language models with human cognition.

number of substitution, deletion, and insertion errors in the generated image captions compared to the reference text. It is calculated based on $WER = \frac{(S+D+1)}{N}$, where S is the number of substitutions, D is the number of deletions, and I is the number of insertions needed to transform the generated image captions into the reference text. A lower WER score indicates better system performance.

While our study mainly focused on algorithmic performance, practical usability is critical. To assess real-world applicability, we ran experiments to measure the system response times, user interaction efficiency, and overall reliability in dynamic environments. This strengthens the applicability of our research to robotics and human-computer interaction. We also tested the processing speed of our new system when deployed using cloud computing with different hardware for image captioning and feedback generation. We experimented with four different variants of our system: (1) text-only feedback generation, (2) text and audio feedback generation, (3) text-only feedback generation with user prompts, and (4) text and audio feedback generation with user prompts. We tested each of these four system variants with three different computing hardware configurations (Table 1).

III. Results

Our ViT-GPT2 vision-language model achieved a high ROUGE-1 score of 48.3%, a ROUGE-2 score of 21.8%, and a ROUGE-L score of 43.9% on the MSCOCO Captions dataset. Our GIT vision-language model achieved a low word error rate of 28.1%. In terms of deployed processing time (Table 2), our text-only feedback generation was the fastest across all computing devices, achieving speeds as fast as 2.2 seconds on the NVIDIA A10G GPU. Incorporating audio feedback led to slight increases in processing times (i.e., approximately 1 second). However, including user prompts significantly increased processing times, with average durations ranging from 11.3 to 15.3 seconds on GPU devices. The processing times varied depending on the computing hardware, with the NVIDIA A10G GPU consistently demonstrating faster information processing speeds compared to the Intel Xeon CPU and the NVIDIA T4 GPU. Processing times on the CPUs were approximately 2-3 times longer than those on GPUs.

IV. Discussion

In this study, we developed a novel multimodal vision-language system for egocentric visual perception, with an initial use case on understanding real-world walking environments. We trained a number of state-of-the-art transformer-based encoder-decoder models using 43,055 image-text pairs of scenes for few-shot image captioning. We also custom-designed a new speech synthesis model and a user interface to convert the generated text into speech for audio feedback to users. Most notably, our system uniquely allows for feedforward user prompts to personalize the generated image captions to the individual and immediate needs and preferences of the user (i.e., incorporating human cognition in the decision making), thus optimizing the closed-loop human-AI interactions for understanding and navigating real-world environments. Moving forward, this research has practical implications for robotics and embodied intelligence.

Table 1. The different computing hardware that we used to test our new multimodal vision-language system for image caption generation.

Computing	vCPUs	System RAM	GPU RAM
Intel Xeon CPU	2	16GB	0GB
Nvidia T4 GPU	4	15GB	16GB
Nvidia A10G GPU	4	15GB	24GB

Table 2. The average processing times for our system variants, including (1) text-only feedback generation, (2) text and audio feedback generation, (3) text-only feedback generation with user prompts, and (4) text and audio feedback generation with user prompts. Each system variant was tested with three different computing hardware.

System Variants	CPU	T4 GPU	A10G GPU
Text feedback	7.5s	2.4s	2.2s
Text and audio feedback	8.5s	3.0s	2.6s
Text feedback with user prompts	30.2s	12.5s	11.3s
Text and audio feedback with user prompts	31.1s	15.3s	12.4s

Our system is able to generate image captions with an average length of 10 words while achieving a high ROUGE-L score of 43.9% using the ViT-GPT2 model and a low word error rate of 28.1% using the GIT model. This is in comparison to previous image caption generation systems like [25], which score a bilingual evaluation understudy (BLEU) of 40.3% and a Metric for Evaluation of Translation with Explicit ORdering (METEOR) of 30.7%. One novelty of our system lies in fine-tuning the vision-language models on large-scale data specific to our application, which differs from previous research that simply applied pretrained models [13]. As mentioned by [26], fine-tuning can significantly improve the decision-making of vision-language models in tasks that require fine-grained visual recognition and visual semantic reasoning. These observations are in agreement with our study, which found that, after fine-tuning, the ROUGE score of the ViT-GPT2 model improved from 40.7% to 43.9%.

Regarding applications in robot control [27], our system uniquely includes the human in the loop by providing audio feedback as per the decision-making of the learning algorithm. While research in human-robot systems has included feedforward mechanisms for control [28]-[30], our system also provides feedback to the user. This integration can enhance user awareness compared to other systems, which could be beneficial for acceptance and trustworthiness of intelligent controllers. Our research increases the human interaction by including user prompts to tailor the generated image captions to the individual user needs and preferences, thus augmenting the vision-language models with human cognition. To our knowledge, this is the first study to develop and explore such capabilities for understanding and navigating real-world environments. As noted in [27] and [31], customizing robot behaviors to individual user preferences (e.g., while walking with a robotic prosthetic leg) is important for task performance and our new multimodal system provides a means by which the research community can explore such principles. Overall, a key innovation of our system is its integration of audio feedback and user prompts, enabling personalized captioning for individual needs and preferences. This feature improves the

adaptability for diverse tasks such as adjusting robot walking control strategies based on terrain descriptions.

Despite these developments, our study is not without limitations. For example, one major challenge of our system is the real-time processing requirements of the large vision-language models, with increased computational costs associated with the user prompts and audio feedback generation. Including the user prompts significantly increased processing times, with average durations ranging from 11.3 to 15.3 seconds on GPU devices. This can limit the practical deployment of our system in resource-constrained environments where GPU computational resources are not readily available.

Moving forward, further research is warranted to improve our system efficiency. Optimizing the large vision-language models to reduce computational demands could help broaden the applicability and impact of our research. Exploring the potential for edge computing to handle the information processing locally could decrease the latency and reliance on cloud computing, thus making our system more practical in diverse applications. Moreover, adding an automatic speech recognition model [32] would be beneficial, where the closed-loop human-AI interactions could be performed through conversational feedback. We are also especially interested in using this research to augment the decision-making of vision-language models with human cognition. In summary, here we developed a new multimodal, interactive vision-language system for egocentric visual perception, with an initial focus on understanding real-world walking environments. This system could be used to support research and development in robotics, embodied intelligence, and human-computer interaction.

ACKNOWLEDGMENT

This research study is dedicated to the people of Ukraine in response to Russia's ongoing invasion.

***Abstract*— Transfemoral amputees don and doff their prostheses at least daily, making inter-session classification performance important for clinical implementation of locomotion mode classification algorithms. Here, we present a deep-learning framework based on domain-adversarial training and few-shot learning fine-tuning to classify locomotion modes in unseen sessions or subjects' data across different prosthesis models. We validated the approach with a leave-one-session-out analysis repeated five times and made comparisons to a prosthesis-specific classifier. The dataset was created by merging data from two different prosthesis models (Vanderbilt University, VU, Gen 2 and Gen 3 powered knee-ankle prostheses), for a total of 31 sessions acquired across multiple days from 11 subjects. Subjects performed five locomotion tasks: level walking, incline and decline walking, and stair ascent and descent. Since transitions between different locomotion modes happen at different gait events, the analyses have been repeated for both heel-strike (HS) and toe-off (TO) events. At HS events, the proposed approach achieves a median f1-score of 99.12% and 92.41% on VU Gen 2 and Gen 3 prostheses respectively. At TO events, the proposed approach reaches a median f1-score of 96.83% with VU Gen 2 and 94.36% with VU Gen 3. The proposed framework is a promising solution for locomotion classification on data of previously unseen sessions or subjects, allowing classification on multiple prosthesis models.**

Keywords—locomotion mode classification, intention decoding, lower limb prostheses, deep learning

I. INTRODUCTION

Lower limb amputations severely impact the quality of life of a person, reducing their independence and mobility [1]. Individuals with an amputation present a less efficient [2], slower, and less stable gait when compared to non-impaired people [3]. These deficits are often exacerbated during the execution of challenging tasks such as stairs and ramps ascent and descent [4]. Powered lower limb prostheses can improve amputees' mobility due to the device's ability to provide net mechanical energy, mimicking the biomechanical functionality of biological joints across different locomotion tasks [5], [6], [7], [8]. These devices effectively assist amputees with various movements, but the process of switching between modes is not seamless. Changing locomotion mode with a key-fob or via mechanical movements can help achieve reliable mode transitions, but it can be perceived as unnatural and cumbersome.

Machine learning (ML) and deep learning (DL) algorithms have shown promising results in locomotion mode classification. These algorithms predict users' intended movements by interpreting prosthesis sensor signals [9], [10]. Both ML and DL approaches have achieved high classification accuracies in laboratory settings when trained on subject-specific data[10], [11]. However, these approaches are limited by their need for properly labelled training datasets from each end user. This limitation is particularly significant because achieving robust performance requires data collection across all desired locomotion activities and the transitions between them, which can be burdensome to collect [12].

To mitigate large subject-dependent training datasets, domain-generalization (DG) and few-shot learning (FSL) strategies can be adopted. DG aims to learn from multiple related but distinct domains (e.g., subjects) in such a way that the model can generalize to a previously unseen domain (e.g., unseen sessions or subjects) [13]. FSL, instead, aims to maximize the learning with limited datasets by transforming the learning process into a similarity comparison with one or more data points from previously seen domains [14]. Recently, both DG and FSL approaches have gained popularity in upper-limb prosthesis control, especially with electromyographic (EMG) signals as they help mitigate EMG's intrinsic subject dependency and temporal instability. DG approaches outperform traditional DL methods in cross-subject hand gesture classification, reaching accuracies similar to subject-specific approaches [15]. Similarly, DG-based DL models have improved the robustness of hand gesture classifiers across sessions held on different days with the same subject[16]. FSL approaches have shown comparable success, achieving convergence with only 20

samples from the target dataset[17] and outperforming traditional methods when dealing with limited datasets [18]

Here, we present a DL approach for transfemoral powered prostheses to classify five locomotion modalities: level walking (LW), stair ascending (SA), stair descending (SD), ramp ascending (RA), and ramp descending (RD). The approach uses signals from onboard prosthesis sensors and combines both DG and FSL methods to improve inter-session accuracy. We validated the approach using a dataset comprising 31 sessions from 11 different subjects, collected using two different prosthesis models: the Vanderbilt University (VU) 2nd and 3rd-generation powered knee-ankle prostheses [19].

II. MATERIALS AND METHODS

A. Dataset

Detailed experimental protocols for data acquisition are described in [20] for the VU Gen 2 prosthesis and in [21] for the VU Gen 3 prosthesis. All subjects were unilateral transfemoral amputees and experienced prosthesis users. The subjects performed locomotion circuits including walking on level ground, ascending and descending a 10° incline, and ascending or descending a 5 or 6-step staircase. During level walking, subjects performed multiple starts and stops, turns, and shuffling to increase step variability. For both prosthesis models, an experimenter managed locomotion mode transitions using a key fob, with each transition occurring 90 ms after heel strike (HS), flat foot (FF), or toe-off (TO) events [22]. The possible transitions are shown in Table 1.

The dataset comprises 24 acquisition sessions from 4 subjects using the VU Gen 2 prosthesis and 7 acquisition sessions from 7 subjects using the VU Gen 3 prosthesis. Data from both prostheses were merged into two single datasets, one for TO and one for HS events. FF events were excluded since the prosthesis always transitions from SA to LW, eliminating the need for classification. To enable DL models to work with both prosthesis generations, we selected only common signals between them: knee and ankle joint angles, velocities, and currents; leg anteroposterior, mediolateral, and vertical accelerations and angular velocities; shank and thigh angles; knee and ankle reference torques; and vertical load.

Signals from 210 ms before to 90 ms after the relevant gait events were selected and downsampled from 1 kHz to 200 Hz for computational efficiency. Information regarding dataset composition before the data augmentation and balancing processes is shown in Table 2.

Before the model training phase, one session was removed from the dataset and used as test dataset. We adopted dataset augmentation techniques on the training dataset to reduce overfitting. We created 2 additional copies of the TO and HS datasets by temporally shifting the input window in a range of ±10 ms. We created 10 additional copies by scaling the original datasets and 8 additional copies by scaling the shifted datasets. During the scaling process, each channel was multiplied by a factor sampled from a uniform distribution between 0.95 and 1.05. Data have been normalized on a channel basis using robust scaling, with a scaling range between the 2^{nd} and 98^{th} percentiles.

To maintain balance during the training process, we selected 20,000 steps for each prosthesis model for SD, RA, and RD locomotion modes in the HS dataset. Since LW steps are more prevalent both in the dataset and in real-world scenarios, we selected 30,000 steps for the LW class for each prosthesis model. This approach helps retain more variability for the dominant class. Similarly, for the TO dataset, we selected 25,000 steps from the LW class and 20,000 from the SA class for each prosthesis model. If a class had fewer steps than the desired threshold, we generated additional copies by adding zero-centered Gaussian noise ($\sigma = 0.025$). During testing, data were scaled and normalized as per the training dataset. The fine-tune dataset is extracted from the test dataset according to the process presented in Section B.2). More than 50 steps were always present for SD, RD, and RA classes and more than 90 for the SA class. The LW class was dominant in both TO and HS datasets, with more than 1000 steps.

B. Classification approach

We leveraged both DG and FSL approaches to develop a neural network capable of working on multiple prosthesis models and generalizing on previously unseen acquisition sessions or subjects. The training approach is based on two sequential steps: the first one leverages DG to pre-train the neural network; the second adopts FSL to fine-tune the network using a small portion of the test dataset. The process is repeated to create two distinct neural networks, one for the classification at HS and one for classification at TO.

1) Pre-training network (DANN-VAE)

A neural network with a hybrid structure between Domain-Adversarial-Neural-Network (DANN) [23] and a Variational-Auto-Encoder (VAE) [24] was adopted to pretrain the network (Fig 1a.) The main objective of the DANN-VAE is

TABLE II. DATASET COMPOSITION.

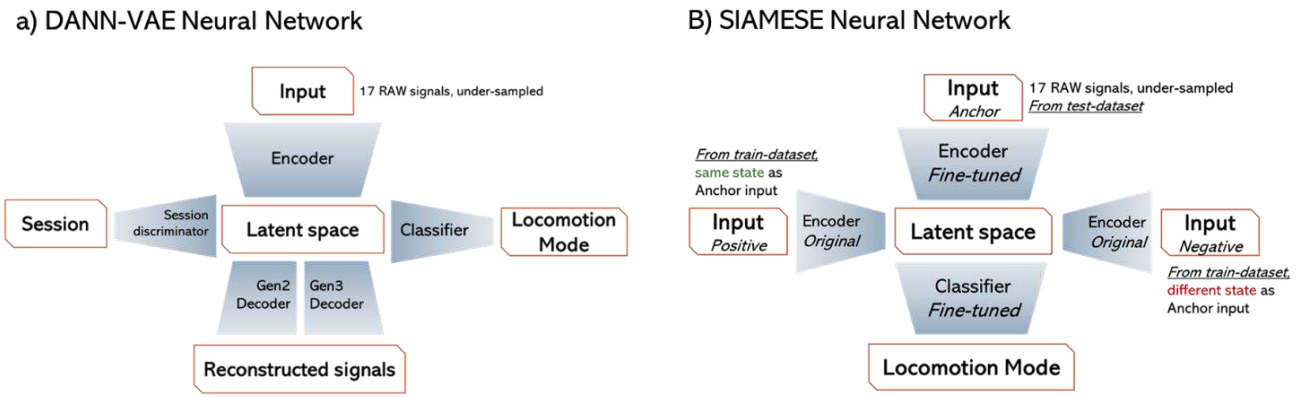

Fig. 1. Overview of the neural network structure used for the pre-training (a) and fine-tuning (b) processes.

to promote the Encoder sub-model to extract features from the input that allow the locomotion mode classification, via the Classifier sub-model, and the reconstruction of the input signals, via the Gen 2 and Gen 3 Decoders. Concurrently, the gradient from the Session discriminator is reversed to encourage the Encoder to extract session-independent features, as explained in [23].

The *Encoder sub-model* consists of an input layer for the time series, a corruptor layer that applies additive zero-centered Gaussian noise (σ=0.05), a sequence of three stride convolution layers with batch normalization and dropout, a flattening layer, and a latent encoder layer. In convolution layers, we used two-dimensional kernels to combine movement-related information across channels and temporal downsampling to encourage learning time-invariant features. Each convolutional layer used 256 filters, Leaky ReLU activations (α=0.2), and L2 normalization (λ=10-6). For the latent layer, we followed the implementation of [24], to map the extracted features to an 80-dimensional manifold.

The *Classifier and Session discriminator sub-models* have the same architecture. They consist of a corruptor layer (σ=0.05), a 64-neuron dense layer with batch normalization and Leaky ReLU activation (α=0.2), a dropout layer, and an output layer with softmax activation. Accordingly to [23], the loss of the Session discriminator is inverted for the training of the Encoder to promote the learning of session-invariant features.

Each *Decoder sub-model* consists of a corruptor layer (σ=0.05), a dense layer with batch normalization and Leaky ReLU activation (α=0.2), followed by a dropout layer and a reshape layer (features, 1, filters), and two stride transposed convolutional layers. The transposed convolutional layers are responsible for expanding the feature compressed by the Encoder to match the original input shape. Each transposed convolution layer uses 256 filters and two-dimensional kernels and is combined with batch normalization and dropout; the first layer uses a Leaky ReLU activation (α=0.2), and the second layer uses a Hyperbolic tangent activation. The hyperparameters σ, α, and λ of the sub-models have been selected in accordance with [25].

2) Fine-tuning network (SIAMESE)

To fine-tune the Encoder and Classifier sub-models, five samples from each prosthesis state are randomly selected from the test dataset. A prosthesis state is intended as the combination of locomotion modes before and after the gait event of interest (e.g., from LW to LW, from LW to RD, etc.). Next, the same dataset augmentation techniques adopted for the training dataset are applied to the fine-tune dataset. For the LW-to-LW state (i.e., steady-state level walking), 5 additional samples have been selected to retain the variability of the dominant class. The number of samples was selected to be low enough to be acquired with a very short calibration session; in this case, performing a circuit involving the desired locomotion modes 5 times.

The fine-tuning is a two-step process and the SIAMESE neural network used for it is shown in Fig. 1b. Firstly, the Encoder sub-model is finetuned using the approach described in [26]: an anchor sample from the fine-tune dataset is given as input to the Encoder, whose output is compared via the triplet loss with the output of two samples from the training dataset, one with the same and one with a different state. Secondly, the Classifier is fine-tuned on the fine-tune dataset only. Lastly, the fine-tuned DANN (DANN FT) is recompiled using the fine-tuned Encoder and Classifier sub-models.

C. Performed tests

Our approach is tested on the HS and TO datasets using a leave-one-session-out approach: one session is used for testing and the others for training. The testing protocol is repeated 5 times. The results of the performed tests are reported using the median f1-score and interquartile range (IQR). The Wilcoxon signed rank test (WSRT) was performed to compare different conditions. The approach is compared with a basic neural network composed of the Encoder, Decoder, and Classifier sub-model (VAE network). The models have been implemented in Keras v.3.4.1. Tests have been performed on a server (256 GB RAM, NVIDIA RTX A6000) using custom Python scripts (Python v.3.9.19).

During the *pretraining phase*, the DANN-VAE network is trained with a batch of 256 for 30 epochs, using the AdamW optimizer [27] with a learning rate of 0.0001 and an exponential decay rate for the 1st-moment estimates of 0.5. To promote training stability a warmup approach [28] has been adopted for the learning rate, starting from 0.00001 and reaching 0.0001 after 3 epochs.

During the *fine-tuning phase*, the Encoder is fine-tuned with a batch of 32 samples for 10 epochs, using the Adam optimizer with a learning rate of 0.0001 and an exponential decay rate for the 1st-moment estimates of 0.5. The Classifier

is fine-tuned for 10 epochs, using a 32-sample batch and the Adam optimizer with a learning rate of 0.00001 and an exponential decay rate for the 1st-moment estimates of 0.5.

The VAE network is trained for 50 epochs using data from a single prosthesis model, with a batch of 256. We used the

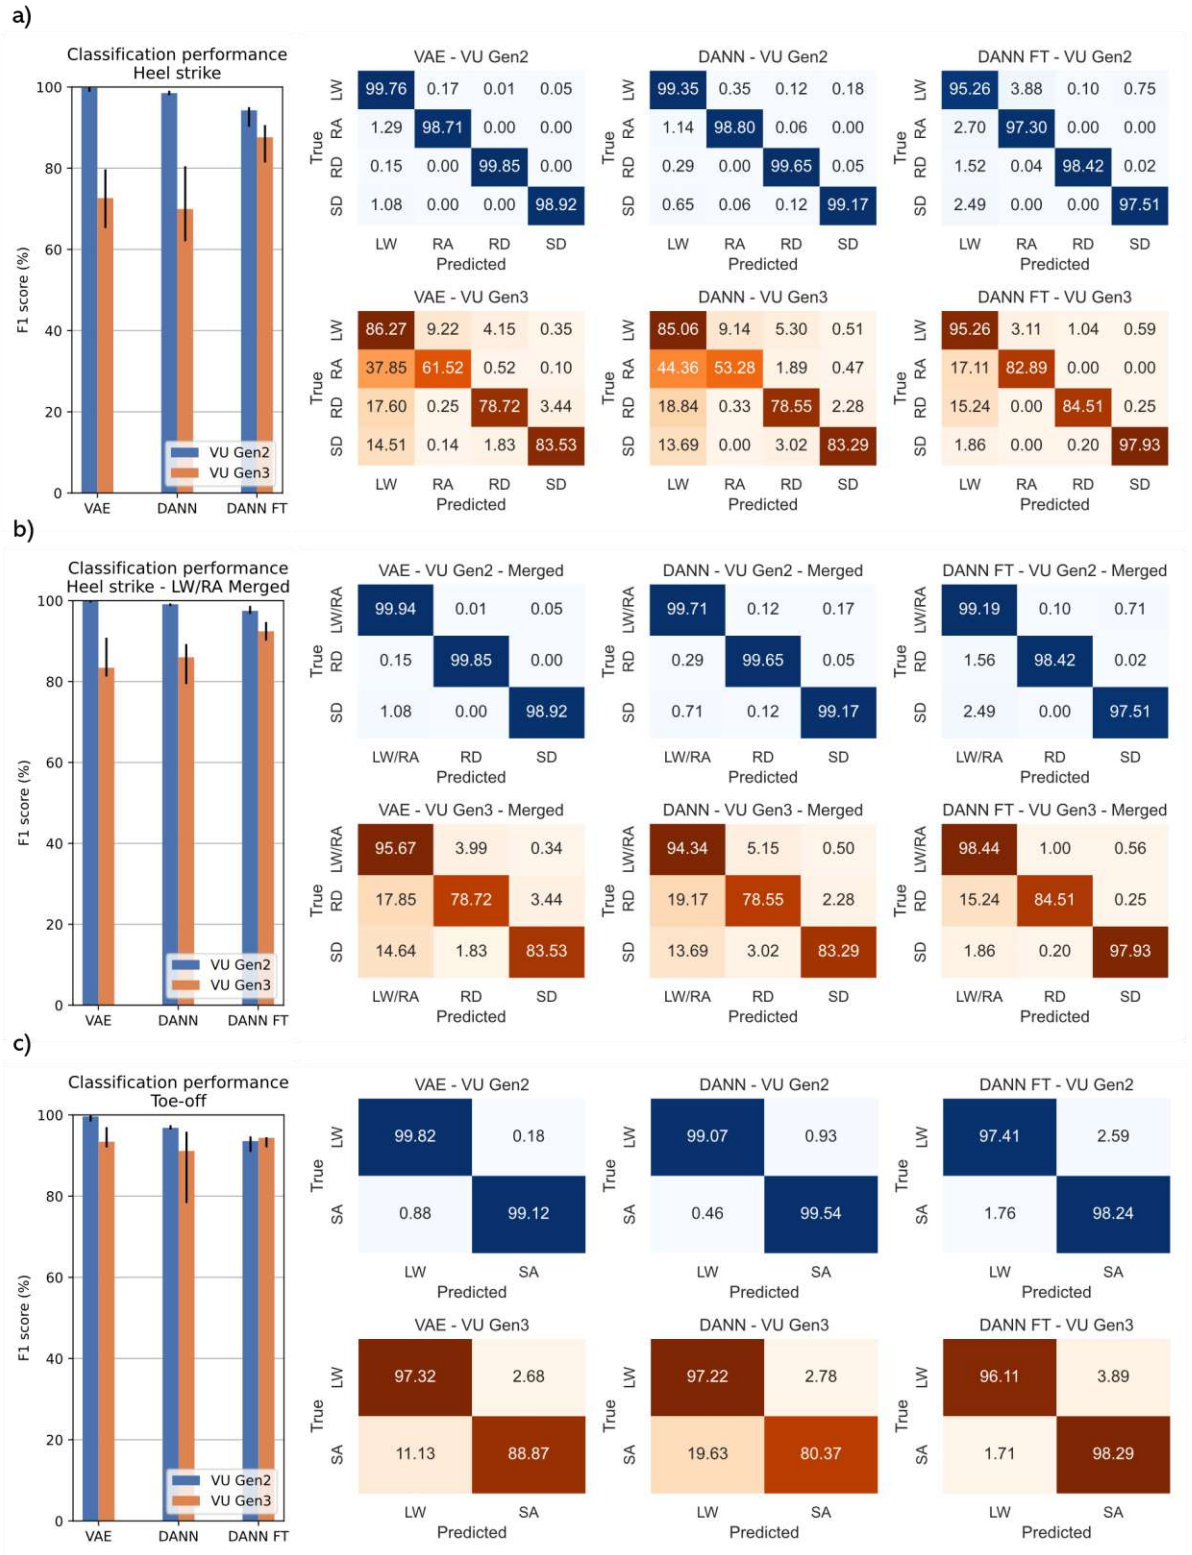

Fig. 2. Performance of VAE, DANN, and DANN FT on the HS dataset without merging LW and RA classes (a); the HS dataset merging LW and RA classes (b); the TO dataset (c). The bar plots show the median performance (F1-score, IQR) across the population. The confusion matrixes show the global accuracy on the population (i.e., each matrix is obtained by summing the population confusion matrixes and dividing by the total number of steps of the class).

Adam optimizer with a learning rate of 0.0001 and an exponential decay rate for the 1st-moment estimates of 0.5.

Notably, the prostheses used the same impedance parameters for the LW and RA activities. Therefore, despite the networks being trained on all the locomotion modes, it is possible to merge the LW and RA classes to improve the classification accuracy, without impacting the devices' usability [29]. Consequently, we present the results both with and without LW and RA classes merged.

III. Results

The accuracies of both the proposed and comparison approaches are different between prosthesis models, with lower accuracy and increased IQR with the VU Gen 3 (WSRT, $p < 0.05$) (Fig. 2). Additionally, on VU Gen 2 data, the tested models resulted in similar performances on steady-state and transition steps (WSRT, $p < 0.05$), while with VU Gen 3, the accuracy on transition steps is lower (WSRT, $p < 0.05$), except for DANN FT on TO dataset (Fig. 3).

Regarding the *VU Gen 2 results* on the HS dataset, if LW and RA classes are kept separated, VAE, DANN, and DANN FT reach median f1-scores above 94% (Fig. 2a, left). VAE and DANN show similar per-class accuracy, while DANN-FT shows a drop in classification performances, especially in the LW class (Figure 2a, right). If the LW and RA classes are merged (Fig. 2b, left), the f1-score of VAE, DANN, and DANN FT networks is above 96%, with the best performer being the VAE with 99.53% (WSRT, $p < 0.05$). The TO dataset results in a similar trend, with VAE, DANN, and DANN FT reaching median f1-scores above 94% (Fig. 2c, left) and VAE being the best performer with a median f1-score of 99.64% (WSRT, $p < 0.05$). The confusion matrixes show similar per-class accuracy between VAE and DANN (WSRT, $p > 0.05$), while DANN-FT shows a drop in classification performances (Fig. 2c, right).

Regarding the *VU Gen 3 results* on the HS dataset, the VAE and DANN approaches show no statistically significant differences in accuracy with and without LW/RA class merging (WSRT, $p > 0.05$). Median accuracies are above 70% with LW and RA separated and 83% with LW and RA merged. The DANN FT reaches a median accuracy of 87.63% without class merging and 92.41% with merging, overperforming both VAE and DANN networks (WSRT, $p < 0.05$) (Fig. 2a, b, left). In general, on VU Gen 3 data, all the proposed networks tend to misclassify RA, RD, and SD classes with LW. The issue is particularly prominent in the RA class. The per-class performance increases noticeably when adopting fine-tuning, especially in the SD class, where the accuracy reaches 97.93% (Fig. 2a, b, right). On the TO dataset, VAE, DANN, and DANN FT show no statistically significant differences in performances (WSRT, $p > 0.05$), reaching 93.40%, 91.14%, and 94.36% median f1-scores respectively (Fig. 2c, left). It is important to point out that DANN FT presents noticeably improved performances in classifying the SA class, reaching a 98.29% accuracy against 88.87% of VAE and 80.37% of DANN (Fig. 2c, right).

IV. Discussion

We developed and tested a DL approach using DG and FSL to classify locomotion intent across previously unseen acquisition sessions (or subjects) and multiple prosthesis models. This inter-session classification is crucial for clinical implementation, as users don and doff the prosthesis at least daily. Reducing the amount of data required for algorithm recalibration is essential to reduce the subject's burden and enhance usability of powered prostheses. Furthermore, the proposed approach's compatibility with multiple prosthesis models provides a strong foundation for further prosthesis-specific classification models.

Despite their similarity, data from the two prosthesis models present differences which are reflected in the results. At HS, the DANN FT network reached median f1-scores above 92% with VU Gen 3 prosthesis and above 97% with VU Gen 2. At TO, both VAE and DANN networks reach higher median f1-scores on VU Gen 2 data. HS results are consistent across the VAE, DANN, and DANN FT models on the VU Gen 2 dataset; DANN FT largely outperforms the

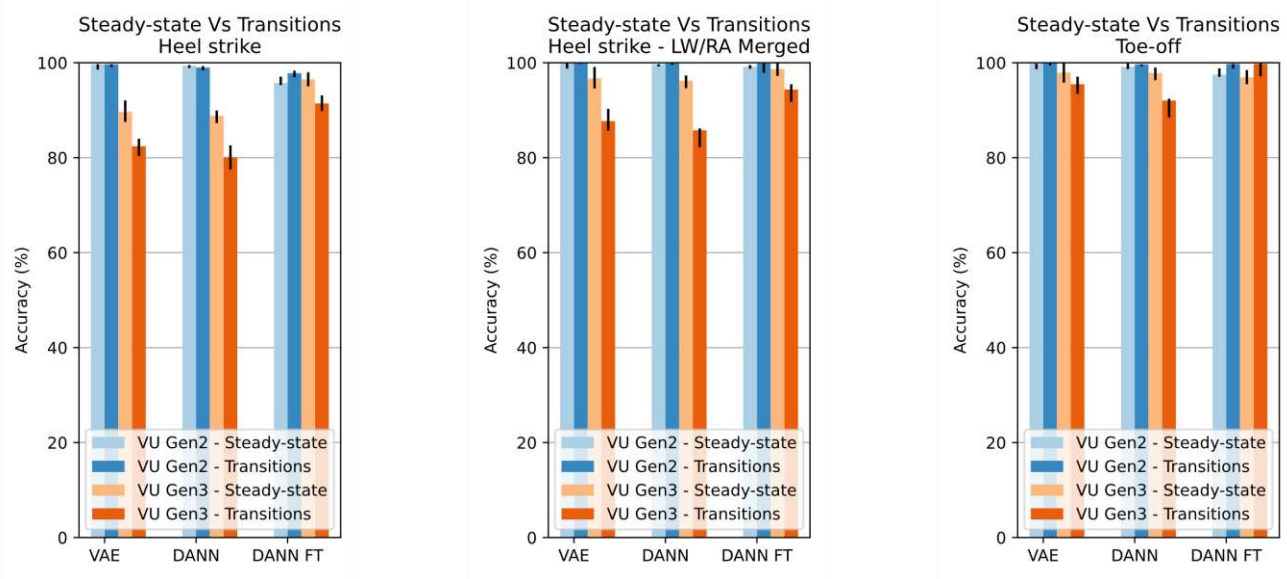

Fig. 3. Accuracy (median, IQR) of VAE, DANN, and DANN FT networks on steady-state and transition steps.

other two approaches with VU Gen 3 data instead. Similarly, DANN FT shows better accuracy in the SA class on the VU Gen 3 TO dataset, while performances drop slightly on the VU Gen 2 dataset. Such a different behavior may be traced to two factors: data quantity and data variability. The VU Gen 2 HS dataset is three times larger than the VU Gen 3 dataset but presents a comparable amount of transition steps, which are more complex to classify. Fig. 3 suggests that a larger dataset can help achieve higher accuracies on transition steps. Additionally, both HS and TO VU Gen 2 datasets contain multiple sessions per subject, promoting better inter-session accuracy since data from the tested subjects are present in the training dataset. Ultimately, session and prosthesis-specific approaches may achieve comparable performances when the dataset is large enough. Specifically, the VU Gen 2 data results suggest that fine-tuning may be avoided when multiple sessions per subject are available in large datasets. As suggested in the literature [18], fine-tuning can noticeably improve global and per-class accuracies when the dataset is smaller and more variable instead, as shown by the results on the HS and TO VU Gen 3 datasets.

The need for a common set of onboard sensors between the different prosthesis models represents the main limitation of the work, preventing the possibility of leveraging additional signals in newer prostheses. Additionally, differences in sensor placement and orientation require a fine inspection of data to ensure coherence and reduce possible errors. In a real-time scenario, signal transformation to match the neural network's expected input must be considered, potentially adding processing time.

In conclusion, the proposed approach successfully created a common base classifier for multiple prosthesis models, achieving accuracies above 92% and up to 99% on data from unseen sessions or subjects. This classifier can be further adapted via fine-tuning for small or highly variable datasets, enhancing both overall and per-class accuracies with only a limited fine-tuning dataset. Specifically, the fine-tuning samples used in this work can be acquired by performing a circuit including the target locomotion modes only five times. Additionally, the classifier's accuracies can be further improved by implementing prosthesis-aware constraints, which limit the possible classification outcomes based on the current prosthesis state.

We will next explore the real-time portability of the proposed approach, by assessing its classification and inference performances online with a powered prosthesis. Additionally, the approach will be tested on other prosthesis models to assess its generalizability.

Comparative Analysis of Neural Decoding Algorithms for Brain-Machine Interfaces

Olena Shevchenko, Sofiia Yeremeieva, and Brokoslaw Laschowski

Abstract – **Accurate neural decoding of brain dynamics remains an open challenge in brain-machine interfaces. While various signal processing, feature extraction, and classification algorithms have been proposed, a systematic comparison of these is lacking. Accordingly, here we conducted one of the largest comparative studies to evaluate different combinations of state-of-the-art algorithms for motor neural decoding in order to find the optimal combination. We studied three signal processing methods (i.e., artifact subspace reconstruction, surface Laplacian filtering, and data normalization), four feature extractors (i.e., common spatial patterns, independent component analysis, short-time Fourier transform, and no feature extraction), and four machine learning classifiers (i.e., support vector machine, linear discriminant analysis, convolutional neural networks, and long short-term memory networks). Using a large-scale EEG dataset, we optimized each combination for individual subjects (i.e., resulting in 672 total experiments) and evaluated performance based on classification accuracy. We also compared the computational and memory storage requirements, which are important for real-time embedded computing. Our comparative analysis provides novel insights that can help inform the design of next-generation neural decoding algorithms for brain-machine interfaces.**

I. Introduction

Brain-machine interfaces have potential to allow patients with physical disabilities to interact with and control robots and computers via neuroimaging techniques such as electroencephalography (EEG). EEG can capture the brain's neural dynamics associated with imagined limb movements, inducing specific oscillatory EEG processes such as desynchronisation of mu (8-12 Hz) and beta (16-30 Hz) rhythms, which reflect motor planning and execution. After task competition (i.e., resting state condition), these rhythms exhibit a synchronization, making EEG a powerful tool for decoding neural signals [1]. However, accurately decoding brain dynamics into control commands remains an open challenge. For example, EEG signals are prone to noise from eye movements and muscle activity [2]. Additionally, their low signal-to-noise ratio requires advanced signal processing and feature extraction to enhance data fidelity and extract meaningful neural information.

Different neural decoding algorithms for brain-machine interfaces have been proposed. For example, [3] developed a two-class neural decoder, comparing H∞ filters and artifact subspace reconstruction (ASR) with four different classifiers, including support vector machine (SVM), minimum distance to mean (MDM), MDM with filter, and linear discriminant analysis (LDA). In pseudo-online cross-validation experiments, they achieved accuracies of 66.2% for a generic model and 69.6% for a personalized model, with H∞ filter and MDM filter yielding the best neural decoding performance.

In terms of deep learning, [4] used recurrent long short-term memory (LSTM) neural networks, comparing them to LDA classifiers. After a two-step signal preprocessing using ASR and independent component analysis (ICA), the authors extracted neural correlates from 1-40 Hz frequency bands. The LSTM neural network outperformed their LDA model during online evaluation, achieving accuracies of 83.3%, 80.5%, and 75.3%. Similarly, [5] compared common spatial patterns (CSP) with LDA and a convolutional neural network (CNN) classifier, finding the CNN significantly outperformed CSP with an LDA model by 15-18%.

Our review of the literature revealed a wide variety of signal processing, feature extraction, and machine learning classification models used for motor neural decoding for brain-machine interfaces, with most studies creating their own algorithms. An unanswered question is: "what is the optimal combination of these algorithms to decode neural dynamics from the brain"? To help answer this question, here we conducted one of the largest comparative studies to develop and test different neural decoding algorithms (i.e., consisting of 48 combinations of state-of-the-art signal processing, feature extraction, and machine learning classifiers, each optimized for individual subjects) using a large-scale EEG dataset to determine the optimal combination for brain-machine interfaces (Fig. 1).

II. Methods

A. Brain Dataset

We used the open-source EEG dataset [6], which includes labels for gait events—"right heel strike" (190 ± 60 ms), "left heel strike" (180 ± 20 ms), "right toe off" (360 ± 20 ms), and "left toe off" (360 ± 20 ms)—from real-world walking experiments. We selected this dataset for its focus on short events, which require precise signal processing for accurate neural decoding. The brain data, recorded at 500 Hz from 26 healthy adults using 66 Ag/AgCl EEG electrodes in a custom 64-channel layout based on the 10-5 system, were referenced online to FCz. Foot movements were captured with 3D accelerometers, and EEG measurements were synchronized offline.

To maintain a large sample size while reducing experimental complexity, we used data from 14 subjects, with an average recording duration of 15 minutes per subject. We set aside the last two minutes of each recording as validation and

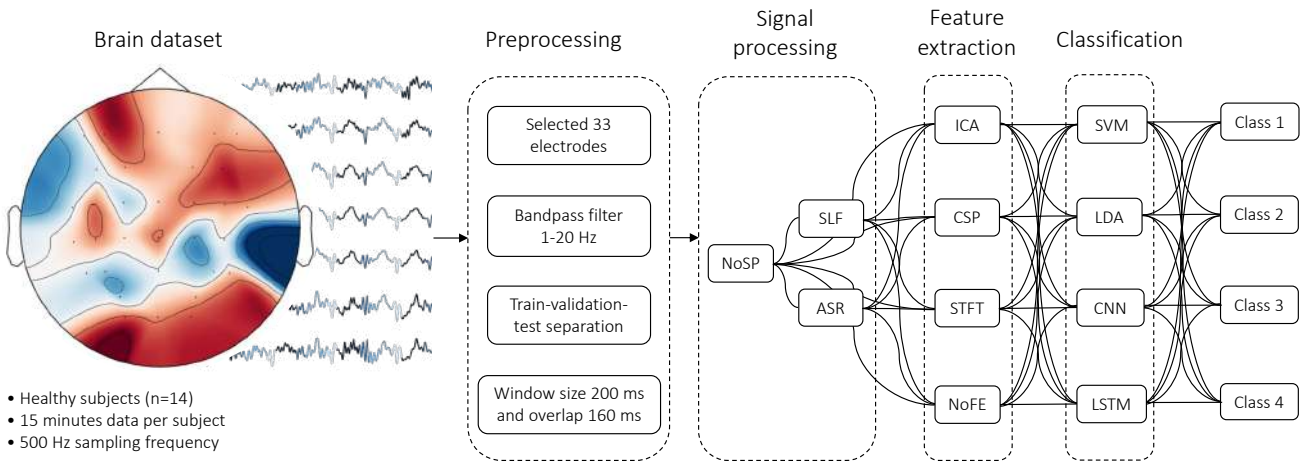

Fig. 1 Our experimental design. We tested different state-of-the-art signal processing, feature extraction, and classification algorithms to find the optimal combination for neural decoding of brain dynamics. Our baseline is no signal processing (NoSP) and no feature extraction (NoFE).

testing sets to prevent data leakage. We kept the sampling rate at 500 Hz. We experimented with several different electrode subsets for EEG channel selection, including a 24-electrode set designed for motor imagery and four custom sets targeting different cortical areas in the brain. Although we found no statistically significant difference in F1-score, the custom set, which included 33 electrodes (F5, F3, Fz, F4, F6, FC3, FC1, FC2, FC4, C5, C3, C1, Cz, C2, C4, C6, CP5, CP3, CP1, CPz, CP2, CP4, CP6, P5, P3, Pz, P4, P6, PO3, PO4, O1, Oz, O2), slightly outperformed the others with a 0.1 increase in F1-score.

For frequency filtering, we tested various combinations of high-pass (0.5–2.5 Hz) and low-pass (20–40 Hz) filters. We found that high-pass filters > 1.0 Hz significantly degraded classification accuracy, while low-pass filters > 20 Hz caused only a slight reduction. The optimal bandpass filter was 1–20 Hz, yielding the highest average F1-score across participants. We divided the data into windows, each labeled by the last element. We tested window lengths between 100-500 ms and overlaps of 20-160 ms. A window size of 200 ms with a 160 ms overlap provided one of the best F1-scores, generating fewer data points (i.e., 22,000 windows vs. 87,000 with a 150 ms window and 140 ms overlap) while ensuring enough data for training without exceeding the smallest class size (Fig. 2). Fewer windows helped reduce the memory storage and compute requirements.

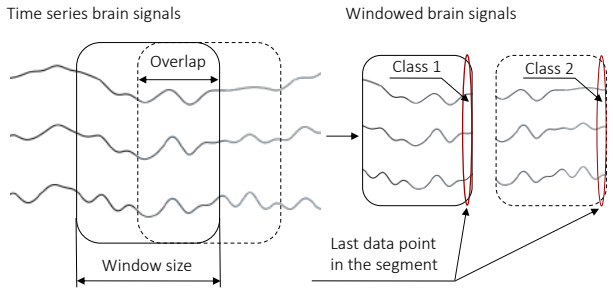

Fig. 2 Schematic of our dataset adaptation used for semi-real-time neural decoding, including segmenting the brain signals with fixed window size and overlap. We defined the class of an entire segment based on the class of the last data point within that segment, even if multiple classes exist in the same window.

Although each time series contains the same number of gait events, the duration of these events varies. Consequently, after sampling the data, as shown in Fig. 2, events with longer durations generated more windows, leading to an imbalanced final dataset. To address this, we evaluated two strategies: down sampling the overrepresented classes and retaining the original distribution. Up sampling was not considered due to the limited research on effective data augmentation techniques for EEG signals. Our analysis revealed that down sampling significantly reduced model performance. Therefore, we opted to retain the current class distributions to preserve the integrity of the neural data.

B. Signal Processing

Common artifact removal methods in brain-machine interface decoding range from simple thresholding to more advanced methods like blind source separation [1], improving signal-to-noise ratio and data quality. In our study, we compared two signal processing algorithms: 1) artifact subspace reconstruction (ASR), designed to handle non-stationary artifacts, and 2) surface Laplacian filter (SLF), which increases local information by estimating the radial current flow at the scalp. We also used normalized data as our baseline, centering values around the mean with unit standard deviation.

Artifact Subspace Reconstruction (ASR) is an automatic method for removing transient, large-amplitude artifacts with minimal computational effort. It learns artifact characteristics directly from data, thus increasing specificity. While ASR cannot completely eliminate all artifacts—such as those from eye movements, muscle activity, or poor electrode contact—it can significantly improve data quality, facilitating further processing like ICA decomposition [7].

Surface Laplacian Filter (SLF), or current source density, enhances neural data by emphasizing local brain dynamics and minimizing distant signal interference. It can improve spatial filtering, reduce noise, and highlight sensorimotor rhythms, by

calculating the second spatial derivative of scalp potentials, enhancing topographical localization and reducing volume-conduction effects. Its effectiveness depends on electrode density and spacing, and is independent of reference electrode choice. Positive estimates represent current flow from the brain to the scalp, while negative values indicate flow from the scalp to the brain [8].

C. Feature Extraction

Feature extraction is important to transform complex brain dynamics into discriminative representations. By reducing data dimensionality, it highlights subtle neural modulations related to movements, focusing on features such as event-related spectral perturbations and sensorimotor rhythms. This not only captures the spatial and temporal dynamics important for movement classification but also enhances the robustness and reliability of motor neural decoding.

We compared three state-of-the-art feature extraction methods used in brain-machine interfaces: common spatial patterns (CSP), which optimizes the spatial filters to distinguish brain dynamics; independent component analysis (ICA), which isolates the independent signals within the neural data; and short-time Fourier transform (STFT), which analyzes the frequency content of neural signals to capture both time and frequency information. We also used no feature extraction as our baseline for comparison.

Common Spatial Patterns (CSP), originally developed for binary classification, decompose signals into spatial patterns that maximize variance between two states. For multi-class classification, we used the "one-versus-rest" method [9], generating spatial filters for each class against the rest. We factorized covariance matrices from each segment to extract eigenvectors corresponding to the largest eigenvalues, forming spatial filters to improve the signal-to-noise ratio and capture discriminative features critical for motor neural decoding [10].

Independent Component Analysis (ICA), widely used in artifact removal and neural decoding, separates brain signals into independent sources. ICA finds an unmixing matrix based on component independence, enhancing the interpretability of brain data by isolating neural and non-neural sources. The independent components extracted serve as features, refining the representation of brain dynamics [11].

Short-Time Fourier Transform (STFT) applies Fourier transforms to windowed signal segments, providing time-localized frequency information. This method captures dynamic, time-specific brain activity, which is important for classifying event-related potentials, such as those associated with movement. In our study, we used a semi-real-time decoding approach with windowed brain signals.

D. Classification

The choice of classification algorithm is essential for motor neural decoding, influencing accuracy, computational efficiency, and real-time performance. We compared four classifiers: two deep learning models (i.e., convolutional neural network, CNN; and long short-term memory network, LSTM) and two classical machine learning models (i.e., support vector machine, SVM; and linear discriminant analysis, LDA).

Support Vector Machine (SVM) is a supervised machine learning algorithm that classifies data by finding the optimal hyperplane that maximizes the margin between classes, thus improving generalization. For non-linear classification, SVM uses a kernel function to map data into a higher-dimensional space where linear separation is possible.

Linear Discriminant Analysis (LDA) is a supervised method for classification and dimensionality reduction commonly used in neural decoding of brain dynamics [12]. The algorithm identifies a one-dimensional subspace such that a linear hyperplane best separates the classes while maximizing the difference in class means. It assigns larger weights to predictors that show greater class distinction.

Convolutional Neural Network (CNN) is a deep learning model that applies convolutions to capture spatial patterns. Increasingly used in brain-machine interfaces, CNNs are well-designed for neural decoding. We used EEGNet, which is the state-of-the-art CNN optimized for EEG neural decoding, which uses depthwise and separable convolutions to create an efficient deep learning model that captures key features while remaining lightweight [13].

Long Short-Term Memory (LSTM) networks are recurrent neural networks designed to process sequential data and capture temporal dynamics. We used the LSTM architecture by [4], which demonstrated over 80% accuracy in decoding human movements from brain signals. The network consists of two LSTM layers, where the output of the first layer serves as input to the second, followed by a fully-connected layer and a softmax activation function to return the class probabilities.

E. Experiments

We designed a new pipeline to compare the different signal processing, feature extraction, and classification algorithms for motor neural decoding. We conducted a total of 672 experiments, testing three signal processing methods, four feature extractors, and four machine learning classifiers, each of which were optimized for individual subjects. This resulted in 48 unique neural decoding algorithms per subject. Our experimental design is shown in Fig. 1. Our pipeline begins with preprocessing, including bandpass filtering (1–20 Hz), train-validation-test separation, and windowing with a fixed 200 ms rolling window size with a 160 ms overlap. The label "NoSP-NoFE" (i.e., no signal processing or feature extraction) served as our baseline for comparison.

We then applied signal processing per subject. For ASR, we trained the model on clean calibration data with a $K = 20$ cutoff, applying it to the train, validation, and test segments. The result was labeled ASR-NoFE. For SLF, we used the spherical spline method, calculating G and H matrices based on electrode distances and Legendre polynomial terms. This produced three datasets for each subject: NoSP-NoFE, ASR-NoFE, and SLF-NoFE.

We then applied the different feature extractors. Our preliminary tests revealed that CSP features caused significant accuracy drops in multiclass classification, so we used projected EEG signals instead for classification. CSP failed to converge with SLF-processed data for four subjects, so we also excluded this combination. For ICA, we used the FastICA algorithm (max_iter = 2000 and tol = 0.0001) fitting the model with the calibration dataset and applying it to the segmented train, validation, and test datasets. For STFT, we applied Fourier trans-

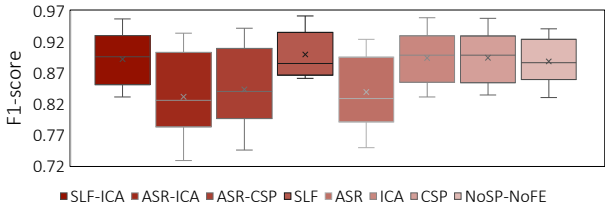

Fig. 3 Neural decoding performance (i.e., weighted F1-score) using our support vector machine (SVM) classifier across all 14 subjects for each combination of signal processing and feature extraction.

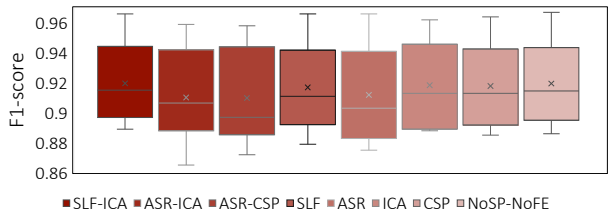

Fig. 6 Neural decoding performance (i.e., weighted F1-score) using our convolutional neural network (CNN) classifier across all 14 subjects for each combination of signal processing and feature extraction.

forms to each time window to obtain time-frequency representations for classifier input.

We then trained the four machine learning classifiers on each subject. We applied data normalization before the classification by standardizing each segment using the mean and standard deviation from the calibration train set. For SVM, we used the radial basis function kernel and optimized the regularization parameter C with cross-validation, testing values from 1 to 1000. For LDA, we used the shrinkage LDA, which regularizes class covariance matrices to prevent instability and overfitting. We selected the best shrinkage value via cross-validation, ranging from 0.01 to 1, using the least squares solver.

We trained our CNN model with hyperparameter optimization using four randomly selected subjects. We tuned batch size, number of temporal filters (F1), depth multiplier (D), and fully-connected (FC) size, with little variation in F1-scores (0.02). The final parameters were F1 = 8, D = 5, and batch size = 64. We also optimized the LSTM hyperparameters, although the results were less consistent than our CNN model. To address this, we used early stopping, scheduled learning rates, and fixed initial weights. The final parameters were batch size = 256, hidden size = 80, and FC size = 75. After training, we performed inference on the test set, calculating accuracy, precision, recall, and F1-score for each class, along with their weighted averages. Additionally, we measured compute time and memory usage. We carried out statistical comparisons using the Wilcoxon signed-rank test, with the null hypothesis that there is no significant difference in F1-scores between models. The NoSP-NoFE model served as our baseline. We ran all experiments on Google Colab with an NVIDIA T4 GPU and 50 GB of RAM. The full implementation of our experiments is available in our open-source repository at https://github.com/OlenaShev4nko/BMI-Decoder-Comparison.

III. Results

Our results are summarized in Table 1. We used weighted F1-score since it is the most representative metric for multiclass classification and can capture misclassification. For all our machine learning classifiers, adding STFT feature extraction significantly reduced neural decoding performance by up to 25%. Among all subjects, the highest-performing neural decoders used our CNN classifier. Data processing appeared to have a modest effect across the different classifiers, but additional processing slightly reduced the performance variability compared to using only data normalization.

For our SVM classifier, SLF produced the highest F1-score, with a Wilcoxon test p-value of 0.0063, indicating a statistically significant improvement over our baseline model.

Table 1. Average F1-scores across all 14 subjects for each neural decoding algorithm, including different combinations signal processing (i.e., SLF and ASR), feature extraction (i.e., ICA and CSP), and machine learning classification (i.e., SVM, LDA, LSTM, and CNN). NoSP means no signal processing and NoFE means no feature extraction.

Classifier	NoSP-NoFE	SLF-NoFE	ASR-NoFE	NoSP-ICA	NoSP-CSP	SLF-ICA	ASR-ICA	ASR-CSP

ASR, in contrast, consistently decreased our neural decoding accuracy. The distribution of SVM results for each signal processing and feature extraction combination is shown in Fig. 3. For LDA, ICA typically produced the highest F1-score, but the Wilcoxon test (p-value = 0.3076) showed no statistically significant difference from our baseline. Fig. 4 shows the LDA results for each combination of signal processing and feature extraction.

For our LSTM classifier, CSP generally yielded the highest F1-score. The Wilcoxon test (p-value = 0.0001) confirmed a statistically significant improvement compared to our baseline. Fig. 5 shows the distribution of LSTM results across subjects. For our CNN classifier, the combination of SLF and ICA achieved the highest F1-scores, but the Wilcoxon test (p-value = 0.8597) showed no significant difference from our baseline. The CNN classification results are shown in Fig. 6. Tables 2-5 show several examples of confusion matrices using our CNN classifier for one subject.

Our model training took 2 minutes for CNN and LSTM, 2.5 minutes for LDA, and 6 minutes for SVM. Our smallest classification algorithm was the CNN model at 0.03 MB, while the LSTM model was 2 MB, and LDA and SVM models were 50.2 MB and 278.5 MB, respectively. Including signal processing and feature extraction increased processing times. The average time per data segment (100 data points, 33 features) was 4 ± 0.3 ms for ASR, 38 ± 3 ms for SLF, 0.3 ± 0.05 ms for ICA, 0.4 ± 0.06 ms for CSP, and 0.2 ± 0.05 ms for STFT.

IV. Discussion

In this study, we conducted one of the largest comparative analyses testing different state-of-the-art signal processing, feature extraction, and classification algorithms to determine the optimal combination for motor neural decoding of brain dynamics. Using a large-scale EEG dataset of human movements in real-world environments, we tested three signal processing algorithms, four feature extractors, and four machine learning classifiers, each of which were optimized for individual subjects, resulting in 672 total experiments (i.e., 48 unique neural decoders per subject). We evaluated the performance of each combination based on weighted F1-score, inference speed, and model size, which have practical implications for real-time embedded computing. The results of our analyses can help inform the design of next-generation neural decoding algorithms for brain-machine interfaces.

Our research showed that CNNs achieve the best neural decoding performance compared to classical machine learning algorithms and other deep learning models such as LSTMs. Our CNN significantly outperformed SVM, LDA, and LSTM models, with the highest F1-score observed when in combination with surface Laplacian filter (SLF) and independent component analysis (ICA) (93%). Although this improvement was not statistically significant compared to our baseline CNN model, it underscores the robustness of CNNs to different preprocessing. These results are consistent with previous research [5], which reported that CNNs optimized on raw EEG signals outperform the conventional CSP+LDA pipeline. Moreover, for neural decoding of human locomotion, we extended the application of LSTM models to four-class classification, exceeding the binary classification of previous research [4]. While [4] found that LSTM with ASR processing outperformed LDA with CSP, we observed the opposite. Our results showed that ASR processing increased performance variability and reduced decoding accuracy, suggesting that its utility requires careful evaluation. Our LSTM neural network achieved its best performance when combined with CSP signal processing, yielding statistically significant improvements over the other combinations.

We also found that SVM achieves its best performance when paired with SLF processing, a statistically significant improvement over filtered and normalized data. These findings align with previous research [3], which found that SVM outperformed LDA under similar conditions. Furthermore, while our LDA classifier demonstrated its highest accuracy when combined with ICA, the Wilcoxon test revealed no significant difference compared to filtered and normalized data. These results highlight how classical models, despite their simplicity, can achieve competitive performance with appropriate signal processing. By comparing these models and signal processing algorithms, our study provides a comprehensive evaluation that bridges gaps in prior literature, offering deeper insights into optimal neural decoder designs.

Despite these developments, our study has several limitations. Our evaluation was limited to pseudo-online experi-

ments aimed at developing and proving the feasibility of our decoding algorithms. However, brain-machine interfaces are real-time, closed-loop systems and thus need to be tested online to demonstrate real-world performance. While we observed trends in higher F1-scores for some algorithms over others, we cannot be certain that these trends will generalize to other datasets or online measurements of brain dynamics. Furthermore, although the two signal processing and three feature extraction algorithms that we studied are among the most popular in motor neural decoding, especially for leg movements, other methods exist and should be considered in future research [3].

To address these limitations, we plan to extend the number of datasets and subjects used to optimize our neural decoding algorithms, including data from more invasive recording technologies. Data from other sensors such as inertial sensors or egocentric vision could be integrated in a multimodal system together with brain data to improve accuracy in predicting human movements [14]-[19]. Furthermore, rather than optimizing neural decoders for individual subjects, as done in our study, future research could explore principles of transfer learning to develop a general model with the best combination of signal processing, feature extraction, and classification, trained on brain data from all subjects [20]. This general model could then be compared to our neural decoding algorithms optimized for individual subjects.

In addition to testing other signal processing and feature extraction algorithms, we also plan to expand the number of machine learning classifiers for comparison such as hybrid CNN-LSTM model, graph neural networks, unsupervised autoencoders and transformers, which have recently gained significant attention. Several studies have already demonstrated that transformers can outperform CNNs in EEG classification and prediction tasks [21]-[22]. A detailed comparison of these models using our new pipeline would be valuable. Combining multimodal signals in neural-machine interfaces could also offer more reliable input for diverse populations and applications [23]. We also plan to deploy our neural decoding algorithms to evaluate real-time embedded computing performance and extend our research to simulated environments [24]. In conclusion here we developed and tested dozens of neural decoding algorithms (i.e., consisting of different signal processing, feature extraction, and machine learning classifiers) using a large-scale EEG dataset to determine the optimal combination for brain-machine interfaces.

Adapting Biomimetic Kinematics for Controlling a Powered-Knee, Passive-Ankle Prosthesis Across Inclines

C. Andrew Seelhoff[1], T. Kevin Best[2] , and Robert D. Gregg[1,2]

***Abstract*— Despite promising benefits for people with limb loss, powered multi-joint prostheses from the research field have not been translated into the clinical space. Commercial powered knee prostheses like the Össur Power Knee™ are paired with passive feet which lack the range of motion of biological ankle joints, especially on steep inclines. This discrepancy prevents the direct translation of emerging biomimetic control methods for powered knee-ankle prostheses, which implicitly assume both joints exhibit normative biomechanics. To enable commercial prostheses to benefit from biomimetic control methods on inclines, this paper adapts a continuous knee kinematic model to minimize the difference in global foot angle compared to able-bodied reference data, under the assumption that the ankle joint is locked. In a pilot experiment with an above-knee amputee participant, our adapted controller produced substantial benefits compared to a baseline controller that only tracks able-bodied knee trajectories. Level-ground walking performance is similar to existing methods despite the change of objective, and on steep inclines, prosthesis load-bearing and center of pressure progression are restored to near-normative levels. These results show a promising pathway towards translation of biomimetic control methods onto existing commercial hardware, allowing near-term impacts with tangible benefits for prosthesis users.**

I. Introduction

There are over two million people with limb loss in the United States [1], and this population is expected grow a further 150% by 2060 [2]. The limb loss population experiences reduced quality of life as most current prosthetic limbs are unable to replicate the joint torques normally provided by intact musculature, resulting in an increased metabolic cost of walking [3], [4]. Activities which require net-positive work, such as walking up ramps or stairs, further exacerbate these deficiencies. In response, the research field has made substantial progress developing multi-joint powered prostheses, which place motors at the knee and ankle joint to allow the limb to propel itself and assist the user during ambulation [5], leading to reductions in metabolic cost, increasing walking speed, and even reducing compensatory behaviors [6]–[8].

There has been limited, but growing, commercial development of powered prostheses, including one powered ankle, the Empower (Otto Bock, Duderstadt, Germany), and three powered knee prostheses: the Power Knee™ (Össur hf, Reykjavík, Iceland), the Intuy Knee (Reboocon, Delft, The Netherlands), and the Bio Leg (BionicM, Tokyo, Japan). The primary obstacles towards clinical adoption of powered prostheses are their bulkiness and complexity compared to existing passive solutions [5]. While commercial powered knees are typically heavier than passive counterparts, they occupy a similar form factor. Powered ankles, however, are much heavier and larger than passive Energy Storage and Return (ESR) feet, which consist of fiberglass or carbon fiber springs. Combining powered joints also presents a complex, interdependent control problem, often involving dozens of user-specific parameters [9]. As a result, commercially-available powered transfemoral prostheses primarily use a *powered-knee, passive-ankle* configuration to minimize distal mass and reduce complexity.

Although ESR feet lack a physical joint, they can emulate a limited ankle range of motion (RoM) through deformation of the elastic heel and keel. ESR feet are designed primarily to facilitate level walking, where able-bodied RoM is relatively limited [10], but in other activities, the prosthesis-side gait kinematics depart substantially from able-bodied data [11], [12]. As a result, prosthesis users experience reduced symmetry and stability [13], [14] and must make gait compensations on inclines, [15], declines [16], and stairs [17]. Effective RoM can be marginally increased by making the ESR foot less stiff, although this comes at a cost of lower energy-return, leading to further physical and perceptual changes to gait [18]–[20].

Because of these limitations of ESR feet, powered knee, passive-ankle prostheses have not yet achieved the versatility of powered knee-ankle prostheses, which can facilitate variable-speed/incline walking [21]–[23], variable-height stair climbing [24], [25], and continuous transitions between these activities [26]. Many multi-joint controllers are designed to reproduce able-bodied joint trajectories to promote more normative gait while reducing (or eliminating) hand-tuned parameters [27]–[29]. Able-bodied joint patterns are typically parameterized by a phase variable, which can be calculated using residual-limb thigh kinematics to synchronize the prosthesis to the user's movement [21], [22], [30]. Our group initially implemented position controllers using continuous-phase/task models of able-bodied joint kinematics [31], [32], although shortcomings in resultant gait kinetics led to the use of data-driven joint impedance during the stance phase [22]. These hybrid kinematic impedance controllers improved joint work [22], [24], symmetry [33], and endurance measures [34] when implemented on a prototype powered knee-ankle prosthesis [35]. However, these biomimetic controllers cannot be directly translated onto

powered-knee, passive-ankle prostheses, as they implicitly expect biological ankle behavior which ESR feet cannot provide on uneven terrains. To have tangible short-term impact, we must adapt multi-joint prosthesis control methods for use with powered-knee, passive-ankle prostheses, especially for inclined walking.

In this work, we introduce a novel knee prosthesis controller designed to account for ESR foot behavior on inclines. As a proof-of-concept, we alter the knee kinematic model of a PD position controller by simulating the effects of an ESR foot on able-bodied foot kinematics. We describe the optimization process for generating continuous knee trajectories as a function of gait phase, walking speed, and incline, focusing on achieving more biomimetic foot angle kinematics in place of biomimetic knee angle kinematics. Pilot experiments with one transfemoral amputee subject suggest the proposed *ESR-Adapted* controller greatly mitigates gait alterations imposed by ESR feet on steep inclines without sacrificing level-ground performance when compared to a biomimetic kinematic control strategy. The results demonstrate the potential for our controller to be further refined and adapted to other gait tasks, improving mobility for users of powered-knee, passive-ankle prostheses and making the case for more widespread adoption of powered prostheses.

II. Methodology

A. Hardware Overview

In this study, we utilize the latest generation Power Knee from Össur (model PKA01). The drivetrain of the Power Knee consists of a brushless DC motor, a harmonic drive transmission, and a compliant linkage that connects the transmission output to the knee joint. The torque-angle relationship of the compliant linkage is nonlinear, stiffening under increasing deflection. The knee assembly weighs 2.7 kg with the battery, and the joint has a 120 deg RoM. The removable lithium ion battery powers the motor and the embedded control electronics.

The sensing suite includes joint and motor position encoders, a shank-mounted inertial measurement unit, and an array of ground reaction force hall-effect sensors [36]. Based on the manufacturer's recommendations, we paired the Power Knee with the Össur Pro-Flex LP carbon fiber ankle-foot prosthesis. We selected the appropriate size and category foot (size R28 category 5) for our participant based on the sizing guidelines in the Pro-Flex LP catalog. The entire prosthesis, including the Power Knee, pylon, foot, shoe, and other hardware components configured for our participant, weighed 3.9 kg.

B. Controller Overview

Previous work in our group has shown success with continuous parametrization of joint angles in walking as a function of gait phase, incline, and speed [31], [32]. We adapted this control architecture for use on powered-knee, passive-ankle prostheses by removing the ankle dependency, yielding a singular position controller for the knee (Fig. 1). We constructed and tested two kinematic models for this

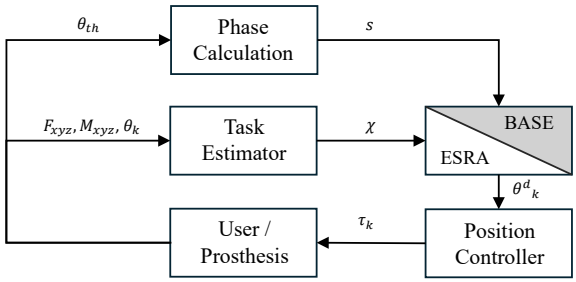

Fig. 1. Block diagram of the proposed control architecture, adapted from [32]. A phase estimate s and task estimate χ feed into either the baseline model (BASE) or the ESR-Adapted model (ESRA). While the BASE model generates a knee trajectory based on able-bodied reference data, the ESRA model described in this work accounts for ESR behavior. Both models produce a desired knee angle θ_k^d which is sent to the PD Position controller, driving the prosthesis. Interactions between the user, prosthesis, and environment generate external forces and moments F_{xyz}, M_{xyz} and alter the knee and thigh angles θ_k, θ_{th}.

controller. The *baseline* (BASE) model is similar to the model used in [31], [32], directly tracking biological knee kinematics assuming the ankle is also actuated within biological ranges of motion. The *ESR-Adapted* (ESRA) model was designed to account for ESR foot behavior.

Both models interfaced with the same PD position controller, which was parameterized by the gait phase s and task vector $\chi = (v, \gamma)$, where v represents the user's forward speed and γ represents the ground slope. The PD controller commanded a torque τ_k and was defined as

$$\tau_k(s,\chi) = k_p e(s,\chi) + k_d \dot{e}(s,\chi), \tag{1}$$

where $e(s,\chi)$ represents the error in knee position $\theta_k(s,\chi)$ compared to a desired position $\theta_k^d(s,\chi)$, and $\dot{e}$ is its derivative. The proportional and derivative gains k_p and k_d were set to values previously used by our group for PD position control of a multi-joint powered prosthesis. The *task space* spanned forward speeds within $v \in [0.8, 1.2]$ m/s and slopes within $\gamma \in [0, 10]$ deg.

C. Knee Kinematic Models

Following previous work from [31], we model the knee angle trajectory for a given task χ as a phase-dependent Fourier Series of degree k with the following equation:

$$\theta_k(s,\chi) = \alpha_0(\chi) + \sum_{n=1}^{k} (\alpha_n(\chi)\sin(2\pi n s) + \beta_n(\chi)\cos(2\pi n s)), \tag{2}$$

where $s \in \{0,1\}$ and the weights $w(\chi) = (\alpha_0, ..., \alpha_k, \beta_1, ..., \beta_k) \in \mathbb{R}^{2k+1}$ are used as decision variables for optimization. Selecting the degree $k = 5$ enables the Fourier Series to successfully replicate able-bodied knee kinematic trajectories without overfitting. With all terms being periodic, the Fourier Series ensures there is continuity between the end of one stride and the start of the next. We can also write (2) as

$$\theta_k(s,\chi) = A(s,\chi) w(\chi), \tag{3}$$

where $w(\chi) = (\alpha_0, ..., \alpha_5, \beta_1, ..., \beta_5) \in \mathbb{R}^{11}$. The matrix $A \in \mathbb{R}^{1500\times11}$ contains 10 concatenated sets of the basis functions 1, $\sin(2\pi s)$, $\cos(2\pi s)$, ..., $\sin(10\pi s)$, $\cos(10\pi s)$ evaluated at 150 discrete values of phase s, linearly spaced between 0 and 1, for the given task χ. Each $\mathbb{R}^{150\times11}$ set of basis functions corresponds to one of the $n = 10$ subjects in an able-bodied reference dataset collected by our group [37].

For both kinematic models, at each task, we aim to find the optimal weights $w_{\text{opt}}(\chi)$ to satisfy our control objective $J(s, \chi, w)$, which differs between the two models:

$$w_{\text{opt}}(s, \chi) = \arg\min_{w\in\mathbb{R}^{11}} J(s, \chi, w). \tag{4}$$

The specific objective functions and optimization methods used for each kinematic model are described below. For each model, we solve the optimization problem for a set of discrete tasks within our task space according to the able-bodied reference data from n = 10 subjects [37]. We include all available speeds ($v = \{0.8, 1.0, 1.2\}$ m/s) and all positive-slope inclines ($\gamma = \{0, +5, +10\}$ deg) from the dataset, resulting in $3 \times 3 = 9$ discrete tasks for evaluation. Then, using the fact that our function for θ_k is linear with respect to w, we perform bilinear interpolation in terms of speed and incline between these nine tasks to generate continuous kinematic surfaces.

1) Baseline Kinematic Model: The baseline kinematic model is created using the existing methodology in [31] for comparison with our proposed kinematic model. Our objective function is the error in knee trajectory:

$$J_{\text{BASE}}(s, \chi, w) = \|(A(s, \chi)w - \theta_k^{\text{ref}}(s, \chi)\|^2, \tag{5}$$

where $\theta_k^{\text{ref}}(s, \chi)$ is the able-bodied reference knee trajectory at phase s and task χ. Similar to A, the reference trajectories for each subject are concatenated vertically to allow for subject-average optimization. Substituting (5) into (4) yields a least-squares optimization problem with a known closed-form solution. Fig. 2 (left) shows the kinematic surface generated through optimization across all inclines at a fixed speed of 1 m/s.

2) ESR-Adapted Kinematic Model: Previous pilot testing revealed that our baseline kinematic model, which assumes the ESR foot behaves exactly as an able-bodied ankle, can result in unfavorable behaviors during activities with high ankle RoM. These shortcomings inform the design of a modified controller which accounts for ESR foot mechanics. This control method requires an objective function that allows the Power Knee to influence foot behavior while accounting for the ESR behavior itself.

First, we model the alterations to biological kinematics caused by an ESR foot. Setting the kinematic origin of the leg at the hip, forward kinematics define the position of each joint center progressing distally, ending with the (global) foot angle and position. An ideal model would simulate the deformation of the ESR foot through ground contact simulation, but the sheer variety of ESR feet in terms of stiffness, RoM, and size make this approach practically infeasible for generalization. As such, we elect to take the reduced RoM to its extreme, modeling the ankle as fixed at its neutral ankle, yielding the following equation for foot angle, defined with respect to the horizontal:

$$\theta_{\text{foot}}(s, \chi) = \theta_{\text{thigh}}^{\text{ref}} - \theta_k + \theta_{\text{ankle}}^{\text{f}} = \theta_{\text{thigh}}^{\text{ref}} - Aw, \tag{6}$$

where $\theta_{\text{thigh}}^{\text{ref}}$ is the reference global thigh angle angle from [37] with all ten subjects' trajectories concatenated vertically and $\theta_{\text{ankle}}^{\text{f}}$ is the fixed ankle angle, which is 0 deg with respect to vertical. All variables are dependent on the current phase s and task χ.

The ankle's rigidity results in an overly-plantarflexed foot throughout stance phase in simulation, which would result in improper loading on the keel of the prosthesis. A feasible optimization objective would be restoration of a biological foot angle trajectory through stance phase. Since there is no ground contact during swing phase, we use a biological knee angle tracking objective after toe-off to allow for biomimetic swing behavior. The first component of this modified objective function is

$$J_{\text{ESRA}}^1(s, \chi) = \begin{cases} \|\theta_{\text{foot}} - \theta_{\text{foot}}^{\text{ref}}\|^2 & \text{for } s \le s_{\text{TO}} \\ J_{\text{BASE}} & \text{otherwise} \end{cases} \tag{7}$$

with the toe-off threshold $s_{\text{TO}} = 0.64$ selected based on able-bodied reference data [37].

In preliminary testing, the foot angle objective alone caused rapid extension of the knee in early stance phase. To balance this behavior and make heel-strike and midstance smoother, we penalize the knee velocity $\dot{\theta}_k(s)$ during the first three-quarters of stance phase, giving the second objective component

$$J_{\text{ESRA}}^2(s, \chi) = \begin{cases} (4 - \frac{4s}{0.75 s_{\text{TO}}})\dot{\theta}_k(s)^2 & \text{for } s \le 0.75 s_{\text{TO}} \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

where the coefficient on $\dot{\theta}_k(s)^2$ linearly decreases from 4 to 0 over the range $s \in [0, 0.75 s_{TO}]$. The knee velocity is given by

$$\dot{\theta}_k(s) = \frac{\partial A}{\partial s}\frac{\partial s}{\partial t}w, \tag{9}$$

where $\frac{\partial A}{\partial s}$ is the element-wise derivative of A with respect to phase, and $\frac{\partial s}{\partial t} = 1$ as we assume each stride has a duration of one second.

Due to the linearity of θ_k, θ_{foot}, and $\dot{\theta}_k$ with respect to w, our final objective function $J_{\text{ESRA}} = J_{\text{ESRA}}^1 + J_{\text{ESRA}}^2$ is also linear in terms of w, allowing us to once again approach this problem using least squares. However, since we do not explicitly command the knee angle, we must enforce joint limits to ensure the Power Knee stays within its RoM, $\theta_k \in [0, 120]$, yielding a constrained least squares problem which can be solved using a Quadratic Program. The resultant kinematic surface is shown in Fig. 2 (right) for a fixed speed of 1 m/s. Fig. 3 shows the simulated foot trajectories for both models in comparison to reference data.

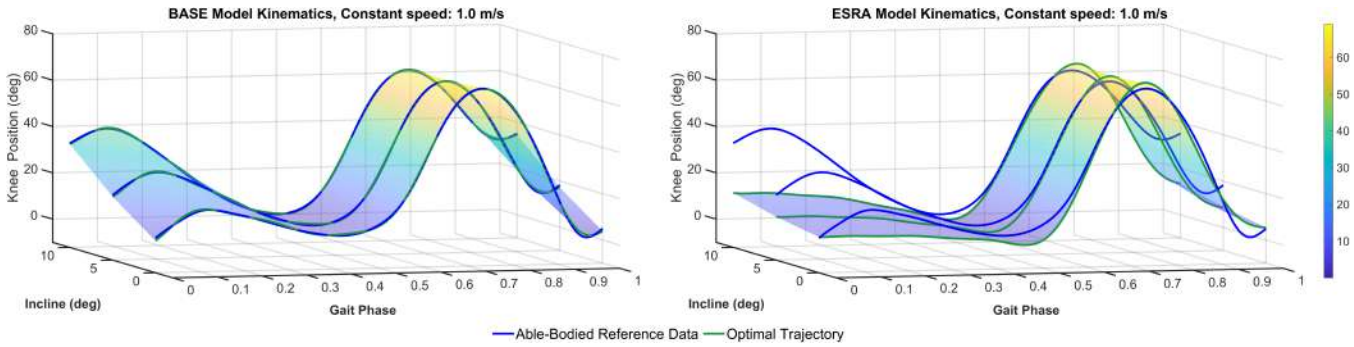

Fig. 2. Kinematic Surfaces for the baseline (BASE) and ESR-Adapted (ESRA) controllers for a constant walking speed of 1 m/s. Note the optimized and able-bodied reference trajectories from [37] overlap for the BASE controller but not for the ESRA controller.

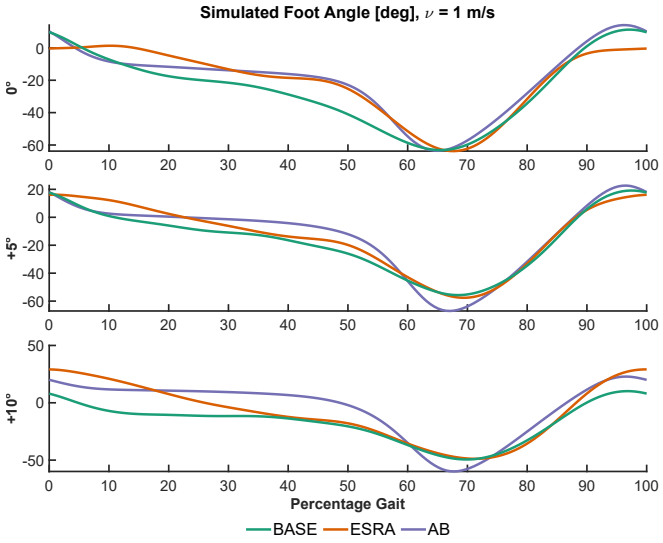

Fig. 3. Simulated optimal foot trajectories for the BASE and ESRA kinematic models, with Able-Bodied data (AB) as reference trajectories.

D. Experiment Design

One pilot transfemoral amputee subject (male, 23 years, 80 kg with prosthesis, 175 cm, activity level K4) was enrolled in our study and provided written informed consent in accordance with the Institutional Review Board of the University of Michigan (HUM00230065). The subject wore a motion capture suit and was equipped with a set of motion capture markers on the legs and torso. For each controller, the subject walked on an instrumented treadmill (Bertec Corporation, Columbus, OH) at a fixed 1.0 m/s speed for three inclines (0, 5, 10 deg) for 150 seconds each. Before each trial, the Power Knee was configured to use the correct controller, and the correct parameter set corresponding to the current incline was manually selected. Although previous work has enabled real-time incline estimation using this control framework [22], we manually set the incline estimate in this preliminary work to isolate the effects of our modified kinematic model.

The instrumented split-belt treadmill collected ground reaction force (GRF) data for each leg at 1000 Hz. A motion capture system (Vicon, Oxford, UK) was used to record 3D positions of all markers at 250 Hz. The first 30 seconds of data for each trial were excluded from processing to restrict our analysis to steady-state walking. We processed the steady-state data in OpenSim 4.5 (Stanford, CA, USA) using the model from Rajagopal et al. [38] with modifications made to account for the Power Knee's inertial properties, similar to [39].

III. Results

Figures 4 presents the average kinematic and GRF trajectories for each trial, along with reference able-bodied data. Table I presents normalized root mean square errors (NRMSE) for kinematics and GRF trajectories for each controller compared to able-bodied reference data, presented as a percentage of the range of each trajectory.

A. Kinematics

On level ground, the two controllers behaved similarly, as shown by similar NRMSE values compared to able-bodied gait (Table I). This result was expected as the ESR foot's RoM is closer to that of normative ankle motion in level walking. In fact, experimental foot angle trajectories only differed slightly, with the BASE controlled foot briefly plantarflexing then dorsiflexing in midstance while the ESRA controlled foot remained planted (Fig. 4, column 1). This deviation grew to 10 deg of excess plantarflexion on steeper inclines (see supplementary video). The corrective behavior by the ESRA controller remained across all three inclines, as NRMSE in foot angle remained approximately the same for the ESRA controller whereas the BASE controller's NRMSE steadily increased with incline (Table I).

Due to differences in their optimization objectives, the controllers exhibited distinct knee trajectories when compared to able-bodied data. The BASE controller was able to retain a near-normative level of stance phase knee flexion, although the peak flexion occurred later in stance, perhaps due to the position controller gains not being strong enough to counteract the ESR foot's limited deflection. The ESRA controller, on the other hand, had stance-phase knee flexion peaks aligned in phase but not in magnitude: the prioritization of foot-angle tracking combined with the fixed-ankle assumption resulted in reduced peak knee flexion and earlier extension of the knee during stance phase (Fig. 4, column 2). At 10 deg, both kinematic models exhibited worsened performance due to ESR feet being unable to replicate the

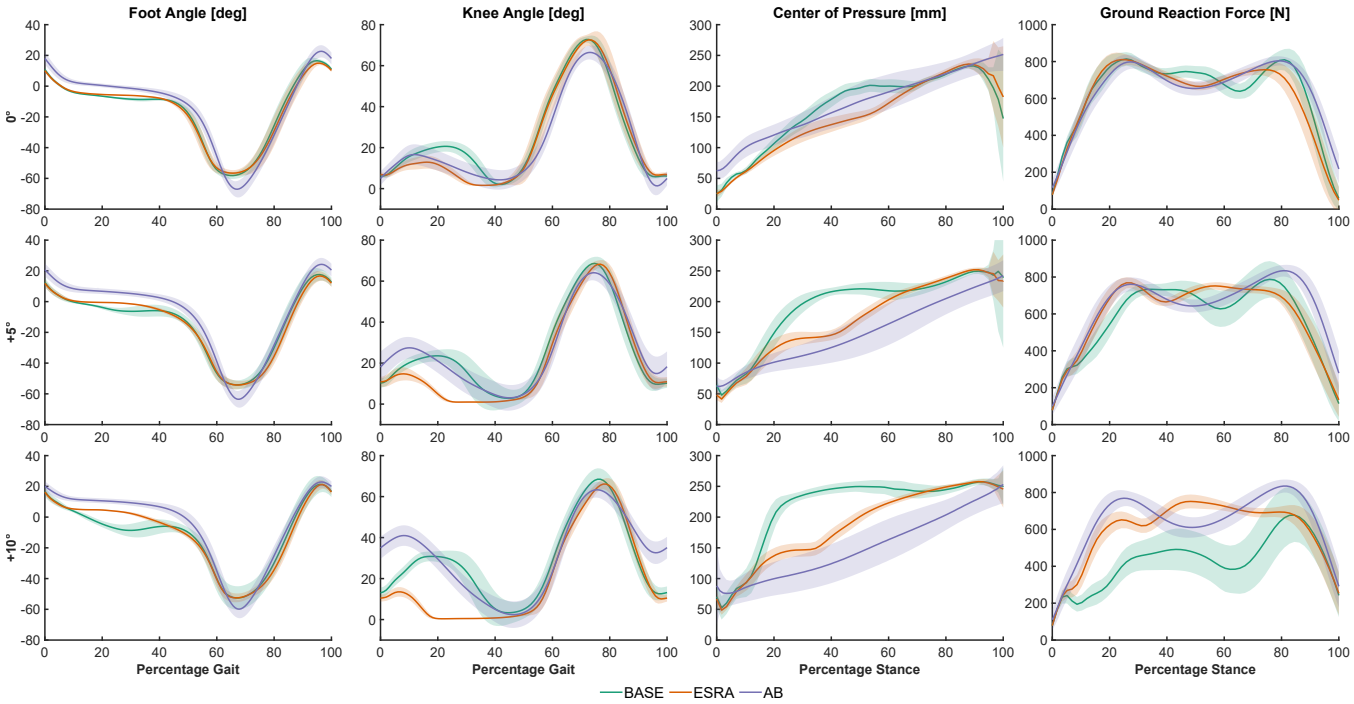

Fig. 4. Average experimental kinematic trajectories and ground reaction force data from both controllers. For able bodied reference data (AB) from [37], inter-subject averages are shown. Shaded regions represent ± 1 standard deviation of data. Note for Center of Pressure and Ground Reaction Force, only stance phase is shown ($s \leq s_{\text{TO}}$).

TABLE I
NORMALIZED ROOT MEAN SQUARE ERROR ACROSS INCLINES

	1.0 m/s, 0°		1.0 m/s, +5°		1.0 m/s, +10°	
	BASE	ESRA	BASE	ESRA	BASE	ESRA
θ_{foot} (%)	7.95	7.56	9.26	8.40	11.59	8.45
θ_k (%)	9.99	7.88	9.06	13.17	16.51	26.89
CoP (%)	25.96	19.80	23.40	11.70	29.72	16.38
GRF (%)	10.84	13.40	14.79	14.78	29.55	13.27

high biological ankle RoM observed at this incline. The reduced stance flexion commanded by the ESRA controller resulted in a substantial increase in knee angle NRMSE (13.17% at 5 deg and 26.89% at 10 deg) compared to the BASE controller, which has the sole objective of knee-angle tracking (9.06% at 5 deg and 16.51% at 10 deg). The periodicity requirement for the optimal trajectories resulted in these deviations from able-bodied gait in late swing phase, as the ESRA controller's heel strike target angle was substantially more extended than that of able-bodied data. We will see below that these deviations from able-bodied knee kinematics are a necessary tradeoff in pursuit of favorable ground contact with an ESR foot on inclines.

B. Ground Interactions

The kinematics results discussed above help explain the causes for changes in ground interaction between the two position controllers. Incorrect placement of the ESR foot throughout stance phase by the BASE controller prevented proper loading of the device, while the ESRA controller's corrected positioning substantially improved prosthesis loading and resultant ground interactions. To analyze these changes, we first examined Center of Pressure (CoP), which we defined as the distance between the heel marker and the point at which the net GRF acts on the foot. As seen in the representative able-bodied trajectories in Fig. 4 (column 3), CoP should smoothly progress through stance phase as the foot rolls over from heel to toe.

The BASE controller did not produce the smooth CoP progression we would expect and instead underwent rapid progression for the first half of stance phase (Fig. 4, column 3). On level ground, the prosthesis geometry allowed the heel to still take the majority of the user's weight, but on steeper inclines, this resulted in forefoot strikes rather than heel strikes. As a result, the foot visibly bounced as the keel unloaded in midstance, where the CoP regressed slightly and lost monotonicity. This trend can be seen through the NRMSE for CoP (Table I), for which the BASE values are substantially higher than those of the ESRA controller across inclines.

The ESRA controller significantly mitigated, but did not completely remove, this rapid progression. Proper foot placement allowed the heel to be loaded, delaying initial rollover making for a smoother stance phase progression. This loading on the ESRA controller was similar in magnitude to able-bodied GRF data, whereas the BASE controlled prosthesis was far under-loaded on steeper inclines (Fig. 4, column 4). While the ESRA controller allowed the user to properly bear weight with their prosthesis throughout stance phase, the loading profile still departed from the standard "M-shape" seen in able-bodied reference data. This trend was most noticeable at 10 deg, where the heel of the prosthesis could not be sufficiently loaded while using the BASE controller.

The user's confidence in the prosthesis lowered due to the resulting irregular foot behavior, leading to lower weight bearing and GRF throughout stance phase, as shown in Fig. 4 (Row 3, Column 4). The NRMSE compared to reference GRF data was 29.55% for the BASE controller and 13.27% for the ESRA controller (Table I).

IV. Discussion

By attempting to follow able-bodied trajectories at the knee, the BASE controller implicitly expects biological ankle behavior from the ESR foot. As the ESR foot cannot fully exhibit normative ranges of motion across steeper inclines, the foot is incorrectly loaded through stance phase, leading to departures from normative kinematics and kinetics. The ESRA controller is able to mitigate these issues rather well, even if the controller cannot completely return the prosthesis to able-bodied behavior.

Another observation is that these notable improvements from the ESRA controller are not a result of increased RoM, but rather shifting foot placement. The model for finding optimal trajectories, along with the controller itself, have no knowledge about the ESR foot or how it will behave: the performance changes emerge solely from the foot landing in a more favorable configuration which can better absorb and return energy through stance phase.

Ultimately, able-bodied gait may not be a proper objective choice for powered-knee, passive-ankle prostheses, since prostheses with ESR feet cannot perfectly replicate able-bodied movement in all tasks. Rather, perhaps a more fitting target for kinematics and kinetics is data from transtibial amputees, whose intact biological knees optimally adjust to using ESR feet. Future work for powered-knee, passive-ankle prostheses could incorporate transtibial amputee gait data for a more achievable reference trajectory set, although a dataset with sufficient data across a range of activities would need to be collected to enable this approach.

A. Limitations

The modeling assumption of a fixed ankle joint is a strong simplification which directly affects the extent of differences between the BASE and ESRA models. This is evident from the large deviations between the simulated (Fig. 3) and experimental (Fig. 4) foot trajectories, as the ESR foot bends enough such that the prosthesis is always more plantarflexed than representative able-bodied data. A foot-deflection model which relates GRF to ankle angle would allow for the limited ankle RoM of ESR feet to be taken into account, although the wide variety of ESR feet would make it difficult to generalize these results. If a generalized ESR foot deflection model could be developed, this would result in less extreme adjustments to knee trajectories for the ESRA controller.

Further, the incline setting in the controller was manually configured by a researcher in these experiments. Outside of the laboratory environment, we aim for these devices to automatically discern inclines as the user walks to allow for seamless adaptation between slopes. Future work will involve collecting data from the device's sensing suite in order to correlate existing signals with the current ground slope. While an additional, foot-mounted IMU sensor could trivialize this task, maintaining the existing sensor set on the Power Knee would be preferable for rapid translation of our control methods to clinical use.

Finally, the results in this work come from a pilot study with a single participant who had familiarity with the controller implemented on the Power Knee. As such, we are unable to generalize any claims about the trends and results observed. We intend to run a validation study with more participants in future work, which will also consider additional terrains such as declined ramps and uneven outdoor surfaces.

V. Conclusion

By indirectly controlling foot angle, as opposed to directly controlling the knee angle, the proposed control method allows for improved ground-contact behavior and proper loading of the ESR foot in a powered-knee, passive-ankle prosthesis. The effect is particularly evident while navigating steeper inclines. In a pilot subject experiment, our proposed controller results in substantial improvements in kinematics and ground interactions, showing that biomimicry can remain a feasible objective despite ESR feet's limited ability to mimic a biological ankle. This work serves as a step towards translation of versatile, biomimetic control methods from the research field onto commercially available clinical hardware, strengthening the case for widespread adoption of powered prostheses.

ACKNOWLEDGMENTS

The authors would like to thank Atli Örn Sverrisson and David Langlois for assistance with the Power Knee hardware and Jeffrey Wensman, CPO for clinical support.

Competing Interest Disclosures

The authors are listed on patents or patent applications related to the HKIC control method.

Hardware and related support was provided by Össur hf (Reykjavík, Iceland), which could have a financial interest in the results of this study. The results and conclusions in this work are entirely those of the authors and may not reflect the views of Össur hf or the National Institutes of Health.

Understanding the importance of feature groups for clinical outcome predictions with machine learning in post-stroke robotic-assisted rehabilitation

Anastasios Tzepkenlis[1*], Cristian Camardella[1], Daniele Leonardis[1], Stefano Mazzoleni[2,3,4], and Antonio Frisoli[1]

***Abstract*—Outcome predictions in post-stroke rehabilitation are a key element to personalize the treatment to the needs of the patient, finally enhancing effectiveness of the therapy. They can form the basis of Decision Support Systems, helping clinicians to progressively tune the therapy depending on patients' clinical status and progress. Diverse data sources, such as clinical, demographic, kinematic and time-related data in robotic-assisted rehabilitation, can provide different prediction results. Understanding which data source, or combination thereof, contains useful information for outcome predictions can improve the development of machine learning tools, Decision Support Systems, and even clinical setups designed to record these useful data. The presented work investigates different feature groups and machine learning methods, using data recorded within a robotic-assisted rehabilitation treatment including 44 stroke patients. Results highlight the effectiveness of using multi-dimensional feature groups to predict post-stroke rehabilitation. While clinical data alone can already achieve a solid basis for predictive modeling, the integration of kinematic and time-related data can significantly improve prediction accuracy of the patient outcome.**

***Index Terms*—Rehabilitation, Robotics, Stroke, Upper limb, Prediction, Machine Learning, Kinematics, Clinical Scale, Permutation Importance**

I. Introduction

Post-stroke rehabilitation plays a crucial role in improving functional recovery for patients, where personalized therapies can significantly enhance outcomes. However, current clinical approaches are often challenged by the heterogeneity of patients' characteristics, variability in clinicians' choices, and the lack of standardized decision-making frameworks. These challenges underscore the need for robust decision-support systems (DSS) to assist clinicians in tailoring therapies based on reliable predictions of recovery outcomes. Predictive models in rehabilitation have demonstrated their potential to reduce uncertainty, optimize treatment strategies, and even minimize costs by enabling adaptive and personalized interventions [1], [2]. Despite advancements in predictive systems, many existing models focus primarily on clinical and demographic features while overlooking the potential of instrumental kinematic and time-related data measured during robotic rehabilitation. To bridge these gaps, exploring the predictive power of diverse feature groups (e.g., clinical, demographic, kinematic, and time-related) is crucial to gain a comprehensive understanding of their individual and combined contributions to predicting post-stroke clinical outcomes such as the Fugl-Meyer Assessment (FMA), the Action Research Arm Test (ARAT) and the Motricity Index (MI). Recent studies have employed various machine learning (ML) techniques to predict motor recovery and functional scores [3]–[5]. Depending on the application and the amount of available data, some algorithms can show higher performance than others [6]. Among these, Decision-Tree based algorithms have often shown superior performance due to their ability to better leverage on small amount of data, which is more common in clinical contexts, also evaluating variable importance, offering insights into the underlying recovery processes [7]–[11]. Typically these algorithms are Random Forest, XGBoost, CatBoost, and LightGBM. Other algorithms often employed in predictive systems are K-Nearest Neighbors, Support Vector Machines, or Linear Regression based techniques [6], [12]. However, existing studies have rarely explored the distinct predictive capabilities of kinematic and time-related features derived from robot-assisted rehabilitation, which could provide clinicians with actionable insights to fine-tune therapy parameters in real time. The difficulty in this context is assessing the predictive capabilities of multiple algorithms having an input set that is always composed of different variables. In this sense, it is indeed difficult both to judge the absolute predictive performance of a certain algorithm, given a certain input set, and to understand how certain types of features can add more information on a general basis. The understanding of these relationships between data and predictive algorithms could be a breakthrough either in finding the optimal characteristics of a pre-existing clinical setup or in equipping modern rehabilitation systems with the appropriate tools. This paper aims to address these limitations by evaluating the predictive power of different feature groups (i.e., kinematic, clinical, demographic, and time-related) using various machine learn-

ing algorithms. Specifically, we assess their ability to predict clinical scales at discharge for post-stroke patients undergoing robot-assisted upper limb rehabilitation. By integrating these diverse feature sets, we seek to identify the most informative predictors of recovery and determine whether combining these features enhances predictive performance. Furthermore, this study contributes to the growing body of evidence supporting the integration of machine learning tools in rehabilitation to facilitate data-driven, explainable, and adaptive interventions for improved patient outcomes [13], [14]. The results of this work have the potential to inform the design of next-generation DSS that prioritizes interpretability and clinical relevance, paving the way for more effective and standardized approaches in post-stroke rehabilitation.

II. Methodology

A. Data Collection and Processing

Forty-four stroke patients participated in an upper limb robot-assisted rehabilitation program using the MOTORE (Humanware Srl, Pisa, Italy) end-effector device. The study ("iMotore" project) was approved by the Ethics Committee Lazio 1 on December 29, 2021 (STS CE Lazio 1/N-873). Figure 1 illustrates the clinical robotic treatment setup. Four patients were excluded due to incomplete treatment, leaving no final clinical assessment. This dataset extends [15], comprising 71 features across four groups: Clinical, Demographics, Kinematics, and Time-Related (detailed in Table I). Clinical (28) and Demographic (16) features are collected at rehabilitation start. Kinematic features (20) derive from processed force and position data recorded by the robot during therapy, shared across seven rehabilitation game scenarios. These exercises assess range of motion, force exertion, trajectory precision, and task execution (e.g., object collection, simulated daily activities). Some also integrate cognitive tasks to enhance motor and mental agility. The system tracks applied forces, movement accuracy, and task completion—autonomous or assisted. Additionally, 7 time-related features indicate patient performance. Sessions performed entirely in autonomous mode, where the robot completed tasks without patient engagement, were excluded. The combined 71 features predict post-therapy clinical outcomes: motor capability scores (FMA, ARAT, MI).

B. Clinical Outcome Prediction Algorithms

The study employed various machine learning algorithms to predict clinical outcomes: Random Forest, XGBoost, CatBoost, HGBR, LightGBM, and KNN. Random Forest leverages an ensemble of decision trees to enhance robustness and reduce overfitting [16]. XGBoost [17] and CatBoost [18] utilize gradient boosting, with XGBoost excelling in efficiency and scalability, and CatBoost being optimized for categorical data handling. HGBR enhances gradient boosting by discretizing features into histograms for faster training and lower memory usage [19]. LightGBM [20], like XGBoost and CatBoost, is a gradient boosting framework, which optimizes training speed and efficiency by using a histogram-based approach, particularly suited for large datasets with many features. Finally, K-Nearest Neighbors (KNN) predicts outcomes based on the proximity of data points in feature space, making it straightforward and effective for smaller datasets [21].

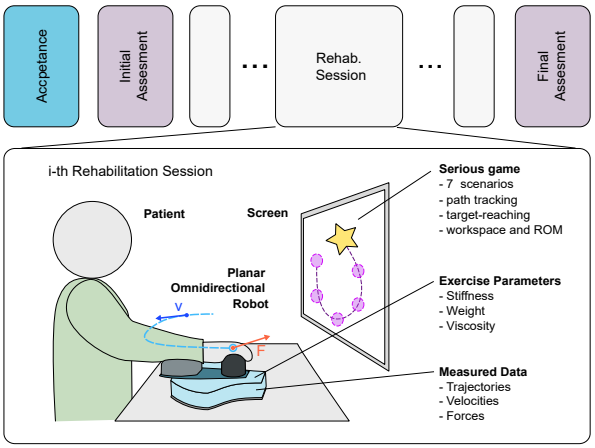

Fig. 1. Scheme of the rehabilitation treatment and setup used to collect the data.

C. Training and Evaluation

Regarding the training and evaluation of the networks, at first we separated the dataset into 80%/20% training/testing based on the number of patients, so 32 patients for training and 8 patients for testing and in total we performed 30 train/test folds. For each of these patients, each completed game session was mapped to the individual clinical outcome score (FMA, ARAT and MI) which was collected at the end of the therapy and the evaluation was calculated as the root-mean-square error between the predicted outcome at the given time against the true outcome at the end of the therapy as noticed in equation (1).

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y - \hat{y}_i)^2} \tag{1}$$

where:

- n: The total number of data points for each patient.
- y_i: The true clinical outcome at the end of the therapy.
- $\hat{y}_i$: The predicted value at the i-th point.

D. Feature Group Analysis

To provide an accurate overview on how each group of features performs on the different networks, we performed an extended ablation study. There, we investigated all possible combinations between the aforementioned groups (Clinical, Demographics, Kinematics and Time-Related). Finally, we evaluated the groups by calculating the cumulative mean of the appearance of each group throughout the ablation study, as seen in Equation 2.

$$\text{Cumulative Mean}_G = \frac{\sum_{G=1}^{N_G} \text{RMSE}_G}{N_G} \tag{2}$$

where:

TABLE I
THE FOUR FEATURE GROUPS, CLINICAL, DEMOGRAPHICS, KINEMATICS AND TIME-RELATED WITH THE CORRESPONDING FEATURES AND DESCRIPTION

- G: Any of the four groups (Clinical, Demographics, Kinematics, Time-Related).
- N_G: The total number of combinations in which the group G appears.
- RMSE$_G$: The RMSE as noted in equation 1 for the combinations that include G.

E. Permutation Importance

We calculate the Permutation Importance (PI) [22], as implemented in sklearn, which is a model-agnostic method to measure feature significance. It works by randomly shuffling the values of a feature and observing the impact on model performance (e.g. RMSE). The decrease in performance indicates the importance of the shuffled feature, as a larger drop suggests a stronger dependence of the model on that feature.

III. RESULTS AND DISCUSSION

The results of the cumulative mean analysis illustrated in Figure 2 highlight the critical role of the Clinical feature group in increasing the accuracy of predictions. This result demonstrates how clinical data is a reliable foundation for model performance across a range of methods and scales. The Clinical group stands as the most influential feature set, achieving the lowest RMSE values and likely capturing key information directly associated with the target outcome. The observed ranking of groups, where Kinematic group follows the Clinical group, then the Time-Related group, and finally the Demographic group, provides insights of the relative importance of these feature sets. This hierarchy suggests that kinematic data may offer additional complementary predictive value, likely reflecting dynamic aspects of the subjects that clinical scales alone cannot fully capture. Time-Related features, while contributing less than Kinematic features, may represent temporal patterns that are less impactful but still relevant. Ranking last is the demographic group, which features' did lead to the least accurate predictions.

In Figure 3, we present the RMSE values across all algorithms and every possible combination of the three clinical scores. The key finding is that incorporating Kinematic features (Clinical + Kinematics), Time-Related features (Clinical + Time-Related), or both (Clinical + Kinematics + Time-Related) generally improves prediction accuracy for most algorithms and clinical scales. Specific combinations for each algorithm that result in an improvement over using

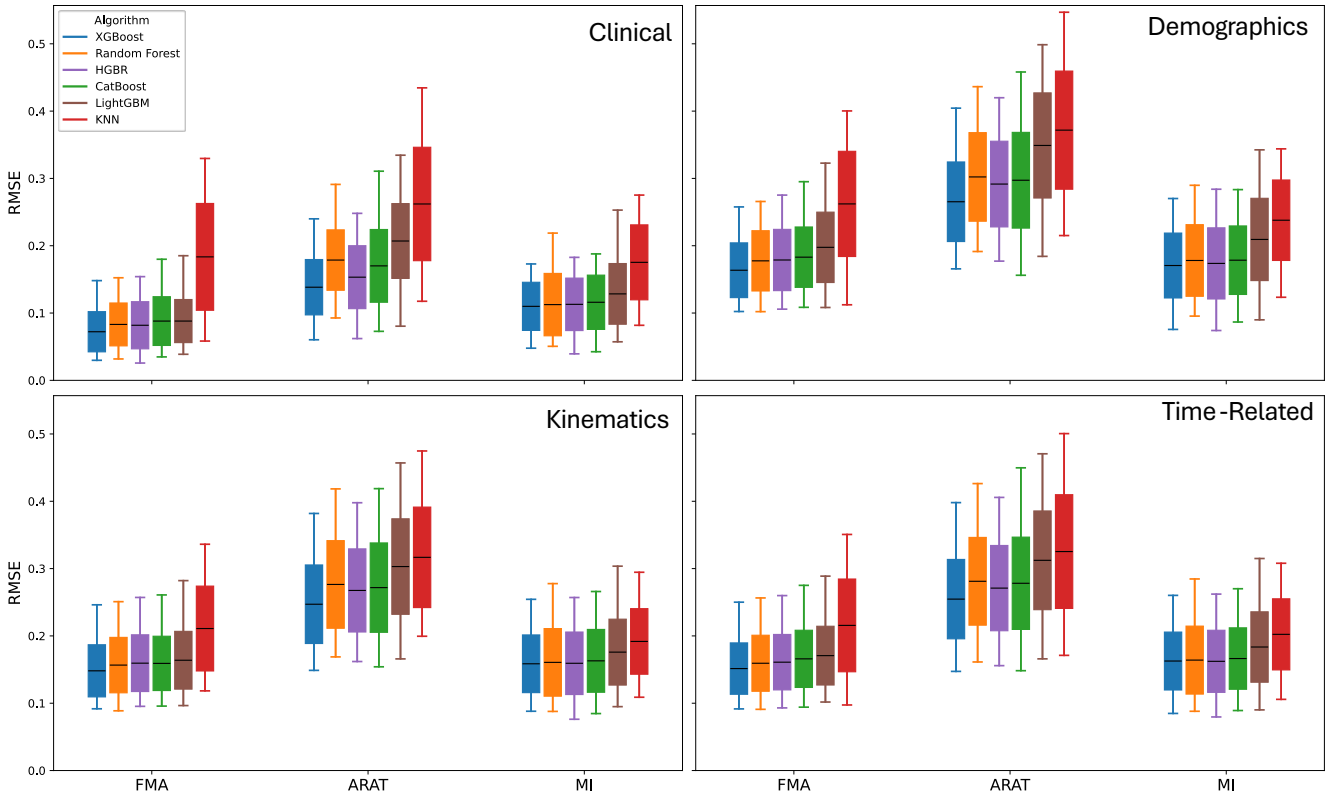

Fig. 2. Boxplot illustrations of the cumulative mean RMSE, calculated using Equation 2, for all the algorithms and for the four feature groups (a: Clinical, b: Demographics, c: Kinematics, d: Time-Related) across the three clinical scores (FMA, ARAT, and MI).

only clinical data are marked with an asterisk (*) above the corresponding boxplots. In most of the analyzed algorithms, it is more likely to find the lowest RMSE when adding kinematic and time-related features meaning that, on average, it is always a good choice employing instrumental data acquisition systems in the clinical setup. Another noteworthy observation is that for the HGBR algorithm, the inclusion of demographic features, either alone or in combination with kinematic and time-related features, consistently enhances prediction accuracy across all three clinical scales. It has to be noted that in literature, researchers often refer to the minimal clinical important differences (MCID) to determine if a significant change in the therapy has to be made, as the smallest change in scores that also are considered clinically important and meaningful in health status perceived by the patient: previous studies set this value around 10/15% of the maximum score [23], [24].

In Figure 4, we present the five most prominent features from each feature group, normalized to enhance visualization clarity. The normalization was applied within this subset by mapping the highest value to the maximum and the lowest to the minimum. As anticipated, the key features within the clinical group for the FMA and ARAT scales are the respective clinical scores at the start of therapy. For the MI scale, however, the most influential feature remains the FMA score at the beginning of therapy. Regarding the Demographic feature group, we observe similarity across all clinical scales and most algorithms that the patient's age and gender as well as the latency are predictors of high importance, leading to more accurate clinical outcome predictions: also height showed to be important, probably caused by a bias of the specific dataset used in this analysis and, thus, to be considered an artifact. Results of this study are also coherent with previous studies where some clinical features were listed as the most relevant one in predicting upper-limb motor recovery [9], [15]. Examining the Kinematic feature group, there is no obvious agreement on which features are more relevant across the algorithms and the three clinical scores. For example, the Duration of the game played by the user is highly relevant for most algorithms when predicting FMA and ARAT. Additionally, factors such as the accuracy in game execution and the user's total effort play crucial roles across all three clinical scales. Notably, the overall game performance feature, representing a total score for the completion of each serious game, is of high importance when predicting the MI clinical scale. Finally, for the Time-Related feature group, a consistent pattern is evident. Across all clinical scales and algorithms, features such as the time difference between the current therapy session and the start of therapy, the total number of serious games completed during a specific rehabilitation session, and the cumulative count of completed game sessions are consistently associated with more accurate predictions.

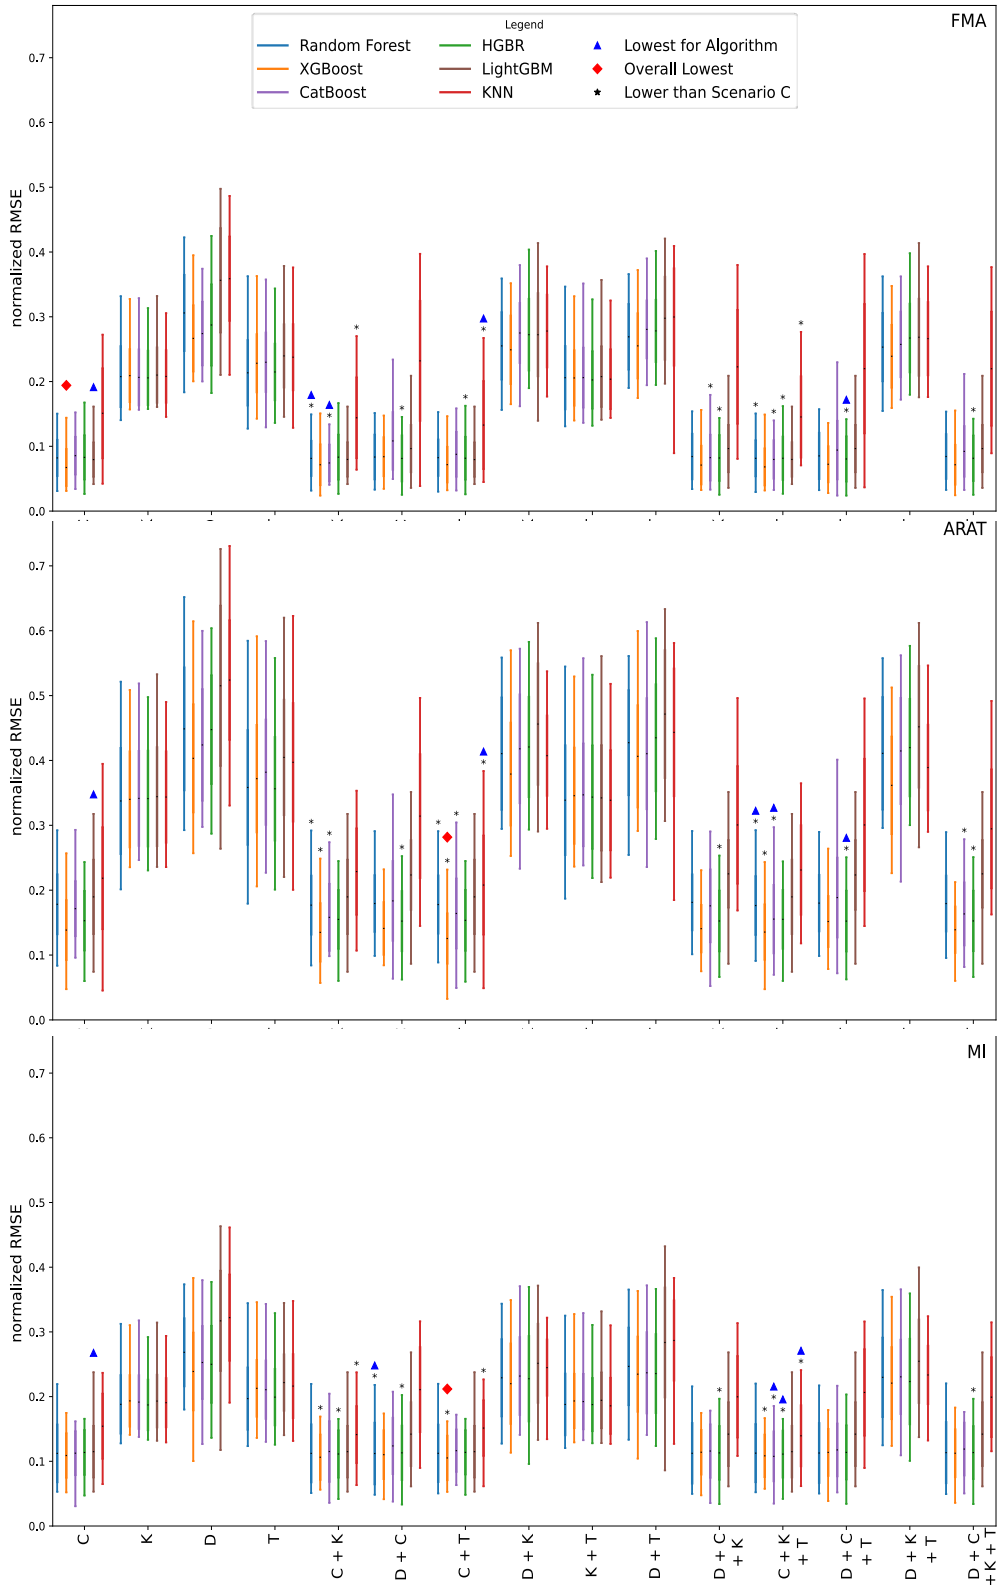

Fig. 3. Boxplot illustrations of all unique combinations of the feature groups (C: Clinical, D: Demographics, K: Kinematics, and T: Time-Related) are provided for the three clinical scores (a: FMA, b: ARAT, c: MI) and all algorithms. Boxplots marked with a star indicate scenarios that outperform the use of clinical information alone for the corresponding algorithm, while the blue triangle indicates the best performance of each algorithm and the red diamond the overall best performance for the clinical scale.

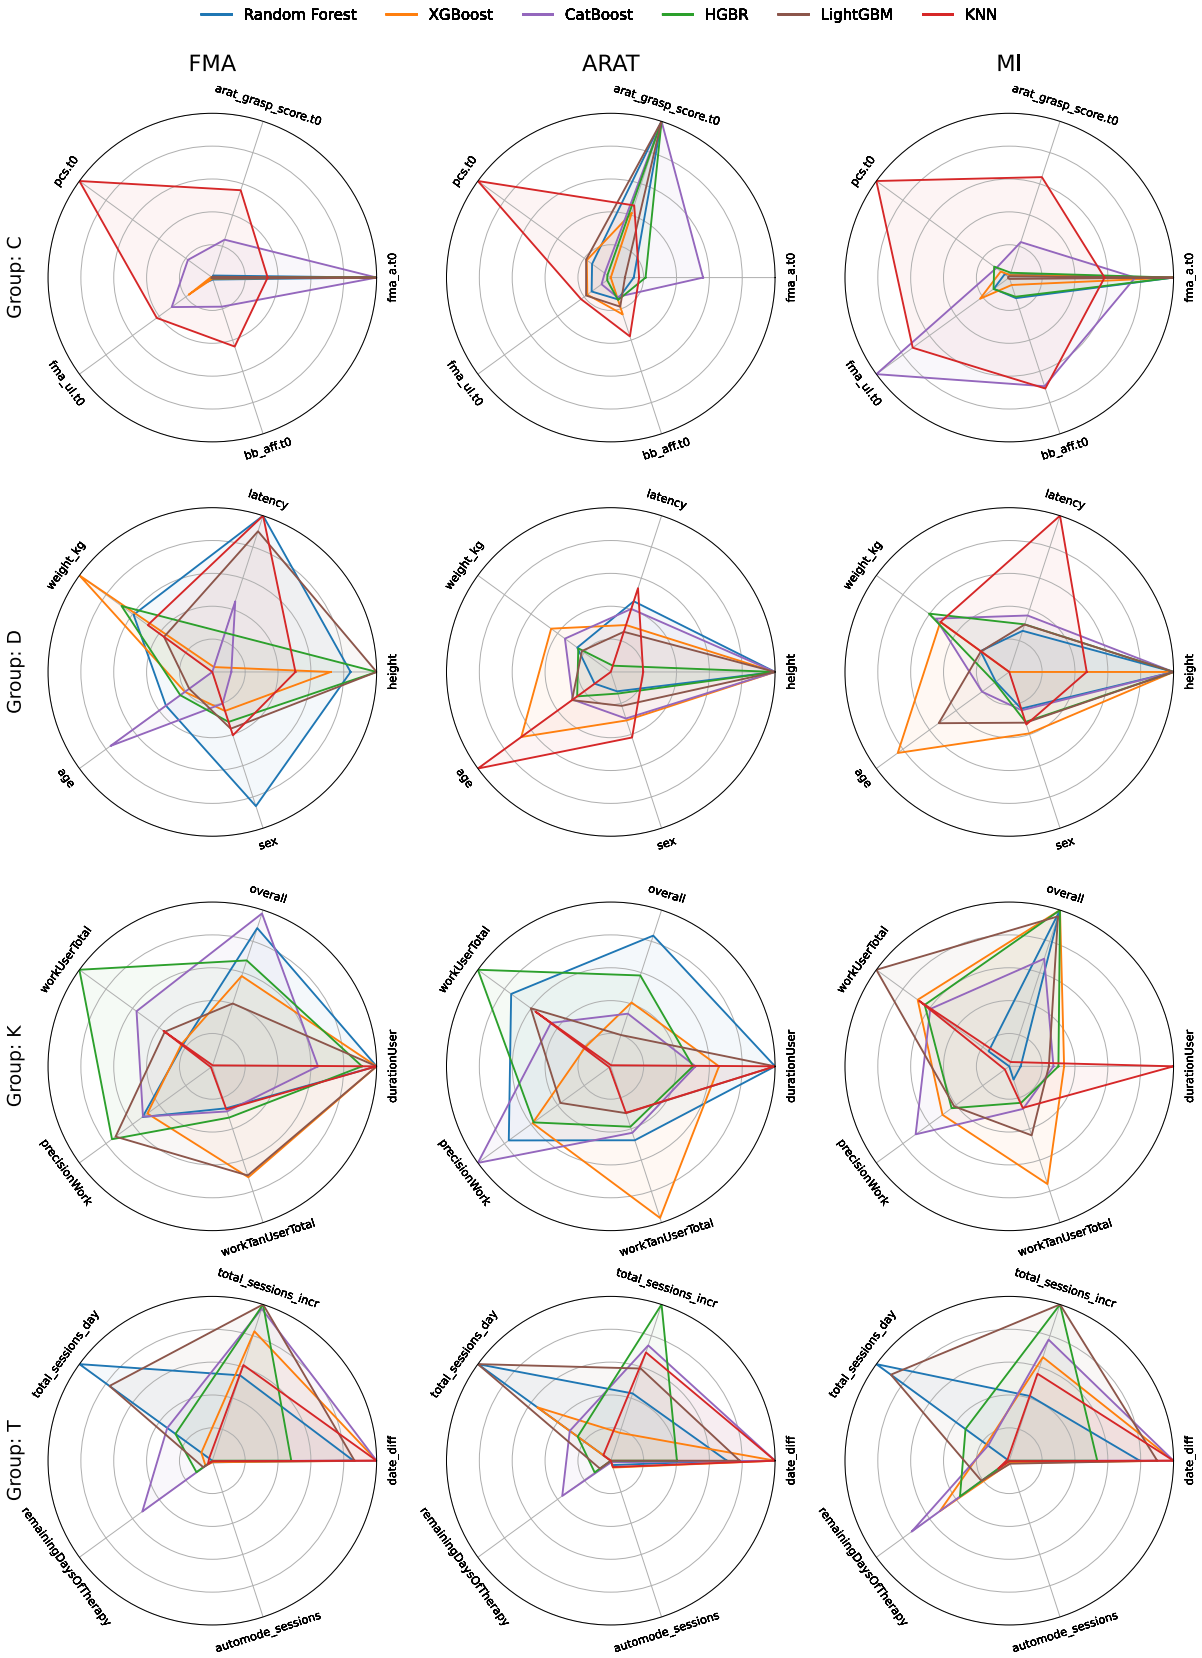

Fig. 4. Radar plots of the four feature groups (C: Clinical, D: Demographics, K: Kinematics, and T: Time-Related), displaying the five most important normalized features, considering both the algorithms and the clinical scales.

IV. Conclusion

This study evaluates the effectiveness of multi-dimensional feature groups in predicting outcomes in post-stroke, robotic-assisted rehabilitation. Clinical features had the most significant impact on reducing RMSE among the four groups (Clinical, Demographic, Kinematic, and Time-Related), constituting a strong foundation for predictive modeling. Kinematic and Time-Related features further improved accuracy, capturing dynamic and temporal aspects of patient performance.

Ablation studies showed that models combining clinical, kinematic, and time-related data outperformed those using clinical data alone, while demographic features were the least predictive. Consistent trends across algorithms indicate robustness. PI analysis revealed that initial FMA and ARAT scores were crucial predictors, while overall game performance influenced MI. Game time and execution accuracy were particularly relevant for FMA and ARAT. Time-Related features, such as the Number of Sessions and time since therapy initiation, were consistently important. Among demographics, patient's age and latency were the strongest predictors.

This study lays the groundwork for defining a minimal clinical setup for effective prediction systems, leveraging clinical assessments and robotic rehabilitation data. Further research is needed to assess the clinical impact of individual and correlated features on stroke recovery.

***Abstract*—This study investigates mirrored deficit fields' effects on bimanual coordination in post-stroke rehabilitation using the NREH-Bimanual robotic platform. We tested our approach with eleven participants (six stroke, five able-bodied), deriving force field parameters from the affected/non-dominant arm's velocity distribution and mirroring them to the unaffected/dominant arm. Movement quality was assessed using Randomness Score, Cumulative Traveling Distance, and Workspace Area across four conditions: null field, unilateral deficit field on affected side, unilateral mirrored deficit field on unaffected side, and bilateral deficit fields. Results showed increased movement quality with deficit field application, particularly when applied bilaterally or to the unaffected arm. The stroke group's affected side improved in Randomness Score (17-24%) and workspace area (16-29%), with enhanced movement perception and speed (~20%) when deficit fields were applied to the unaffected side. These findings demonstrate mirrored deficit fields' potential as a novel rehabilitation strategy for improving bimanual coordination in stroke patients through interlimb coupling mechanisms.**

Keywords—Bimanual coordination, motor rehabilitation, deficit field, interlimb coupling, stroke rehabilitation, error augmentation, robotic rehabilitation, motor learning, velocity-dependent force field, movement exploration

I. INTRODUCTION

Stroke often leads to persistent motor deficits, significantly impacting individuals' ability to perform daily tasks and participate in society [1]. Among these deficits, impaired bimanual coordination is particularly debilitating, affecting tasks that require coordinated movements of both arms, such as dressing, eating, and manipulating objects [2]. Therefore, developing effective rehabilitation strategies to improve bimanual coordination in stroke patients is crucial.

Conventional rehabilitation approaches typically focus on repetitive movements and task-specific training. However, recent research has explored the potential of error augmentation (EA) techniques to enhance motor learning and recovery [3, 4, 5, 6, 7]. EA involves introducing perturbations or disturbances during movement, forcing the nervous system to adapt and learn new motor control strategies. Multiple systematic reviews have demonstrated that EA-based interventions can effectively improve upper extremity performance and recovery in stroke patients [5, 6, 7, 8], with recent evidence supporting its integration into robotic therapy approaches [9]. One method of implementing EA is through the application of deficit fields (DFs), which are force fields designed to exacerbate movement errors and promote increased exploration of the movement space [10].

Previous studies have primarily focused on applying DF to a single limb, demonstrating its potential for improving unilateral motor control [10, 11, 12]. However, these studies have not explored DF's effects on bimanual coordination, as they typically apply DF only to the affected limb. Our study introduces a novel approach by applying DF to both arms—using a conventional DF on the affected/non-dominant arm and a mirrored DF on the unaffected/dominant arm. This allows us to investigate the impact of bilateral force perturbations on interlimb coordination and movement exploration, which has not been previously examined. Mirror therapy, using visual feedback of the unaffected limb, has shown promise in stroke rehabilitation [13, 14]. Our approach extends beyond visual feedback by incorporating physical perturbations through deficit fields to engage multiple sensorimotor learning pathways.

We hypothesize that mirroring the DF parameters derived from the affected/non-dominant arm to the unaffected/dominant arm will lead to increased exploration and enhanced motor learning in both groups. This approach is based on the principle of interlimb coupling, which facilitates coordinated movement patterns between limbs through bilateral neural mechanisms [15, 16]. By applying mirrored DFs, we aim to induce interlimb coupling, which facilitates coordinated movement patterns between limbs through bilateral neural mechanisms.

Using the NREH-Bimanual robotic platform, we investigated mirrored deficit fields' effects on bimanual coordination. Participants generated personalized parameters through free exploration with their affected/non-dominant arm, which were then mirrored. Movement quality was assessed using three metrics (Randomness Score, Cumulative Traveling Distance, and Workspace Area) to evaluate this approach's potential as a novel stroke rehabilitation strategy.

II. METHODS

A. Participants

Eleven participants were recruited for this study: six individuals with chronic stroke (≥6 months post-stroke) and five able-bodied controls. Stroke patients exhibited mild to moderate upper limb impairment, with Fugl-Meyer

This project was supported by the Translational Research Program for Rehabilitation Robots, National Rehabilitation Center, Korea [NRCTR-IN23004, NRCTR-IN24004].

Assessment scores [17] > 20. Ethical approval was obtained from the Institutional Review Board (IRB No#: NRC-2020-06-040), and all participants provided written informed consent before participating in the study.

Included six stroke survivors (5 male, 1 female; average age: 67.00 ± 8.36 years; time since stroke: 17.83 ± 6.96 years; Fugl-Meyer Assessment (FMA) of motor function and joint range of motion, scored from 0-66 for the upper extremity: 47.00 ± 13.50; Box and Block Test (BBT) assessing hand dexterity and functional ability, measuring the number of blocks transferred in one minute: 12.17 ± 10.20; Action Research Arm Test (ARAT) providing a comprehensive assessment of arm and hand functional ability, scored from 0-57: 33.50 ± 21.57; Modified Barthel Index (MBI) assessing activities of daily living, scored from 0-100: 94.67 ± 3.90 and five able-bodied participants (3 male, 2 female; average age: 34.00 ± 5.58 years).

B. NREH-Bimanual robotic platform

The NREH-Bimanual robotic platform [18, 19] was employed to apply forces to the participants' arms during the experiment. This device allows for precise control of forces and accurate measurement of arm movements in two dimensions. Participants were seated comfortably facing the robot, with their arms supported by the robot arms. Visual feedback of hand position was provided on a display integrated into the NREH-Bimanual (Fig. 1).

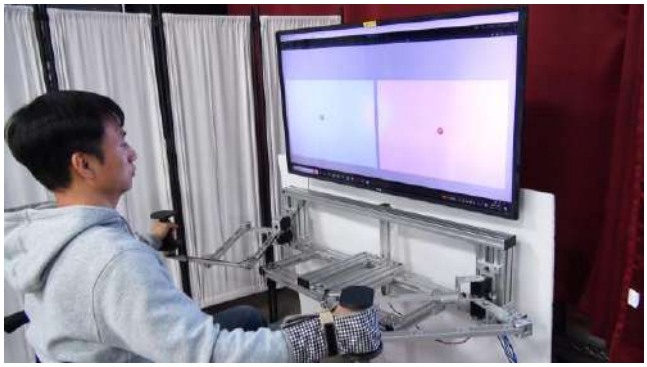

Fig. 1. NREH-Bimanual robotic platform.

C. Experimental Procedure

To generate the Deficit Field, participants first completed a Free Exploration task using their affected (or non-dominant) arm for 4 minutes within a 600×400 mm workspace. During this task, participants were instructed to explore freely in various directions and at different speeds. This task was used to customize the Deficit Field parameters for subsequent conditions. A 2-minute rest period was provided following this task. All experimental tasks were performed simultaneously with both arms to ensure bimanual coordination throughout the sessions.

Participants then performed the following experimental conditions, each lasting 2 minutes and followed by a 2-minute rest period:

- **Condition #1:** Null Field (NF). No force field was applied. This served as a baseline measure of exploratory behavior.
- **Condition #2:** Unilateral DF on Affected/Non-dominant Side. DF was applied only to the affected arm in stroke patients, or the non-dominant arm in able-bodied participants.
- **Condition #3:** Unilateral DF on Unaffected/Dominant Side with Mirrored DF. DF, with mirrored parameters from the affected/non-dominant arm, was applied only to the unaffected arm in stroke patients, or the dominant arm in able-bodied participants.
- **Condition #4:** Bilateral DF with Mirrored DF on Unaffected/Dominant Side. DF was applied to both arms. The affected/non-dominant arm received its individually tuned DF, while the unaffected/dominant arm received the mirrored DF.

Participants were instructed to maximize exploratory movements, covering as many directions and speeds as possible during each condition. In particular, Condition #2 and Condition #3 were applied in random order. The total training session concluded after completing the four conditions and their associated rest periods.

D. Deficit Field

The deficit field (DF) was implemented as a velocity-dependent force field [10, 11] that perturbed hand movements based on the velocity data collected from one arm using the NREH bimanual system. To analyze velocity distribution, a two-dimensional histogram was generated to discretize the distribution of velocity vectors. The histogram bin boundaries were created by equally dividing the velocity data range, defined by the minimum and maximum values of the measured data, into 20 bins. The histogram was then normalized to obtain the velocity density (defined as D), which represents the probability distribution of velocities in each bin.

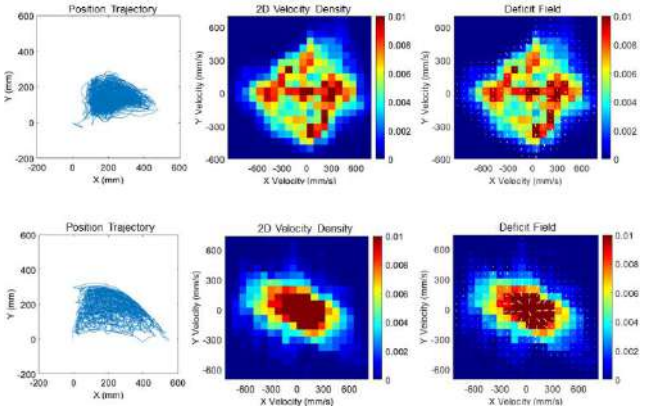

Fig. 2. Free exploration trajectories, normalized velocity density, and deficit fields derived from normalized velocity density using gradients for the affected right hands of two stroke participants. Top row: data from the first participant; bottom row: data from the second participant.

The force field was generated by calculating gradients (p_x, p_y) from the velocity density D. The gradient magnitude was calculated as $mag = sqrt(p_x^2 + p_y^2)$, and force vectors were defined as $F_x = -p_x/mag$ and $F_y = -p_y/mag$. The gradient direction was inverted to act from high to low velocity density regions, facilitating movement exploration into less frequently

visited areas. To prevent excessive force perturbations, a gradient threshold of 0.005 was applied, rescaling the gradient magnitude to a maximum of 0.005 when it exceeded this threshold. This normalization ensured smooth force transitions while preventing abrupt changes in force magnitude. Fig. 2 illustrates this process, showing the velocity density distribution, gradient computation, and resulting force field visualization.

The direction and magnitude of the force field were personalized based on each participant's individual motor characteristics [20, 21]. For stroke patients, parameters were derived from velocity data during free exploration of the affected arm, while for able-bodied participants, these were calculated from the non-dominant arm. In the mirroring condition, these parameters were mirrored and applied to the unaffected/dominant arm, following principles of interlimb coupling and motor learning [22, 23, 24, 25]. Using the Robotis XM540 actuator, the force field was limited to a maximum handle force of 30N, with a gradient threshold of 0.005 to ensure safe, comfortable interaction.

E. Metrics

To evaluate arm functionality during randomness movements performed using both hands to control the handles, the following metrics were used:

- **Randomness Score (RS)** [10, 11]: The RS quantifies exploratory behavior by assessing movement variability and distribution. To compute RS, position and velocity data from each arm were recorded in a 600 mm × 400 mm workspace. This workspace was divided into a 5 × 5 grid (25 zones). Within each zone, a velocity histogram was generated using horizontal and vertical velocity components ranging from -2.00 m/s to 2.00 m/s, with each axis discretized into 20 bins (bin size: 0.2 m/s). During the scoring process, a zone received a maximum score of 100 if all velocity histogram bins were filled, indicating a high degree of velocity diversity. The final RS was computed by averaging the scores across all 25 zones, with higher RS values reflecting greater movement diversity and exploration.
- **Cumulative Traveling Distance**: The cumulative distance traveled by the arms during the task is calculated as the sum of all movements. A greater total traveling distance indicates higher arm activity, reflecting increased effort. A larger distance is considered desirable as it implies more active movement. Since all conditions were performed for a fixed duration, an increase in cumulative traveling distance inherently suggests an increase in average speed.
- **Workspace Area**: Two robotic arms were positioned in a 2D plane where participants held the end-effectors. This metric quantifies changes in the convex hull area covered by arm movements.

Given our small sample size (stroke: n=6, able-bodied: n=5), we used descriptive statistics to analyze outcome trends and examined individual participant data to understand response patterns across conditions.

III. RESULTS

We analyzed three key metrics - Randomness Score (RS), Cumulative Traveling Distance (CTD), and Workspace Area - to evaluate the effectiveness of the Deficit Field (DF) conditions. These metrics were compared across all four experimental conditions for both stroke and able-bodied participants.

A. Randomness Score

Analysis of Fig. 3 shows that in the stroke group, the application of DF showed a clear trend of increasing RS. Unilateral DF applied to the affected arm (condition #2) led to an increase in RS compared to the null field condition (condition #1). Applying the mirrored DF to the unaffected arm (condition #3) also resulted in an increase in RS, highlighting the potential for interlimb coupling.

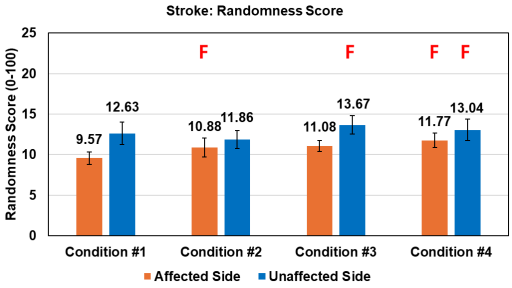

Fig. 3. Randomness Score across conditions in stroke patient (C1: Null Field, C2: Unilateral DF on Affected Side, C3: Unilateral Mirrored DF on Unaffected Side, C4: Bilateral DF). 'F' marks indicate the application of the Deficit Field (DF) on the corresponding arm. In Condition #4, DF was applied bilaterally, so 'F' appears on both arms.

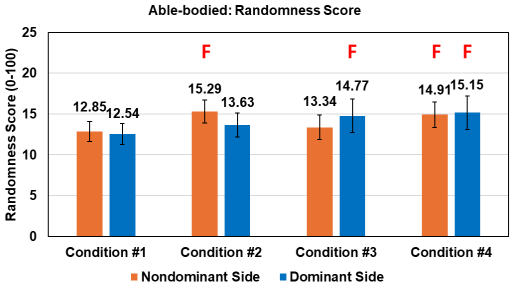

Fig. 4. Randomness Score across conditions in able-bodied patient (C1: Null Field, C2: Unilateral DF on Nondominant Side, C3: Unilateral Mirrored DF on Dominant Side, C4: Bilateral DF). Error bars show standard deviation. 'F' marks indicate the application of the Deficit Field (DF) on the corresponding arm. In Condition #4, DF was applied bilaterally, so 'F' appears on both arms.

As shown in Fig. 4, the able-bodied participants demonstrated similar increases in RS with DF application. Under unilateral DF conditions (conditions #2 and #3), RS was higher compared to the null field condition (condition #1), with the effect being more pronounced in the arm to which DF was applied. In the bilateral DF condition (condition #4), the RS difference between the nondominant and dominant sides was reduced, possibly due to the intact sensorimotor systems of able-bodied individuals.

Participants were instructed to explore the workspace freely for 2 minutes in each condition, varying their movement directions and speeds. Compared to baseline (Condition #1),

the mean Randomness Score (mean ± SD) increased for both groups. The stroke group's affected side showed improvements of 12.99±6.02% in Condition #2, 16.89±5.36% in Condition #3, and 24.30±9.43% in Condition #4. Similarly, the able-bodied group's nondominant side improved by 23.43±8.30%, 5.00±4.30%, and 14.52±7.45% in Conditions #2, #3, and #4, respectively.

B. Cumulative Traveling Distance

Analysis of Figs. 5 and 6 shows distinct patterns in both groups when DF was applied. In the stroke group, CTD increased progressively, with the highest values observed in bilateral DF condition (condition #4). Notably, DF application to the unaffected side promoted movement more effectively than to the affected side. The affected side showed improvements of 13.59±9.39%, 23.98±9.27%, and 34.52±10.72% in Conditions #2, #3, and #4 respectively, compared to baseline.

In the able-bodied group, unilateral DF conditions (#2 and #3) resulted in decreased CTD in the arm without DF, suggesting redistribution of sensorimotor resources. However, bilateral DF (condition #4) produced balanced engagement, with the nondominant side showing changes of 2.83±6.48%, -2.25±6.95%, and 6.01±4.97% in Conditions #2, #3, and #4 respectively. This demonstrates bilateral DF's potential for promoting symmetrical motor performance.

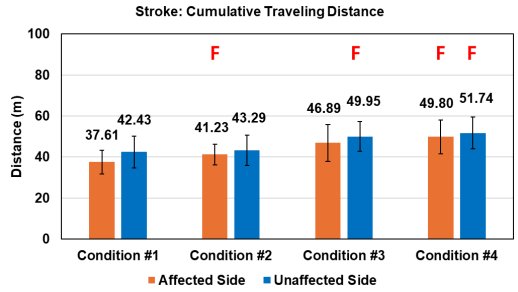

Fig. 5. Cumulative Traveling Distance in stroke patients for the same conditions as in Fig. 3.

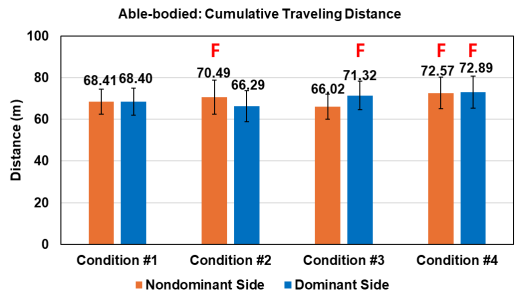

Fig. 6. Cumulative Traveling Distance in able-bodied patient for the same conditions as in Fig. 4.

C. Workspace Area

Analysis of Figs. 7 and 8 revealed distinct workspace patterns for both groups. In the stroke group, unilateral DF (Condition #2) increased the affected side's workspace while decreasing the unaffected side's area. When DF was applied to the unaffected side (Condition #3) or bilaterally (Condition #4), both arms showed increasing workspace. The affected side showed improvements of 10.36±2.92%, 15.70±9.82%, and 28.52±14.95% in Conditions #2, #3, and #4 respectively, with the largest increase under bilateral DF.

In the able-bodied group, unilateral DF produced opposing effects: when applied to one side, that side's workspace increased while the other decreased slightly. Bilateral DF (Condition #4) resulted in workspace expansion for both sides, particularly the dominant side. The nondominant side showed changes of 22.28±11.24%, -3.31±7.58%, and 19.52±11.80% in Conditions #2, #3, and #4 respectively. These results suggest able-bodied individuals adapt effectively to force conditions, achieving immediate and symmetric workspace expansions.

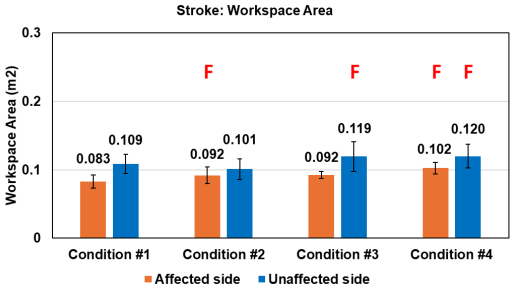

Fig. 7. Workspace Area in stroke patients for the same conditions as in Fig. 3.

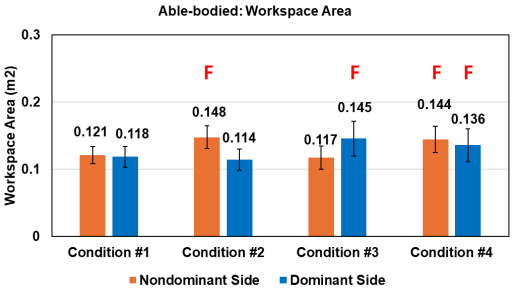

Fig. 8. Workspace Area in able-bodied patient for the same conditions as in Fig. 4.

D. Qualitative Observations

Qualitative observations during the experiment provided further insights into participants' behavior. When DF was applied to the affected side in Condition #2, the stroke group generally had difficulty recognizing the force exerted by the DF. However, when DF was applied to the unaffected side (Condition #3), participants were able to recognize the force more clearly. Notably, one stroke participant reported feeling that both hands moved noticeably faster when DF was applied to the unaffected side. Supporting this observation, the stroke group's average speed in Condition #3 increased by approximately 20% compared to Condition #1, suggesting a potential facilitation effect from applying DF to the unaffected side.

IV. Discussion

This study investigated the effects of mirrored deficit fields (DF) on bimanual coordination and exploration in both stroke patients and able-bodied individuals. Our findings demonstrate that applying DF, particularly with mirrored parameters, enhances exploratory behavior and motor performance, as evidenced by increased Randomness Scores

(RS) and workspace area. This effect was observed even when the DF was applied to the unaffected/dominant arm, suggesting the presence of interlimb coupling and its potential to facilitate motor learning in the affected limb.

While our small sample size (stroke n=6, able-bodied n=5) precludes statistical inference, the consistent trends observed across participants suggest potential benefits of the mirrored DF approach. The magnitude of improvements in both RS and workspace area, particularly in the bilateral DF condition, provides preliminary evidence for the effectiveness of this intervention. Individual participant data revealed that all stroke patients showed some degree of improvement in at least one outcome measure, with five out of six patients showing improvements across all measures in the bilateral DF condition. In the able-bodied group, all participants demonstrated consistent improvements in both RS and workspace area during bilateral DF application, suggesting the robustness of this approach across different populations.

The observed increase in RS with DF application can be attributed to the principles of error augmentation and motor adaptation [5, 6, 9]. By perturbing movements, DF creates a challenging environment that encourages the nervous system to actively explore new movement solutions and adapt to the imposed constraints [20, 21, 22]. This increased exploration, reflected in higher RS, may facilitate the discovery of more efficient and coordinated movement patterns, potentially leading to improved bimanual performance.

The significant increase in RS with mirrored DF on the unaffected/dominant arm (condition #3) is particularly noteworthy. This finding supports our hypothesis of interlimb coupling, where motor learning and adaptation in one limb can influence the motor control of the other limb [23, 24, 25]. By mirroring the DF parameters from the affected/non-dominant arm, we observed increased exploration in the unaffected/dominant arm, suggesting that force field parameters derived from one arm can effectively challenge movement patterns in the other arm. This suggests that interlimb coupling can be exploited to enhance motor learning and promote recovery in the affected limb, even without direct intervention.

The observed interlimb coupling effects can be explained through multiple mechanisms. At the neural level, interhemispheric interactions facilitate bilateral motor control through transcallosal pathways [26]. Biomechanically, force transmission through the trunk contributes to bilateral movement coordination. From a motor control perspective, the nervous system employs shared bilateral planning and movement synergies, while integrated proprioceptive and visual feedback provides crucial sensory information for coordinated movement [27]. These mechanisms collectively support the efficacy of bilateral approaches in rehabilitation and guide the development of advanced robotic rehabilitation strategies [28].

While mirror therapy utilizes visual feedback from the unaffected limb, our mirrored deficit field approach provides active force-based perturbations engaging both proprioceptive and motor learning pathways. This multi-modal engagement may explain our observed improvements. Our robotic assessment metrics (RS, CTD, Workspace Area) complemented traditional clinical scales like FMA and ARAT by providing detailed insights into movement quality and exploration patterns.

Furthermore, the bilateral DF condition (condition #4) resulted in the most significant improvements in both RS and workspace area for both groups. This highlights the potential of bilateral DF application to promote symmetrical motor performance and facilitate coordinated movement patterns between both limbs. The robust response to bilateral DF aligns with our understanding of interlimb coupling mechanisms and suggests that simultaneous bilateral training may be particularly effective in rehabilitation settings [12, 23]. By challenging both limbs simultaneously, bilateral DF may encourage the nervous system to develop more efficient and adaptive motor control strategies, leading to enhanced bimanual coordination.

The small sample size (six participants with stroke and five able-bodied participants) warrants caution in generalizing the findings to the broader stroke population. The long-term retention effects of mirrored DF training were not assessed. The transfer of improved motor performance to activities of daily living was not evaluated. The optimal parameters for DF application need to be further investigated through systematic parameter space exploration. Future studies with larger samples and longer follow-up periods are needed to address these limitations.

Despite these limitations, this study provides valuable insights into the potential of mirrored DF as a novel intervention strategy for enhancing motor learning and functional recovery in stroke. By promoting interlimb coupling and challenging bimanual coordination, mirrored DF may offer a unique opportunity to optimize rehabilitation programs and improve outcomes for individuals with stroke.

The clinical implications of this study demonstrate the potential of mirrored DF training to enhance bimanual coordination and motor learning in stroke rehabilitation. This approach offers several clinical benefits: enhanced motor learning through the promotion of motor learning in the affected limb by leveraging interlimb coupling and facilitating the transfer of learned strategies from the unaffected limb; improved bimanual coordination by challenging both limbs simultaneously to encourage the development of more coordinated and efficient movement patterns; and increased patient engagement through the novel and challenging nature of mirrored DF training. Future research should focus on larger-scale clinical trials to validate these findings and investigate the long-term benefits of this approach. Additionally, further exploration of optimal DF parameters and integration with other rehabilitation strategies will be crucial to maximize its therapeutic impact.

V. Conclusion

This study demonstrated the effectiveness of mirrored deficit fields in enhancing bilateral arm movements through interlimb coupling mechanisms. Using our novel NREH-Bimanual robotic platform, we implemented a velocity-dependent force field derived from free exploration data and investigated its effects across four distinct conditions in eleven participants (six stroke patients and five able-bodied individuals).

Our findings revealed three significant outcomes: (1) The application of deficit fields enhanced movement exploration, as evidenced by increased Randomness Scores (up to 24.30% improvement) and workspace areas (up to 28.52% expansion); (2) The mirrored application of DF parameters from the affected to the unaffected arm demonstrated particular effectiveness, suggesting successful utilization of interlimb coupling mechanisms; (3) Bilateral DF application showed the most substantial improvements in movement quality, with enhanced movement perception and increased average speed (approximately 20%) in stroke patients.

Future research directions should focus on: 1) Conducting larger-scale clinical trials with diverse stroke populations, 2) Developing algorithms for real-time optimization of individual DF parameters, 3) Investigating the long-term retention of motor improvements, and 4) Exploring the transfer effects to activities of daily living. This work provides promising evidence for the potential of mirrored DF as an effective rehabilitation strategy for enhancing bimanual coordination and motor recovery in clinical settings.

General Purpose Haptic/Biometric-Based Dynamic Difficulty Adjustment for Post-stroke Upper-limb Rehabilitation Games

Yiyang Shang[1], Sasan Bahrami[2], Samuel Gaardsmoe[3], Alwyn Johnson[4], Michelle J. Johnson[5], Paul Diefenbach[6]

***Abstract*—Rehabilitation therapy can be more effective and engaging when interactive technologies are involved. To enhance this experience, we integrated a haptic/biometric-based (HBB) Dynamic Difficulty Adjustment (DDA) system into the enAblegames™ platform, which already uses body tracking for therapeutic gaming. This system adapts game and haptic difficulty in real time based on each patient's biometric data and performance, making therapy more personalized.**

We tested this system with 11 participants, comparing their experiences with and without DDA. The results were promising—36% preferred DDA-enhanced games, compared to just 7% for non-DDA, and in a single-game scenario, preference for DDA increased by 50%.

These early findings suggest that HBB-DDA can make rehabilitation more engaging and tailored to individual needs. While more research is needed to understand its full impact, this system has the potential to improve patient experience and therapy outcomes.

I. INTRODUCTION

Rehabilitation after stroke often requires a long recovery process [1], and patients may lose the motivation to continue to comply with exercise regimens from their clinical advisors, leading to diminished functional outcomes [2]. Wrapping rehabilitation exercises with games, often called exergames [3], can help maintain patient engagement during a therapy session and across a prescribed therapy period consisting of multiple sessions. [4] Recognizing the need to personalize these games to a patient's mental and physical function level, the idea of developing methods to promote the dynamic adjustment of exercise-based games has emerged as a promising approach to enhance user engagement and optimize training outcomes during rehabilitation [5], [6], [7], and [8]. Incorporating adaptive gameplay and dynamic difficulty adjustment (DDA) in serious games for rehabilitation shows promising results [9], and [10]. These strategies enhance patient engagement, motivation, and overall rehabilitation outcomes, contributing to more effective and personalized interventions across various rehabilitation domains. The continuous advancement of serious games in rehabilitation holds significant potential for transforming patient experiences and improving rehabilitation programs [11], [12], and [13]. Although prior studies have shown that there is a need for DDA in games used in rehabilitation robotics [14], [15], and [16], few games have been developed for this purpose. There is a need to develop a DDA package that can be applied to games of varied design structures to best address different therapy goals while having a multitude of distinct games to reduce boredom among patients [8], [17], [18], and [19]. Furthermore, since the application of rehabilitation robotic technologies varies in complexity and types of impairment profiles treated, there is a need for flexibility in a DDA system to leverage player biometric and robotic inputs (in addition to game performance data) to best determine adaptive game levels. In particular, when dealing with force-feedback technologies, the DDA system should provide both in-game dynamic feedback and haptic feedback to execute these adaptations. This paper details the development and use of a novel DDA algorithm called Haptic/Biometric-Based (HBB) Dynamic Difficulty Adjustment (DDA) HBB-DDA in therapy games, followed by a discussion of how this DDA approach compares to previous systems.

II. RELATED WORKS

With the aim of tailoring the gaming experience to each patient's particular talent and rehabilitation goals, methods for adopting dynamic difficulty adjustment (DDA) in therapeutic gaming have been investigated, [10], [20], and [21]. Several studies in [15], [16] ,and [22] highlighted the significance of personalization in therapeutic video games, aligning challenges with patients' abilities and rehabilitation goals, and enhancing patient engagement and compliance, which are crucial for effective rehabilitation programs. DDA models typically work by adjusting the difficulty levels of game tasks. According to the flow model, a task's difficulty should match the user's capabilities to prevent boredom from too few challenges and anxiety from too many challenges [23]. People exhibit various "flow zones" because

they have diverse preferences for the levels of challenge [23], and [24]. The concept of DDA has been expanded beyond conventional exercise games [6] to virtual reality exercise games for rehabilitation [8], a field tangential to our research. Huber et al. explored DDA through Experience-driven Procedural Content Generation in VR exergames, enhancing engagement by adapting challenges to player performance, which is critical for rehabilitation, and also focused on tailored challenges in rehabilitation exergames [7]. In addition, DDA has been used in robot-assisted therapy, a fast-developing method for recovering from stroke injuries [25], [26], [27], and [28]. Robots frequently use games to keep patients motivated during workouts [29], [29], and [30], and dynamic player modeling has proven to be an effective tool in this setting [31], and [32]. For example, in order to maximize the efficacy of rehabilitation, scientists [33] , and [14] investigated dynamic player modeling in therapeutic robotics games by continuously modifying game obstacles based on player skills. Evolutionary algorithms [14], [34], and [35] have also been used to continuously assess user performance and adjust the level of difficulty of the game in real-time, resulting in more customized and successful rehabilitation experiences. Ozkul [36] presented a fresh and creative approach that combined performance data with real-time emotion feedback as the input to their DDA algorithm, In addition to improving customized therapy, and this integration [35]. Engagement/participation in therapy sessions has a significant impact on how well a patient recovers [37]. Researchers have also investigated the use of physical games for stroke recovery, including digital components to improve therapy, using the digital box and Blocks Test [38], [39], and [40]. Their strategy focuses on blending physical and digital elements to produce enjoyable and efficient rehabilitation experiences [41], [42], [43], and [44].

Our paper describes a new DDA algorithm and a pilot study that examines power generation, game performance, and user preferences in the context of robotic therapy games. Although the focus of our study is mostly on digital therapy games with DDA, the general goal is to utilize technology to improve rehabilitation results.

III. Architecture

A. Design and implementation

This study is part of a multi-year project to design and evaluate a reconfigurable haptic robotics platform integrated with adaptive video games for use in rehabilitation therapy for stroke patients. During the first year, a prototype robot hardware [45] and software platform was developed to test the viability of this approach. The HBB-DDA integration leverages the traditional DDA design, extending it with novel biometric and haptic support. It will also be revised based on the findings presented in this paper.

The Haptic TheraDrive, a one-degree-of-freedom robotic device, enhances upper-limb rehabilitation through personalized adaptive resistance and feedback. It is integrated with therapy and assessment exergames designed to make rehabilitation engaging and effective by tailoring exercises to patient needs and significantly advancing stroke recovery strategies. Figure 1 shows a subject using the hardware of a robot in various configurations. The control algorithm is designed to permit the robot to apply varying levels of assistive or resistive forces to its end effector. Typically, users are seated in front of or on the side of the robot, with their dominant or non-dominant resting comfortably on the handle of the end-effector. The user must move the robot handle to interact with the icon in the game. The mapping of handle rotation to the game icon depends heavily on the game objectives.

Fig. 1: Patient using robot in all configurations

B. Therapy Games

Integrating the Haptic TheraDrive system with exergames for therapy or assessment allows personalization and affordable post-stroke upper limb rehabilitation. The assessment games were designed to assess motor and cognitive performance [46]. Therapy exergames, tailored to patient capabilities and therapeutic requirements, leverage adaptive difficulty settings to ensure optimal engagement and recovery outcomes (Fig. 2). This approach enhances patient motivation and fosters a personalized and effective rehabilitation experience.

C. Haptic Biometric-Based Dynamic Difficulty Adjustment

We integrated a novel haptic/biometric-based dynamic difficulty adjustment (HBB-DDA) system into the enAblegames™ platform to dynamically modify assistive/resistive forces and game difficulty based on user needs. This system adapts robotic force feedback, in-game difficulty, and player guidance in real time using motor and cognitive capabilities, performance metrics, and therapist-defined parameters.

The HBB-Dynamic Adjustment System (fig 3) of the game comprises two main subsystems: the Dynamic Difficulty Adjustment System (DDA) and the Dynamic Feedback System (DFS). These are informed by the Standard Difficulty Adjustment (SDA) system. The DDA adjusts the game's difficulty in real time according to the patient's performance and physiological data. The DFS uses the patient's profile to modify the feedback elements of the game, including text, user interface, and visual and sound effects. The System for Kinematic Input (SUKI) processes player inputs, whether kinematic, robotic,

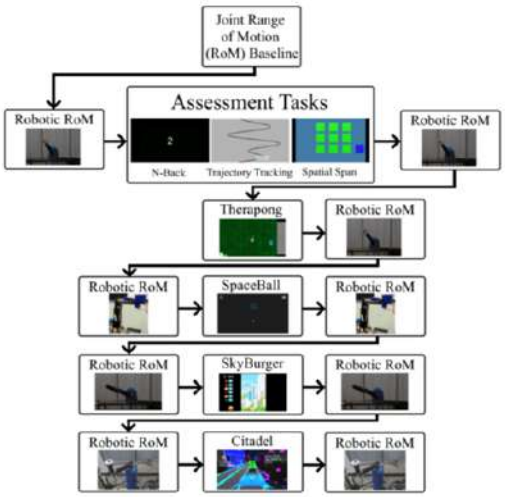

Fig. 2: Experimental workflow during robot-assisted exercise. Participants performed assessment tasks, therapy games, and standardized range of motion (ROM) [47] movements at each position shown in Figure 1 to determine their motor capability while operating the robot.

or biometric. A cloud-connected parameter system allows therapists to control the interaction of these systems, such as haptic feedback, ROM adaptation, and level count. A tracking system records game data, including robotic inputs, and saves it to the cloud for evaluation. The patient's haptic adjustments play a role in the DDA diagram. These subsystems modify the game to meet the patient's needs, providing appropriate challenges without overwhelming them.

DDA, a standalone unit, works with three systems within the enAblegames package: Static Difficulty Adjustment, Feedback, and SUKI:

1) SDA: The Standard Difficulty Adjustment (SDA) system manages fixed game settings, including cognitive difficulty and feedback preferences, using cloud-stored patient profiles that can be adjusted locally when needed.

2) Feedback: The customizable feedback system, guided by SDA settings, dynamically adjusts visual, audio, and text-based cues to indicate difficulty changes and encourage players, with intensity controlled by SDA data.

3) SUKI: The System for Unified Kinematic Input (SUKI) [48] was extended to integrate robotic and biometric inputs into a unified format, mapping data like robot angle, pinch angle, and heart rate to game controls while dynamically adjusting input ranges based on patient profiles stored and updated in the cloud.

The DDA receives data from SUKI and updates patient data and motor performance data, which is linked to game logic. Changes in difficulty are sent to a feedback system that includes text-based, sound-based, background-based, and visual effects. The DDA system used here is a modified version of the Partially Ordered Set Master algorithm suggested by Missura in 2011 [49] for DDA adjustment. This study offers a method for representing and adapting user flow zones within a game using physiological data analysis. To determine a patient's flow zone, we constantly altered the game's complexity by introducing the POSM algorithm, which dynamically adjusts the difficulty based on a 'harder than' relationship between levels. Each difficulty level has a belief vector that directs the prediction process. Further refinement of this vector based on observations and the patient's emotional state during a game session updates the game's difficulty. [37] [36].

Algorithm 1 Partially Ordered Set Master with Physiological Feedback

Require: A partial order $\succeq$ on K different levels, $\beta \in (0, 1)$

for t = 1, 2, ... **do**
  $\forall k \in K$: let $A_t(K) = \sum_{x \in K, x \geq k} w_t(x)$
  $\forall k \in K$: let $B_t(K) = \sum_{x \in K, x \leq k} w_t(x)$
  Decide $k_t^* = \arg\max_{k \in K} \min\{B_t(k), A_t(k)\}$
  Observe $o_t \in \{-2, -1, 0, 1, 2\}$
  Emotion State $e_t \in \{0, 1, 2, 3, 4\}$
  if $o_t = 2 \vee (e_t = 0 \wedge o_t \neq -2)$ **then**
    $\forall k \in K$: let $w_{t+1}(k) = \begin{cases} \beta w_t(k), & k \leq k_t^* \\ w_t(k), & \text{otherwise} \end{cases}$
  else if $o_t = -2 \vee (e_t = 5 \wedge o_t \neq 2)$ **then**
    $\forall k \in K$: let $w_{t+1}(k) = \begin{cases} \beta w_t(k), & k \geq k_t^* \\ w_t(k), & \text{otherwise} \end{cases}$
  end if
end for

Based on the observation O_t, the algorithm updates belief vectors for each difficulty level and predicts the difficulty level. Unlike the suggested study, HBB-DDA has more flexibility in updating belief vectors. First, variable β varies based on whether the difficulty level is harder or easier than the current one. If the patient is a hardcore player, β for harder difficulties will be larger. Second, the observation has five values: 1 for doing good, 0 for average, -1 for doing poorly, and 2 -2 for extreme performance. HBB-DDA can also take the game signal to indicate when the player is doing too well or too badly before the session ends and make changes immediately to prevent boredom or frustration.

In addition to regular performance observation, we added biological data to provide insight into the arousal value of the player's emotional state, including heart rate (HR) and Galvanic Skin Response (GSR). Baseline measurements of GSR and HR were obtained before the gaming sessions. During gameplay, deviations from the baseline indicated stress levels. We converted deviations to stress levels by comparing the size of the deviation to the baseline. Discrepancies between GSR and HR were resolved using GSR over HR data. When the indicators aligned, the DDA algorithm incorporated performance data to operate on GSR and HR values.

IV. Pilot Study

A pilot study was conducted to assess the effectiveness of our robotics and gaming platform for stroke rehabilitation using the Haptic TheraDrive system. Approval was obtained from the University of Pennsylvania IRB (IRB#849090).

Physiological measures, such as Galvanic Skin Response (GSR) and Heart Rate (HR), were integrated to assess

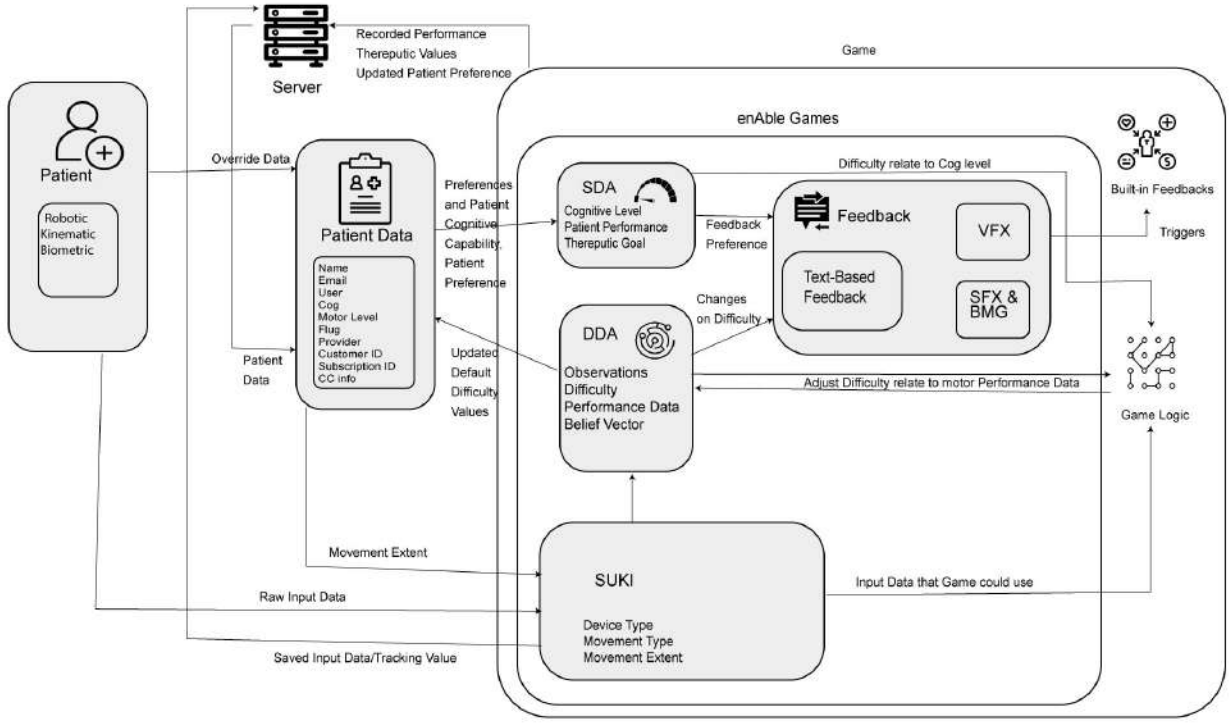

Fig. 3: DDA Diagram and its interaction with different modules

participants' engagement and stress levels. This approach explored the impact of adaptive technologies on rehabilitation outcomes, highlighting the potential benefits of customized game design for enhanced patient recovery and engagement.

Eleven stroke subjects tested the combined robot and gaming system. Informed consent was obtained from all patients. Upper limb motor and cognitive impairments varied from mild to moderate (UE-FM 23-66, MoCA score from 12-29). Subjects played one therapy game (TheraPong) without DDA and three therapy games (Citadel, SkyBurger, and SpaceBall) with and without the HBB-DDA system engaged while using the robot. The DDA adjusted game parameters and robot force feedback but not biological signals. Subjects completed surveys after each game and DDA conditions.

The result shows this system adapts the game's difficulty level in real-time using user performance and biometric feedback, enhancing patient engagement and potentially improving therapeutic outcomes. The use of haptic feedback and biometric data represents a significant innovation in rehabilitation technology, enhancing patient-therapy experiences. In a preference study, 36% preferred DDA game trials over 7% without DDA, with 57% having no preference. In the most difficult game, Spaceball, DDA preference reached 50% over 12% without DDA.

The HBB-DDA integration extends traditional DDA design with biometric and haptic support, and will be revised based on this paper's findings.

The study examined power, calculated as force times linear velocity, which changes during gameplay. Normalized to the maximum and lowest values, this power quantifies the physical labor performed by patients during therapeutic games.

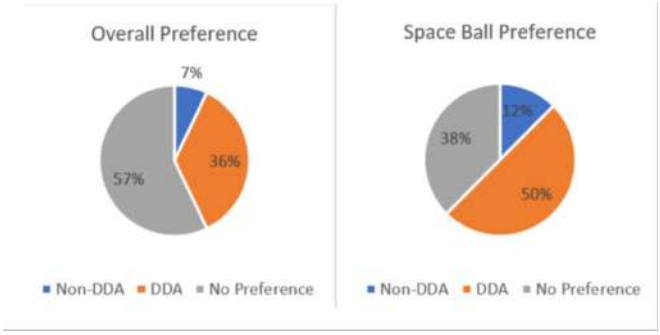

Fig. 4: Pie chart of user preference usage of DDA

The power score summary shows how participation correlates with improvements in motor control, as expressed by UE-FM scores. The research found a stronger relationship between exerted power and motor function than with cognitive performance, indicating that physical components of therapy games are more important for evaluating motor recovery. This is crucial for customizing treatment to maximize recovery.

V. Discussion

Our findings indicate that the HBB-DDA system, mixed with haptic power measures, has enhanced player engagement and personalized rehabilitation. This adaptability is crucial for long-term neuromotor disabilities, as maintaining interest impacts recovery. The system adjusts haptic feedback, game settings, and player interaction, making it versatile for therapists. Despite promising results, further research is needed with a larger sample and expanded biometric markers. Since the pilot, the system has supported eight exergames

TABLE I: Games used in the study

Game	About	How to Play	DDA Values
Citadel	Citadel is a futuristic driving simulator where you must hit arrow signs and avoid octagon signs to get the highest speed and score.	• Move the spaceship by rotating the handle. • Dodge the octagon signs, or else you will slow down. • Pass through the arrow signs to speed up and gain points. • The more arrow signs you collect, the more your speed increases.	• The Speed floor • The speed ceiling • Percentage of the green block
Skyburger	SkyBurger is a stacking game where the player must stack the listed ingredients to make a sandwich.	• Move the burger by rotating the handle. • Collect all ingredients that are shown on the list according to their labeled quantity. If you collect the wrong ingredient, you will lose points. • Avoid the top bun until you complete the recipe; otherwise, you will lose the round. • Once all ingredients in the recipe are collected and the bun is placed on top, you will win the round.	• Each level is based on DDA
Spaceball	Spaceball is a shooting game where you must shoot numbered circles until they read "zero".	• To start the game, press the button. • Aim the cursor toward the target by turning the handle. • Shoot the numbered shapes until the number goes to 0. • Avoid shooting the rotating shields around the circle.	• The range of position the target might spawn • Number of the shots the target needs • Number of shields on the target • Moving speed of the target

with ongoing improvements, including enhanced communication, expanded player profiles, and a new hierarchical game parameter system. These refinements position the HBB-DDA system as a potential benchmark for personalized rehabilitation.

VI. Conclusion

The enAblegames platform's introduction of the Haptic/Biometric-Based Dynamic Difficulty Adjustment (HBB-DDA) technology has demonstrated the system's potential to in rehabilitation therapy. Early findings show that participants clearly prefer games that use the DDA system, with a sizable portion expressing no preference. This suggests that the system's adaptability is successfully meeting the needs of different patients. By keeping patients motivated and involved in their recovery, this individualized approach not only improves therapeutic outcomes but also makes rehabilitation more pleasurable.

Retrofitting Soft Assistive Robots with Sew-free Sensing Garments for Joint Motion Tracking and Kinematic Feedback

Anoush Sepehri[1], Michael T. Tolley[2], Tania K. Morimoto[3]

***Abstract*— Tracking human movement is essential during robot-assisted rehabilitation to provide kinematic feedback for monitoring range of motion, counting repetitions of a certain movement, or achieving closed-loop control. Current strategies for tracking and analyzing human motion, however, are costly, not easily accessible, or challenging to integrate with existing soft assistive robots. In this work, we present skin-tight sensing garments using commercial flex sensors that can be rapidly manufactured using a sew-free lamination strategy. We designed and fabricated sensing garments that can be worn underneath an existing soft robotic wrist orthosis to provide kinematic feedback on flexion and extension of the wrist. We conducted preliminary experiments and demonstrated that our sensing garment can track the position of the wrist with less than 5° of root mean squared error (RMSE) when compared to motion capture. We also demonstrated that our garment design and fabrication approach can be easily extended to other joints and rehabilitation devices to track uniaxial motions by developing a sensing garment for the index finger to provide kinematic feedback when used with a commercial soft rehabilitation glove. Our sensing garments are easy to manufacture, consist of inexpensive and readily available materials, and show promise as a method for providing real-time kinematic feedback of the user during robot-assisted rehabilitation activities.**

I. Introduction

Tracking and analyzing the movement of humans is essential in a variety of medical applications such as mobility tests, diagnosis of pathological movement, and monitoring activity during daily living [1], [2]. Over the last two decades, researchers have begun developing soft robots that can be worn to provide physical assistance to enhance rehabilitation treatment. Consequently, monitoring human movement while operating an assistive device has become necessary for closed-loop control [3], identifying the intention of the user [4] or estimating joint spasticity [5].

While providing kinematic feedback can increase the potential use-cases for soft assistive robots, these systems often use unconventional actuation methods (i.e., fluid-driven soft actuators) [6]. As a result, common sensing strategies seen in rigid robots (i.e., rotary encoders) are not suitable for these systems [7]. While researchers have been actively investigating new sensing strategies that can be integrated into soft robots [8], most soft assistive robots are initially developed without any form of kinematic sensing [9], [10], [11], thus limiting their practical use.

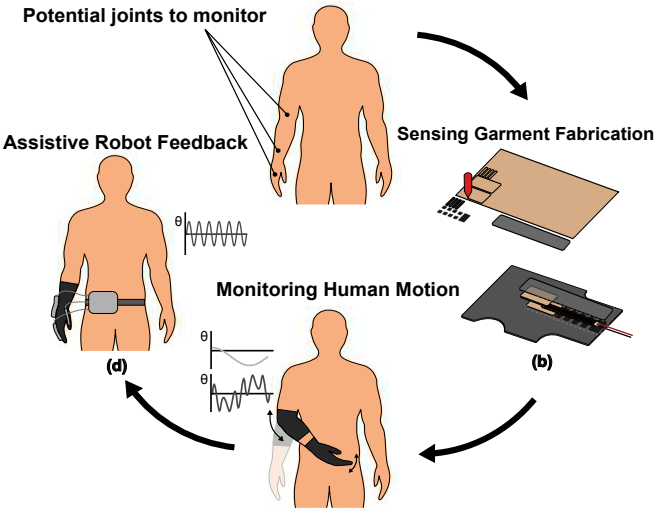

Fig. 1. We propose a simple and repeatable method to manufacture sensing garments for use with existing soft assistive robots. A sensing garment can be manufactured using a sew-free lamination strategy for the targeted joint and desired uniaxial motion to track. The sensing garment can then be used to track human movement and worn under a soft assistive robot to provide kinematic feedback for different purposes (e.g., monitoring or control).

A. Existing Motion Tracking Strategies

The clinical standard for tracking human movement is vision-based motion capture (e.g., VICON or Optitrack) [12]. While vision-based systems are capable of sub-millimeter accuracy and can be used for complex, full body motions, they require stationary cameras and can be expensive, thus limiting their use to clinical and laboratory environments. Furthermore, vision based tracking methods can suffer from occlusion, especially for tasks such as hand pose tracking [13].

Inertial measurement units (IMUs) are widely used for tracking human movement, both with and without an assistive device. While IMUs provide a minimally invasive way to track 3D motion, they suffer from drift, thus limiting their use to short-term experiments [14]. Previous work that has used IMUs for motion tracking [15] and for sensing kinematics of a wearable upper extremity soft robot [3] have reported drift of up to 0.8° RMSE per minute. Periodic re-calibration can help minimize drift over longer time horizons, however, this introduces extra steps that can complicate the tracking process.

Over the last 15 years, researchers have developed soft, stretchable sensors using liquid metal [8], textiles [16], and

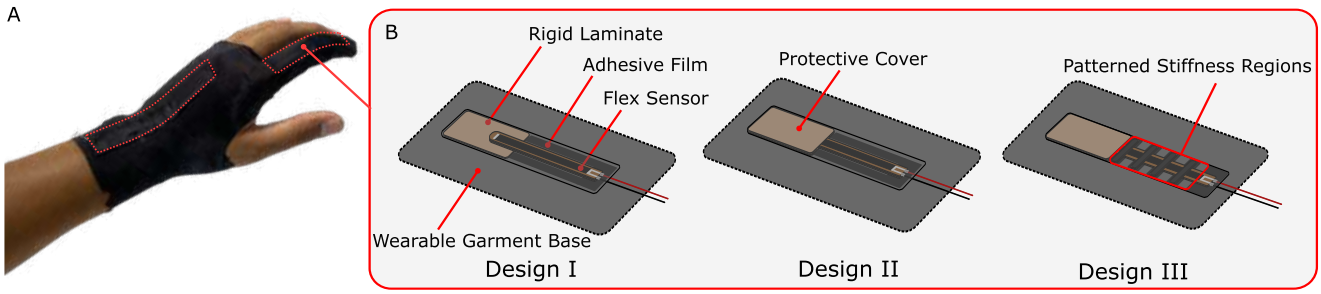

Fig. 2. The proposed sensing garments for tracking human motion. (A) Examples of the sensing garment for monitoring flexion and extension of the wrist and index finger. (B) Three proposed designs to integrate the flex sensor onto the joint. Design I included a rigid laminate that the sensor can slide along during motion. A stiffening layer (not shown here) was under the flex sensor to increase its buckling strength. Design II built upon Design I by adding a protective cover so that the sensor has a rigid groove to slide in. Design III built upon Design II by patterning the adhesive film and included rigid laminates along the sensor body to ensure uniform creasing of the fabric and to increase the contact pressure between the sensor and the joint.

conductive yarns [17]. While these sensors have been successfully integrated into wearable systems, several challenges are apparent. Isolating deformation modes is extremely challenging due to the compliance of the sensor [18]. As a result, interaction forces can lead to poor tracking performance when the sensor is mounted on the body. Menguc et al. [19] designed a soft sensing suit for gait measurement, but reported up to 15° RMSE that were likely due to slippage, forces, and deformation of the sensor when on the body. Integrating soft sensors into a wearable assistive device can pose new challenges because of the added components that can interact with the sensor. For example, Park et. al. had to use a specific shoe and ankle brace when designing a soft robotic ankle orthosis to ensure minimal interaction between the device and liquid metal sensors around the ankle [20]. In general, careful consideration is required when integrating the sensor into the assistive device, thus increasing the design and fabrication complexity of the entire system.

Commercial flex sensors are thin, lightweight laminates that change in resistance when bent. They are readily available, occupy a small footprint, and are robust to pressure and external forces, thus making them attractive for wearable applications. Currently, there is only limited work studying flex sensors as a method for tracking human movement. Existing work has typically focused on developing proof-of-concept gloves for monitoring flexion and extension of the fingers and were not used to retrofit existing assistive devices [21], [22], [23]. The fabrication of these gloves has also generally required a cut-and-sew process that is not only labor-intensive and time-consuming, but requires a skilled sewing machine operator as discussed in previous literature [9], [24]. Other work that used flex sensors with a rehabilitation device only used the sensors to activate discrete actions (i.e., using the tenodesis effect to open and close the fingers [25]). Being able to measure continuous variables, such as the angle of a joint during robot-assisted rehabilitation, would provide new opportunities for rehabilitation treatment, thus warranting further investigation.

B. Contributions

To help address the challenges in kinematic sensing during robot-assisted rehabilitation, we developed a method to rapidly manufacture sensing garments for tracking human motion (i.e., for tracking the user while they move their joints) and for providing kinematic feedback when used with a soft assistive robot (i.e., for tracking a robot while it moves the joints of a human; see Fig. 1). We used the term sensing garments throughout this work to describe a thin, skin-tight textile sleeve that is worn around the joint. We developed a simple and repeatable multi-layer heat lamination strategy to integrate commercial flex sensors onto textile sleeves to track uniaxial motions for different joints. A key requirement that we considered was that the sensing garments should be able to be worn underneath an existing soft assistive robot to act as a sensing "skin" to provide kinematic feedback without requiring modifications to the design or the operation of the device itself. We fabricated three different sensing garments for tracking flexion and extension of the wrist and evaluated the calibration results when used with and without a soft robotic wrist orthosis to identify design features that improved calibration accuracy. We then fabricated sensing garments for tracking flexion and extension of the wrist and fingers and validated the sensing accuracy in controlled motion tracking experiments with and without a soft assistive robot. The results in this work demonstrate that our sensing garments can be a simple and viable method for retrofitting soft assistive robots to provide kinematic feedback during robot-assisted rehabilitation activities.

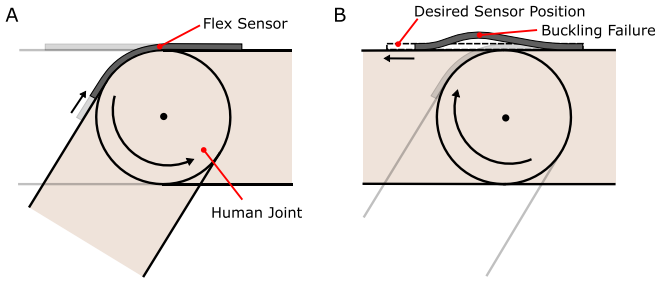

Fig. 3. Due to unavoidable misalignment between the neutral axis of the sensor and the joint, we found that the sensor must be able to slide freely within the sensing garment while conforming to the curvature of the joint. (A) During counterclockwise motion, the sensor is under tensile load and must slide backwards. (B) During clockwise motion, the sensor is under compressive load and must slide forwards. The sensor will buckle and fail if the compressive forces on the sensor exceeds its buckling strength.

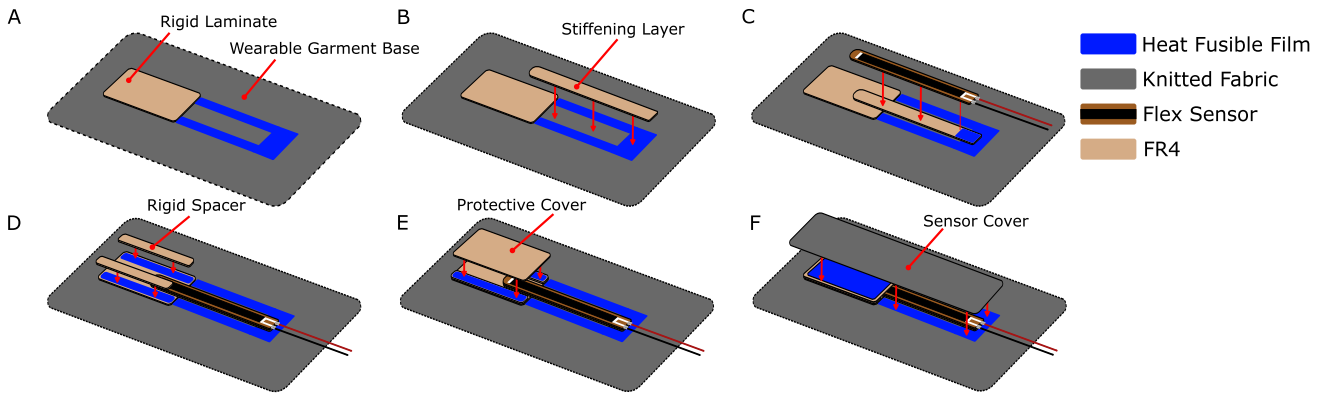

Fig. 4. Representative steps to fabricate Design II of the sensing garments. (A) The rigid laminate was first bonded to the garment base. (B) A stiffening layer was then bonded under the sensor to increase its buckling strength. (C) The flex sensor was attached to the stiffening layer. (D) 1 mm thick spacers were added to the rigid laminate. (E) A protective cover was attached to the top of the spacers to provide a low-friction groove for the sensor to slide through. (F) A sensor cover made from knitted fabric was attached over the laminated layers to hold the sensor against the skin.

II. Sensing Garment Design and Fabrication

A. Sensing Garment Designs

We used commercially available flex sensors (Bend Sensor, Flexpoint Sensor Systems, Inc), that have been previously used in soft wearable devices [5], [21], [22], [23], [25]. We selected the 2 inch bi-directional sensor with no protective laminate layer because previous literature suggested that the protective layer degraded tracking performance due to creep [21]. We wired the bi-directional flex sensor as a voltage divider and read the signal output using a microcontroller (UNO, Arduino) as suggested in the sensor manual.

One of the biggest challenges when using flex sensors to monitor human movement is that the sensor must slide to account for misalignment between the neutral axis of the joint and the sensor (see Fig. 3). We aimed to address this challenge by designing and evaluating three versions of the sensing garments that allowed for sliding of the sensor relative to the joint (see Fig. 2). We designed each sensing garment for monitoring flexion and extension of the wrist because it allowed us to evaluate our sensing garments when bending in both directions. The results from testing on the wrist therefore generalized to other joints for tracking uniaxial motions in one direction (e.g., elbow extension).

The simplest strategy to integrate a flex sensor onto the body is to place the sensor in a sleeve that is attached directly over the joint [22], [23]. We observed, however, that the flex sensor would frequently buckle (see Fig. 3). We addressed this issue in Design I of our sensing garment by bonding a rigid laminate to the wearable garment base to provide a smooth surface for the tip of the sensor to slide along. The rigid laminate was a 0.2 mm thick fiber-reinforced epoxy laminate material (FR4). We also added a 0.2 mm thick piece of FR4 directly under the flex sensor to act as a stiffening layer to increase the buckling strength of the sensor. We then used a piece of fabric to cover and hold the sensor against the joint.

When the sensor slid along the joint in Design I, we observed considerable friction between the sensor and the fabric. In Design II, we added a 1 mm rigid spacer and protective cover, both made from FR4, on top of the rigid laminate to allow the tip of the sensor to slide freely without being in contact with the fabric. We hypothesized that minimizing sliding friction between the sensor and the fabric would reduce the hysteresis when compared to Design I.

In Design III, we patterned the adhesive film along the length of the sensor to control the stiffness of the sensing garment for more uniform creasing of the fabric during motion. We also added strips of FR4 along the patterned adhesive film to increase the pressure holding the sensor in contact with the joint. We hypothesized that these modifications would further improve the hysteresis and reliability of the sensing garment in comparison to Design II.

B. Multi-layer Fabrication Procedure

We used a multi-layer lamination process to integrate the flex sensor into a skin-tight wearable garment around the wrist (see Fig. 4 for representative steps for Design II). A similar fabrication strategy was previously proposed to design a rehabilitative glove [9] and soft assistive robot for the shoulder [24]. Each sensing garment consisted of layers of knitted fabrics (24710, Darlington Fabrics) and FR4 bonded together using heat fusible thin films (Ultrahold Iron-on Adhesive, HeatnBond). We first used a CO_2 laser cutter to cut the FR4, heat fusible thin film, and fabric to the appropriate shapes prior to laminating. While any commercial sleeve that is compatible with the adhesive film can be used as the wearable garment base, we fabricated our own using the knitted fabric for faster design iteration across different joints. We chose a knitted fabric because the elastic properties of the material allowed the sensing garment to conform to the joint during motion. To bond the FR4 and knitted fabric together, we bonded one side of the adhesive film to the FR4 using a heat press for 4 s at 250°C. We then positioned the exposed side of the adhesive film directly on the knitted fabric and used the heat press for 12 s at 250°C to create a permanent bond. We used repositioning adhesive (Spray Mount Adhesive, 3M) to prevent the layers from moving relative to one another when using the heat press. We repeated these steps to bond the FR4, knitted fabric, and flex sensor together for each of the designs previously discussed.

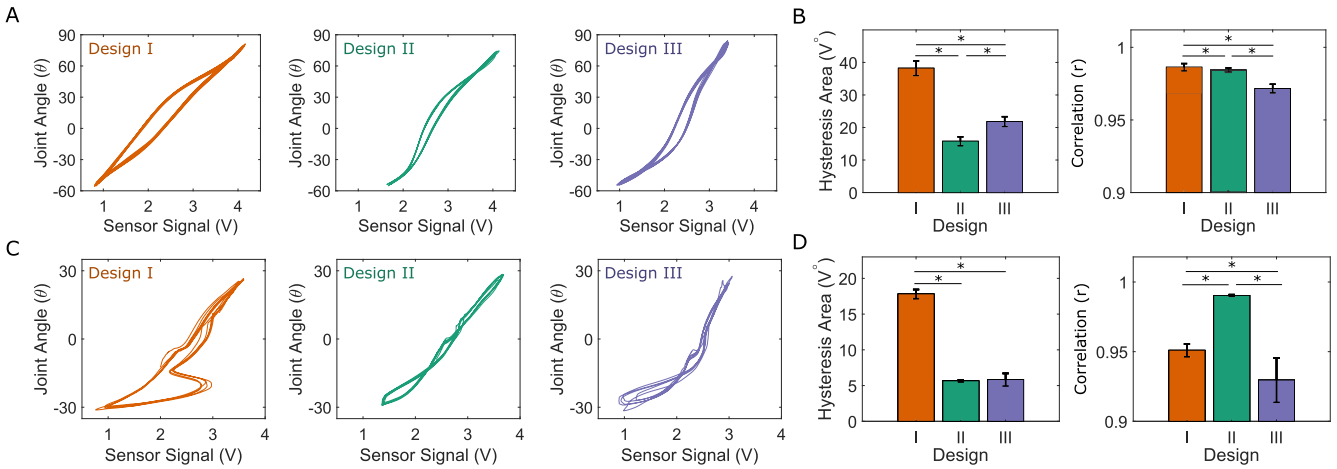

Fig. 5. Experimental results to compare the different sensing garment designs. (A) Characterization results without an assistive device. Positive and negative angles represent flexion and extension of the wrist respectively. (B) Hysteresis area and Pearson correlation coefficients for each of the calibration curves in (A). (C) Characterization results when the soft robotic wrist orthosis was worn over the sensing garments. (D) Hysteresis area and Pearson correlation coefficients for each of the calibration curves in (C). All bar plots include mean and standard deviation error bars. Statistical significance ($p < 0.05$) between different sensing garment designs was marked using an asterisk.

III. Sensing Garment Comparison

A. Characterization Procedure

We used an OptiTrack motion capture system to measure the true joint position when calibrating the sensing garments. First, the user donned the sensing garment and the reflective markers for the motion capture system. We generated two rigid body coordinate frames, one for the hand and one for the forearm, and calculated the homogeneous transformation matrix between them to estimate the angle of the wrist. Data was sampled at 60 Hz and synchronized with the flex sensor using a synchronization device (eSync 2, OptiTrack).

We conducted calibration experiments to identify which sensing garment design was best for tracking human motion and providing kinematic feedback when used with a soft assistive robot. Because the goal of this work was to evaluate the functionality of our sensing garments, all data was collected on the authors. For experiments without any assistive robot, the user moved their wrist through their active range of motion for approximately 45 seconds. We tested the sensing garment when used with a soft assistive robot by using a soft robotic wrist orthosis that we previously developed [26]. The device consisted of two textile pneumatic actuators that provided flexion and extension assistance for the wrist. The user first donned the sensing garment, then donned the assistive device as intended. While the user was completely relaxed, we programmed the device to move through a predefined range of motion for six full cycles, taking approximately 145 seconds to complete. We limited the range of motion to approximately 60 degrees of flexion and extension for all experiments when using the soft robotic wrist orthosis.

B. Results and Discussion

We first compared the calibration curves, which map the sensor signal to the joint angle, for each of the three sensing garment designs when no assistive device was used (see Fig. 5A). We calculated the hysteresis area and the Pearson correlation coefficient for each of the calibration curves to estimate the linearity (see Fig. 5B). We used the Shapiro-Wilk test to confirm normality in or data and conducted an unpaired, two-tailed T-test with a 0.05 significance threshold to compare each design. Design II had the lowest hysteresis area with only a 0.3% decrease in linearity in comparison to Design I. We attributed the reduction in hysteresis to the protective cover which minimized frictional losses as the sensor moved along the joint. Patterning the adhesive film and adding FR4 slots in Design III did not reduce

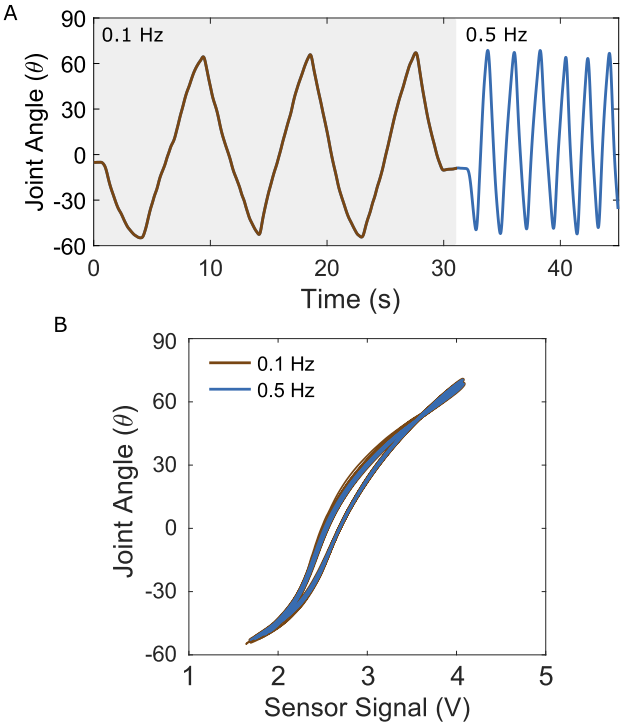

Fig. 6. Evaluating the tracking accuracy of our sensing garments for different joint velocities. (A) The raw kinematic data from the motion capture system. (B) Calibration curves corresponding to the data in (A). The calibration curves are nearly identical, thus suggesting our sensing garments are reliable over a range of speeds relevant for rehabilitation activities.

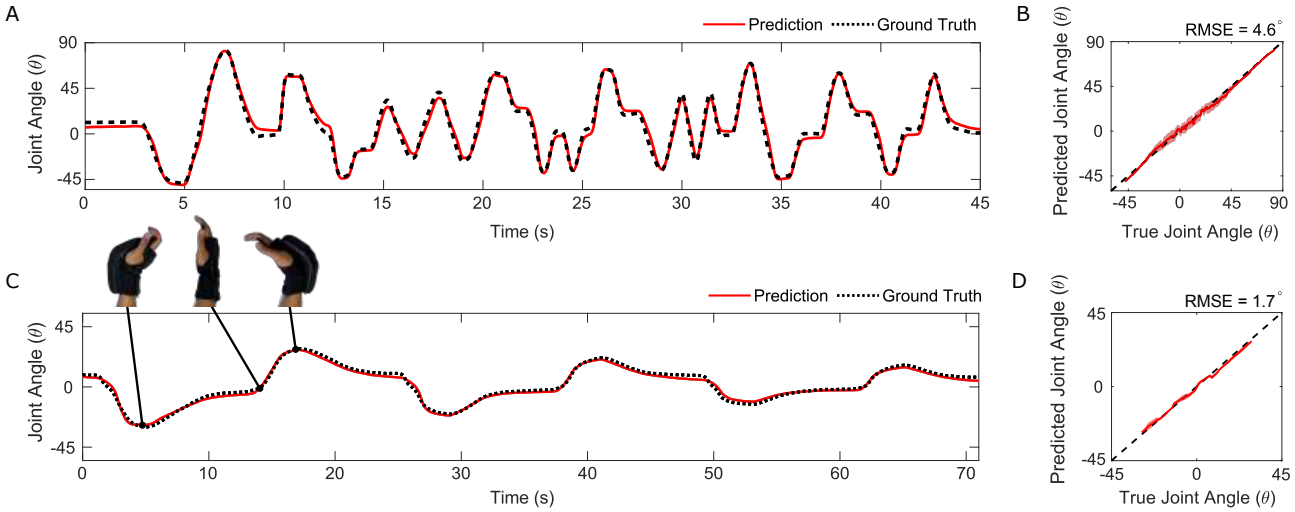

Fig. 7. Experimental results for tracking flexion and extension of the wrist. (A) Validation results for tracking motion of the wrist without the soft robotic wrist orthosis. The user moved their wrist through an arbitrary trajectory that covered their active range of motion. (B) Comparison between the predicted and true joint angles for the data in (A). The shaded area represents the standard deviation of the prediction. (C) Validation results when using the soft robotic wrist orthosis for continuous passive motion therapy. (D) Comparison between the predicted and true joint angles for the data in (C).

the hysteresis further, and instead, likely increased the non-linearity of the calibration results.

We then compared the calibration curves for each of the three sensing garments when used with the soft robotic wrist orthosis (see Fig. 5C and Fig. 5D). We used the Shapiro-Wilk test to confirm normality in our data and determined that the Pearson correlation coefficient estimates for Design III could not be assumed to be normally distributed. As a result, we used the Mann-Whitney test with a 0.05 significance threshold to compare the Pearson correlation score for Design III with the other two designs. For all other comparisons, we used the same unpaired T-test as before. During wrist extension, the flex sensor in Design I buckled, resulting in poor calibration results. We believe that this occurred because of the contact forces between the soft robotic wrist orthosis and the sensing garment that prevented the sensor from sliding along the wrist. Design II and Design III showed no signs of sensor buckling, likely due to the protective cover that prevented the soft robotic wrist orthosis from constraining the motion of the sensor. Design II had a higher linearity score when compared to Design III but there was no significant difference in the hysteresis. We decided to move forward with Design II for the rest of this work because it had the best performance in terms of hysteresis and linearity during calibration.

IV. Motion Tracking Characterization

A. Evaluating Calibration Accuracy at Different Speeds

We first investigated how the tracking accuracy of our sensing garment changed when the user moved at different speeds because previous literature has shown that faster movements can lead to larger tracking errors [19]. Given that the average dominant frequency of wrist movement is 1 Hz [27] and that rehabilitation activities are generally delivered in a slow, controlled manner (i.e., continuous passive motion therapy) we chose to evaluate the accuracy of our sensing garment for movements at 0.1 Hz and 0.5 Hz. The user first donned the sensing garment and moved their wrist through their full range of motion at approximately 0.1 Hz for 30 seconds. The user then moved their wrist through their full range of motion at approximately 0.5 Hz for 15 seconds (see Fig. 6A). We used the data collected at 0.1 Hz to fit a cubic spline to map the signal from the flex sensor to the joint position. We then evaluated the accuracy of the fitted spline against the data collected at both speeds.

When comparing the data collected at 0.1 Hz and the data collect at 0.5 Hz, the hysteresis area reduced by 21%. The Pearson correlation coefficient, however, only changed by 0.5% and the shape of the calibration curve stayed approximately the same (see Fig. 6B). Our spline calibration had an error of 5.2° and 3.7° RMSE for the data collected at 0.1 Hz and 0.5 Hz respectively, thus suggesting that our sensing garments can achieve high accuracy at different speeds that are relevant for rehabilitation activities.

B. Tracking Human Motion

We evaluated the tracking accuracy of our sensing garment in controlled motion tracking experiments with and without a soft assistive robot. We followed the calibration procedure outlined in Section III and fit the data using a cubic spline, as discussed in the previous section. We immediately collected the validation dataset after calibrating the sensing garment to minimize any effects garment shifting could have on the tracking performance. When collecting the validation dataset without an assistive device, the user moved their wrist through an arbitrary trajectory that covered their active range of motion for approximately 45 seconds. To collect the validation dataset with the soft robotic wrist orthosis, we programmed the device to simulate continuous passive motion therapy over different ranges of motion.

The tracking RMSE of our sensing garment was 4.6° over 45 seconds of self-directed motion by the user and 1.7° when used to provide kinematic feedback for the soft robotic wrist

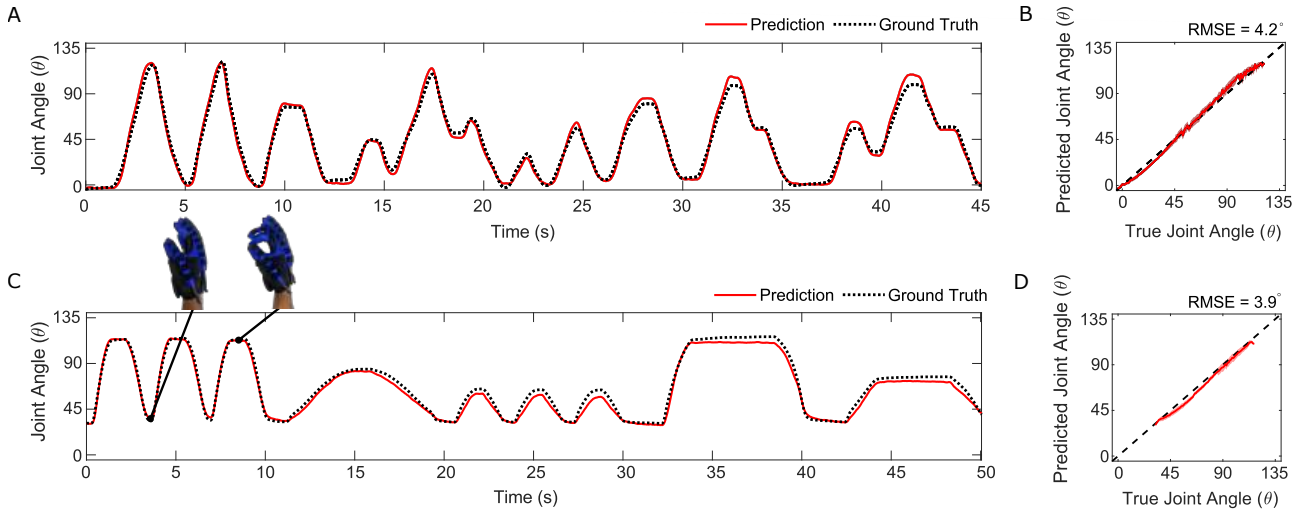

Fig. 8. Experimental results for tracking flexion and extension of the index finger. (A) Validation results for tracking motion of the finger without the rehabilitation glove. The user moved their finger through an arbitrary trajectory that covered their active range of motion. (B) Comparison between the predicted and true joint angles for the data in (A). The shaded area represents the standard deviation of the prediction. (C) Validation results when using the rehabilitation glove for flexion and extension assistance of the finger. (D) Comparison between the predicted and true joint angles for the data in (C).

orthosis (see (see Fig. 7A) and Fig. 7C). We also found that our sensing garment could predict the position of the joint with low variance over the full range of motion of the wrist (see Fig. 7B and Fig. 7D).

V. Generalization to Other Joints and Uniaxial Motions

In this section, we investigated how our design principles and fabrication method can be used to develop sensing garments for other joints and soft assistive robots to provide kinematic feedback for uniaxial motions. We fabricated a sensing garment for the index finger to monitor flexion and extension by tracking the angle of the proximal interphalangeal joint. We targeted the finger because hand impairment is one of the most common disabilities after a stroke [28] and because there are many commercially available soft assistive robots for the hand without integrated sensing that could benefit from our garments. We purchased a pneumatically actuated rehabilitation glove (Becggse, Amazon) that consisted of bellowed plastic actuators that flex when pressurized. We used the same electro-pneumatic regulators that we used for the soft robotic wrist orthosis to control the input pressure to the bellowed actuator on the index finger.

We followed the same procedure to collect the calibration and validation datasets that we used when evaluating the sensing garment for the wrist. The true angle of the finger was measured using motion capture and was based on the position of the distal tip relative to the base of the finger. We selected arbitrary pressure inputs that spanned a wide range of motions when collecting the validation dataset with the soft commercial rehabilitation glove. It should be noted that when the bellowed actuator on the rehabilitation glove was not pressurized and the user was relaxed, the fingers were flexed to approximately 30° due to the intrinsic stiffness of the glove. We only used positive pressure to operate the rehabilitation glove, hence we ignored all angles smaller than 30° in our experiments.

Our sensing garment could successfully track the position of the finger even when worn underneath the rehabilitation glove. The RMSE when compared to motion capture was approximately 4.2° and 3.9° when used with and without the rehabilitation device and once again had low variance over the entire range that we evaluated (see Fig. 8).

VI. Discussion

Our sensing garments can be worn underneath a soft assistive robot and can track human motion with less than 5° RMSE. Literature suggests that 5° RMSE is acceptable for many research and clinical applications, although requirements are dependent on the task [29]. We believe 5° RMSE is acceptable for tasks such as achieving closed-loop control for a soft assistive robot where tracking errors of the controller can range from 3° to 6° RMSE [3], [5].

Existing work that used flex sensors to track human motion generally focused on designing gloves to track flexion and extension of the fingers by placing the sensor inside a fabric sleeve sewn directly over the fingers [22], [23]. This method to integrate the sensor on the body, however, led to buckling failure when used for joints such as the wrist, most likely due to the larger discrepancy between the neutral axis of the sensor and the joint. In this work, we identified design features that can be created using FR4 that eliminated buckling failure, improved calibration accuracy, and ensured our sensing garments could be used for joints other than the finger and with existing soft assistive robots.

Existing sensing gloves that used flex sensors are also typically fabricated using a cut and sew method [22], [23]. We assembled our sensing garments using a sew-free heat lamination strategy,thus eliminating the need for a skilled sewing machine operator and complex cut-and-sew procedures that can lead to potential sources of error [9], [24].

It is well known that any shifting of the sensor on the body could lead to errors when tracking human motion [15], [30]. While we did not observe any shifting during our tests due

to the short duration of our experiments, future work should investigate features, such as high-friction layers between the sensing garment and the skin, to minimize shifting during extended use. Future work should also evaluate our garment design with the target population (e.g., stroke survivors) to consider constraints during donning and doffing. Lastly, since most soft assistive robots provide simple, single-degree-of-freedom assistance [4], [9], [11], [31], we focused on tracking uniaxial motions. Future work should explore ways to integrate the flex sensors onto the body to measure multi-degree-of-freedom motions to increase the potential use cases of our sensing garments.

VII. Conclusion

In this paper, we presented wearable sensing garments for monitoring human movement using commercial flex sensors. Our sensing garments are easy to manufacture, made from readily available materials, and are suitable for different joints for tracking uniaxial motions. They offer suitable accuracy for rehabilitation applications and can serve as a sensing "skin" for soft assistive robots without any form of integrated sensing. This work provides new opportunities for motion analysis during rehabilitation treatment that is accessible to a wide audience of researchers and users.

***Abstract*— Excessive coronal or axial plane moments in lower extremity joints are commonly linked to musculoskeletal injuries. However, deliberately inducing such moments can be advantageous in personalized rehabilitation by addressing specific biomechanical needs. The tilted-plane ergometer, designed to tilt the pedaling plane and adjust pedal orientation, facilitates desired limb alignment during pedaling. This study examined changes in joint dynamics, and muscle activity across various ergometer configurations using a musculoskeletal modeling approach. Five participants performed pedaling tasks under four distinct configurations, with data collected via a motion capture system and a force-torque sensor integrated into the pedal. Configurations favoring abducted pedaling planes reduced knee adduction moments and increased ankle abduction moments, while axial rotation moments were modulated through targeted pedal orientations. Conversely, adducted pedaling planes combined with inverted pedal orientations significantly increased internal rotation moments at the knee and ankle, alongside inducing posterior directional forces at the hip and ankle joints. Estimated muscle activity varied across configurations, demonstrating the device's adaptability in targeting specific biomechanics. These findings underscore the potential of the tilted-plane ergometer to effectively modulate joint biomechanics, positioning it as a promising tool for personalized rehabilitation interventions.**

Keywords—bicycle ergometer, biomechanics, tilted pedaling plane, musculoskeletal modeling, personalized rehabilitation

I. INTRODUCTION

In personalized rehabilitation, the primary goal is to tailor interventions to protect specific structures from excessive loading or, conversely, to stimulate recovery by applying targeted mechanical stress. Rehabilitation strategies should also focus on engaging muscles critical to functional recovery while minimizing adverse mechanical effects on the joints and surrounding structures. For instance, following total hip arthroplasty, rehabilitation should focus on strengthening the hip abductors while avoiding internal rotation and adduction moments to prevent dislocation [1]. For ACL injury recovery, restoring hamstring function is essential while minimizing anterior tibial forces to protect the ligament or graft [2].

Excessive coronal or axial plane moments in lower extremity joints are often implicated in musculoskeletal injuries [3]. However, deliberately inducing such moments can be beneficial in personalized rehabilitation when addressing specific biomechanical deficits [4]. In order to address this need, we developed a tilted-plane ergometer enabling movement across multiple pedaling planes (Fig. 1). The device offers dynamic control of joint loading by tilting the pedaling plane beyond a single degree of freedom (DoF) into a tilted orientation. Additionally, it enables precise adjustment of pedal-foot orientation to guide specific lower limb alignments, facilitating the desired load distribution across the joints [5].

Our previous research has demonstrated that the tilted-plane ergometer effectively alters muscle activation patterns and joint kinematics [6, 7]. However, its influence on joint kinetics remains insufficiently studied. Net joint forces and moments, or partial joint reaction forces (JRFs), can be calculated using inverse dynamics based on external force data and kinematic measurements. Estimating actual JRFs, which incorporate the contributions of muscles and ligaments, requires a more sophisticated approach using musculoskeletal modeling [8]. By leveraging multibody dynamics frameworks that integrate rigid body components, kinematic actuators, and muscle-based force and torque actuators, it is possible to accurately simulate muscle forces and actual JRFs [9].

In this study, we utilized a 6-axis force-torque sensor integrated into the pedal and a motion capture system to evaluate JRFs under various pedaling configurations using a

This research was supported by a grant from the MD-PhD/Medical Scientist Training Program and Korea Health Technology R&D Project (grant number: RS-2022-KH129263) through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health and Welfare, Republic of Korea.

musculoskeletal modeling approach. Our findings revealed that pedaling configurations with abducted planes (yaw = -30° for the right pedaling plane in Fig. 1(b)) reduced knee adduction moments (KAMs) and increased ankle abduction moments, while axial rotation moments were adjusted through specific pedal orientations. Conversely, configurations with adducted pedaling planes and inverted (roll = +15° for the right pedal in Fig. 1(b)) pedals significantly increased internal rotation moments at the knee and ankle and generated posterior directional forces at the hip and ankle joints. These results highlight the potential of the tilted-plane ergometer to serve as a highly adaptable tool for optimizing rehabilitation by enabling individualized biomechanical adjustments to target specific therapeutic goals.

II. Materials and Methods

A. Participants

Five participants (mean age: 30.8 ± 5.6 years, height: 1.70 ± 0.09 m, weight: 68.8 ± 10.0 kg), consisting of two females and three males, were enrolled in this study. All participants had no history of musculoskeletal injury within the past six months or major lower extremity surgery. Written informed consent was obtained from each participant, and the study adhered to ethical guidelines for human research. The experimental protocol was approved by the Institutional Review Board of Korea University College of Medicine (IRB number: KUIRB-2024-0015-01). Before the experiment, a physical therapist and an orthopedic surgeon conducted a general physical assessment to ensure that participants had no pain or mobility limitations that could interfere with their participation in the study.

B. Device and Experimental Design

The tilted-plane ergometer used in this study was developed by our team to facilitate multi-planar lower limb movements tailored for individual rehabilitation needs. The device allows adjustment of the pedaling plane in the XY plane by modifying the yaw angle of the plane-tilting joint (Fig. 1), corresponding to the abduction/adduction angle in the coronal plane. A universal joint ensures synchronized crank rotation while supporting tilted-plane pedaling. Figure 1b highlights the adjustable pedal mechanism, integrated with a 6-axis force-torque sensor (DynPick WEF-6A1000-30, WACOH_TECH Inc., Japan), capable of measuring forces and torques within ±1000 N and ±30 Nm, respectively, at a

sampling rate of 2000 Hz. The pedal design permits fine-tuning of roll, pitch, and yaw angles for customized foot positioning.

The pedaling conditions and experimental procedures followed the framework established in our previous studies, detailed in [6] and [7]. Four configurations (Fig. 2a) were evaluated: (1) NEU: a baseline setup with neutral pedaling, no tilt, and no pedal adjustments. (2) ABE: pedaling plane tilted -30° in the abduction direction (yaw, based on right side), with the pedal set to -5° eversion (roll) and +5° internal rotation (yaw). (3) ABI: an abducted pedaling plane with the pedal adjusted to +15° inversion and -30° external rotation. (4) ADI: a +15° adduction-direction tilt (yaw) combined with +15° pedal inversion (roll). Participants pedaled at level 8 intensity (of 14 levels), maintaining a speed of 15-17 km/h. After a brief calibration, each participant completed 25 cycles for each condition, with a 2-minute rest interval between trials to minimize fatigue. The sequence of conditions was randomized for each participant to reduce potential order effects.

Motion capture was performed using a Vicon motion capture system (Vicon, Oxford, UK) with eight cameras operating at 100 Hz. A total of 25 passive reflective markers were strategically placed on the participants, following established protocols with minor adjustments [10] (Fig. 2b). Anatomical landmarks near the joints were marked to identify joint centers, while additional markers were attached to well-visible areas like the anterior surfaces of the thigh and tibia to ensure accurate tracking. For the pelvis, the posterior superior iliac spine (PSIS) markers were obstructed by the backrest, so alternative tracking markers were positioned on the lateral upper iliac wing.

To synchronize the motion capture and force-torque data, an inertial measurement unit (IMU, WT901BLECL5.0, WIT Motion, China) was mounted on the anterior aspect of the right thigh. This IMU was pre-synchronized with the force-

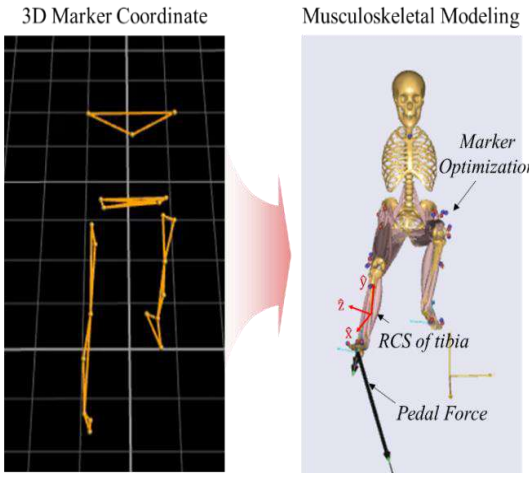

Figure 3. Musculoskeletal Modeling. The process of musculoskeletal modeling, starting from real-time data acquisition (left) to the integration of musculoskeletal modeling with external pedal force data (right). (*RCS: reference coordinate system*)

torque sensor. By aligning the sagittal plane angle data independently captured by the IMU with the motion capture system, both data streams were effectively synchronized, ensuring accurate integration of force-torque and motion data.

C. Musculoskeletal Modeling

The musculoskeletal model was created using AnyBody Modeling System 7.4 (AnyBody Technology, Aalborg, Denmark), a software designed to process 3D motion capture data with high precision and reliability [11]. We utilized a full-body template within the AnyBody Managed Model Repository but focused solely on the lower extremities, excluding upper body muscles and skeletal structures distal to the scapula. It incorporated 1 DoF for each knee joint, 3 for the ankle and hip joints, 6 for the pelvis, and 3 for the connection between the pelvis and thorax. To align with the study's experimental marker setup, the model's tracking marker positions were adapted from the basic template, originally based on the Plug-in-Gait model. The model was then scaled to match each participant's specific segment lengths and body weights, ensuring individual accuracy. Personalized models were driven by kinematic data obtained from 3D skin marker coordinates [9]. Unlike standard templates that typically rely on kinetic data from force plates, this model was customized to incorporate force-torque data from sensors placed at the middle plantar region of the foot. The model was further modified to apply these force-torque inputs directly to a designated node on the middle plantar side, making it more suitable for the experimental design (Fig. 3).

The force and moment axes were defined in a relative coordinate system for each body segment: the x-axis representing posterior-to-anterior, the y-axis distal-to-proximal, and the z-axis medial-to-lateral directions (Fig. 3 right panel). When calculating joint reaction forces and moments, the axes are referenced at the proximal end of the distal segment, meaning the reaction forces and moments are expressed relative to the reference frame of the distal segment. In this study, force-torque sensors were applied only to the right-side pedal; therefore, all data were collected exclusively from the right lower limb.

D. Data Prosseing and Analysis

Kinematic, kinetic, and estimated muscle activation data were segmented by the pedaling cycle, with the data normalized to a time axis spanning 0–100% of each cycle. The pedaling cycle was defined as beginning at the position of maximum hip flexion, consistent with our previous studies. The push phase (or power phase) was identified as the first half of the cycle, during which the hip and knee joints extended to apply pushing forces to the pedal, generating rotational motion. The pull phase (or recovery phase) was designated as the latter half of the cycle.

For each participant, mean values were calculated for each phase-frame, and the combined data across participants were summarized as means and standard deviations (SDs) to evaluate differences between ergometer conditions. Kinetic data, including net and actual JRFs, were normalized to each participant's body weight to facilitate group-level analysis. For statistical comparisons, a paired t-test or Wilcoxon signed-rank test was applied to compare each data between the baseline NEU condition and other configurations, based on the normality and homoscedasticity of the data. All data processing and analyses were conducted using MATLAB version R2024a (MathWorks, Inc., Natick, MA, USA).

III. Results

A. Kinematic Data

Figure 4 presents the kinematic results for hip and knee joint angles across different conditions, shown as mean values with SDs. The sagittal angles of the hip and knee joints, reflecting flexion/extension movements, exhibit similar patterns across all configurations. However, an offset of approximately 10˚ was noted in knee joint motion under the ADI condition. Compared to the baseline NEU condition, the hip joint showed slightly increased adduction in the ABE condition, while greater abduction angles were observed in the ABI and ADI conditions. Notably, the axial rotation pattern in the ABE condition differed significantly from NEU and ADI, with a reduced range of motion (ROM).

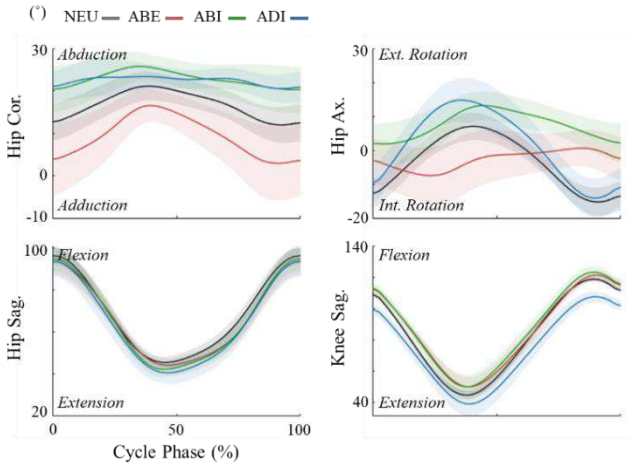

Figure 4. Joint angle. Lower extremity joint angles during the pedaling cycle are compared across different ergometer conditions. Lines represent the mean joint angles, and shaded areas indicate standard deviations. The results are averaged across all participants. (*Sag.: sagittal, Cor.: coronal, Ax.: axial, Ext.: external, Int.: internal*)

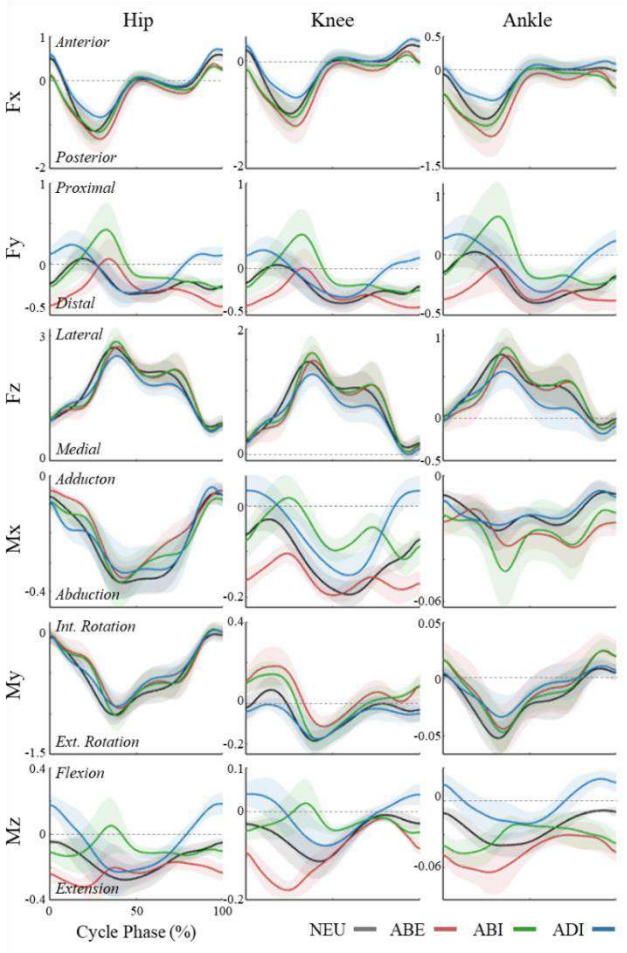

Figure 5. Net joint reaction force and moment. Net joint forces (N/kg) and moments (Nm/kg), normalized to each participant's body weight, are compared across different ergometer conditions throughout the pedaling cycle. (*Fx/y/z: force components along the x, y, and z axes; Mx/y/z: moment components about the x, y, and z axes*.)

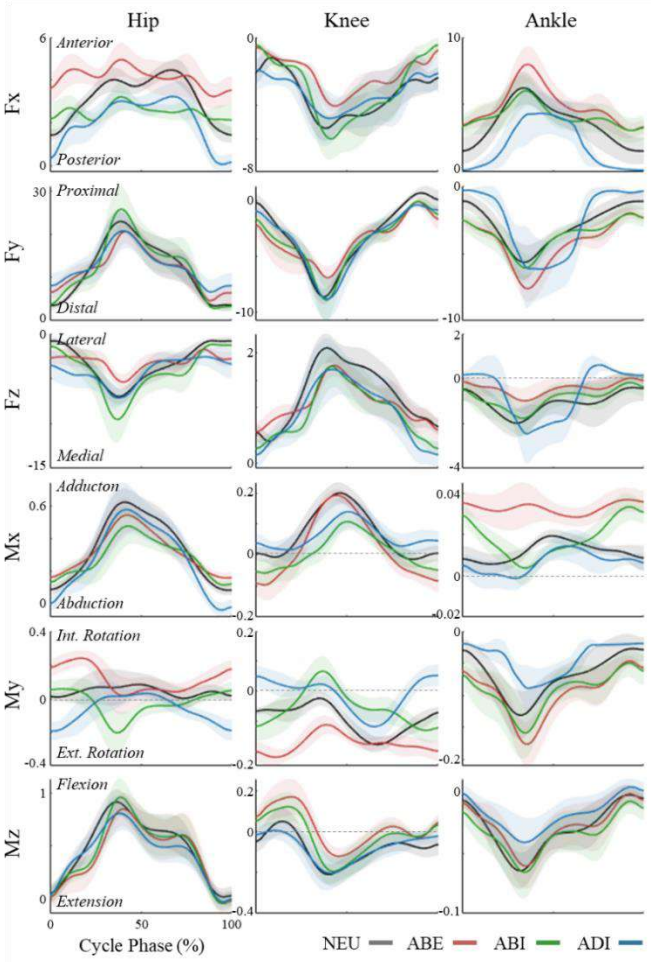

Figure 6. Actual joint reaction force and moment. Estimated actual joint reaction forces (N/kg) and moments (Nm/kg), normalized to each participant's body weight, are compared across different ergometer conditions throughout the pedaling cycle.

B. Kinetic Data

Figure 5 presents the net JRF results for the hip, knee, and ankle joints across the three axes. The x-axis and z-axis components of the net joint force (*nFx* and *nFz*) exhibited similar patterns across all three joints. However, the y-axis component (*nFy*) showed decreased proximal-directed forces in the ABE condition and increased values in the ABI and ADI conditions compared to NEU, consistently across the joints. For the x-axis component of the net joint moment (*nMx*), a reduction in KAM was observed in the ABE condition. Regarding the z-axis net joint moment (*nMz*), the ABE condition demonstrated increased extension moments, while the ABI and ADI conditions showed increased flexion moments across all three joints. The y-axis component of the net joint moment (*nMy*) exhibited a consistent pattern across all conditions, except for increased internal rotation moments observed in the knee joint under the ABE and ABI conditions.

Figure 6 presents the actual JRF results, which exhibited distinct patterns compared to the net JRF data. The x-axis actual joint reaction force (*aFx*) increased in the hip and ankle joints during the ABE condition but decreased in the ADI condition. When accounting for muscle forces, the KAM during the ABE condition increased during the latter push phase and initial pull phase, although the overall values remained lower than those in the NEU condition. Interestingly, the KAM in the ABI condition showed a reduction in the actual JRF analysis, in contrast to the increased values observed in the net JRF analysis. The ankle joint's x-axis actual joint reaction moment (*aMx*) increased in both the ABE and ABI conditions. For the axial rotation moment (y-axis actual joint reaction moment, *aMy*), the hip joint exhibited an increased internal rotation moment in the ABE condition, while the ABI and ADI conditions demonstrated increased external rotation moments. This pattern contrasted with the moment trends observed in the knee joint.

Statistical analysis revealed significant increases in *aFx* across all three joints during the ABE condition, contrasting with significant decreases in *aFx* in the ADI condition. KAM was significantly reduced in both the ABE and ADI conditions, indicating decreased medial contact forces. The *aMx* value showed a marked increase in the ABE condition. For the hip joint's *aMy*, an internal rotation moment was observed in the ABE condition, while external rotation moments were noted in the ABI and ADI conditions, which was opposite to the pattern observed in the knee joint (Fig. 7).

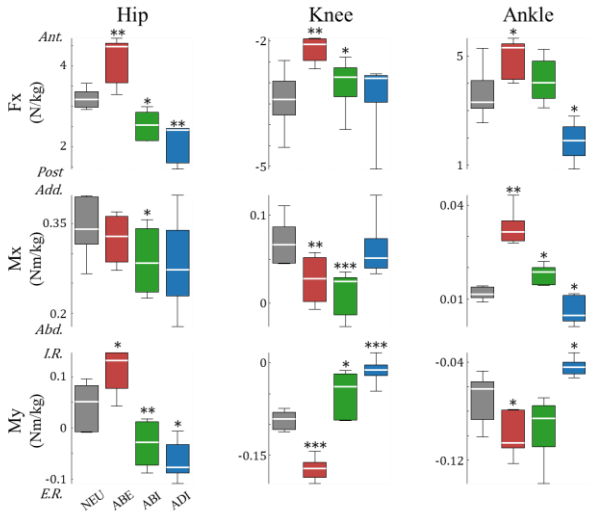

Figure 7. Box plots for actual joint reaction force and moment. The box plots show medians (white line), 25th–75th percentiles (box), and min–max values (whiskers). Statistical comparisons with baseline NEU are indicated by asterisks: $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$. (*Lat.: lateral, Med.: medial, Add.: adduction, Abd.: abduction, I.R./E.R.: internal/external rotation*)

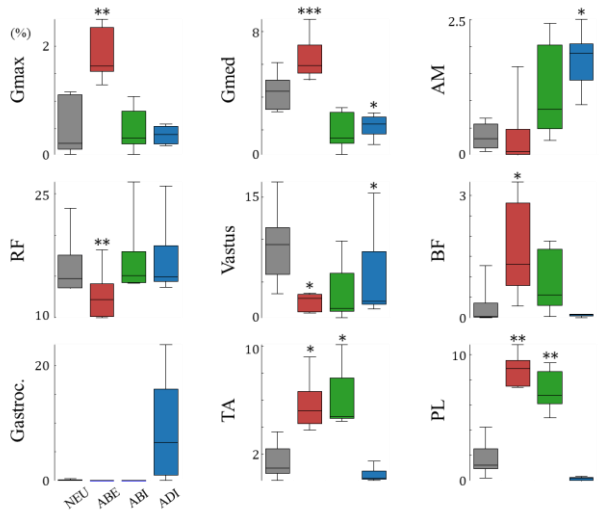

Figure 9. Box plots for muscle activity. The box plots depict the median (black line), interquartile range (25th–75th percentiles, box), and the full range (min–max, whiskers) of mean muscle activation levels for each participant. Statistical comparisons with the baseline NEU condition are denoted by asterisks: $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$.

C. *Muscle Activation*

Figure 8 illustrates the muscle activation patterns, derived by normalizing the estimated muscle forces to the maximal force capacity of each muscle. The gluteus maximus (Gmax), a primary hip extensor, showed the highest activation during the latter pull phase to the middle push phase in the ABE condition. Similarly, gluteus medius (Gmed), a key hip abductor, exhibited greater activity in the ABE condition, peaking during the latter push phase. Conversely, the adductor magnus (AM), a hip adductor, was primarily activated in the ABI and ADI conditions, although the timing of activation varied between these conditions. While rectus femoris (RF) activity showed minimal changes, the vastus muscles demonstrated decreased activation across all three conditions. Biceps femoris (BF) activity increased in the ABE and ABI conditions but decreased in ADI. The gastrocnemius was exclusively activated in the ADI condition, whereas tibialis anterior (TA) and peroneus longus (PL) displayed increased activation in the ABE and ABI conditions.

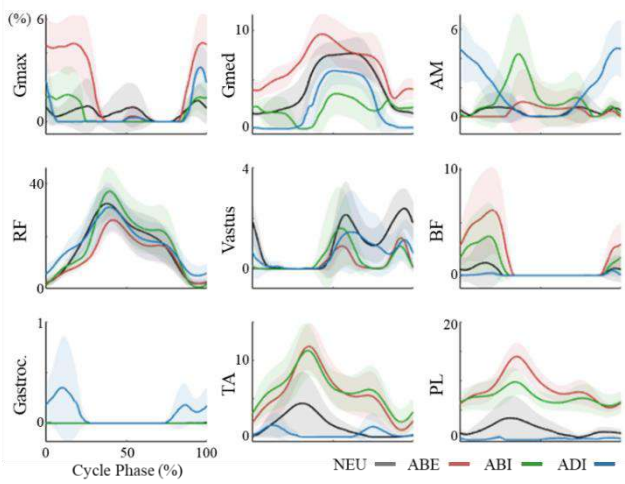

Figure 8. Estimated muscle activation. Estimated muscle activity, derived from normalized muscle force, are compared across different ergometer conditions throughout the pedaling cycle. (*Gmax: gluteus maximus, Gmed: gluteus medius, AM: adductor magnus, RF: rectus femoris, BF: biceps femoris, Gastroc.: gastrocnemius, TA: tibialis anterior, PL: peroneus longus*)

Statistical analysis was performed to compare mean muscle activities with the NEU condition, and the results are presented as box plots in Fig. 9. ABE condition showed a significant increase in the activity of the Gmax and Gmed, while the ADI condition demonstrated significantly higher activation of the AM. Knee extensor muscles (RF and vastus) exhibited significantly reduced activity in the ABE condition, whereas the knee flexor (BF) showed increased activation. TA and PL displayed significantly higher activity in the ABE and ABI conditions.

IV. Discussion

This study explored the biomechanical effects of tilted-plane ergometer, emphasizing kinematic, kinetic, and muscle activation changes under various pedaling configurations. A musculoskeletal modeling approach was employed, integrating motion capture data and force-torque profiles obtained from a sensor-equipped pedal.

Kinematic analysis revealed notable changes in joint alignment across configurations. The ABE condition increased hip adduction, in contrast to the hip abduction observed in the ABI and ADI conditions. Additionally, unique axial rotation patterns distinguished the ABE and ABI conditions from NEU and ADI. These findings are consistent with our prior study using inertial measurement units and RGB-D cameras, which also reported variations in joint angles under different conditions.

The kinetic results provided valuable insights into how the tilted-plane configurations affected net and actual JRFs. In the ABE condition, KAM was significantly reduced, consistent with kinematic changes inducing a dynamic valgus alignment, potentially beneficial for reducing medial knee loading [12]. Interestingly, while previous study associated the ABI

condition with a dynamic varus alignment and increased KAM, as reflected in the net JRF results, the actual JRF analysis revealed reductions in KAM. This discrepancy highlights the importance of incorporating muscle forces for more accurate estimations of joint loads. Additionally, the ABE condition demonstrated increased hip internal rotation moments, which may have implications for conditions requiring rotational load adjustments, such as femoro-acetabular impingement or labral tears [13].

Muscle activation analysis revealed that the ABE condition significantly increased activation of Gmax and Gmed, particularly during the push phase, emphasizing Gmed's crucial role in hip abduction and postural stability. In contrast, the ADI condition increased activation of AM, a hip adductor critical for pelvic and knee stability. Vastus muscle activity decreased under both ABE and ADI conditions, aligning well with previous findings from surface electromyography (EMG) studies. However, BF activity exhibited a notable increase in the ABE condition and a decrease in ADI. For muscles below the knee, gastrocnemius activation, while significantly elevated in experimental EMG data, was minimal in the modeling results except for the ADI condition. TA and PL demonstrated heightened activity in the ABE and ABI conditions, deviating from prior reports. As this study did not focus on a direct comparison of EMG and model-based results, discrepancies between the two approaches were not quantitatively assessed. Future research integrating detailed analyses of both methods could offer deeper insights into these variations.

This study highlights the applicability of the tilted-plane ergometer as a rehabilitation tool, enabling clinicians to address specific biomechanical deficits through dynamic adjustments to pedaling trajectories. For example, the reduction in KAM observed in the ABE and ABI conditions may alleviate medial knee joint loading in patients with osteoarthritis or cartilage injuries. Similarly, the increased external rotation moments in the ABI condition could support the management of patellar instability [14] or aid in early rehabilitation following total hip arthroplasty, potentially preventing hip dislocations.

Despite its promising results, the study has several limitations. The musculoskeletal model used represented the knee joint as a hinge joint with a single DoF in the sagittal plane, disregarding coronal and axial plane motions. However, actual knee movement involves small but meaningful coronal and axial rotations that vary with flexion angles [15]. Given that the knee was consistently flexed beyond 30˚ in this study's ergometer setup, these additional motions cannot be entirely ignored. As such, caution is necessary when interpreting the results, as the hinge joint constraint in the model may oversimplify actual knee mechanics. Additionally, the study's small sample size limits the generalizability of the findings. Future studies should aim to include a larger and more diverse participant pool. Long-term clinical trials are also needed to validate the therapeutic benefits of the tilted-plane ergometer in specific patient populations.

The tilted-plane ergometer demonstrated its potential as a customizable rehabilitation tool by effectively modulating joint kinetics and muscle activation patterns. Its ability to introduce multiple options for pedaling plane and limb alignment, even in a seated exercise setting, allows for tailored adjustments that promote desired targeted training while avoiding harmful loads. This study highlighted the device's capacity to induce significant kinetic and kinematic changes through angle modifications, providing a versatile platform for personalized rehabilitation. To maximize its clinical utility, the development of protocols that integrate these biomechanical adjustments into targeted treatment plans will be crucial, making the device a promising tool for individualized therapeutic strategies.

Unilateral Compliant Surfaces in Post-Stroke Gait Retraining: Enhancing Symmetry and Stability

Vaughn Chambers and Panagiotis Artemiadis*, *IEEE Senior Member*

***Abstract*— Stroke is a leading cause of disability worldwide, frequently resulting in gait dysfunction characterized by asymmetries in kinematics and kinetics, reduced push-off force, and diminished muscle activity. These impairments contribute to slow, unstable, and energy-intensive walking, significantly lowering the quality of life and increasing fall risk. Current rehabilitation strategies often fail to deliver a lasting and comprehensive recovery. This study investigates the use of unilaterally compliant terrain as a novel intervention for post-stroke gait rehabilitation. A brief 3 to 4-minute exposure to unilateral low-stiffness terrain was tested on six stroke survivors, yielding statistically significant aftereffects that persisted for up to 5 to 6 minutes post-intervention. Improvements included increased vertical push-off force, reductions in asymmetry in vertical push-off force, and improved center of pressure symmetry, which is related to balance during walking. These promising results suggest that unilaterally compliant terrain may enhance the effectiveness of gait retraining and contribute to more lasting functional recovery for stroke survivors.**

I. Introduction

A stroke, caused by a blocked or ruptured blood vessel in the brain, is a leading cause of disability, particularly affecting gait. Up to 85% of stroke survivors experience hemiplegia, or partial paralysis on one side of the body, which disrupts interlimb coordination – long thought to be controlled at the spine but now attributed to the brain as well [1–4]. Post-stroke gait is marked by slower speeds, instability, and a higher risk of falls [5]. At the timing level, impairments include increased stance and swing times and altered support phases [6–8]. Kinematic deficits involve reduced dorsiflexion, hip and knee flexion, and hip extension [9]. Decreased propulsion [6] and overall lower-limb muscle activity [6, 8] are also evident, though muscle activity patterns are highly variable among individuals. The resulting asymmetry is the hallmark of post-stroke gait, leading to inefficient and unstable walking [10].

Post-stroke gait rehabilitation has long focused on strategies such as body-weight-supported treadmill walking, which enables patients to practice walking in a safer environment with reduced fear of falling and, in some cases, with partial weight offloading to ease movement [11]. Split-belt treadmills, where belts move at different speeds, have shown promise, producing aftereffects lasting up to 10 minutes in both healthy individuals and stroke patients [12–14]. One study demonstrated significant improvements in step length asymmetry and walking speed after a stroke survivor underwent a month-long split-belt treadmill intervention – 30-minute sessions, three times per week – with these gains persisting even one month post-training [15]. While these approaches show varying degrees of success, post-stroke gait rehabilitation remains far from addressing the full spectrum of challenges [16,17]. Expanding rehabilitation strategies by integrating novel physical approaches, targeting diverse neurological pathways, and interacting with patients in innovative ways is likely to enhance outcomes [18].

Integrating robotics into post-stroke gait rehabilitation represents a promising avenue for innovation. Although robots have been extensively explored for upper-limb rehabilitation over the past 25 years [19, 20], their application to gait retraining is still developing. Robots provide unmatched precision and repeatability, making them particularly suited for complex and repetitive tasks like walking [21]. Exoskeletons, orthoses, and other robotic assistive technologies have been investigated for post-stroke gait rehabilitation [22, 23]. However, these technologies often demonstrate limited effectiveness [18], suggesting that further innovation is needed to fully realize their potential.

Efforts to advance robot-assisted post-stroke gait rehabilitation have increasingly focused on low-stiffness environments, particularly unilaterally compliant environments. These terrains theoretically drive neural plasticity by targeting multiple neural pathways. Proprioception is challenged as one foot deflects below the typical ground level, requiring novel postural adjustments [24, 25]. Force feedback is perturbed as the ground reaction force profile is altered during key phases of gait [26, 27]. Additionally, asymmetric balance and interlimb coordination are disrupted, creating a unique stimulus to address gait asymmetry [4,28]. Traditionally, compliant environments have been explored through single or multiple steps on varied surfaces during overground walking [29]. Recently, the Variable Stiffness Treadmill (VST) was developed to provide repeated and precise, compliant surface conditions [30,31]. This split-belt treadmill adjusts stiffness via a linear actuator altering the moment arm of applied forces [30]. Using the VST, experiments with healthy individuals have demonstrated significant brain activity and contralateral muscle responses to unilateral perturbations [3, 4]. Notably, a study found that repeated unilateral stiffness perturbations in healthy subjects produced significant aftereffects, highlighting their potential for post-stroke rehabilitation [32].

This study utilizes a new device, the VST 2, an advanced robotic split-belt treadmill specifically designed to investigate

unilaterally reduced ground stiffness as a novel post-stroke gait rehabilitation intervention [33]. The VST 2 builds on its predecessor with significant enhancements, including a larger walking area, improved stiffness accuracy, vertical deflection capabilities, and the ability to independently adjust the stiffness of each belt, enabling precise and targeted perturbations. Using this device, the study evaluates the effects of a single 3-4 minute unilateral low-stiffness intervention on six hemiplegic stroke patients. The intervention produced statistically significant aftereffects lasting up to six minutes, including increased vertical push-off force, reductions in asymmetry in vertical push-off force, and improved center of pressure symmetry, which is related to balance during walking. These results suggest that unilateral low-stiffness walking has strong potential as an effective and innovative rehabilitation tool for restoring more natural and symmetric gait patterns in stroke survivors.

II. METHODS

This study investigated the short-term aftereffects of repeated unilateral stiffness perturbations on the gait of stroke survivors. Participants walked in a unilaterally compliant environment, and the effects on their gait were subsequently evaluated on rigid ground. Six stroke survivors participated in the study, including two males and four females, with an average age of 61.8 ± 7.8 years. Three had left-side hemiplegia, and three had right-side hemiplegia. All participants were relatively active and could walk without assistive devices, though one subject used a sling for arm support while walking. The treadmill's handrails were the only other form of assistance provided. A physical therapist, familiar with each subject's physical capabilities, supervised the experiments to ensure safety. All participants provided informed consent, and the study was approved by the University of Delaware Institutional Review Board (IRB ID# 2068278-1). The experimental setup is shown in Fig. 1.

A. Experiment Hardware Components

The primary device used in this study was the Variable Stiffness Treadmill (VST) 2, a robotic split-belt treadmill capable of independently adjusting the vertical stiffness of each belt across a range from 17 kN/m to rigid (5 MN/m) [33]. At its lowest stiffness, the treadmill allows for several inches of vertical deflection under an adult subject, with finer adjustments as the stiffness approaches rigid. The device offers precise control with an average stiffness resolution of 0.07 N/m. Adjustable handrails on either side provide support to subjects while maintaining visibility for motion capture markers. The treadmill also includes safety features, such as a body-weight support system (Litegait Inc.), which was used purely as a precaution without offloading any subject's weight.

During trials, each subject's movement was tracked using 22 reflective markers placed on their lower body, with an 8-camera motion capture system (Vicon Motion Systems Ltd.). Marker placement followed a previous study's protocol [32], and VICON Nexus software was used for data collection and processing. Additionally, force data was captured using Force mats (TekScan 3140 with VersaTek Cuffs, TekScan Inc.) located beneath the treadmill belts. These mats, equipped with 4224 force-sensing cells per belt, measured forces at a spatial resolution of 1 cm and a frequency of 65 Hz, enabling the calculation of total applied force and center of pressure location.

Fig. 1: The Variable Stiffness Treadmill (VST) 2 with the subject wearing motion capture markers, EMGs (under wraps), body-weight-support harness, and heart rate monitor (under harness). The left platform can be seen deflecting as the subject steps on it.

Muscle activity was recorded using Trigno electromyographic (EMG) electrodes (Delsys Inc.), placed on ten muscles across both legs following ISEK guidelines [34]. Targeted muscles included the tibialis anterior (TA), medial gastrocnemius (GA), vastus medialis (VA), rectus femoris (RF), and biceps femoris (BF). Heart rate monitoring was performed throughout the experiment using a Polar H10 chest strap, which recorded data at 1 Hz. The physical therapist present used the monitor to oversee subject safety and was prepared to halt the experiment if necessary; however, no interruptions occurred. Since most participants were on beta-blocker medication, the collected heart rate data were not analyzed for exertion levels.

B. Experiment Protocol

In this study, participants walked in an asymmetrically compliant environment where the treadmill's stiffness was adjusted to create an imbalance. The treadmill belt under the nonparetic leg was set to a lower stiffness, while the paretic leg remained on a rigid surface. This configuration was designed to perturb gait in a way that encouraged greater reliance on the paretic limb, aiming to promote rehabilitation through controlled asymmetry. The experiment consisted of three phases in series with no breaks in between: baseline (20%), adaptation (30%), and observation (50%). During the baseline and observation phases, both treadmill belts were rigid, while in the adaptation phase, the nonparetic

side experienced reduced stiffness. Subjects were informed of transitions with a one-minute warning and a five-second countdown to ensure preparedness. This setup was intended to challenge neural pathways without causing discomfort or fatigue.

Perturbing the nonparetic limb was chosen for several reasons. First, keeping the paretic limb on rigid ground ensured subject comfort, a priority for both participants and the supervising physical therapist. Second, perturbing the nonparetic side encouraged subjects to engage their paretic limb more actively, contrasting the typical assistive approach of exoskeletons. Most critically, prior research has shown that perturbing one limb activates the corresponding brain hemisphere responsible for the opposite limb [3], making this strategy particularly effective for engaging the brain areas controlling the paretic side.

Subjects selected a comfortable walking speed by incrementally testing speeds between 0.3 and 0.6 m/s, with input from the physical therapist. The stiffness level was similarly calibrated, testing values between 21 and 45 kN/m to achieve approximately 2–3 cm of deflection while maintaining comfort. Depending on the subject's capacity, the experiment duration was set to either 10 or 12 minutes. Finally, throughout the experiment, subjects reported perceived exertion every two minutes using the Borg Rating Scale (6–20) [35], with a threshold of 17 set for immediate termination. No subject reported values above 9, and heart rate monitoring by the physical therapist confirmed safety throughout.

C. Processing and Statistical Analysis of Collected Data

In this study, motion capture, muscle activity, and force data were synchronized using a trigger signal from the VICON Lock Lab system. This ensured the alignment of all data streams for accurate analysis. Heel strikes were identified via the force mats, with a strike detected when force rose from 0 to 5% of the subject's body weight. Toe-offs were determined kinematically by the most posterior position of the toe marker during a gait cycle. Gait cycles were defined based on heel strikes of the nonparetic leg. Force mat data, sampled initially at 65 Hz, was upsampled to 100 Hz using linear interpolation for alignment with motion capture data. The center of pressure (CoP) was calculated by translating force mat measurements to the motion capture frame and normalizing the anterior-posterior CoP relative to the subject's estimated center of mass, determined from the average position of four pelvic markers (left and right anterior and posterior superior iliac spines). Muscle activity data are not discussed in this paper.

All statistical analyses in this study were conducted using the Wilcoxon rank-sum test, a non-parametric alternative to the t-test that does not rely on assumptions about the data's distribution or shape [36]. An alpha level of 0.05 was used to determine statistical significance. The primary focus of this study was to evaluate aftereffects, so statistical comparisons were made between the observation phase and the baseline phase. Rather than analyzing responses during the intervention, the analysis targeted changes that persisted post-intervention, comparing these to pre-intervention behavior. Specifically, tests were performed between the last 30 gait cycles of the baseline phase and the first 30 gait cycles of the observation phase (early observation), as well as between the last 30 gait cycles of the baseline phase and the last 30 gait cycles of the observation phase (late observation). This approach aimed to identify both immediate and sustained aftereffects of the intervention, which was the main goal of the study.

III. Results

Figures 2 and 3 illustrate findings related to average vertical push-off ground reaction force (GRF) across all six subjects. This force, quantified as a percentage of body weight (PBW), was determined as the second peak of the vertical GRF during the stance phase. Significance lines at the top of the graph indicate the comparisons between data sets, with arrows showing the direction of change – upward for an increase and downward for a decrease. Blue lines represent the nonparetic limb, red lines indicate the paretic limb, and purple lines combine results from both limbs.

All subjects demonstrated a statistically significant aftereffect of increased vertical push-off force in both their paretic and nonparetic legs. On average, the nonparetic leg's push-off force increased from a baseline of 98.20 PBW to 100.20 PBW (a 2.04% increase) in early observation and 99.42 PBW (a 1.24% increase) in late observation. The paretic leg showed more substantial gains, rising from a baseline of 90.63 PBW to 97.42 PBW (a 7.49% increase) in early observation and 94.69 PBW (a 4.48% increase) in late observation. These results, illustrated in Fig. 2, not only indicate significant improvements on both sides but also suggest a shift toward greater symmetry, which is further explored in the subsequent discussion.

Although this study focused on vertical ground reaction forces, these forces are related to horizontal propulsive forces through kinematic interactions. Under consistent kinematics, an increase in vertical force would imply a corresponding increase in horizontal propulsion. In summary, the observed significant average increase of about 8% in vertical push-off force across all six subjects is an encouraging outcome, potentially contributing to improved step length and walking speed during overground locomotion.

A notable aftereffect also observed is the improvement in symmetry of vertical push-off forces between the paretic and nonparetic limbs. As highlighted earlier, while both limbs demonstrate increased push-off forces following the intervention, they also exhibit a shift toward greater symmetry. Before discussing the results, it is essential to clarify that asymmetry is always calculated by subtracting the paretic side's parameter value from the nonparetic side's parameter value. Therefore, a positive asymmetry value indicates that the nonparetic side's parameter is greater than that of the paretic side. On average, the baseline asymmetry in vertical push-off force among the six participants was 17.45 PBW. This asymmetry significantly decreased to 10.10 PBW (a

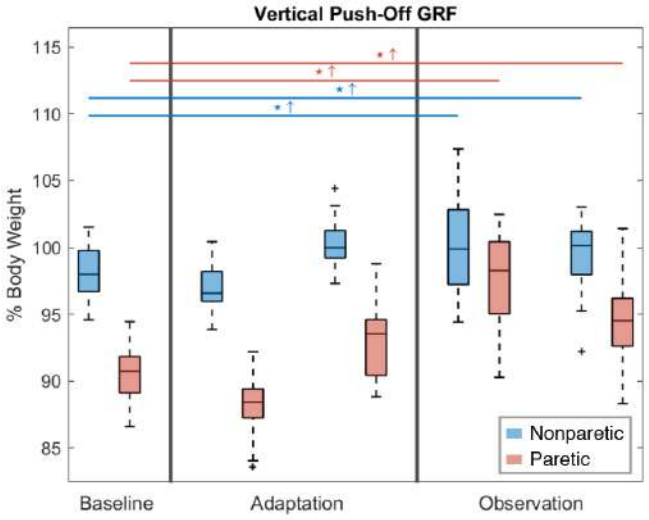

Fig. 2: Average vertical push-off ground reaction force (GRF) for all six subjects. The push-off force was calculated as the second peak of the vertical force during the stance phase. Significance lines are shown connecting the two data sets compared, with an arrow pointing to the direction of change.

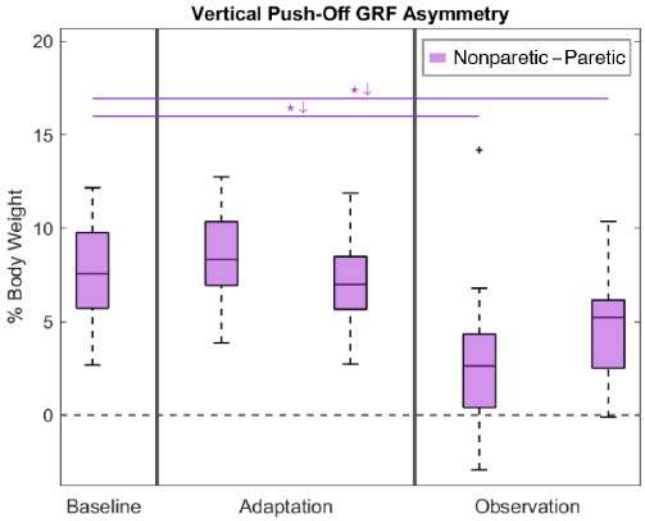

Fig. 3: Average vertical push-off ground reaction force asymmetry across all six subjects is shown. The push-off force was determined as the second peak of the vertical force during the stance phase. Asymmetry was determined by subtracting the paretic side's push-off force from the non-paretic side's push-off force. Significance lines connect the compared data sets, with arrows indicating the direction of change.

42.12% reduction) in early observation and $15.93\ PBW$ (an 8.71% reduction) in late observation, as shown in Fig. 3. These reductions in asymmetry are statistically significant and represent meaningful progress toward more balanced gait mechanics.

Improved symmetry in push-off force may indicate enhanced coordination and a more equal distribution of effort between the paretic and nonparetic limbs. This shift is crucial, as asymmetries in force production are often linked to inefficient and unstable walking patterns, increasing the risk of falls and energy expenditure. The observed improvements suggest that the intervention not only strengthens both limbs but also promotes more natural and efficient gait dynamics, a critical goal in post-stroke rehabilitation.

The total center of pressure (CoP) path also exhibited a more symmetric aftereffect following the intervention. The CoP was measured using force mats positioned beneath the treadmill belts, with normalization applied relative to the subject's center of mass in the anterior/posterior direction to account for drift. In Fig. 4, the orientation depicts the subject as if viewed from above, walking toward the top of the page.

As illustrated in Fig. 4 (top), five key parameters are derived from the CoP path plot. The anterior/posterior length of each lobe, corresponding to the time a limb is in single support, is represented by nonparetic and paretic Y1. The anterior/posterior distance between the front of one lobe and the back of the opposite lobe, referred to as Y2, relates to step length, with each parameter labeled according to the lobe being referenced. Lastly, lateral asymmetry measures the medial/lateral distance between the meeting point of the nonparetic and paretic lobes and the midpoint between their most lateral points. In a healthy, symmetric gait, nonparetic and paretic Y1 values would be equal, nonparetic and paretic Y2 values would match, and lateral asymmetry would measure zero, indicating balanced movement.

Subject 3 was selected as a representative example for discussion (see Fig. 4, bottom), while all subjects had similar results. As a reminder, asymmetry is calculated by subtracting paretic side values from the non-paretic side. During the baseline phase, Subject 3 exhibited a Y1 asymmetry of $-12\ mm$, which improved to a more symmetric $-3\ mm$ in early observation and $2\ mm$ in late observation. Similarly, the Y2 asymmetry decreased from $-88\ mm$ in the baseline phase to $-49\ mm$ in early observation and $-54\ mm$ in late observation, indicating a notable shift toward symmetry after the intervention.

IV. Conclusion

This study highlights the transformative potential of integrating unilateral compliant environments into post-stroke gait rehabilitation. By utilizing the Variable Stiffness Treadmill (VST) 2, designed to create asymmetrical terrain conditions, the research demonstrated statistically significant improvements in key gait metrics among stroke survivors. Notable aftereffects included increased vertical push-off force, reductions in asymmetry in vertical push-off force, and improved center of pressure symmetry, which is related to balance during walking. These improvements, observed after a brief 3-4 minute intervention, underline the immediate efficacy of this novel approach in promoting more symmetric and functional walking patterns.

This study introduced a novel use of unilateral low-stiffness terrain as a rehabilitation tool, offering a fresh approach to gait retraining. Unlike traditional methods such as body-weight-supported or split-belt treadmill training,

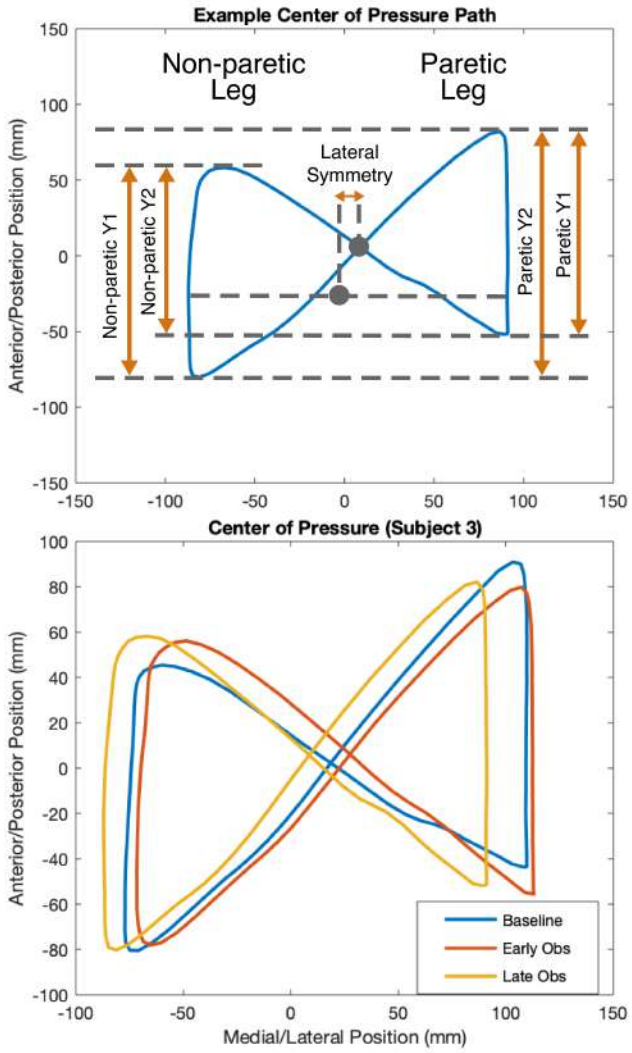

Fig. 4: Illustration of the center of pressure (CoP) path: an example path (top) and the CoP path for Subject 3 (bottom). CoP data was collected using force mats beneath the treadmill belts and normalized relative to the subject's center of mass in the anterior-posterior direction to compensate for drift. The plots are oriented as though viewed from above, with the subject appearing to walk toward the top of the page.

which provide broad benefits, this approach introduces targeted perturbations designed to engage neural plasticity and proprioceptive adaptation more effectively. By employing controlled asymmetry, the methodology aims to stimulate compensatory mechanisms and support neural reorganization, diverging from conventional symmetrical rehabilitation techniques. The integration of advanced robotic systems like the VST 2 ensures precision and consistency in delivering these interventions, enhancing their potential therapeutic impact. A future study that would benchmark this approach against traditional approaches is possible.

This study demonstrated that many after-effects persisted for the full 5-6 minute observation period following just a brief 2-3 minute intervention. This suggests that the induced changes may have had an even longer duration, had the experiment been extended. These findings are both exciting and promising, highlighting the potential for short, targeted interventions to produce lasting after-effects in stroke survivors. However, further research, with a larger sample size, is necessary to explore the longevity and mechanisms of these after-effects, as well as their implications for clinical applications and rehabilitation strategies.

The findings of this study open new avenues for robot-assisted gait rehabilitation. By introducing controlled instability through compliant surfaces, this approach directly addresses gait asymmetry – a hallmark challenge in post-stroke recovery. The results suggest that integrating this technology into clinical practice could foster faster, more robust recovery, reducing reliance on assistive devices and improving long-term mobility. Future research could expand on these findings, exploring the integration of such systems into personalized rehabilitation protocols, potentially transforming the standard of care for stroke survivors.

***Abstract*— Myoelectric prosthetic hands and terminal devices are a standard of care for individuals with upper limb loss or congenital limb difference, typically controlled using surface electromyography electrodes. While numerous outcome measures exist to assess user performance with a myoelectric prosthesis, many are time-consuming and impractical for clinical settings. This paper introduces the Myoelectric Control Resolution Assessment (MCRA), a rapid and device-agnostic outcome measure requiring only a caliper, making it accessible even in low-resource settings. The MCRA evaluates the smallest volitional movements a user can generate with their myoelectric prosthesis, normalizing measurements to account for mechanical variability of the terminal device. Simulation results demonstrate the MCRA's ability to provide accurate, consistent, and unbiased control resolution estimates in as few as five measurements. The MCRA's simplicity and efficiency make it accessible to both prosthetic clinics and research organizations. It holds potential for clinical evaluation, myoelectric control algorithm comparison, training, and longitudinal studies, representing a novel advancement in the evaluation of myoelectric control fidelity and highlighting its potential for widespread clinical and research applications.**

Keywords—myoelectric control, pattern recognition, surface electromyography, prosthetic hands, outcome measures

I. Introduction

Myoelectric prosthetic hands and terminal devices represent a current standard of care for individuals with limb loss or congenital limb difference. These terminal devices come in a wide range of appearances and functions, from clamp-like grippers to simple single degree-of-freedom (DOF) hand to multi-articulating hands with isolated finger control [1-3]. Regardless of the design, nearly all commercially-available myoelectric prostheses are controlled using a direct control scheme, wherein surface electromyography (sEMG) electrodes located of a pair of agonist/antagonist muscles are used to proportionally control the opening or closing speed of the terminal device [4, 5]. Additionally, in recent years, machine learning approaches to myoelectric control are becoming more common in research and commercial applications [6-8], however proportional control is still typically applied to the speed, and not the position, of the terminal device. Although this control scheme is simple in concept, dual-site myoelectric control requires training and practice to learn and develop this skill.

For both clinical and research assessment purposes, numerous outcome measures have been proposed to characterize a user's performance when using an upper limb prosthesis [9]. Many outcomes involve the user's ability to complete a selection of activities of daily living (ADLs) using the prosthesis, however these often require specific or proprietary equipment to perform and can be very time-intensive, taking upwards of an hour to complete and thus rendering them infeasible for use within a clinical setting [10, 11]. Other outcome measures simplify the tasks observed during the evaluation, often only involving a single task. While these simpler outcomes can be useful for quickly characterizing performance during grasping tasks, it is only grossly capable of evaluating myoelectric control, differentiating only between adequate and inadequate control but unable to measure the ability to control the level of force applied to objects.

The ability to modulate grasping force is a frequent design priority for prosthesis users [12, 13], especially given the higher grasping forces possible with prosthetic hands compared to biological hands [14]. Similarly, many users have indicated an interest in artificial sensory feedback to aid in their grasp force perception [15-17]. This sensory feedback enhances the process of motor learning of new skills and motor adaptation of learned skills (such as prosthesis control) [18], which in turn improves muscle (and thereby myoelectric) control [19, 20]. Some outcome measures, like the Virtual Egg Test (VET) [21] or the Pick & Lift Test (PLT) [22], are able to evaluate this fine myoelectric control, however they also require specialized equipment, making them inaccessible for general clinical use.

The purpose of this paper is to propose and describe a rapid and device-agnostic outcome measure for myoelectric fidelity: the Myoelectric Control Resolution Assessment (MCRA). The MCRA requires only a caliper to perform and can be completed in as few as five measurements, making it accessible even to prosthetic clinics and research organizations in low-income or underserved areas. The mathematics behind the MCRA are detailed and a simulated proof-of-concept is presented to demonstrate feasibility of the assessment.

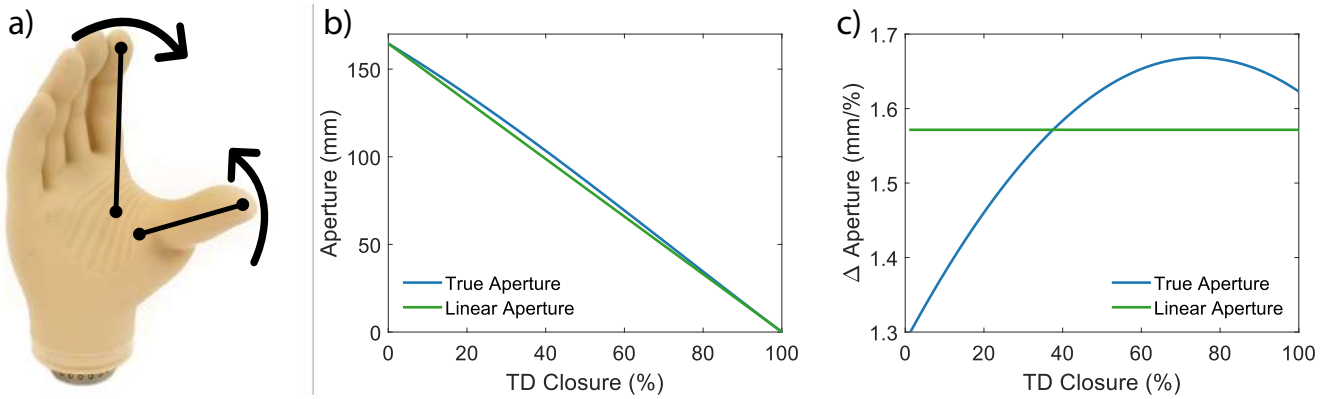

Fig. 1. (a) Because of the geometry of the terminal device (TD), the fingertips follow curvilinear trajectories between the open and closed postures. (b) As a result, the aperture between the fingertips follows a non-linear profile (blue) throughout the range of motion. (c) This non-linear profile means that the rate of change in aperture (i.e. the derivative of (b)) is non-uniform compared to a theoretical linear aperture closure (green). For this prosthetic hand, a given control signal will yield a smaller change in aperture while the hand is fully open (0%), compared to when it is nearly closed (100%). The MCRA aims to mitigate this variability arising purely from the geometry of the terminal device by transforming the measured aperture (blue) into a theoretical linearized closure (green), such that consistent results are given regardless of where in the range of motion aperture measurements are taken.

II. Methods

A. Development

Development of the MCRA builds upon an unvalidated test used in previous studies comparing the fidelity of myoelectric prosthetic hands using implanted EMG electrodes and surface EMG electrodes [23]. Briefly, the participant starts with their prosthetic hand fully open, and the aperture between the index finger and the thumb is measured using calipers. Next, the participant is instructed to close the prosthetic hand by the smallest margin possible. Once the participant has further closed the hand, the aperture is measured again. This process is repeated until the prosthesis is fully closed. The same process is repeated in the opposite direction – the aperture is measured, the hand is opened by the smallest margin possible, and the aperture measurement is repeated. The movement resolution is then calculated as the average of the changes in aperture between subsequent measurements – in other words, the average smallest volitional movement that the participant can generate. This protocol has been used to evaluate both aperture resolution as well as resolution of force generation [24].

This protocol has the advantage of being completed quickly, requiring only a matter of minutes to take several measurements. Furthermore, no special or expensive equipment is required to conduct the test, only a caliper (or even a ruler or tape measure) is required. However, a limitation of this approach is that, because of the mechanics of the hand (Fig. 1a), the rate of change of the aperture (the distance between the fingertips) is not constant across the range of motion of the hand (Fig. 1b). The aperture changes at a slower rate when the hand is fully open, and more quickly when the hand is nearly closed (Fig. 1c). As a result, evaluating control resolution will result in better performance with the fingers closer together than with the fingers apart, even if the underlying myoelectric control is identical.

The MCRA is proposed to account for this variability. The raw measurements are converted into a normalized measure based on the overall range of motion – in other words, yielding a *percentage* of range of motion As a result, identical myoelectric inputs will yield identical outcomes, and variability will be lower.

B. Derivation

Consider a conventional myoelectric prosthetic hand configured to perform only a palmar grasp (Fig. 1a). We define the aperture α as the linear distance (e.g. inches or millimeters) measured between the thumb and the index finger which contact when the hand is fully closed. The aperture of the prosthesis throughout its range of motion is determined by the mechanical design of the prosthesis – for example, the length of the fingers, offset between the flexion rotation axes, and actuation ratios between the fingers.

The aperture α can be said to change as a function of the normalized prosthesis closure x, such that:

$$\alpha(x) = B(x) \tag{1}$$

where x is the current hand closure compared to the overall range of motion (e.g. as a percentage of the range of motion) and B is the function describing the mechanical closing of the prosthetic hand. This closing function B can be determined by analyzing the mechanical design of the prosthesis, or approximated via a piecewise or polynomial fit function based on physical aperture measurements with repeated, consistent myoelectric (or simply electric) inputs.

Determining the normalized prosthesis closure x based on direct measurement of the aperture α is a simple matter of inverting the closing function:

$$x(\alpha) = B^{-1}(\alpha) \tag{2}$$

The Myoelectric Control Resolution MCR of any given measurement $\alpha(i)$, compared to the previous measurement $\alpha(i-1)$, is then calculated as:

$$MCR(i) = T \cdot \Big(x\big(\alpha(i)\big) - x(\alpha(i-1))\Big) \tag{3}$$

where T is the time required to fully actuate the terminal device, which serves here as a normalizing factor such that the

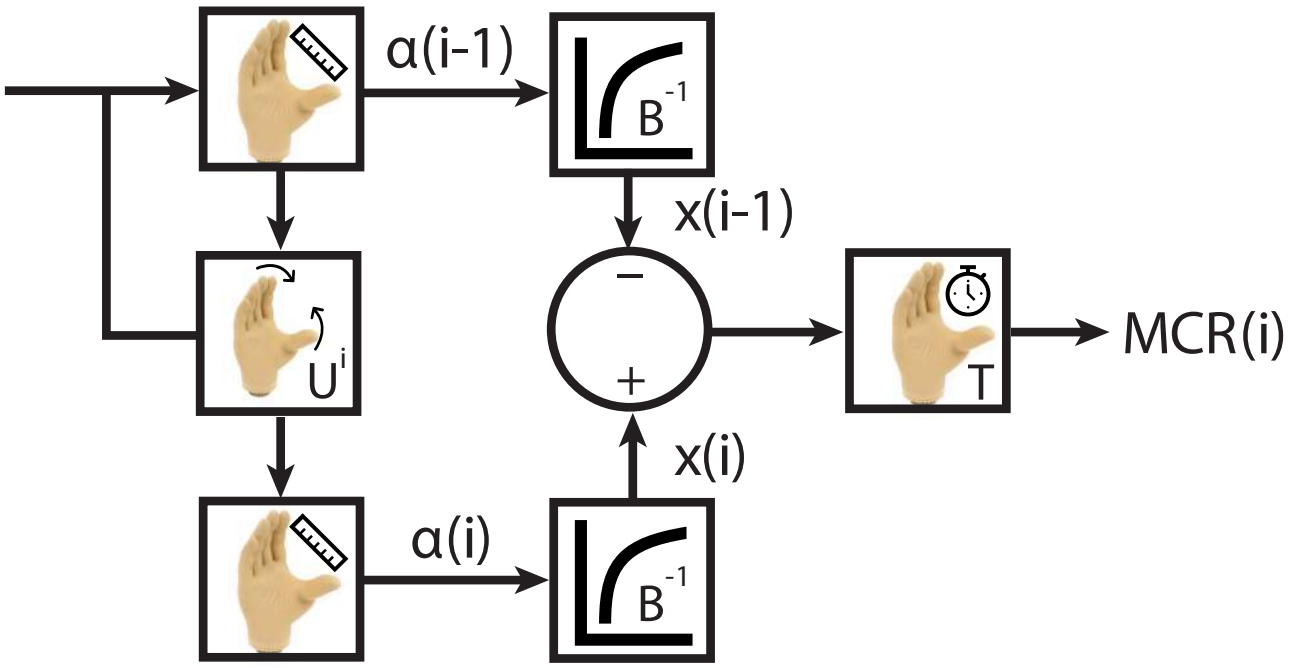

Fig. 2. The protocol for performing the MCRA is as follows. The aperture α of the terminal device is measured before and after the user actuates the terminal device according to motor command U^i. The apertures α are converted into a normalized closure x by means of the inverted closing function B^{-1}. After calculating the difference between the two normalized closures x, the myoelectric control resolution MCR is calculated by adjusting the difference by the closing time T.

MCR will be identical regardless of the maximum actuation speed of the terminal device and its control algorithm. This definition of MCR can be interpreted as an equivalent duration of maximum-speed prosthesis operation, where smaller durations indicate greater control over the prosthesis.

C. Protocol

The protocol for performing the MCRA (Fig. 2) is as follows:

1. Start with the terminal device in a fully-opened position. The experimenter measures the aperture of the terminal device using e.g. a caliper.
2. The experimenter instructs the participant to close the terminal device by the smallest amount possible. The terminal device must visually move – only hearing the sound of the motors activate is not sufficient.
3. Once the terminal device has completed its movement, the aperture of the terminal device is measured again.
4. Both aperture measurements are converted into normalized prosthesis closure using the inverse closing function, and the difference between them is calculated. This difference is then multiplied by the closing time to yield the MCR.
5. Repeat steps 2-4 until the terminal device is fully closed. MCR is averaged across all measurements.
6. Repeat steps 1-5 with the terminal device in the fully-closed position, where the participant is asked to volitionally open the terminal device by the smallest amount possible. This yields separate MCRs for terminal device closing and terminal device opening.

D. Simulation

To characterize the performance of the MCRA, the mechanical closing of a commercially-available prosthetic hand (SensorHand Speed; Ottobock SE & Co. KGaA, Duderstadt, Germany) was simulated based on physical measurements of the ungloved mechanism (Fig. 1b-c). The protocol described above was simulated for 1,000 participants as follows. Starting from a fully open position, the simulated participant would proceed to close the terminal device at an average of 5% increments of the total range of motion (e.g. their simulated average minimum actuation), with either 5%, 10%, or 15% variability in their movements (similar to EMG amplitude variability observed in previous research [25]). Caliper measurements were simulated to measure the aperture of the terminal device. This process was repeated until the terminal device was fully closed; any trials where the control signal would have extended the terminal device beyond its range of motion were discarded. The entire protocol was simulated for both closing and opening control.

The control resolution, as determined by both the raw aperture measurements and the MCR, is calculated as a cumulative average of the current and all previous measurements. For example, the second calculated control resolution would be the average of the first two differences in aperture or MCRs, the third calculated control resolution would be the average of the first three differences, and so on. This simulates the procedure as it would happen within a

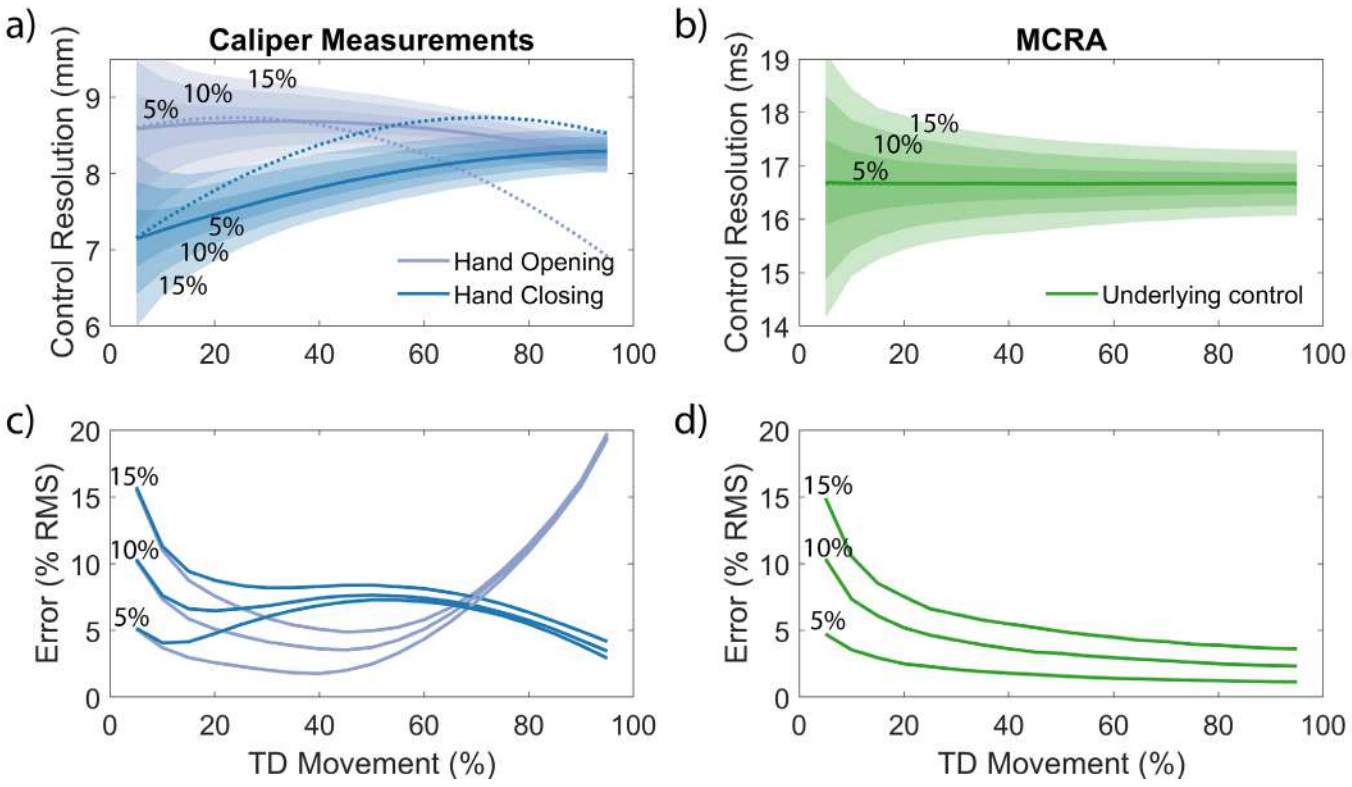

Fig. 3. (a) Measuring myoelectric control resolution directly using calipers yields biased results, even when the underlying motor commands are identical. Control resolution will be worse when opening the hand (violet) compared to closing the hand (blue) due solely to the geometry of the terminal device. (b) Applying a corrective factor to caliper measurements eliminates this bias and can provide more accurate and uniform estimates of both opening and closing control with fewer measurements. Dashed lines indicate the true resolution across the operating range, solid lines indicate the mean of all previous measurements that would be taken from the starting position, and shaded areas indicate standard deviation of measurements at different levels of movement. MCRA control resolution is measured in units of equivalent milliseconds of maximum-speed prosthesis operation. (c-d) The control resolution error from caliper measurements (c) starts the same as the MCRA (d) for the first measurement, but diverges due to the cumulative averaging of previous measurements. Expected MCR error consistently decreases with additional measurements, reaching half of the underlying control variability in only 5 measurements.

clinic, where the participant is continually closing or opening the prosthesis, and the previously-measured aperture is used as the reference for calculating the next control resolution.

III. Results

The outcomes from the simulated task are shown in Fig. 3. Directly estimating the control resolution using caliper measurements of the terminal device aperture (Fig. 3a) yields inconsistent outcomes depending on the direction of movement (closing or opening) and the current aperture (due to cumulative averaging). When measuring during closing (blue), aperture changes are smaller when the hand is more open, but the aperture changes at a faster rate as the fingers near closing. This results in an underestimation of the underlying control resolution (dashed lines) due to the cumulative averaging over the course of successive measurements (solid lines). The opposite phenomenon is observed when estimating opening control resolution (violet); changes in aperture are larger when the hand is fully closed, and gradually slow as it nears its full range of motion. As a result, control resolution using direct aperture measurements are biased towards larger resolution and worse performance. These biases are also observed in the expected error of the estimates (Fig. 3c) – measurement error does not always monotonically decrease with additional measurements, but can in fact increase because of the divergence between the cumulative averages and the true underlying control resolution.

When performing the MCRA (Fig. 3b), each measurement is corrected by the inverse closing function to translate directly to the underlying control; thus, there is no bias in control resolution estimates, regardless of whether the terminal device is opening or closing. Furthermore, the expected error of estimates (Fig. 3d) monotonically decreases when averaging across multiple measurements.

IV. Discussions

The purpose of this paper was to propose and describe a rapid and device-agnostic assessment for myoelectric control resolution. This assessment can be conducted using only a caliper, making it accessible to clinicians and researchers in low-income or underserved areas. Simulations show that the expected error of the MCR, compared to the true underlying control resolution, drops of half of the combined movement and measurement variability in as few as 5 trials. Assuming that each measurement takes approximately 10 seconds, the assessment can be completed in about one minute; although full opening or closure of the prosthesis is not required, additional measurements will further reduce this expected error in a monotonic fashion. The required number of assessments should be determined alongside validation of the MCRA compared to functional and quality-of-life outcomes.

The derivation of the MCRA, as proposed in this paper, estimates the underlying control resolution of the participant's myoelectric signals via measurements of the aperture of a terminal device. However, the underlying theory behind the MCRA can be extended to a number of other types of measurements. For example, the protocol upon which the MCRA is based has been used to evaluate both aperture resolution [23] as well as resolution of force generation [24]. It would be possible to develop a variation of the MCRA that uses prosthesis force as the measured variable instead of aperture; the only difference would be that a different closing function B would be required to properly calibrate the assessment. This could be especially useful if consistent device is used to measure force generation, as this opens the doors for at-home and longitudinal testing of MCR. Furthermore, despite the name of the assessment specifically indicating myoelectric control, other bioelectric control signals could be evaluated using the proposed assessment, including mechanomyography [26], electroneurography [27], and ultrasound [28] and myokinetic interfaces [29].

Although the protocol proposed in this study describes the use of a prosthetic hand or terminal device as the instrument of the MCRA, the MCRA can easily be extended to evaluate the control of any other prosthetic joint. For example, estimating the control resolution of a myoelectric prosthetic elbow could follow an identical protocol as for the hand simply by defining the "aperture" as the distance between the end of the terminal device and the shoulder; in such an instance, this distance would likely be measured using a tape measure instead of a caliper. Even a powered wrist control via myoelectric signals could be evaluated if the rotation angle is measurable. Regardless of the prosthetic joint being controlled and the variable being measured, the MCRA ensures that the true underlying myoelectric control resolution is being estimated, such that no differences should be observed between different measurement methods so long as the closing functions are accurate.

Because of the simplicity of the MCRA, there are some limitations that should be noted. Firstly, the control "resolution" evaluated as part of the MCRA is not expected to be consistent across all amplitudes of myoelectric signals. The MCR is, in essence, a measure of the minimum viable actuation; it does not speak to the smallest *change* in volitional myoelectric signal generation that a participant can generate. As a result, a change in the activation threshold of myoelectric control could affect the estimated control resolution by making small volitional movements easier or harder to control. Additionally, the MCRA assumes that the prosthesis only moves in a single direction during the assessment (e.g. only opening or only closing). This may present challenges to participants who are new to myoelectric control and have difficulty volitionally separating between antagonistic motions. This also may present challenges for myoelectric control schemes that are based on position control (as opposed to velocity or force control, where the prosthesis does not move when the user relaxes their muscles). Evaluating MCR for such a control may require calculations based on the rate of change of prosthesis operation, rather than trial-by-trial measurement, and would therefore require specialized equipment to accomplish.

Another limitation is that a different mechanical closing function is required for the MCRA to be generalizable. This would likely require a broad collaborative effort to define these closing functions for commercially-available prosthetic terminal devices, and to make these functions publicly available for clinicians to use. If a closing function is not available for a prosthesis but one desires to characterize MCR for a prosthesis user regardless, then the drawbacks of the raw caliper aperture measurement methods can be partially addressed by repeating measurements from the start of the range of motion (e.g. measuring closing resolution from the fully-opened position and measuring opening resolution from the fully-closed position). While this will mitigate the issue of bias from successive measurements, it should be noted that the opening and closing resolutions will no longer be directly comparable. MCR estimated in this way should only be used to make longitudinal comparisons for each movement separately.

***Abstract*—Manual wheelchair users face many physical and physiological demands when maneuvering and participating within their community. One aspect of daily life which has not been thoroughly examined is how carrying a load affects their mobility. This study presents data collected from 10 participants completing a short outdoor course. Each participant completed the course twice: with and without an additional backpack, carrying approximately 10% of their bodyweight. Inertial and heart rate data from wrist mounted sensors were analyzed to determine the effect of loading on manual wheelchair user mobility and cardiovascular strain. The results of the Wilcoxon sign-rank test showed that carrying a load significantly increased the travel time ($z = -2.035$, $p = 0.042$) and heart rate ($z = -2.073$, $p = 0.038$) of the participants. Furthermore, analysis of the propulsion data suggested different strategies were used by the participants to compensate for the loaded condition. This highlights the need for developing individualized rehabilitation strategies to address the unique needs of manual wheelchair users for improving their quality of life.**

Keywords—community mobility, physical exertion, manual wheelchair users, inertial sensors, heart rate.

I. Introduction

The physical demands of Manual Wheelchair Users (MWU) during mobility and participation in the community, and their ability to meet demands play a crucial role in shaping their overall quality of life [1], [2]. MWU are often faced with diverse challenges in navigating outdoor environments, particularly when encountering different terrains and loading conditions [3]. These environmental aspects can impose significant exertion on MWU, impacting their mobility and overall participation in daily activities. Understanding the effects of exertion is crucial for those seeking to improve wheelchair design, enhance rehabilitation strategies, and to support the independence and quality of life of MWU [4], [5], [6], [7].

One of the factors that can influence the mobility and participation of MWU in the community is the shoulder demands of manual wheelchair use across a spectrum of activities such as wheelchair propulsion, weight carrying, and terrain maneuverability [8]. Past research has explored the different physical demands faced by MWU and highlighted the significant biomechanical challenges they encounter [8], [9]. The incidence of shoulder injuries among MWU, primarily due to repetitive strain during wheelchair propulsion, plays a vital role in their mobility and participation [9], [10], [11]. Long-term wheelchair users often experience shoulder pain, which can be intensified by additional load carrying [11], [12], [13]. Load carrying, whether it be personal belongings, groceries or other necessities, can alter the dynamics of wheelchair propulsion by increasing the physical effort required and affecting the user's ability to maneuver effectively [14], [15], [16], [17], [18]. Despite the importance of load bearing, there has been limited research that specifically investigates its impact on the mobility and exertion of MWU, particularly in real-world, outdoor settings.

Studies have integrated the use of inertial measurement units (IMU) for assessing mobility and participation of MWU. Research has demonstrated the efficacy of IMUs in capturing detailed biomedical data [19], [20], [21], [22], [23]. The effect of different terrain on manual wheelchair propulsion is crucial to fully understand shoulder function and its impact in the real-world environment [3]. Studies have shown that rough terrain increases the effort of MWU, thereby increasing the risk of shoulder injuries [8]. The use of technology like IMUs not only aids in understanding the challenges faced by MWU, but also offers potential solutions to enhance their community participation by informing the design of more adaptive and supportive mobility aids.

The ability to navigate different environments safely and efficiently is crucial for social engagement [24]. While various studies have examined the general mobility and upper extremity demands of MWU [25], [26], [27], there is a need for further assessment of their ability to engage in community activities especially in environments where they might need to carry groceries, personal items or other external loads.

This work was supported in part by the US Department of Health and Human Services, Grant No. 90ARHF0006.

This study aims to assess the kinematic and heart rate response of MWUs when carrying a load on an outdoor course using IMUs and a heart rate monitor. By using these sensors, this research seeks to provide insight into how load carrying affects key aspects of wheelchair mobility and cardiovascular response, and its relationship to community mobility and participation in a real-world setting.

II. METHODS

A. Participants

The participants in this study were selected based on the following inclusion criteria: they were at least 18 years old, were experienced manual wheelchair users who relied on their wheelchair for daily mobility, were able to self-propel and transfer independently, and reported no shoulder injury or surgery within the last year.

A total of 10 participants were recruited for the study. The sample included 7 males and 3 females, with a mean age of 34 ± 9 years and BMI of 28.8 ± 7.1 kg/m2. Each participant provided written informed consent prior to participation. The study was approved by the University of Wisconsin-Milwaukee Institutional Review Board (protocol #24.059). A summary of participant demographic information is presented in Table I, including age, gender, BMI, level of injury, and wheelchair propulsion type based on visual observations made by the tester during data collection.

TABLE I. PARTICIPANT DEMOGRAPHICS; SCI – SPINAL CORD INJURY, BMI – BODY MASS INDEX

#ID	Gender	Age	Weight (lbs)	BMI	Injury Type	Propulsion Pattern
1	Male	41	160	23.6	SCI L3 incomplete	Semicircular[a]
2	Male	26	183	32.4	SCI T10 incomplete	Semicircular
3	Male	32	245	40.8	Sacral Spina Bifida, incomplete SCI	Arc[b]
4	Male	39	225	29.7	SCI T8 incomplete	Arc
5	Male	38	135	19.4	SCI T6 incomplete	Arc
6	Female	22	140	23.3	Neuromuscular autoimmune condition	Semicircular
7	Female	22	245	39.5	Spina Bifida L3-L5	Semicircular
8	Male	47	220	28.2	SCI C6/C7 incomplete	Arc
9	Female	43	150	28.3	Spina bifida T12	Semicircular
10	Male	30	155	22.9	SCI T10-T12 incomplete	Semicircular

[a] Hands follow the pushrim in a roughly half-circle motion, then drop below the pushrim during recovery

[b] Hands move in a short downard and backward motion along the pushrim

B. Equipement and Hardware

- **IMU**: In this study, IMUs were used to capture detailed data on the motion dynamics of the wheelchair and user. An IMU was secured to the participants' right wrists, and one on the frame of the wheelchair. The placement of the IMUs on the wrist and wheelchair (Fig. 1 – left) is described in a previous study [22]. The IMUs were triaxial Blue Trident IMUs (Vicon Motion Systems Ltd., Oxford, UK) and recorded linear acceleration and angular velocity.
- **Heart Rate Monitoring**: A commercially available Garmin Forerunner 735XT (Garmin Ltd., Olathe, KS, USA) wristwatch was used to record time and heart rate. The heart rate monitor with a photoplethysmography sensor was used to assess the cardiovascular effort during the test. The heart rate data were used to compare the physiological demand of the two test conditions and identify any significant increases in exertion when carrying an additional load.
- **Ramp and Course Description**: The study was conducted outdoors to simulate a real-world environment with conditions typically encountered by MWU. Cones were laid out to mark the course which included a ramp (with an incline, plateau, and decline) and a gravel surface representative of those found in urban settings. The ramp was constructed from a nonskid aluminum with a uniform surface to minimize variability in rolling resistance. The incline/decline had a slope of 8.33% to meet ADA ramp requirements, with a sloped length of 0.9 meters and a top plateau length of 1.8 meters. The gravel area consisted of loose uneven stones of varying sizes, and created a rough, unstable surface approximately 1.5 meters long. The course also included flat segments and turns around traffic cones to create a realistic and challenging environment for the participants, approximately 22 meters long (see Fig. 1 – right for a sketch of the course).

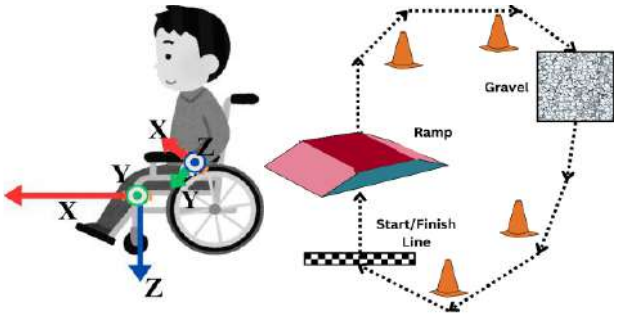

Fig 1. LEFT: Wheelchair user with two inertial sensors. Vector orientation of the IMU axes on the wrist and wheelchair is shown. RIGHT: Sketch of the course and all its elements.

C. Study Protocol

Before testing, the participants were given an explanation of the study's objectives and the steps they would follow. Each participant had the wristwatch and IMU secured to their right wrist and an IMU on their wheelchair. The study began with a familiarization phase, during which each participant went through the course once without data collection.

The study involved two testing conditions: the unloaded condition performed first, followed by the loaded condition, with a break in between for setup and rest. Participants did not report fatigue after the unloaded condition.

- **Unloaded Condition**: Participants were instructed to propel themselves around the course at a comfortable self-selected pace while maintaining safety on the ramp and other challenging sections.
- **Loaded Condition**: Participants were required to complete the same course while carrying an additional load equivalent to 10% of their body weight in a backpack, rounded to the nearest 5 pounds. The loaded condition was designed to simulate real-world scenarios in which wheelchair users might need to carry personal belongings or other items while navigating their local environment.

D. Data Processing

For each participant, Blue Trident IMU and Garmin wristwatch data were collected and processed for both conditions. IMU data were used to determine events of the individual's propulsion cycle from the y-axis acceleration of the wrist-mounted IMU (push rim-hand contact and release points, thus identifying the push and recovery phases) [22], as well as to calculate their cadence. The y-axis angular velocity from the gyroscope of the IMU on the wheelchair was used to detect sections in the course where sudden, sharp increases in angular velocity indicated wheelchair pitch rotations, such as when the front wheels were elevated to enter the ramp or gravel section. IMU data were filtered using a low pass Butterworth filter (6 Hz) to remove any noise and artifacts that might have resulted from vibrations or sudden movements not related to propulsion. Heart rate data were averaged across the entire course to provide a clear picture of the cardiovascular demand under each condition.

All statistical analyses were performed using SPSS software (version 28, SPSS Inc., Chicago, IL, USA). The analysis compared the participants' performance and physiological responses between the two testing conditions: loaded and unloaded. Missing heart rate data from participant 5 was excluded from the statistical analysis. A Shapiro-Wilk test for normality showed that the loaded completion time was not normally distributed ($p < 0.05$). As a result, a Wilcoxon signed-rank test was used to compare cadence, heart rate, and completion time differences between loaded and unloaded conditions across participants, with a p-value of less than 0.05 indicating significant differences. This non-parametric test assessed the impact of additional load on participants' mobility and exertion.

III. Results

Fig. 2 shows the y-axis angular velocity of the wheelchair-mounted IMU, with peaks indicating backward wheelchair tilt and valleys indicating forward tilt in the sagittal plane, which correspond to course obstacles such as going up and down the ramp and traversing the gravel. Descriptive statistics for the entire course, shown for all participants and averaged across them, are presented in Table II. The displayed time is how long the participant took to complete the course from start to finish during both the loaded and unloaded conditions, while mean heart rate is the average heart rate of the participant, measured during the course.

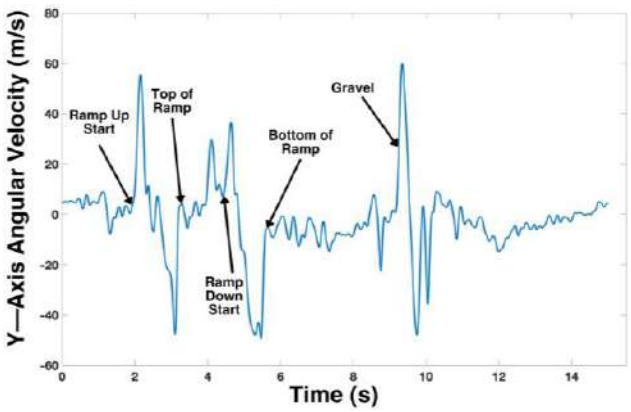

Fig 2. Wheelchair IMU y-axis angular velocity for Participant 1 for unloaded condition, with marked wheelchair pitching movements indicating different segments of the course.

TABLE II. TRIAL RESULTS; UD – UNLOADED, LD – LOADED, HR – HEART RATE

ID	UD Time (s)	LD Time (s)	UD Cadence (cycle/min)	LD Cadence (cycle/min)	UD Mean HR (bpm)	LD Mean HR (bpm)
1	15	15	60.0	52.0	95.9	99.6
2	16	17	56.2	45.9	93.3	109.4
3	13	15	50.8	52.0	115.4	113.8
4	10	16	88.4	86.2	104.3	101.4
5	16	22	45.0	57.3	-	-
6	18	34	63.3	40.9	80	90.4
7	19	17	37.9	45.9	106	110.4
8	18	25	60.0	59.1	78.9	97.5
9	11	11	70.9	65.4	93.1	96.3
10	10	11	72.0	87.3	121.1	116.4
$\bar{X}$ (σ)	14.6 (3.5)	18.3 (7.0)	60.5 (14.5)	59.2 (16.2)	97.5 (13.4)	104.1 (9.0)

Fig. 3 also shows the cadence during the ramp segment for the unloaded and loaded conditions for each participant, calculated from the y-axis acceleration of the wrist IMU. The calculated cadence exhibited distinct responses to the external load, varying among participants for both the entire course (Table II) and while traversing the ramp (Fig. 3). Some participants showed little to no change in cadence between loaded and unloaded conditions, while others increased or decreased their cadence in the loaded condition. There was no statistically significant difference in cadence across participants between the loaded and unloaded conditions for the entire course (Wilcoxon $z = -0.306$, $p = 0.760$). Conversely, there was a significant difference in the time taken to complete the course (Wilcoxon $z = -2.035$, $p =$

0.042) and the mean heart rate (Wilcoxon z = -2.073, p = 0.038) between the loaded and unloaded conditions.

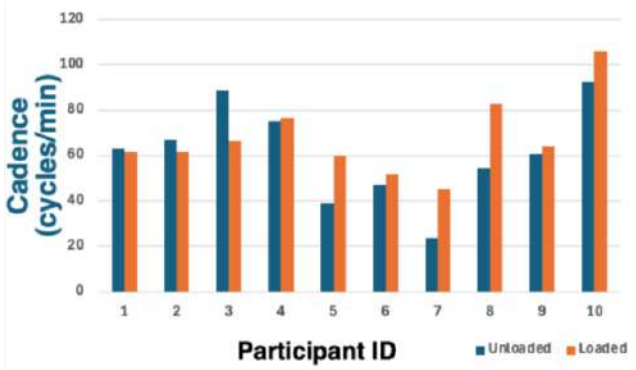

Fig 3. Unloaded and loaded cadence for each participant while traversing the ramp.

IV. Discussion

To gain a comprehensive understanding of the impact of load carrying on wheelchair propulsion, the quantitative data from the IMUs and heart rate monitor were analyzed. This approach allowed for the examination of how physical performance and physiological exertion varied between loaded and unloaded conditions and from person to person.

The increase in both the heart rate (p = 0.038) and the time to complete the course (p = 0.042) for the loaded condition underscores the dual impact of load carrying on both physical and cardiovascular performance. From a biomechanical perspective [11], [12], [13], the additional weight likely increased the force required to overcome course obstacles, resulting in a longer completion time and a greater cardiovascular exertion during the loaded condition.

A closer examination of the cadence data illustrated in Fig. 3 and listed in Table II revealed considerable variability in how each participant reacted to carrying the extra weight. This variability likely explains the lack of statistical significance in cadence between the loaded and unloaded conditions, potentially attributed to participants adopting different propulsion patterns when faced with the additional load. Some participants may have chosen to maintain or decrease their cadence by exerting more force per stroke, while others may have increased their cadence but applied less power into each stroke to manage the increased effort required for propulsion. This variability highlights individual differences in coping mechanisms and physical conditioning among MWU, emphasizing the need for effective methods of individualized assessment.

These findings have important implications for the assessment and training of MWU to improve their mobility and participation in their community. The significant increase in completion time and heart rate under the loaded condition supports the need for training and rehabilitation programs that specifically address physical fitness and the challenges of load carrying to build strength and endurance necessary to handle such conditions in the daily lives of MWU. The difference in the cadence responses also suggests that a one-size-fits-all approach for wheelchair training may not be appropriate. A personalized training program that considers the user's physical condition and preferred propulsion strategies may be more effective. This study also highlights the importance of regular cardiovascular monitoring, as the increased heart rate under the loaded condition suggests that even moderate loads can significantly stress the cardiovascular system. This also agrees with previous findings on the effect of loading on MWUs [14], [15], [16], [17], [18].

While this study provides valuable insights, there were limitations that must be acknowledged. Given the relatively small sample size, future studies with larger and more diverse populations could provide additional understanding of the impact of load carrying on different groups of wheelchair users. Additionally, as only one trial per condition was collected for each participant, future studies should include multiple trials and average the results. Future studies should consider varying the order of the conditions to avoid any effects of fatigue. Furthermore, future research can explore the long-term effects of regular load carrying on wheelchair users, particularly in relation to musculoskeletal health and the risk of overuse injuries. By investigating these questions, future research can continue to enhance our understanding of wheelchair mobility and contribute to the development of solutions that promote independence and well-being for MWU.

V. Conclusion

This study explored the impact of load carrying on mobility and physical exertion of MWU by comparing inertial and heart rate data under loaded and unloaded conditions. The findings illustrated the increased physical and cardiovascular strain associated with load carrying that could affect daily mobility and the overall well-being of MWU. Awareness of the potential for increased fatigue and the need for pacing during activities that involve carrying weight can help users make more informed decisions about managing their daily routines. Additionally, the variability in individual responses emphasizes the importance of personalized approaches in training and rehabilitation, where individual capabilities and techniques are taken into account. This study contributed valuable insights into the challenges faced by MWU when carrying loads, providing a foundation for further research and practical applications aimed at enhancing the mobility and quality of life of MWU.

***Abstract*— Brain-computer interfaces (BCIs) offer promising potential to aid neurorehabilitation by transforming motor imagery (MI) signals into control commands, bypassing damaged neural pathways to support motor recovery. However, a key challenge in BCI research is achieving an effective balance between classification accuracy and real-time responsiveness, as both are critical for enhancing user embodiment and control for neurorehabilitation outcomes. This study investigates the impact of trial length and feedback update interval (FUI) on classification accuracy in an MI-based BCI system. Using EEG data from five subjects across 50 sessions, we evaluated classification performance across various trial length (1–5 seconds) and FUI (0.2–1 second) configurations. Results revealed that both trial length and FUI significantly influenced classification accuracy, with longer trial length (4–5 seconds) and FUI (0.4–1 seconds) yielding the highest accuracy. However, post-hoc analyses indicated a saturation effect, with no significant differences in the accuracy for these parameters. These findings underscore the importance of balancing signal stability with responsiveness for optimal BCI performance, providing insights into parameter settings that can enhance BCI usability in neurorehabilitation. Future work may explore adaptive approaches to dynamically adjust these parameters based on real-time requirements, potentially offering a more responsive and efficient BCI for clinical rehabilitation.**

Keywords*— Brain-computer interface, Real-time, Motor imagery, Virtual reality, Neurorehabilitation, Common spatial patterns, Linear discriminant analysis, Responsiveness, Feedback update interval

I. INTRODUCTION

Sensorimotor rehabilitation is critical in treating conditions such as spinal cord injury (SCI) and stroke, aiming to restore motor function and improve quality of life [1], [2]. Recent research highlights brain-computer interfaces (BCIs) as a promising technology to promote neuroplasticity, positioning BCIs as a potential adjunct to current rehabilitation interventions after neural trauma [1]. BCIs record brain activity and translate into control commands, bypassing peripheral nerves and muscles to control external devices [3]. Specifically, motor imagery (MI) BCIs use electroencephalography (EEG) to detect imagined movements—thoughts of motion without physical movement—enabling users with neurological impairments to interact within real or virtual environments despite disrupted motor pathways [1], [4]. EEG-based BCIs are particularly advantageous due to their non-invasive nature, portability, and high temporal resolution [5], [6]. Although advancements in BCI-driven rehabilitation have significantly improved the quality of life for individuals post-stroke or SCI [7], [8], BCIs are not yet widely adopted in clinical practice [9].

A core challenge in BCIs is achieving real-time responsiveness, which is essential for effective neurorehabilitation [10], [11]. For BCIs to be effective, they must rapidly and accurately transform neural signals into commands. Despite advancements, BCI research has often emphasized classification accuracy over real-time responsiveness, impacting users' perception of control [12]. In applications requiring immediate interaction, reducing processing delays is crucial to enhancing both user experience and system functionality [13]. Continuous BCI control relies on real-time feedback, and delays can disrupt users' perception of agency [12], [14], potentially hindering the relearning of motor skills. Conversely, timely feedback reinforces intended brain activity patterns, promoting effective motor learning and neuroplasticity in rehabilitation [11], [15].

Optimizing BCI responsiveness involves balancing trial length (EEG data segment used to produce one classification output) and feedback update interval (FUI; sliding window length used to generate subsequent classification outputs) (Fig. 1): shorter configurations may enhance responsiveness but risk signal instability and misclassification, while longer configurations provide more stable signals but may introduce delays [12]. A recent study has explored the effect of trial length on classification accuracy in offline BCI systems; however, they did not consider the influence of FUI, nor did they report results for continuous real-time BCI control [12]. Another study examined the impact of shorter FUIs on behavioural and neurophysiological measures following BCI training for a single stroke patient, but its effect on BCI accuracy was not addressed [11]. Moreover, longer trial length and FUI configurations may capture richer MI spatial patterns, enhancing classification accuracy, thus exploring the

This work was supported by the Queensland Motor Accident Insurance Commission (MAIC), Australia, as part of BioSpine research project.

trade-off between responsiveness and performance may improve neurorehabilitation outcomes.

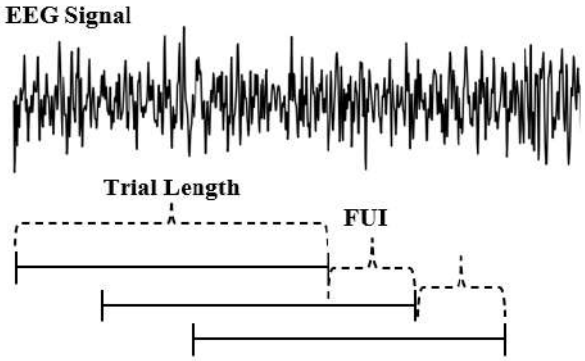

Fig. 1. Example of EEG signal partitioned into trial length and feedback update interval (FUI) using sliding window technique.

This study addresses this gap by analysing the relationship between trial length, FUI, and BCI classification accuracy. Our objective is to identify configurations that support both high accuracy and real-time feedback, enhancing BCI usability in neurorehabilitation. Using data from five subjects across 50 sessions, we evaluated classification accuracy across different trial length and FUI combinations. By identifying optimal settings for these parameters, our findings aim to contribute to the development of more responsive and robust BCI systems, ultimately improving rehabilitation outcomes for individuals relying on BCI technology..

II. Materials and Methods

A. Experimental Setup and Signal Processing

Fifty sessions 2-class MI EEG datasets from five healthy naïve subjects (2 females, aged 24-40 years) were used in this study [16] (Fig. 2). During each session, subjects sat on a comfortable chair wearing an OpenBCI EEG (USA) and Oculus VR headset (USA). Subjects were immersed via a virtual pathed environment designed in Unity 3D (Unity Technologies, USA). Continuous 16-channels (AFz, F4, Fz, F3, FC6, FC2, FC1, FC5, C4, Cz, C3, CP6, CP2, CP1, CP5, and Pz) dry EEG signals at 125 Hz were recorded for three phases: calibration, cued-online, and self-paced online BCI. Here, we only used calibration phase data to train the BCI model and cued-online data to simulate real-time feedback scenarios. A Zero-phase bandpass finite impulse response filter was used to filter the EEG data between 4–30 Hz [17]. Afterwards, common spatial patterns (CSP) was applied to extract discriminative features from the EEG data, enhancing the variance differences between two classes. CSP operates by maximizing the variance for one class while minimizing it for the other, producing a set of spatial filters that project the EEG signals into a feature space optimal for classification [18], [19]. Following feature extraction, linear discriminant analysis (LDA) was employed as the primary classifier. LDA is a widely used algorithm in BCI research due to its efficiency and simplicity. It operates by finding a linear combination of features that best separates the classes, which is particularly effective for MI-based BCI tasks. The CSP-derived features were input to the LDA model for classification, providing real-time feedback to the user [20]. The MI-BCI was implemented using Python (MNE and scikit-learn libraries) in the Robotic Operating System (ROS) to enable real-time EEG data acquisition and processing, as well as synchronisation with the VR environment [16]. An Intel Xeon 3.6GHz with 32GB RAM was used to implement the system and data collection. All the offline simulations were performed on Dell G3 laptop with an Intel Core i7 (8th Gen, 2.2 GHz) processor and 16 GB RAM. Using our EEG sampling rate of 125 Hz the processing times remained consistent across different conditions with an average model calibration time of 3.0±0.2s and real-time classification of 6.6±1.3ms. Notably, model calibration is conducted before real-time BCI control, ensuring it does not impact real-time classification performance.

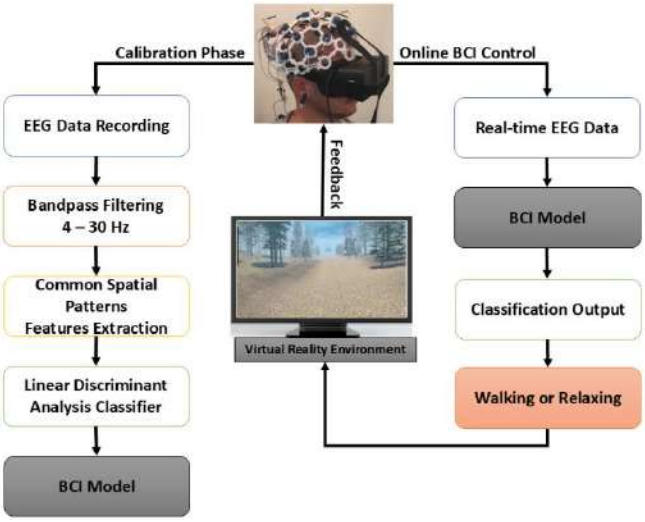

Fig. 2. Overview of the BCI data collection and processing framework. Each session began with a calibration phase, where individualised classification models were created based on the subject's EEG data. This was followed by a cued-online BCI phase, where participants performed motor imagery (MI) tasks while receiving real-time feedback through an immersive virtual reality (VR) interface.

B. Data Collection

During the calibration phase of each session, participants alternated between relaxation and walking MI with virtual reality (VR) feedback, while EEG data were recorded. In the VR environment, participants had a first-person view of their avatar walking during the walking MI task or no movement for the relaxation task. The calibration phase included five runs, with each run containing 10 trials per MI task (totalling 100 trials). Each trial lasted 12 seconds and followed a set sequence: a fixation cross from 0 to 2 seconds, followed by audio cues "relax" or "walk" from 2 to 4 seconds to prompt the participant to begin the MI task, which they performed from 4 to 10 seconds. At 10 seconds, participants heard "stop" as audio feedback, and a rest period continued from 10 to 12 seconds. After each run, participants had a one-minute break. They were instructed to minimize eye blinks and body movements, especially during the task period.

Following the calibration of the classification model, a cued-online phase was conducted to assess each participant's performance in real-time BCI control. This phase began with a welcome screen displayed from 0 to 10 seconds. The cued-online phase consisted of three 60-second trials for each MI task, during which the participants were prompted by an audio

cue to perform the specified MI task continuously for 60 seconds. During the data collection, real-time VR biofeedback was provided based on the decoded MI command using 5s trial length and 1s FUI, allowing participants to see immediate feedback on their performance. Unlike the calibration phase, the cued-online phase included no fixation crosses, cues, or rest periods between trials. In total, the cued-online phase lasted six minutes and ten seconds.

C. *Performance Analysis*

To evaluate the performance of BCI control, we simulated various real-time BCI scenarios using different combinations of trial length (1-5 seconds with increments of 1 second) and FUI (0.2-1 second with increments of 0.2 second) to determine the optimal balance between real-time feedback and classification accuracy. The CSP-LDA classifier was calibrated using offline data corresponding to each trial length, and classification accuracy was calculated for cued-online data. Classification accuracy, our primary metric, was calculated using true positives (TP: walking MI correctly classified as walking), false positives (FP: relaxing MI misclassified as walking), true negatives (TN: relaxing MI correctly classified as relaxing), and false negatives (FN: walking MI misclassified as relaxing). This accuracy metric is defined as

$$Classification\ Accuracy = \frac{TP + TN}{TP + TN + FP + FN}$$

By analysing these configurations, we determined optimal parameters that enhance the responsiveness and reliability of BCI systems for real-time applications, especially in neurorehabilitation settings where both accuracy and continuous control are essential.

D. *Statistical Analysis*

A two-way ANOVA was conducted to assess the main and interaction effects of trial length and FUI. This was followed by post-hoc comparisons to further analyse the impact of each parameter on classification accuracy.

III. RESULTS

Classification accuracy increased as both trial length and FUI increased (Fig. 3). For a 1-second trial length, average accuracy increased from 54.4±1.1% to 67.1±2.1% as FUI increased; for a 2-second trial, accuracy improved from 58.6±1.3% to 70.7±1.7%; for a 3-second trial, accuracy increased from 61.4±1.69% to 72.1±1.9%; for a 4-second trial, accuracy increased from 63.3±2.1% to 72.6±1.7%; and for a 5-second trial, accuracy increased from 65.42±2.5% to 72.8±1.9% with larger FUI.

ANOVA results indicated significant main effects for both trial length ($F = 236.29$, $p < 0.001$) and FUI ($F = 40.45$, $p < 0.001$), along with a significant interaction between them ($F = 14.60$, $p < 0.001$). Post-hoc tests ($p < 0.001$) confirmed that classification accuracy was highest for longer trial lengths (4–5 seconds) combined with FUI (0.4–1 second). These parameter settings exhibited a synergistic effect, achieving notable accuracy improvements compared to other configurations. However, no significant accuracy differences were observed between the longest trial lengths and FUI, indicating a possible saturation point in performance gains.

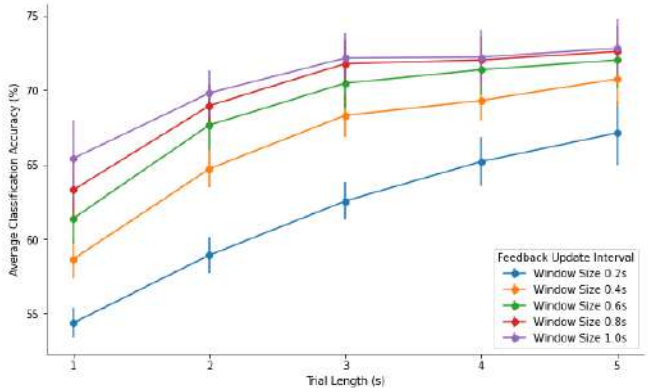

Fig. 3. Average classification accuracy (%) with standard deviation (error bars) across 50 sessions for different trial lengths (1–5 seconds) and feedback update interval (FUI; 0.2–1 second) combinations.

IV. DISCUSSION

This study highlights the importance of optimising trial length and FUI for effective MI-based BCIs in neurorehabilitation. Our findings demonstrated a consistent increase in classification accuracy with longer trial lengths and FUI, suggesting that these configurations may capture richer information from EEG signals associated with MI tasks. The highest accuracies were achieved with trial lengths of 4–5 seconds and FUI of 0.4–1 second, a combination that enabled stable classification by leveraging a broader temporal representation of MI signals. This outcome aligns with existing literature, which suggests that increased time windows provide better separation of EEG activity, thus enhancing BCI performance [12].

Despite the accuracy gains associated with larger time windows, a key consideration is the trade-off between accuracy and real-time responsiveness. For neurorehabilitation and other real-world applications, responsiveness is crucial to providing users with timely feedback, reinforcing motor relearning, and promoting neuroplasticity [10], [11], [15]. Extended processing times could diminish this experience by introducing delays, which could reduce users' perceived control over the BCI system and ultimately affect the efficacy of the rehabilitation process [12], [14]. Therefore, while longer configurations yield higher accuracy, they may not always be practical in scenarios requiring immediate interaction, such as neurofeedback-based rehabilitation for individuals recovering from SCI or stroke.

The significant interaction between trial length and FUI further emphasizes the need for a balanced parameter configuration to achieve optimal performance (Fig. 3). While a previous study has demonstrated the influence of trial length on offline classification accuracy, they did not consider FUI's impact or address results in the context of continuous real-time BCI control [12]. Our findings extend this understanding by showing that the benefit of a longer FUI is most pronounced at extended trial lengths, where sufficient signal information is available for accurate classification. Similarly, earlier research investigating shorter FUIs in stroke rehabilitation reported improvements in behavioral and

neurophysiological measures but did not explore their effect on classification accuracy [11]. Our results bridge this gap, revealing that while longer trial lengths and FUIs enhance accuracy by capturing richer MI spatial patterns, this improvement plateaus with no significant difference in classification accuracy beyond 4-second trial lengths and 0.4-second FUI, indicating a saturation effect. This finding suggests that increasing these parameters beyond a certain point does not substantially enhance accuracy and could introduce unnecessary delays, underscoring the need for careful parameter tuning to balance performance and user experience.

Recent clinical studies have aimed to validate the effectiveness of BCI-based rehabilitation in individuals with neurological impairments, with trials demonstrating functional improvements [25], [26], [27]. However, the widespread translation of BCI-based rehabilitation into real-world medical applications remains limited due to challenges in signal reliability, user variability, and long-term engagement [16]. To address these limitations, various strategies have been explored, including transfer learning approaches to reduce calibration time [24] and virtual reality (VR)-integrated BCIs to enhance user performance and engagement over longitudinal use [16]. Additionally, hybrid BCIs that integrate EEG with other physiological signals have been investigated to improve classification accuracy and robustness [21], [22], [23]. Despite these advancements, systematic investigations into fundamental system parameters such as trial duration and FUI are often overlooked in the design process [11], [12]. Our study systematically evaluated how these factors affect classification performance, informing design choices beyond arbitrary selection. Moreover, while no universal parameters apply to all applications, our findings offer valuable guidelines that can serve as a starting point for MI-BCI optimization. This contribution is particularly relevant for applications involving longitudinal training, where optimizing user adaptation and system responsiveness is crucial for long-term usability and performance improvement.

This study has several limitations that highlight opportunities for future research. The analysis was conducted on data from unimpaired individuals; replicating it with data from neurorehabilitation end-users could yield valuable insights, as their EEG signal characteristics and control strategies may differ significantly. We used consumer-grade dry EEG systems sampled at 125 Hz. Employing EEG systems with higher sampling rates could provide richer data, potentially enabling further reductions in FUI without compromising accuracy. This study focused on a two-class BCI; extending it to multi-class BCIs could explore whether similar trends persist and how trial length and FUI impact multi-class performance. While CSP-LDA was used for classification, advanced methods like deep learning could offer deeper insights and enhanced performance. Future work can expand on this foundation by exploring how different machine learning models, including deep learning architectures, interact with the identified optimal trial lengths and FUI. Incorporating more advanced classifiers may enhance system adaptability and improve classification accuracy, particularly for long-term BCI use. However, it is crucial to maintain a balance between model training and execution computational speed, classification accuracy, and real-time feasibility, especially in neurorehabilitation applications where system responsiveness is critical. Real-time feedback was provided exclusively in the 5s trial length and 1s FUI condition, while other configurations were assessed using offline simulations. This design choice allowed for controlled comparisons. However, as neurofeedback involves a learning process, participants may have optimized their cognitive strategies for the tested configuration, potentially influencing results. Future studies will address this by conducting real-time experiments across all trial length and FUI conditions, allowing participants to adjust their cognitive strategies dynamically. This approach will provide a more comprehensive understanding of how real-time neurofeedback modulates BCI performance under different settings. Finally, the limited sample size may restrict generalizability, and future studies with larger, more diverse participant pools could provide more robust findings.

In practical applications, such as virtual or real-time rehabilitation scenarios, adaptive parameter adjustments could be beneficial. For instance, during periods when high accuracy is required, the system could employ longer trial lengths and FUI, while shorter configurations could be used when immediate responsiveness is prioritized. Future work could explore adaptive BCI models that adjust trial length and FUI dynamically based on user performance or real-time feedback requirements. Such an approach could support a more flexible and responsive BCI system that meets both accuracy and responsiveness demands.

These findings contribute to our understanding of how parameter settings influence BCI performance, offering a pathway to develop more responsive and robust BCI systems for neurorehabilitation. By identifying optimal parameter configurations, this study provides valuable insights for advancing BCI usability, ultimately enhancing rehabilitation outcomes for individuals with motor impairments. Further research, potentially incorporating adaptive algorithms and testing in clinical settings, is recommended to refine these configurations and validate their effectiveness in diverse rehabilitation applications.

V. CONCLUSIONS

This study examined the effects of trial length and FUI on classification accuracy in a MI-based BCI system, aiming to identify optimal parameters for effective and responsive neurorehabilitation applications. Results demonstrated that both parameters significantly impact classification accuracy, with longer trial lengths (4–5 seconds) and larger FUI (0.4–1 second) producing the highest accuracy. However, accuracy gains reached a saturation point beyond these values, highlighting the need to balance responsiveness with signal stability for real-time BCI performance. These findings underscore that while longer configurations enhance accuracy, they may introduce delays incompatible with immediate interaction needs in neurorehabilitation. Future work could focus on adaptive parameter tuning that adjusts in real time, offering both precision and responsiveness. This approach may pave the way for more reliable and efficient BCIs, ultimately improving therapeutic outcomes and usability in clinical settings for individuals with motor impairments.

Design of a Rope-Driven Finger Exoskeleton System with a Universal Double Grooved Roller for Adaptive Rehabilitation

Wenqi Li, Le Bao, and Wansoo Kim*, *Member, IEEE*

***Abstract*— Impaired hand function caused by neurological conditions, such as stroke, severely limits individuals' ability to perform daily tasks, highlighting the importance of accessible rehabilitation devices. Although the double grooved roller design in existing rope-driven exoskeletons reduces weight and enhances compactness, the different amount of change in the upper and lower traction cords when the fingers are flexed and torsioned can easily lead to slack and slippage of the traction cords, which affects the accuracy of movement. To address these limitations, a rope-driven exoskeleton system with a universal double grooved roller is designed for assisting finger movement based on a study of the index finger. In order to enhance the universal performance of the exoskeleton, in this study, 40 groups of index finger flexion and extension movements with upward and downward stretching are collected and statistically analyzed to find out the universal ratio of double grooved rollers. The experiment tested the finger-driving capability of the exoskeleton device, achieving a range of motion up to 94% of unassisted natural motion, with stable performance during repetitive movements. Additionally, the finger-driving success rate for seven subjects with varying finger sizes reached 100%, and the test results were analyzed in detail. The designed system demonstrates feasibility, reliability, and universality, offering a viable new solution for adaptive hand rehabilitation.**

I. Introduction

Neurological diseases such as stroke often lead to impaired hand motor functions, severely reducing patients' quality of life by limiting their ability to perform daily activities independently [1], [2]. Hand rehabilitation is crucial for these patients to regain their ability to care for themselves in daily life [3].

The advancement of wearable robotic devices has significantly increased interest in rope-driven finger exoskeleton, which combine lightweight design and flexible actuation to provide a more natural and user-friendly rehabilitation experience [4], [5]. In addition, the rope-driven system has low noise, high safety, low cost, and can reduce joint loads by arranging the actuator in non-critical areas through long-distance transmission [6], [7]. These features make rope-driven exoskeletons highly suitable for applications in medical rehabilitation and industrial assistance.

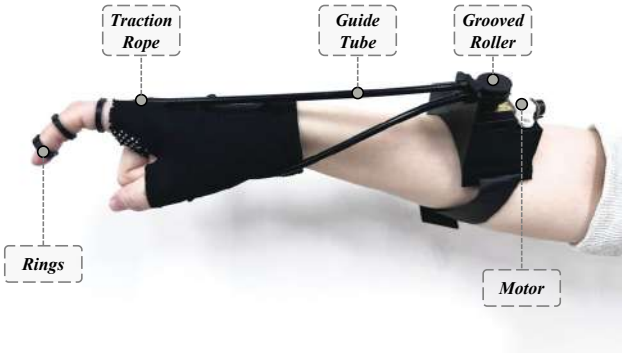

Fig. 1: The designed rope-driven finger exoskeleton system with double grooved roller.

Despite these advantages, existing rope-driven exoskeleton designs face significant challenges in addressing the variability of finger flexion and extension motions. In the study by Burns et al. each finger is equipped with two motors, one for flexion and one for extension [8]. While this can cope with the difference in the amount of change during finger flexion and extension, each finger is equipped with two motors, which increases the weight of the exoskeleton and takes up more installation space. Flexo-glove proposed by Mohammadi et al. is a lightweight and modular flexible exoskeleton glove [9]. Its drive system is designed to realize bi-directional movement of flexion and extension through the design of double grooved roller. However, traditional rope-driven devices often suffer from uneven force distribution, slack, or slippage due to the varying length changes in traction ropes during finger flexion and extension. This in turn affects the stability and accuracy of control and increases the patient's discomfort of use.

To address these limitations, this study proposes a novel double grooved roller design to accommodate the difference in length change of the traction rope when controlling finger flexion and extension. This design connects the traction rope for controlling flexion and extension by setting a large grooved and a small grooved, so as to ensure the tension of the traction line in motion and avoid slipping and slacking. The designed device can reduce the use of motors, thus reducing the cost, reducing the weight of the mechanical structure, and enhancing the user experience. This study provides new ideas for the design of low-cost, home-useable

hand rehabilitation devices.

The main contributions of this study are:

- Sampled 40 sets of data, analyzed to a generic scaling ratio value, and designed a rope-driven finger exoskeleton with a universal double grooved roller by this ratio value.
- The designed rope-driven exoskeleton system was verified to be effective in driving fingers by testing the exoskeleton device's ability to drive fingers.
- The feasibility of the rope-driven exoskeleton and the versatility of the universal double grooved roller was experimentally verified through comparative experiments with multiple subjects of different sizes.

II. Methodology

In rehabilitation, the index finger is often trained individually as a focal point [10], because it requires special attention in terms of strength output, dexterity, and coordination. The muscles (e.g., flexor digitorum superficialis, flexor digitorum profundus) and nerves (median nerve, radial nerve) associated with the index finger are more sensitive than those of other fingers, which is an important indicator for monitoring the rehabilitation effect. Therefore, in this study, a finger rope-driven exoskeleton system is designed for flexion and extension rehabilitation maneuvers of the index finger and is planned to be extended to the rehabilitation control of other fingers.

A. System Overview

As shown in Fig. 1, the designed system is mainly composed of finger rings, traction ropes, double grooved roller, guide tubes and motor. Among them, the finger fixation ring is used to stabilize the finger joints and ensure that the force exerted by the rope can be directly converted into flexion and extension motions [11]. The rope-driven structure consists of two independent ropes, each responsible for either flexion or extension motions. These ropes are strategically arranged along the dorsal and palmar sides of the fingers to realize flexible finger control by stretching or relaxing.

However, during the stretching and relaxing of the leash, the flexion and contraction of the fingers require different lengths of leash retraction and release. In this regard, a roller with double grooves is designed to control the flexion and relaxation of the finger with the rope on the top and bottom of the roller, respectively. The large and small grooves of the roller are designed to provide different ratios in a single motor revolution based on the ratio of the rope changes, thus realizing the precise movement of the finger. Compared to existing studies, both flexion and extension movements of the fingers can be controlled using only a single motor [8]. In addition, the different radii of the double grooved rollers can reduce the slack of the traction rope during flexion and extension [9].

B. Sampling and Analysis

Since fingers stretch up and down differently during flexion and extension, 40 sets of data are collected in this study

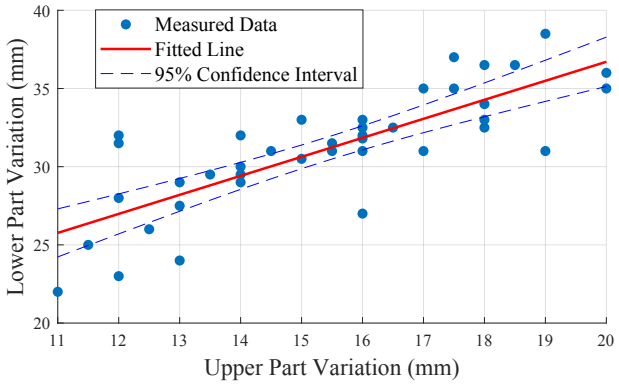

Fig. 2: Linear regression analysis of finger upper and lower extension variations.

in order to observe the changes in the fingers during flexion and extension. Finger fixation rings of different sizes are printed using 3D printing for stabilizing the finger joints during movement, ensuring that the force exerted by the rope could be directly translated into flexion and extension movements. The measurements were made by fixing finger rings on the distal phalanx, middle phalanx and proximal phalanx of the index finger of the subject and connecting the rings with a string on the upper and lower sides of the finger respectively. Attach the traction rope to the distal phalanx ring and record the displacement of the proximal phalanx ring along the traction rope during index finger flexion and extension.

Fig. 2 represents the measure data. To understand the relationship between the upper and lower rope length variations during finger flexion and extension, a linear regression analysis was conducted on the collected data. The resulting regression equation represents the line of best fit for the observed data as follows

$$\Delta L_1 = 1.22 \cdot \Delta L_2 + 12.39 \ , \tag{1}$$

where ΔL_1 is the lower rope-driven structure expansion and ΔL_2 is the upper rope-driven structure expansion. Most of the data in the figure lie within the 95% confidence interval.

In addition, the Pearson correlation coefficient [12], in Equation (2), can be used to analyze the correlation between ΔL_1 and ΔL_2.

$$r = \frac{\sum(\Delta L_{1,i} - \overline{\Delta L_1})(\Delta L_{2,i} - \overline{\Delta L_2})}{\sqrt{\sum(\Delta L_{1,i} - \overline{\Delta L_1})^2}\sqrt{\sum(\Delta L_{2,i} - \overline{\Delta L_2})^2}} \ , \tag{2}$$

$$t_{\text{statistic}} = r \cdot \sqrt{\frac{n-2}{1-r^2}} \ , \tag{3}$$

$$dof = n - 2 \ , \tag{4}$$

$$p = 2 \cdot (1 - F_t\left(|t_{\text{statistic}}|, dof\right)) \ . \tag{5}$$

where $\Delta L_{1,i}$ and $\Delta L_{2,i}$ denote different data points, respectively, $i = 1, 2, \cdots n$. $\overline{\Delta L_1}$ and $\overline{\Delta L_2}$ are the means of these data, respectively. The result is obtained r equal to 0.796, which indicates a strong positive linear correlation between

the two variables. The $t_{\text{statistic}}$ is 8.312 calculated through the r-value. The dof is degrees of freedom. The degree of freedom is 38, where n is the total sample size 40. The p-value is calculated as twice the probability that a t-distributed random variable with dof exceeds the absolute value of the t-statistic, as Equation (5). The p-value is 4.46×10^{-10}, which is further evidence of a strong correlation since the p-value is much less than 0.01.

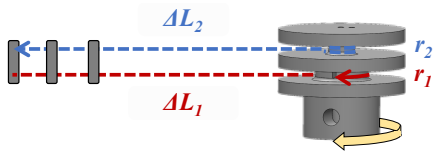
To design a finger exoskeleton device suitable for the majority of people, this study uses data within the 95% confidence interval as representative sizes. These data are then analyzed to determine the generalizable ratio of flexion and extension. First, the ratio η_j of ΔL_1 and ΔL_2 is calculated for each set of data, as well as the mean value of all ratios $\overline{\eta}$:

$$\eta_j = \frac{\Delta L_{2,j}}{\Delta L_{1,j}} \quad (j = 1, 2, \cdots m) \ , \tag{6}$$

$$\overline{\eta} = \frac{1}{m} \sum_{j=1}^{m} \eta_j \ , \tag{7}$$

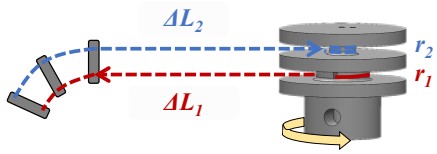
where m is the total amount of data and the mean value results is 0.488.

Finally, the standard deviation σ of the ratio is further calculated to assess the stability of the proportionality relationship in the data set. The standard deviation is calculated using the following equation:



$$\sigma = \sqrt{\frac{1}{m-1} \sum_{j=1}^{m} (\eta_j - \overline{\eta})^2} \quad (j = 1, 2, \cdots m) \ . \tag{8}$$

As a result, the standard deviation σ is obtained as 0.146, indicating that the ratio is relatively stable and less fluctuating among different individuals. The linear regression analysis and Pearson's correlation coefficient calculation and mean ratio analysis showed that there is a significant linear relationship between ΔL_1 and ΔL_2, and the ratio between them is relatively stable. The above results provide a basis for further modeling the universal relationship between the upper and lower finger stretch.



C. Grooved Roller Design for the Rope-Driven Exoskeleton

The double grooved roller design enables simultaneous control of flexion and extension movements by adapting to different rope length changes. As shown in Fig. 3, the dimensions of the two tracks of the roller wheel consist of circles with different radii to cope with the different amounts of up and down stretching when the finger flexes and extends. As the roller wheel rotates, the rope pulls the rings on the finger joints in different directions.

In order to realize the precise control of finger flexion and extension movements by the rope, the design of the double grooved roller needs to have two keys requirements. First, the paths above and below the rope-driven structure must be independent to avoid entanglement of the traction ropes and to ensure motion stability. Secondly, the size of the large and small grooves of the roller needs to adapt to the different

(a) Clockwise rotation causes finger flexion.

(b) Counterclockwise rotation causes finger extension.

Fig. 3: The principle of the double-grooved roller traction for finger flexion and extension.

lengths of the two traction ropes in the flexion and extension process to reduce the loss of driving force, and at the same time, the design of the roller disk has a strong versatility, which can meet the needs of most of the individuals, simplify the production process, and facilitate the promotion of large-scale.

In accordance with these design requirements, the double grooved roller has different sized grooves: the large groove connects to the lower part of the finger ring for controlling finger flexion and the small groove connects to the upper part of the finger ring for controlling finger extension. The upper traction rope is wrapped clockwise around the small groove and the lower traction rope is wrapped counterclockwise around the large groove. In this way, when the double groove roller turns clockwise, the traction rope on the small groove relaxes and the traction rope on the large groove tightens to achieve finger flexion. Conversely, when the double-grooved wheel is turned counterclockwise, finger flexion is achieved. The design of the double grooved rollers allows the traction ropes to run along different radial trajectories on the rollers so that the traction ropes not interfere with each other. By analyzing the data from several experiments, the length change ratio of the upper and lower traction lines is determined and used as the basis for the design of the double grooved roller dimensions, so that the rope-driven system can meet the demand for different amplitude of finger flexion and extension movements.

In this design, a rope-driven structure is used to control the flexion and extension movements of the fingers. In order to accurately describe the motion relationship of the system, the lengths of the ropes required for the upward and downward flexion and extension of the index finger are defined as ΔL_1 and ΔL_2 and the radii of the grooved rollers corresponding to the upward and downward movements of the index finger are defined as r_1 and r_2. Since the double grooved rollers shared a concentric axis, they maintain the equal number of revolutions n. This ensures a proportional relationship between the pulley radii r_1 and r_2 of the grooves and the rope lengths required for flexion and extension movements.

Hence, this relationship is expressed as follows:

$$n = \frac{\Delta L_1}{2\pi r_1} = \frac{\Delta L_2}{2\pi r_2} \ , \tag{9}$$

$$\frac{r_1}{r_2} = \frac{\Delta L_1}{\Delta L_2} \ . \tag{10}$$

The experimental analysis determined an optimum ratio $\overline{\eta} = 0.488$ from the previous section, representing the most suitable proportional relationship for the majority of users. We define 0.488 as the universal size ratio. When designing the double-grooved roller, it was necessary to balance this ratio with the material constraints of 3D printing. If the groove radius is too small, the strength of the structure of the roller may be compromised, leading to potential breakage or deformation during use. To ensure durability while maintaining the optimized ratio, the smaller radius r_1 was set to 2 mm, which resulted in a corresponding larger radius r_2 of 4.1 mm. This configuration provides a robust and universal design that accommodates diverse user requirements while ensuring mechanical stability.

III. Experiments and Analysis

A. Experimental Setup

The experimental portion of the study consisted of a single set of tests of the finger actuation ability of the exoskeleton device, as well as comparative tests on seven subjects with different hand sizes. The experiments are used to observe the trajectory of the fingers under rope-driven traction and to verify the reliability and versatility of the exoskeleton with double grooved roller. In this case, the experimental subjects were all healthy adults between the ages of 20 and 30. The study was reviewed by the Hanyang University Institutional Review Board under the number HYU-2024-100.

The scene of the experimental setup is shown in Fig. 4. The motor rotates forward and backward according to the signals from the buttons, ensuring that the index finger's range of motion remains within reasonable limits. A camera was utilized to record hand movements, specifically tracking

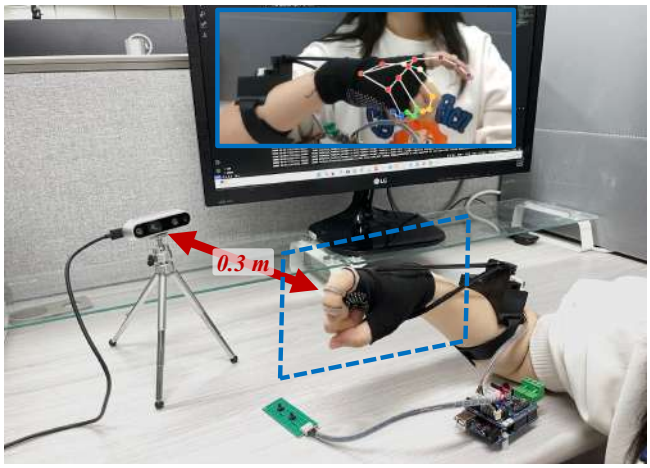


Fig. 4: The scene of the experimental setup.

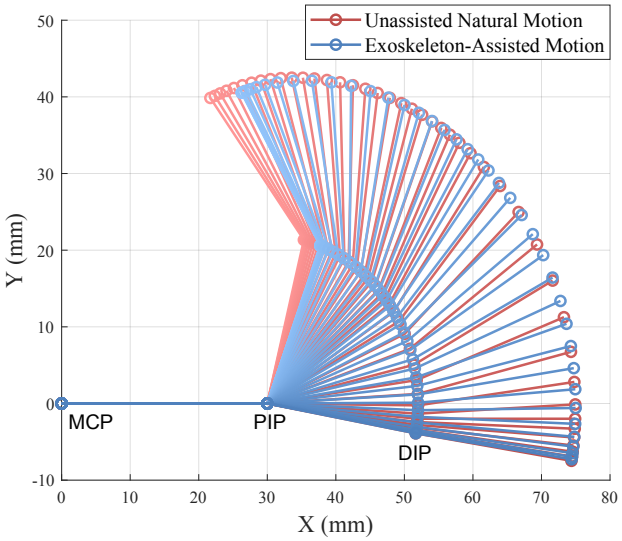

Fig. 5: Finger motion trajectories obtained through visual recognition.

changes in joint angles during flexion and extension. The Mediapipe framework was employed for its real-time skeletal tracking capabilities [13], with noise-reduction filters applied to enhance data accuracy. To ensure more effective data capture, the tester's index finger movement plane must be parallel to the camera, and maintained at a relative distance of 0.3 m. After obtaining the plane position information of the index finger joint, the angles of Distal Interphalangeal Joint (DIP) and Proximal Interphalangeal Joint (PIP) of the index finger are calculated by trigonometric functions [14].

B. Usability Validation of the Finger Exoskeleton

The range of motion of the index finger in unassisted natural state (without the exoskeleton) and when wearing the exoskeleton and being pulled by the rope-driven traction were recorded in the experiments.

As shown in Fig. 5, the MCP and PIP joint positions of the fingers were set to remain fixed (i.e., X-axis direction), and the changes in the angles of the PIP and DIP joints were recorded. When the exoskeleton rope-driven system provided assisted traction on the index finger, the trajectory of the finger was very close to the range of motion of the finger in its unassisted natural state. The active area of the finger under exoskeleton traction was calculated to be $1677.5\ mm^2$, and the active area of the finger in the unassisted natural state was $1576.8\ mm^2$, with an area overlap of approximately 94%. This indicates that the rope-driven exoskeleton did not affect the activity of the index finger while providing external support, verifying the effectiveness of the rope-driven structure.

With the exoskeleton on, the subject performed multiple flexion and extension movements of the index finger, during which the angle of the DIP and PIP joints changed as shown in Fig. 6. It can be seen that the flexion and extension movements of the finger driven by the exoskeleton remained

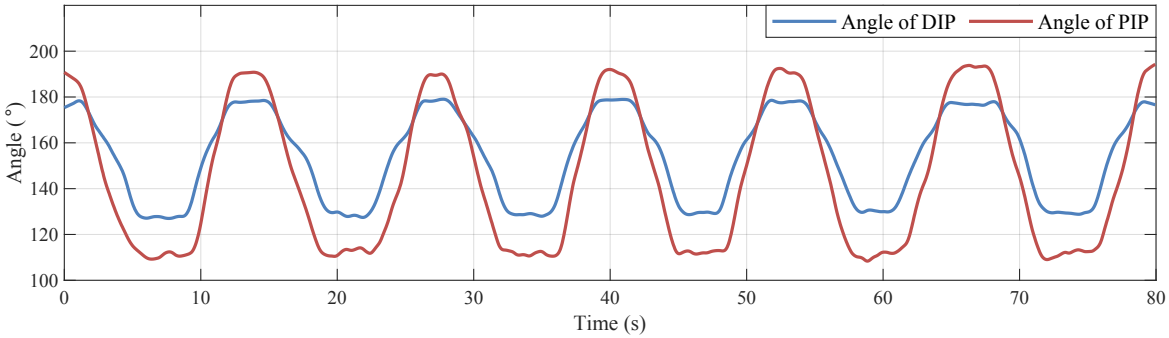

Fig. 6: Angle variation curves of the index finger's DIP and PIP joints while wearing the exoskeleton.

TABLE I: Experimental results of the exoskeleton on flexion and extension movements in subjects with different finger sizes.

No.	Position	Finger Size	DIP			PIP			Rotation Count	Tightness	Task Completion
			With Exoskeleton	Without Exoskeleton	Completion	With Exoskeleton	Without Exoskeleton	Completion			
1	OnLine	Medium	50°	45°	111.1%	80°	90°	88.9%	1.5	Suitable	Yes
2	In 95%CI	Small	45°	40°	112.5%	95°	100°	95%	1.4	Suitable	Yes
3	In 95%CI	Medium	50°	43°	116.3%	85°	90°	94.4%	1.5	Suitable	Yes
4	In 95%CI	Large	40°	35°	114.3%	70°	95°	73.7%	1.6	Suitable	Yes
5	Out 95%CI	Small	40°	45°	88.9%	80°	90°	88.9%	1.3	Suitable	Yes
6	Out 95%CI	Medium	42°	36°	116.7%	84°	90°	93.3%	2.1	Loose	Yes
7	Out 95%CI	Large	45°	38°	118.4%	90°	95°	94.7%	1.7	Slightly Loose	Yes

highly stable during multiple reciprocal movements. The magnitude of the angular changes of the DIP and PIP joints remained the same even in the case of multiple repetitive motions, indicating that the exoskeleton was able to provide stable assistive forces. This result suggests that the designed exoskeleton not only has reliable actuation ability, but also can maintain the stability of the motion during prolonged and high-frequency maneuvers.

C. Universality Validation of the Finger Exoskeleton

In order to purposefully verify the versatility and effectiveness of the designed double grooved roller, seven subjects with varying finger sizes (large, medium, and small) participated in the experiment to evaluate the exoskeleton's adaptability. The test results are shown in Table. I.

All the seven subjects wearing the exoskeleton device completed flexion and extension activities of the index finger in the experiment. Among them, the measured value of subject No. 1 is highly consistent with the fitting line and belonged to the medium finger size; subjects No. 2 to 4 are people with universal size, belonging to the large, medium, and small finger sizes; and subjects No. 5 to 7 are not people with universal size, belonging to the large, medium, and small finger sizes, respectively. The number of rotations of the motor, the looseness of the traction rope, and the completion of the bending maneuver while wearing the exoskeleton were recorded during the experiment to assess the assistive effect of the exoskeleton.

The results of the experiment showed that all seven subjects were able to perform the intended task while wearing the exoskeleton, while the tightness of the traction rope varied within a reasonable range. The four subjects with the universal size performed more consistently, meeting the reasonable range of variation set by the experiment, with the right amount of slack in the traction rope during movement. Of the three subjects who did not have the universal size, one subject's leash remained stable and accomplished the task well, suggesting that the elastic properties of the fingers allow for some error and that the exoskeleton was still able to assist effectively. The other two subjects showed a slight loosening of the leash in one and a significant loosening of the leash in the other during the course of the experiment, suggesting that the double grooved rollers were not perfectly sized, and that the number of motor revolutions increased, even though they both accomplished the flexion-distension task.

IV. Discussion

The usability of the designed rope-driven exoskeleton was demonstrated through hand trajectory recording experiments on a single subject. A universal size double grooved roller was validated through an experiment comparing test results from multiple groups of subjects. Through the experiment, it was shown that the double grooved roller can be designed to fit most people's sizes, but for those with large deviations may need to be individually sized. In addition, the joint angle ratios of the DIP and PIP were compared between wearing the exoskeleton and not wearing the exoskeleton. With the exoskeleton, the range of motion of the DIP of the index finger in most of the subjects exceeded the range of motion

of the index finger in its natural state. The range of motion of the PIP did not exceed the natural state, but there was not a great deal of difference, either. From this result, it is clear that the rope-driven exoskeleton system does not limit the range of motion of the fingers.

The double grooved roller with universal proportions designed in this study improve the common problem of traction rope loosening during finger flexion and extension of exoskeleton devices compared to the traditional double grooved roller with the same diameter [9]. By optimizing the ratio design of the rollers, it is more in line with the biomechanical characteristics of human hand movement, reducing the slackness of the traction rope at different stages of movement and improving the precision of the exoskeleton during finger flexion and extension. This improvement not only enhances user comfort and control precision during operation, but also helps to broaden the scope of application of the finger exoskeleton to meet the needs of different individuals in rehabilitation training or strength assistance.

V. Conclusion

In this paper, a rope-driven exoskeleton with a universal-size double grooved roller is proposed to improve the stability and adaptability of the system. Compared with conventional designs, the universal-size double grooved roller reduce the risk of rope slippage and provide a more stable trajectory by independently controlling the path of the upper and lower flexion ropes.

This study analysed the extension of the upper and lower traction ropes during index finger flexion in 40 subjects. Statistical analyses showed a strong positive linear relationship between them, and proportional means within 95% confidence intervals were used to determine the optimal size ratio of the double grooved ropes.

Experimental results showed that the exoskeleton-assisted index finger movement closely approximated the natural range with an overlap of 94%. The angular changes of the DIP and PIP joints were consistent over multiple cycles, indicating reliable and stable actuation. Moreover, comparative experiments with seven individuals with different finger sizes further confirmed the versatility of the dual-slot roller. The design adapted to differences in finger length and flexion/extension angles, improving the stability of the leash. When comparing assisted and unassisted movements, the angular variability of the DIP and PIP joints was 111.12% and 89.84%, respectively, indicating minimal effect on natural movement. The proposed roller design improves the stability and accuracy of the rope actuation system and reduces the risk of slipping and slackening of the haul rope, while improving user comfort.

Future study will expand from healthy subjects to individuals with impaired hand function and evaluate the effectiveness of the system. Additionally, the scope will be extended from traction on the index finger to other fingers, with the incorporation of pressure sensors to further optimize the control design of the hand exoskeleton.

Synchronicity: A Measure of Multi-Joint Movement Coordination in Device Assessment

Yuri Gloumakov*, Erin Y. Chang, and Hannah S. Stuart

***Abstract*— This work explores the concept of movement coordination over time; smooth multi-joint gestures are a hallmark of healthy and normative body function. Deviations from normative movement coordination are linked to various health conditions, such as stroke or injury, and can lead to further complications if not addressed. Identifying abnormal movement and quantifying its degree is therefore crucial. Although some quantitative assessments exist, final evaluations often require expert input from occupational or physical therapists. We investigate the characterization of joint movements using motion capture as an objective indicator of synchronous behavior and propose a new quantitative metric to assess device and rehabilitation interventions, *synchronicity*. We apply our metric to three studies with various populations that compare normative hand use to movement with wrist braces, transradial prostheses, and a wrist exoskeleton, revealing that synchronicity may be an indicator of device embodiment and function.**

I. Introduction

The musculoskeletal system is made of complex, though highly coordinated, series of interactions. While the upper-limb function is a perfect example of versatile motion [1], it nonetheless operates in a lower dimensional manifold [2], and therefore, much like gait [3], can be evaluated for normativity [4]. Physical injuries, stroke, or amputation disrupt these interactions, and can lead to compensatory movements [5] that could result in overuse injuries [6], impacting individuals' health, physical [7], and social functioning [8]. Both rehabilitation programs and robotic interventions (such as prosthetics or exoskeletons) aim to restore upper-limb function to normative levels while minimizing body compensation, however, the evaluation of a patient's rehabilitation progress or success of device intervention remains largely qualitative. In this work we explore a new quantitative perspective to movement coordination across different upper-limb interventions (Fig. 1).

Most common quantitative assessments involve measuring the time to complete a task [9], progress and success rate [10], or measuring joint range of motion [11]. More complex body compensation metrics have also been used, such as measuring the length of the Cartesian path a joint travels [12], as well as multi-modal measures that account for a set of metrics simultaneously [13]. And although these metrics are used to compare the performances between interventions and normative behavior, they do not directly observe whether the attribute of motion coordination is preserved. Data driven methods have additionally been explored to classify movement appearance of "natural human motion" [14], though human perception continues to be the ultimate arbiter in physically simulated characters [15]. Cosmeses – prosthetics or prosthetic coverings designed for the primary purpose of cosmetics – are popular but they typically do not enhance movement coordination. We wish to understand how motion coordination itself affects device appearance and acceptance, an idea we wish to coin "motion cosmesis."

Fig. 1. We quantify the coordination of the torso, shoulder, and elbow joints. In this work we explore how different upper-limb conditions, namely normative, braced, prosthesis, and exoskeleton use, impact the normativity of motion of the remaining joints, and whether we can capture this effect using the proposed *synchronicity* metric.

Unlike the morphological cosmesis of prosthetic devices, the appearance of *synchronicity* in movement, the coordinated appearance of motion, is also functional. In social robotics, greater multi-joint movement coordination can lead robots to better communicate through their movements,

exhibit increased transparency, and improve synchronization with human teammates by aligning with their expectations [16], [17]. In contrast, optimized movements that do not consider natural human motion has been found to harm coordination, negatively impacting task efficiency and participants' perception of the collaboration [18]. In surveys conducted on upper-limb amputees, users of primarily functional prostheses, such as body-powered hooks, cited an ongoing desire to improve natural movement [19]. Today, morphological cosmesis plays a significant role in users choosing devices based on social acceptance [20], and the appearance of multi-joint synchronicity likely does as well.

Efforts to establish normative movement have involved minimizing jerk [21], minimizing variance [22], and studying human pose-to-target relationships [23]. Motion capture with human participants has also been used to generate human-like robot [24] and upper-limb prosthesis [25] motion by learning motor coordination, though timing is often neglected causing robot movement to occur at unrealistic and non-human velocities [26]. Translating these methods to evaluate movement coordination in humans is not clear, since people's joints by default exhibit human-like motion profiles.

To address this gap, we propose a metric called "*synchronicity*" to evaluate the degree of coordination among a set of body joints. Robotic movement is typically seen as the isolation of individual joints, and is precisely the opposite of synchronous movement, and is colloquially considered an impressive skill in people. Upper-limb myoelectric prosthetic devices that include a wrist or an elbow, as well as some robotic manipulators (e.g. [27]), are often operated by users controlling the joints sequentially, moving one joint at a time to position the end-effector. In addition to the cognitive load associated with operating multiple joints simultaneously, this limitation arises primarily from having access to very few control inputs, a particular challenge for those already missing portions of their limb. We hypothesize that operating a worn device, such as a brace, prosthesis, or exoskeleton, will cause residual joints to also become sequential as the user attempts to minimize the cognitive load associated with positioning the end-effector. We explore whether more coordinated conditions tend to score higher across these interventions. In the remainder of this paper, we describe the human subject datasets (Section II) used to test the proposed *synchronicity* metric, detailed in Section III. We then present the results (Section IV), comparing *synchronicity* scores across interventions, followed by a discussion of the metric and conclusions (Section V).

II. Datasets

In this work we used three datasets featuring reaching and manipulation movements of the upper-limb across a broad range of tasks and populations (Fig. 2), all of which were collected in an attempt to assess an intervention and its impact on body compensation. The datasets include three subject populations: normative subjects using their own hand with and without a wrist brace and using virtual prostheses, amputee subjects using either their intact hand or their own transradial prosthesis, and spinal cord injury (SCI) population using their own hands with and without the assistance of an exoskeleton device. In all cases, the data included the motion capture markers placed around the participants' hips

(if standing), torso, humerus, and forearm, from which joint angle data was extracted; for seated tasks, the pelvis was considered fixed to the chair. All subjects provided written and informed consent.

A. Dataset 1: Grid Reaching

The first dataset used in this study is the publicly available ROAG dataset [28], featuring a set of reaching motions performed by 7 normative (ages 24-56) and 2 transradial amputee participants (ages 23 and 53) [5]. A grid of vertical and horizontal cylindrical targets were placed in front of the participants 0.6 m away with the targets evenly spaced at 300 mm intervals across a 7×7 square grid, for a total of 49 locations (Fig. 2a). Each recording included a single reaching movement with participants' dominant arms starting at their sides and ending when they reached the target. Motion was captured using 27 retroreflective markers and 12 Bonita cameras (Vicon, Oxford, UK) recording at 100 Hz.

In addition to recording normative reaching, the normative participants reached for the targets under different braced conditions that limited their wrist degrees-of-freedom (DOF): 2-DOF brace (DonJoy ComfortFORM Wrist Support Brace, DJO Global, Vista, CA, USA) restricted flexion-extension movement and ulnar-radial deviation, herein referred to as *brace1*, and a 3-DOF brace, made by combining the 2-DOF brace with an elbow brace (Orthomen, Foothill Ranch, CA, USA), that additionally limited pronation-supination, herein referred to as *brace2*. The amputee participants performed the reaching tasks with both hands, once with their able hand and once with their prosthesis. Although both participants had wrist functionality in their prosthesis, they were instructed to pre-position their wrist prior to each recording. In total there were 2450 reaching motions: 49 targets × 2 orientations × (7 normative participants × 3 conditions + 2 amputee participants × 2 conditions).

B. Dataset 2: ADL in Virtual Reality

The second dataset includes 11 reaching and transferring movements made with objects related to Activities of Daily Living (ADL), detailed in Table I, by 12 right-handed normative participants (ages 18-53). These tasks were performed entirely in a virtual reality environment (VRE) (Fig. 2b) and included both standing and sitting tasks during which the participants sat on a real chair; no other physical props were used. Motion tracking was performed using the same system as the previous dataset.

The participants completed each task while operating various devices (3-DOF wrist or 4-DOF elbow-wrist) with various control modes (sequential, simultaneous, or trajectory) using a K-Mix MIDI keyboard (Keith McMillen Instruments, Berkeley CA, USA) worn on their torso using foam shoulder pads (Gait Gunner, Altamont, NY, USA), and operated with their unused hand. The virtual prostheses were overlaid on their right hand, so that they perceived and operated the device as if it were theirs. The participants also performed the tasks with their own hand and while wearing a 3-DOF wrist brace, same as in the previous dataset, that locked their wrist in place. When operating the wrist or elbow-wrist prostheses, they were instructed to operate it with one of three control methods, described as follows:

- **Sequential:** In this mode participants are provided with a single input that operates one joint at a time. Operation of different joints (including grasping) is switched between using an additional button.
- **Simultaneous:** In this mode, participants are given access to multiple inputs, each matching a different joint, allowing them to control the joints simultaneously.
- **Trajectory:** Similar to the sequential control mode, participants operate one trajectory at a time using a single input, switching between trajectories using a button. In this mode, trajectories are a fixed set of coordinated joints that move along predefined 1-DOF paths. 3-DOF trajectories refer to fixed prosthesis wrist movements, while 4-DOF trajectories involve a different set of coordinated elbow and wrist movements. The data used to generate the trajectories is publicly available online [29], with details found in our prior work [2].

Due to physical constraints, not all tasks were feasible for some of the participants, and the final dataset includes only 896 manipulation recordings out of 1056 attempts. This study protocol was approved by Yale University Institutional Review Board, HSC# 1610018511.

TABLE I
VIRTUAL REALITY TASKS

standing tasks[a]	
briefcase	reach towards the handle of briefcase resting on the floor
cell phone	transfer the cell phone to the ear
cook	reach towards the handle of a pan resting on a stove
cup	reach towards the cup on the counter
doorknob	reach towards the doorknob
can	reach towards a can on the top shelf
screwdriver	reach towards the screwdriver resting on the table
sitting tasks[a]	
cup	reach towards the cup on the table
fork	reach towards the fork resting next to the plate
spoon	reach towards the spoon resting next to the plate

[a]Standing tasks started and ended with the subjects' hands by their side while for sitting tasks the hands were to start on their laps.

C. Dataset 3: Wrist Orthosis for SCI

The third dataset includes four participants (Table II), all with SCI at the C5-C7 level (herein referred to simply as SCI) and similar American Spinal Injury Association Impairment Scale (AIS) scores, that completed a series of transfer tasks with or without motorized assistance while wearing the motorized wrist driven orthosis (MWDO) exoskeleton. The device is intended to augment existing tenodesis functionality [30], offering additional grasp security while reducing body compensation [12]. The device was donned in both *passive* (device unassisted) and *motorized* (device assisted) modes, toggled by the experimenters between tasks, to study the impacts of shared actuation. In the motorized condition, the device augmented the tenodesis grasp aperture using wrist angle, while in the passive mode the device merely

TABLE II
SCI PARTICIPANT DEMOGRAPHICS

	Subj 1	**Subj 2**	**Subj 3**	**Subj 4**
Sex	Female	Male	Male	Male
Age	64	35	33	35
Injury Level	C5-6	C5-6	C5-6	C5-6
Years Post-Injury	50+	16	12	19
AIS Score	A	A	A	B

supported existing tenodesis capability much like a non-motorized exoskeleton brace would.

Motion was captured using 32 active markers and 4 Impulse X2E cameras (PhaseSpace, San Leandro, California, USA) recording at 120 Hz. The active LEDs were attached to the participants using straps and the modified shoulder pads, and onto the MWDO using double-sided tape. The tasks required participants to grasp and release the same 3D-printed stamp-like object in three orientations, transferring it between three locations (Fig. 2c). The object was to be picked up by its large flat surfaces, 14 mm wide, using prehensile grasping. The participants completed the tasks seated at a comfortable distance from the table, adjusted to their preferred height, and were asked to reset their hands between transfers using the "start & end" pedal. In total, there were 432 transfers: 3 orientations × 6 transfer targets × 2 conditions × 3 repetitions × 4 participants. This study protocol was approved by the University of California, Berkeley Institutional Review Board #2020-02-12983.

III. METHOD

Synchronization of body segments occurs when a reaching movement involves all relevant body features moving simultaneously towards their target position. Over a single movement we can calculate *synchronicity S* as the dot product of the velocities $\mathbf{v}_n(t)$ of each time varying feature normalized by the number of features *N* and duration of the movement *t*:

$$S = \frac{\mathbf{v}_1 \cdot \mathbf{v}_2 \cdot \mathbf{v}_3 \cdot \ldots \cdot \mathbf{v}_N}{N * t} \tag{1}$$

The value of *S* is not informative on its own; it's value is derived relative to other test conditions. A larger *S* implies that joint movements are largely coordinated while a smaller *S* suggests that they are more sequential.

Body features can be represented in various ways. Cartesian representation is a precise method to track body segment positions over time, but it requires additional effort to identify morphological significance and makes data comparison across participants more difficult. On the other hand, Euler angle representation of each body joint is more commonly used in clinical settings and evaluations [11]. Despite the multiple ways to formulate Euler angles around a 3-DOF joint, efforts have been made to define joint definition standards that capture anatomical relevance [31]. Euler angles result in 3-DOF for the torso, 3-DOF for the shoulder, and 1-DOF for the elbow. However, two issues arise when using Euler angles to calculate *S*. First, torso and shoulder angles carry greater weight due to having additional DOF. Second, if shoulder movement occurs primarily along a single axis, the shoulder's two other DOF would zero-out the dot product. While the motion may still present normative movement, it would receive a lower *synchronicity* score.

To represent each joint with the same number of features, regardless of its DOF, we use quaternion representation; for our purposes, rotation matrix representation would be equally sufficient. Quaternions can be transformed into any other orientation using an axis-angle representation; there exists an axis around which a quaternion could rotate with some angle to reach any other quaternion. As a joint moves from one orientation to another during the reaching motion, the angle transformation represents its velocity over time. Therefore, each joint, whether a 3-DOF ball-and-socket joint or a 1-DOF hinge joint, can be represented by a single angular velocity. For a 1-DOF hinge joint, the quaternion angle transformation will be identical to the conventional angle measurement. Quaternion representation for each joint was made with respect to its parent joint: the elbow quaternion with respect to the shoulder, the shoulder with respect to the torso, the torso with respect to the pelvis, and the pelvis with respect to the global reference frame.

Synchronicity scores of the residual joints were calculated in three ways: using (1) all the residual joints, i.e. torso, shoulder, and elbow (referred to as torso-shoulder-elbow for simplicity), or a pair of residual joints, i.e. either (2) torso and shoulder joints (referred to as torso-shoulder), or (3) shoulder and elbow joints (referred to as shoulder-elbow). The second dataset, virtual reality prosthesis use, was the only one that included an elbow device, and therefore only the torso-shoulder score was calculated for those testing conditions. Distributions of *synchronicity* scores across conditions were tested for similarity using a two-tailed t-test. Calculations were performed in MATLAB 2023b.

IV. RESULTS

With the goal of comparing testing conditions, we primarily focus our evaluation on whether there are statistically significant differences between them rather than between participants or tasks. The *synchronicity* results for the grid reaching dataset can be seen in Fig. 3. Prosthesis scores significantly differed from other scores across all joint combinations. Additionally, *brace2* scores significantly differed from both *brace1* and normative scores in *synchronicity* measurements that included the elbow.

Synchronicity scores for the virtual reality dataset are displayed in Fig. 4. Rather than presenting the scores for each task separately, we only include the aggregate results across the whole study. *Synchronicity* between the elbow and the other joints was not calculated for the *seq4*, *sim4*, and *tra4* prosthesis control conditions, as they refer to the cases where subjects operated the elbow-wrist device; this left only the torso and shoulder as the residual joints. Across all joint combinations, normative scores significantly differed from scores calculated for 3 or more of the virtual prosthesis conditions. *Synchronicity* of the braced condition differed significantly from all other conditions across all

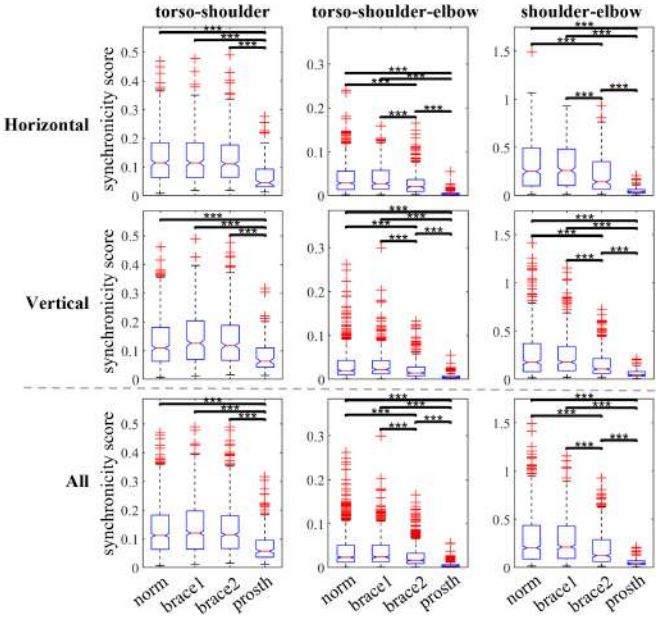

Fig. 3. *Synchronicity* scores for horizontal and vertical reachings, as well as the aggregate of the two, across each condition (*norm*: all normative participants, *brace1* and *brace2*: normative participants with each brace, *prosth*: amputee participants with transradial prosthesis). Column 1 contains scores for the torso and shoulder joints, column 2 contains scores for the torso, shoulder, and elbow joints, and column 3 contains scores for the shoulder and elbow joints. ***p<0.001

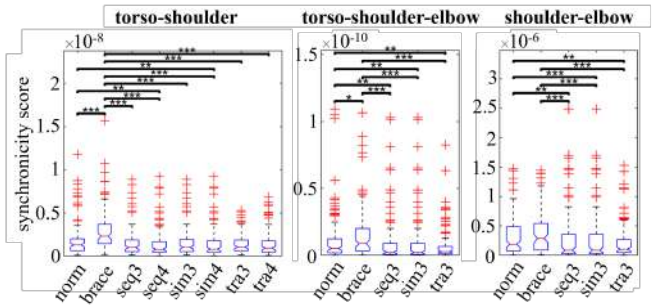

Fig. 4. *Synchronicity* scores from the virtual reality dataset, across each condition (*norm*: all normative participants, *brace*: normative participants with brace, *seq3* and *seq4*: sequential control with each DOF, *sim3* and *sim4*: simultaneous control with each DOF, *tra3* and *tra4*: trajectory control with each DOF). Column 1 contains scores for the torso and shoulder joints, column 2 contains scores for the torso, shoulder, and elbow joints, and column 3 contains scores for the shoulder and elbow joints. *p<0.05, **p<0.01, ***p<0.001

joint combinations, except for the normative condition when assessing the shoulder-elbow combination.

Due to large variability in participant performance, *synchronicity* scores for the SCI dataset is displayed separately for each participant (Fig. 5). While two tailed t-tests were performed between pairs of test conditions, none of the pairs were found to be significantly different at $\alpha = 0.05$.

V. Discussion

For the grid reaching dataset, we observe no major differences between the horizontal and vertical tasks. The primary aim was to determine if *brace2* (which fixes the 3-DOF of the wrist in place) effectively simulates the lack of wrist functionality faced by most prosthesis users. However, it

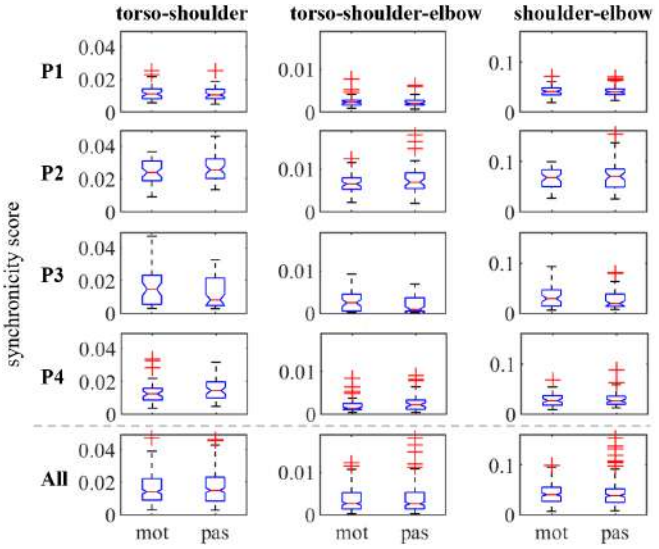

Fig. 5. *Synchronicity* scores for each participant with SCI and the participants aggregated, across both exoskeleton modes (*mot*: motorized, *pas*: passive). Column 1 contains scores for the torso and shoulder joints, column 2 contains scores for the torso, shoulder, and elbow joints, and column 3 contains scores for the shoulder and elbow joints.

appears *brace2* did not affect the residual limb in the same way, despite having identical DOF limitations. Instead, prosthesis users' *synchronicity* scores were significantly lower than those in other modes, even though the torso, shoulder, and elbow joints were unimpaired. *Synchronicity* between shoulder and elbow joints was lower for *brace2* than for the normative or *brace1* conditions, but higher than for prosthesis use. This suggests that there is likely additional cognitive load when the end effector is not embodied.

In the virtual reality dataset, we observe that the brace condition generally had a higher *synchronicity* score than even the normative condition. As before, we suspect that the embodiment of the hand does not diminish in the braced condition as it does with prosthesis use, so the *synchronicity* of the residual joints may not be affected. Higher scores seem to suggest that users may be performing larger movements to compensate for the lack of wrist mobility. We also observe that prosthesis use negatively impacts *synchronicity* scores. Torso-shoulder *synchronicity* did not appear to be significantly different between the two prosthesis conditions, regardless of the mode. This suggests that removing an additional normative joint does not reduce the coordination of the residual joints, indicating that the embodiment may be binary rather than gradual. Further testing with a greater resolution of controllable joints is required to confirm this.

In the SCI dataset involving the exoskeleton device, we observe no significant differences between device conditions. We hypothesized that device intervention would improve residual joint coordination, but found that, similar to the previous two datasets, embodiment appears to play a larger role in residual joint coordination. Since only hand closure is affected, we suspect that embodiment remains largely intact as participants continue using their own hand, which can be more intuitive to orient than another tool. If the device

required additional inputs, such as sequentially opening and closing the hand as with prosthetic devices, we would expect a reduction in coordination, similar to the previous dataset.

A. Conclusion

This work examines the concept of movement coordination, referring to the synchronous joint motion that is typical of normative movement, which we quantified and term *synchronicity*. *Synchronicity* is not only crucial for social interactions but also serves as a valuable quantitative metric in clinical evaluations. We analyzed three datasets of upper-limb motions, encompassing normative movement, wrist braces, transradial prostheses, and a wrist exoskeleton. Our results show that prosthesis use significantly reduces *synchronicity*, while braces and the exoskeleton do not. This suggests that device embodiment is the primary driver of residual joint movement coordination. Nonetheless, its clinical value requires further validation. Future research will involve studying pre- and post-rehabilitation patients, comparing outcomes with medical professionals' evaluations of movement coordination and quality, using data-driven computer vision methods to validate the new metric, and gathering observer feedback to deepen our understanding of normative movement and model-based movement behavior.

Abstract—Despite the growing demand for healthcare services due to an aging population, patients may avoid traditional rehabilitation centers due to high costs, discomfort, and time constraints associated with in-person assessments. Home-based rehabilitation offers a promising alternative, but effective kinematic monitoring and assessment remain challenging, especially for real-time applications. To address this gap, we have developed real-time, full-body kinematic analysis and visualization based on 12 wearable inertial measurement units (IMUs). Full body real-time kinematics estimation (20Hz) was evaluated during walking, running, squatting, boxing, yoga, dance, badminton, and various seated extremity exercises and IMU estimations were compared with optical motion capture to determine accuracy. Results showed that walking was the most accurate with 5.4 deg median RMSE, and the overall median RMSE was 7.2 deg for all activities. A mean of 1.0 deg RMSE against offline computations (100Hz) was also demonstrated, with a mean latency of 44.1 ms from sensor data acquisition to kinematic output. This approach holds the potential to revolutionize rehabilitation by enabling rapid assessment and real-time biofeedback for motion performance in orthopedic and neurological conditions and could significantly enhance treatment outcomes and patient compliance.

Index Terms—inertial measurement unit, biomechanics, real-time, inverse kinematics, wearable sensors.

I. Introduction

Wearable systems have revolutionized rehabilitation by offering real-time data and personalized feedback for human physiological functions and performance across various activities. [1]–[3]. Traditional rehabilitation methods, often conducted in hospitals and healthcare centers, rely heavily on the expertise and availability of medical professionals. These methods are typically conducted in laboratories with specialized equipment, which can be uncomfortable and time-consuming for patients. Additionally, physiotherapy programs at home often suffer from patient non-compliance, particularly post-surgery, due to a lack of time, specialist feedback, and tangible benefits [2]. The integration of wearable systems in rehabilitation processes effectively mitigates these issues by providing convenient, patient-centric [3], sustainable, and comfortable rehabilitation assessments for the elderly and patients, which can substantially improve recovery outcomes and facilitate the monitoring of progress, reducing the intensified labor demands on healthcare providers.

Human kinematics analysis is crucial in professional research fields such as human-computer interaction [4], ergonomics, and biomechanics, and is essential for disease analysis [5]. It also holds significant potential for practical applications in everyday scenarios, such as rehabilitation assessment for patients with musculoskeletal impairment [6] [7] or neurological disorders like Parkinson's disease [8] [9], which are common among the aging population [10]. While kinematics analysis of human movement is generally conducted post-measurement using inverse kinematics (IK) algorithms, real-time kinematics solutions offer broader applicability in rehabilitation by enabling quick assessment and feedback for individual human movement. Real-time wearable-based kinematics can promote advancements in rapid diagnoses, correction of rehabilitation, and motion ability improvement. Real-time visual, haptic, or audio biofeedback about human motion can also enhance user engagement and enjoyment [11], leading to more effective movement execution and, consequently, the effectiveness of rehabilitation.

Optical motion capture (OMC) systems, which track retroreflective markers placed on the bony landmarks, are considered the gold standard in biomechanics research due to their ability to provide high-resolution, accurate 3D kinematic data [12]. However, OMC systems are expensive, typically confined to a small capture volume

in the lab, and need professional operators to operate the system and accurately find the anatomical landmarks. They also require a line of sight to each marker, making them susceptible to marker occlusion and displacement. Wearable systems overcome these limitations of OMC systems by their lightweight, portability, usability, and affordability, resulting in the growing interest in inertial motion analysis [13] [14]. Inertial measurement units (IMUs), typically consisting of accelerometers, gyroscopes, and magnetometers, which provide information about the motion of the sensor in space, are the most commonly used portable compact sensors in wearable systems. With sensor orientations obtained through various sensor fusion algorithms, wearable IMUs can commonly offer a portable solution for motion capture [15], enabling data collection in different daily living scenarios outside the laboratory. IMU-based real-time kinematics analysis facilitates home-based rehabilitation, reducing the labor intensity for medical staff and improving work efficiency.

The conversion from IMU orientation to joint angle is typically achieved by defining a general human skeletal model. OpenSim is a versatile open-source software platform for musculoskeletal modeling and simulation, developed to study the mechanics and control of movement [16]. It features a repository of pre-built musculoskeletal models that users can access and modify for specific needs and offers a powerful visualization tool for graphical representation of musculoskeletal structures and animation of simulations. OpenSim's IK tool can solve the inverse kinematics problem and determine the joint angles of a model by minimizing the sum of the weighted squared orientation errors, aligning the model's markings with experimental data [17]. The IMU IK Tool available in OpenSim 4.2, however, estimates the pose of an OpenSim model that best matches experimental IMU orientations using an optimization method [18].

II. Methods

A. Pipeline of Real-Time Kinematics Estimation

The workflow for real-time kinematics estimation involves the transmission of data from IMU nodes to the hub (SageMotion, Kalispell, MT, USA) and subsequently to a computer for processing (Fig. 1). The SageMotion hub wirelessly collects data from IMUs, specifically accelerometer and gyroscope readings, and transmits this information, along with timestamps and computed quaternions, to a computer via socket communication. The computer software then translates the quaternions from IMUs into human body kinematics, utilizing the IMU inverse kinematics and visualization tools from OpenSim version 4.5. To ensure accurate and stable IMU orientation data with less drift, the gyroscope offset is calibrated using SageMotion's built-in calibration application, requiring all sensors to remain stationary for 2 seconds.

Prior to inverse kinematics computation, OpenSim's IK solver is configured experimentally with a constraint variable of 10.0 and an accuracy of 0.01 following empirical optimization for a balance between speed and precision, and a musculoskeletal model from the OpenSim repository is selected. We chose model Rajagopal2015 [19], which is a commonly used full-body model for gait analysis, and modified it by removing all the muscles and releasing the clamp of all joints to accommodate a broader range of human movements beyond walking. The model is then calibrated by virtually placing IMUs on each segment, referencing their orientation differences relative to a base IMU attached to the pelvis during a static calibration process, which involves the user assuming the initial pose of the selected model. IMU orientations are determined by collecting data for 2 seconds and averaging the rotations of each sensor during this period. Given that OpenSim's IMU placement mechanism presupposes a shared world frame for all IMUs to calculate orientation differences against body segments [20], maintaining a uniform coordinate system across all IMUs is crucial. To achieve this uniformity and to circumvent magnetic field interference, the VRU sensor fusion algorithm is implemented, synchronizing the activation of all sensors in an identical orientation, with magnetometer data excluded from the process.

The real-time inverse kinematics pipeline is executed through two concurrent threads (Fig. 1). In the data acquisition thread, the computer constantly receives quaternions from the Raspberry Pi in the SageMotion hub and saves them into a buffer queue. In the IK processing thread, a temporary queue stores quaternions from the buffer queue in the event of data loss. The data drop is detected by comparing the current time stamp and the previous time stamp. Data drops are identified by comparing current and previous timestamps, and compensated by sending the last validated quaternions to the inverse kinematics process to fill any gaps. The thread prioritizes drawing quaternions from the temporary queue if it contains data, otherwise retrieves quaternions from the shared buffer queue. These quaternions are then either logged into a table for further analysis or discarded, based on the predefined frequency (20Hz) for inverse kinematics calculations. The IMU IK Tool of OpenSim calculates real-time kinematics from the quaternions table and outputs the joint angles, while the visualization tool simulates the real-time human movement by animating the selected skeletal model.

We also monitor the time delay from IMU data reception at the hub to joint angle computation and the time required to solve inverse kinematics. Timestamps for these intervals are recorded in accordance with the Network Time Protocol and saved for post-trial analysis. The computational hardware used in this experiment is a laptop (Windows 11 64-bit, AMD Ryzen 7 5800H with Radeon Graphics 3.20 GHz processor, 15.9 RAM).

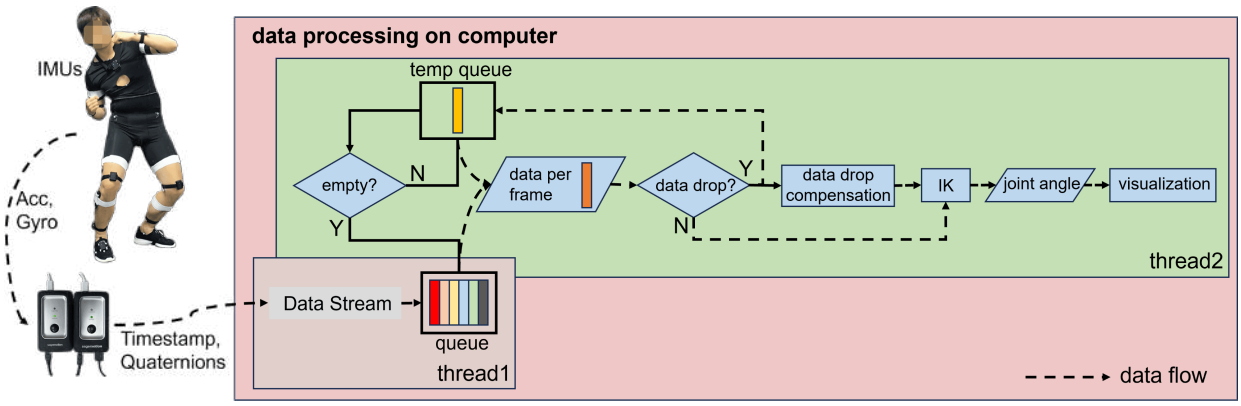

Fig. 1. Overview of the real-time analysis data flow and pipeline of real-time inverse kinematics (thread 1 represents data acquisition, thread 2 represents IK processing)

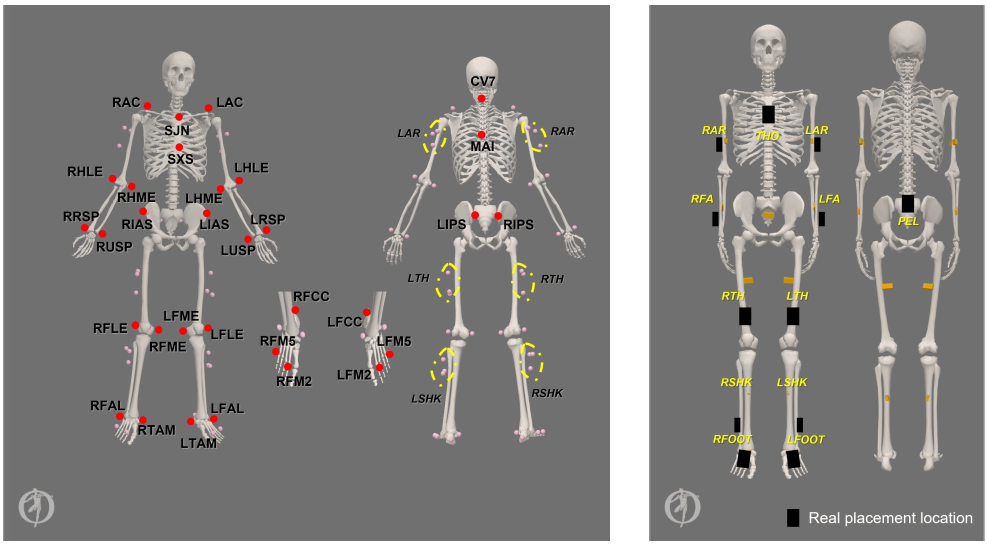
B. Experiment Protocol

1) Subjects: Seven subjects (all male; age: 21.9±1.1; height: 1.76±0.06m; mass: 71.1±13.8kg; BMI: 22.4±5.4kg/m²) with no history of musculoskeletal or neurological disorders volunteered to participate in this study. All subjects provided written informed consent before being tested, and the experimental protocol was reviewed and approved by the ethics committee of Shanghai Jiao Tong University (No. E2021013P).



2) Marker Placement: Retroreflective markers were placed on 32 anatomical landmarks to determine the segments: posterior surface of the calcaneus (LFCC/RFCC), head of the second metatarsal (LFM2/RFM2), head of the fifth metatarsal (LFM5/RFM5), fibula apex of lateral and tibia apex of medial malleoli (LFAL/RFAL/LTAM/RTAM), lateral and medial femoral epicondyles (LFLE/RFLE/LFME/RFME), left and right anterior superior iliac spines (LIAS/RIAS), left and right posterior superior iliac spines (LIPS/RIPS), sternum jugular notch (SJN), left and right acromion (LAC/RAC), seventh cervical vertebra (CV7), sternum xiphisternal joint (SXS), midway between the inferior angles of most caudal points of the two scapula (MAI), lateral and medial humerus epicondyles (LHLE/RHLE/LHME/RHME), and radius-styloid and ulna-styloid processes (LRSP/RRSP/LUSP/RUSP). Eight clusters with three markers on each were placed on the segments of the shank (LSHK/RSHK), thigh (LTH/RTH), upper arm (LAR/RAR) and forearm (LFA/RFA) for stable optical tracking (Fig. 2(a)). Marker trajectories were recorded at 100 Hz with a twelve-camera optical motion capture system (Vicon, Oxford Metrics Group, Oxford, U.K.).

3) IMU Placement: Twelve IMU sensors with built-in real-time calibration and sampling rate of 100 Hz (SageMotion, Kalispell, MT, USA) were turned on in the same orientation and then securely strapped to each subject. Sensors were placed at the following locations to minimize soft tissue artifacts: dorsal foot, distal lateral shank, distal anterior thigh, middle lateral upper arm, distal dorsal forearm, sacrum, and sternum (Fig. 2(b)). For this experiment, a neutral pose (N-pose) with hands facing each other (Fig. 2(b)) was used for calibration, setting all joint angles to zero, except for forearm pronation and supination, which were set at 90 degrees.

4) Experimental Procedure: After proper attachment of markers and IMUs, subjects performed flexion for elbow and knee, rotation/flexion/adduction for hip and shoulder, flexion/dorsification for ankle to calibrate joint centers. Each trial began with a 2-second static N-pose, followed by a synchronization step where subjects swung their right shank three times while standing on their left foot. Subjects then completed eight trials of various activities, including walking, running, squatting, boxing, yoga, dance, badminton, and extremity exercises while sitting (Fig. 3). Activities were performed on a treadmill for walking and running at a self-selected comfortable speed. Squatting was performed 10 times in each trial with varying speeds and intensities. Boxing included a range of movements of jab, cross, hook, footwork, and defensive blocks, which were selected randomly by the subjects. Yoga (Dragon Pose, Phantom Chair Pose, Warrior II Pose, Warrior III Pose, and Warrior I Pose) involved holding each pose for at least 8 seconds and slowly changing the pose. The dance included a variety of fitness movements of sidesteps, jumps, arm swings, and hip rotations. Badminton trials consisted of performing familiar actions with a racket. Seated exercises focused on rehabilitation movements, including knee extension, elbow flexion, and hip flexion. All trials except squatting were performed for around 1.5 minutes. The gyroscope calibration of all IMUs was done approximately every 20 minutes.

C. Data Processing

1) Ground Truth Kinematics: The experimental optical motion capture data were converted from .c3d files to .trc format using a C3D file reader of the OpenSim library. The .trc file specifies the positions of markers in 3-dimensional

(a) Marker placement on anatomical landmarks and marker clusters placement on segments

(b) IMU placement calibration on N-pose model

Fig. 3. Activities: walking, running, squatting, boxing, yoga, dance, badminton and seated extremity exercises

space and is a standard format for subsequent import and analysis in OpenSim. For each subject, the musculoskeletal model was scaled to match the marker positions on anatomical landmarks identified during the static trial. Subsequently, inverse kinematics was applied to the scaled model to achieve the highest accuracy in marker tracking across each trial. The joint angles extracted during motion were recorded using OpenSim's analysis tools, establishing the ground truth kinematics.

2) Offline Predicted Kinematics: Raw data, comprising quaternions and timestamps, were captured at a 100 Hz sampling rate by the SageMotion hub. Any missing data points were linearly interpolated, and the complete dataset was then processed on the computer using the aforementioned software for offline inverse kinematics analysis.

3) Online Predicted Kinematics: After each trial, the timetable of the real-time output joint angles and associated time delay data were saved for further analysis.

4) Data Synchronization: To synchronize the three data sources—optical motion capture IK data, offline IMU IK data, and online IMU IK data—we utilized the right knee flexion angle values obtained during the initial three swings of each trial. Cross-correlation was applied to align these datasets.

The ground truth kinematics, offline predicted kinematics, and online predicted kinematics were compared to evaluate the accuracy and performance of the real-time wearable human inverse kinematics system. Additionally, the mean time delay and computation time for real-time IK were analyzed.

III. Results

We analyzed the real-time estimation accuracy for each joint's rotating angle across all subjects and trials (representative results in Fig. 4), and the estimation accuracy of each type of movement of human kinematics for all subjects (Fig. 5). The RMSE of the entire experiment prediction compared with OMC results had an average of 9.1° and a median of 7.2°. Walking had the highest accuracy of all activities with a 5.4° median RMSE. In addition, the RMSE for real-time estimations (20Hz) against offline results (100Hz) had an average of 1.0° and a median of 0.6° over all trials, with the highest RMSE of 2.4° observed during running trials. Fig. 4 illustrates the comparison of ground truth kinematics from OMC, offline predicted kinematics, and online predicted kinematics during a dance trial of one representative subject. The average time delay of the system is 44.7 ms and the average time for solving inverse kinematics is 15.5 ms on the laptop computer.

IV. Discussion

In this work, we developed a wearable system equipped with 12 IMUs capable of computing and visualizing full-body kinematics in real-time using OpenSim. We tested the system by assessing both human upper and lower body real-time kinematics for a diverse range of activities, including walking, running, squatting, boxing, yoga, dance, badminton, and seated extremity exercises. Results of the experiments demonstrated the system's accuracy in real-time kinematics estimation by achieving a mean RMSE of 9.1 degrees compared to optical motion capture systems and a mean RMSE of 1.0 degrees against offline calculation.

The discrepancies between our estimations and the ground truth were primarily attributed to the N-pose calibration process as the estimation of rotating angles proved more accurate than that of absolute joint angles. Factors contributing to the calibration error included the inaccuracy of marker placement on anatomical landmarks, nonstandard N-pose of the subject, and the inherent variability of the human skeleton. Notably, the hip flexion and lumbar extension angles deviated most significantly from the N-pose OpenSim model's default zero values, likely due to the challenges in identifying pelvic landmarks and individual differences in hip tilting habits while being told to stand straight. These joint angle offsets also came from differences between the subject's actual skeleton and the selected musculoskeletal model. The relatively poor estimation of arm flexion angle and arm rotation angle may be related to the ignored degree of freedom of the scapulae and clavicles [21] [22] in the model. Furthermore, the forearm's pronation and supination were not accurately predicted, primarily because of especially significant skin motion artifacts of the forearm. The IMU on the forearm, assumed to rigidly follow the radius, does not account for the non-rigid alignment between the skin and the radius or the IMU's movement relative to the skin. The accuracy of walking trials was the highest among all activities, presumably because the adopted Opensim musculoskeletal model was originally designed for human gait simulation. Despite the sacrifice of model extensive applicability, the design of activity-specific models has a high probability of improving the accuracy of kinematic estimations achieved utilizing this computing method.

The error between online and offline estimation is usually small, as some lines for online and offline prediction in Fig. 4 coincide. The error mainly arises from the difference in sampling rate. While offline prediction calculates IK at 100Hz, online prediction is computed at 20Hz, which can introduce errors especially during a sudden change of motion speed, such as when running and jumping, to have a peak prediction value difference. Additionally, consecutive data drops can affect estimation accuracy and increase the time delay in real-time visualization. The median RMSE of 0.6° indicates the small difference between sampling rates of 100Hz and 20Hz, suggesting that 20Hz of computational frequency is sufficient for real-time human IK in the selected activities.

Previous studies have employed the IMU IK Tool of OpenSim to develop wearable systems capable of estimating real-time human kinematics. Lavikainen et al. developed software capable of real-time inverse kinematics (IK) calculations at a rate of 45 Hz [23]. The software's performance was evaluated through walking tests involving varying numbers of IMUs, different computer systems, and different thread configurations. Real-time results were compared to offline computations to assess the efficacy of online processing. Slade et al. designed the hardware and software for a portable real-time wearable system [24] operating at 30 Hz. However, upper and lower body kinematics were only tested separately and all sensors of the system were connected to the microcontroller through cables, which could interfere with human movement and cause inconvenience to wear. While most wearable systems focus on gait analysis and have tests mainly on ambulation tasks [25] [26], the proposed system was tested across a broader range of activities to ensure its applicability in diverse rehabilitation scenarios for training and assessment. We also utilized the visualization tool

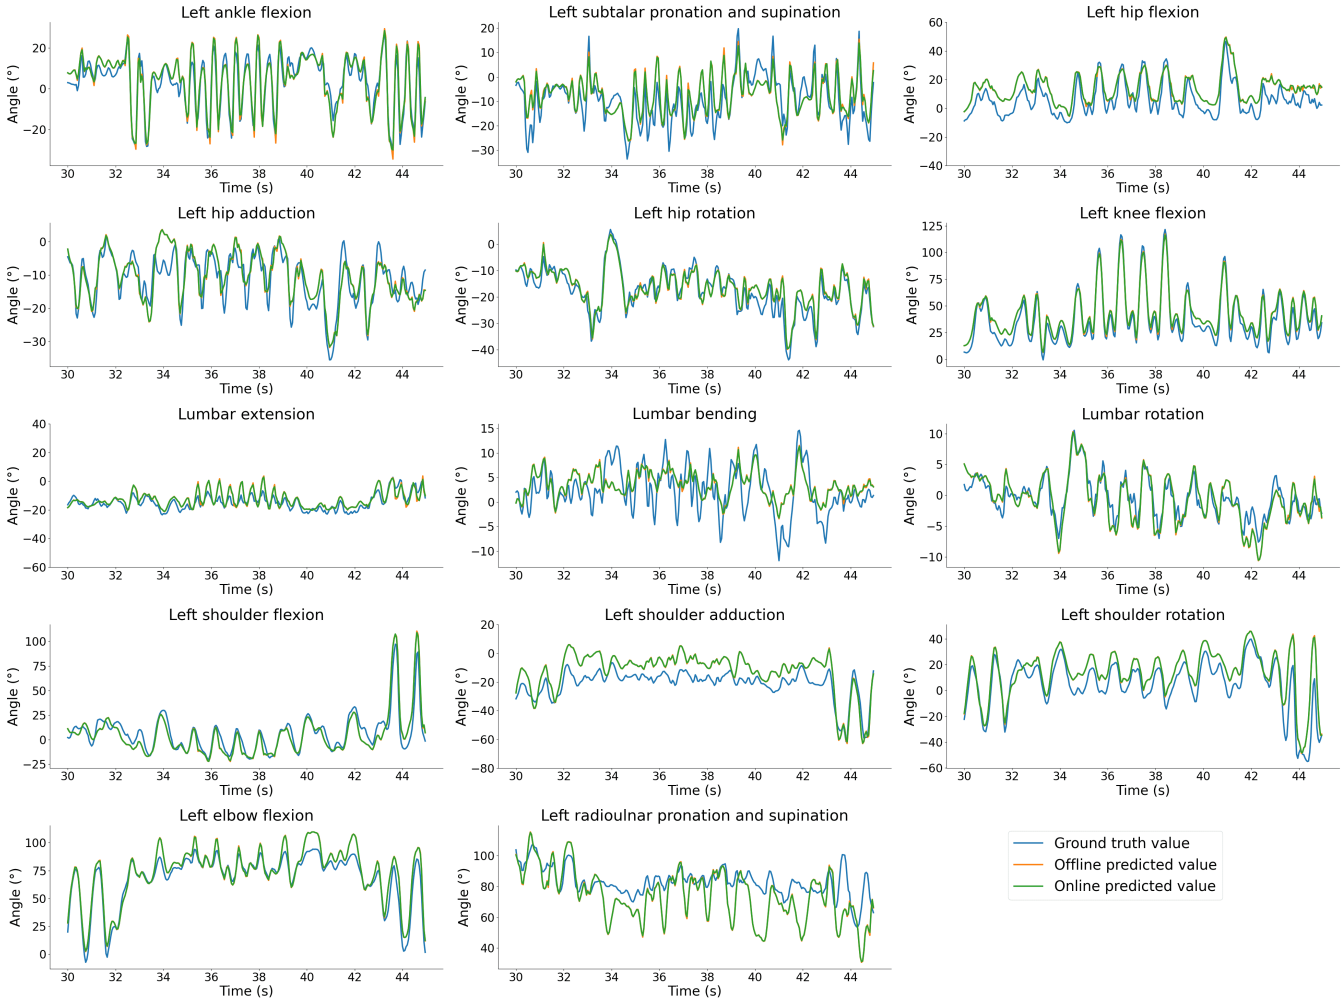

Fig. 4. Left side joint angle results of one representative subject during the dancing trial

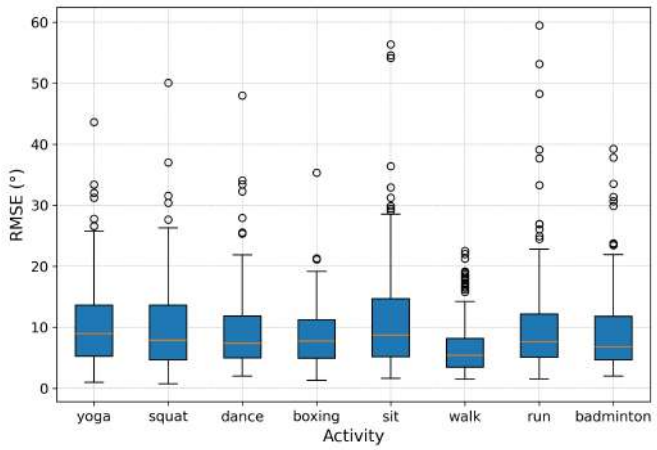

Fig. 5. Human body kinematics estimation RMSEs across all activities (circles refer to individual trials)

of OpenSim to provide real-time feedback on kinematics estimation performance and identify any sensor issues, which could enhance patient engagement if integrated into actual rehabilitation processes. The development of this wearable system offers the possibility of rapid rehabilitation assessment and real-time motion feedback for orthopedic and neurological conditions, alleviating the workload on medical professionals and facilities. It holds the potential to provide a more convenient and faster way of human movement assessment, increase patient engagement in rehabilitation training, and by further enhancing feedback features, provide personalized feedback and customized rehabilitation plans, thereby improving rehabilitation outcomes.

VI. Conclusion

The paper presented a 12-IMU wearable system to track full-body kinematics in real time. Results demonstrated the robustness of our approach in accurately assessing human body joint angles across diverse activities of walking, running, squatting, boxing, yoga, dance, badminton, and extremity exercises while sitting. These findings indicate the potential of our wearable system for convenient, personalized, sustainable, and comfortable rehabilitation assessments.

Future research should focus on developing portable, wireless real-time human kinematics for broader rehabilitation applications. An accurate, flexible calibration method is needed, particularly for patient and elderly populations who may find standard calibration challenging. Extensive clinical trials with these groups are essential to validate the system's practicality in healthcare settings.

Abstract—The research paper examines the challenges of remote control delays in exoskeleton-aided physiotherapy. It focuses on the implications of telerehabilitation requirements for safe treatment. As the global share of disabled and elderly people increases, the demand for effective teleoperated physiotherapy solutions rises, necessitating precise control over robotic systems. The study utilizes a mixed-methods approach to assess delays in communication between a rehabilitation exoskeleton and the control system's based on the digital twin in VR (virtual reality) components at different stages. Moreover, additional delays coming from distant operations are assessed. Key findings reveal that the average latency for joint control on shorter distances remains below 300 ms - considered acceptable for comfortable manual teleoperation. The delays between setting the device's configuration and reaching it by a physical exoskeleton differ for particular joints and depend mainly on the torque-to-moment of inertia ratio. The total communication cycle should not exceed 400 ms, which can be further reduced by using a 6G network in the future or ADS (Automation Device Specification) communication protocol instead of the database. Ultimately, the study provides a foundation for developing algorithms that can mitigate delays and improve the efficacy of telehealth solutions with physically supportive devices.

I. Introduction

Rehabilitation robots can physically support physiotherapists and automate their work, also considering patients' safety [1]–[4]. Thanks to the mechatronic devices, repetitive exercising trajectories can be looped and realised with high accuracy. Moreover, with the technology of the digital twin connected to wearable sensors, a single therapist can supervise multiple devices operating patients simultaneously [5]. This is also possible for the ones in different locations [6]. Once programmed, exercising trajectories can be repeated for single users with no time limitations. However, with the progress of the patient or appearing pain and discomfort, it can be necessary to shift the recorded paths [7], [8]. To make it more immersive and ensure the movements ar smooth and accurate, the process can be recorded with the digital twin operated in virtual reality as within the conventional treatment [5]. However, this is a significant challenge, especially when it comes to telerehabilitation [5].

During conventional onsite physiotherapy, a specialist supports or resists the patient's movements with their hands, which enables two contact points. This process can be transferred to the robotic setup. However, with the end-effector type rehabilitation robots, only one contact point is possible, as they are underconstrained for

physical therapy [9]. On the contrary to the end-effector robots, exoskeletons enable precise mobilisation of every joint degree of freedom separately with the correlated drive's torques [10]. Moreover, they monitor every joint separately as well. For this reason, they are superior for individualised telerehabilitation with limited visual observation possibilities.

While a change of exercising trajectory is required, immersive technologies can be used to mimic conventional interventions in the cyber-physical environment [11]. The physiotherapist can modify the motion in the virtual world, which is then reflected by the rehabilitation robot in a distant location [12]. To increase the immersion, virtual reality (VR) based digital twins are constructed [5]. They visualise the real-world operation of the device, which is physically interfacing with the extremity, and give the opportunity to interact with the patient remotely by interacting with the model. With such a technology, specialists can perform telerehabilitation as if they were performing conventional therapy onsite - simply by dragging the virtual representation of the patient with their two hands [5].

However, this method raises novel challenges. The local infrastructure must enable a stable internet connection and meet the cybersecurity medical standards [5]. Moreover, rehabilitation systems' control algorithms must be prepared for signal losses and limitations correlated with establishing a secure network connection to the robotic system and ping related to the distance. Furthermore, even if no of the mentioned hazards appear, the distant control over robots brings delays, which can control less accurate trajectory following [13]. In extreme cases, the lags can restrain the possibility of almost real-time control.

The presented study aims to investigate delays and accuracy obtained with international teleoperation over a rehabilitation exoskeleton. The trials are intended to assess the impact of every component in the communication chain on the delays and find the bottleneck of the process. Additionally, alternative solutions to the cloud databases typically used in current trials, and mainly suitable for setting parameters of the treatment, not teleoperating the device [14], [15], are proposed. Moreover, the correlation between receiving the desired point and the following accuracy is also analysed. The results should be the basis for building algorithms that meet the safety criteria and analysing risks for teleoperation in robot-aided physiotherapy.

II. Methodology

A. Experimental setup

The teleoperation experiments were conducted remotely in Warsaw (Poland), without involving any human participants. Therefore, no significant lag between master (computer with the digital twin) and slave (exoskeleton) devices occurred. Further delay tests were performed at a distance between Istanbul (Türkiye) and Warsaw (Poland). The controlled object was the SmartEx-Twin exoskeleton attached to the test frame, as presented in Fig. 1. It has four controllable degrees of freedom (DOFs), driven by the mentioned servomotors, which correspond to the following motions of a human lower extremity:

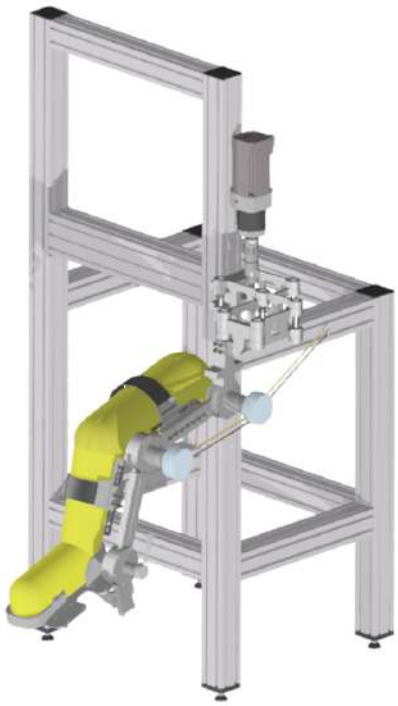

Fig. 1. Visual of the experimental setup with the SmartEx-Twin exoskeleton with the model of the extremity as attached during the planned physiotherapy (yellow model)

- DOF1: Hip abduction/adduction or internal/external rotation (dependent on the rotation of the DOF2; motor: Beckhoff AM8142-0NG0-0000; gearbox: Beckhoff AG2250-+PLE80-M02-32-0E1-F4);
- DOF2: Hip flexion/extension (motor: Maxon 607327; gearbox: Maxon 223089;
- DOF3: Knee flexion/extension (motor: Maxon 607327; gearbox: Maxon 223087);
- DOF4: Ankle flexion/extension (motor: Maxon 651613; gearbox: Maxon 166165).

These degrees of freedom are fully controllable with the DC motors with planetary gearboxes and integrated encoders via their dedicated position controllers. Their control signals include trajectory points which they follow. These data can be sent directly from the industrial computer (IPC), the master controller of the system, or the database server prepared within the robotic system. The trajectories in the database can be either modified manually by sending the point series from the computer database or registered with the interactive digital twin of the exoskeleton in virtual reality (see

TABLE I
Parameters of the exoskeleton DOFs (torque and velocity columns correspond to their peak values)

DOF	ROM min	ROM max	Torque	Velocity
1	-20 deg	40 deg	120 Nm	47 rpm
2	-30 deg	120 deg	31 Nm	38 rpm
3	0 deg	150 deg	21 Nm	64 rpm
4	-50 deg	20 deg	4.6 Nm	71 rpm

schematic communication flow in Fig. 2). A real-life possible implementation of the described system was visualised in the previous author's paper related to the topic [5].

Within the tests, the Exoskeleton is located in Poland and connected to the wireless network, simulating a possible home-like environment for telerehabilitation with the tested speed parameters as below:

- Latency: 24 ms;
- Download speed: 27.26 Mb/s;
- Upload speed: 33.13 Mb/s.

The DOFs of the exoskeleton have the available ranges of motion (ROMs), maximum torques of the corresponding motors and maximum rotation velocities of the corresponding motors, as presented in Table I.

B. Experimental routine

The experiments were run in three series of trials to determine three types of lags. These are:

1) Pre-loading the trajectory into the IPC (Beckhoff C6015) and controlling the drives simultaneously by setting the desired points into position controllers of the motors while measuring real-life rotations in every exoskeleton joint;
2) Downloading the trajectory point by point in real-time from the cloud database by the IPC and controlling the drives simultaneously by setting the desired points into position controllers of the motors while measuring real-life rotations in every exoskeleton joint;
3) Sending the trajectory point by point in real-time into the cloud database from the digital twin (visualized in VR and operatable by the physiotherapist) of the system, downloading the trajectory point by point in real-time from the cloud database by the IPC and controlling the drives simultaneously by setting the desired points into position controllers of the motors while measuring real-life rotations in every exoskeleton joint.

For every session, the realised joint trajectories were registered. Every time, the set desired trajectories were the same and consisted of continuous smooth trajectories within the whole range of a particular DOF with changing velocity. Based on the registered and desired trajectories, the delays and accuracy in realised trajectories were computed. The delays at the A-B loop were computed as the differences between the time of

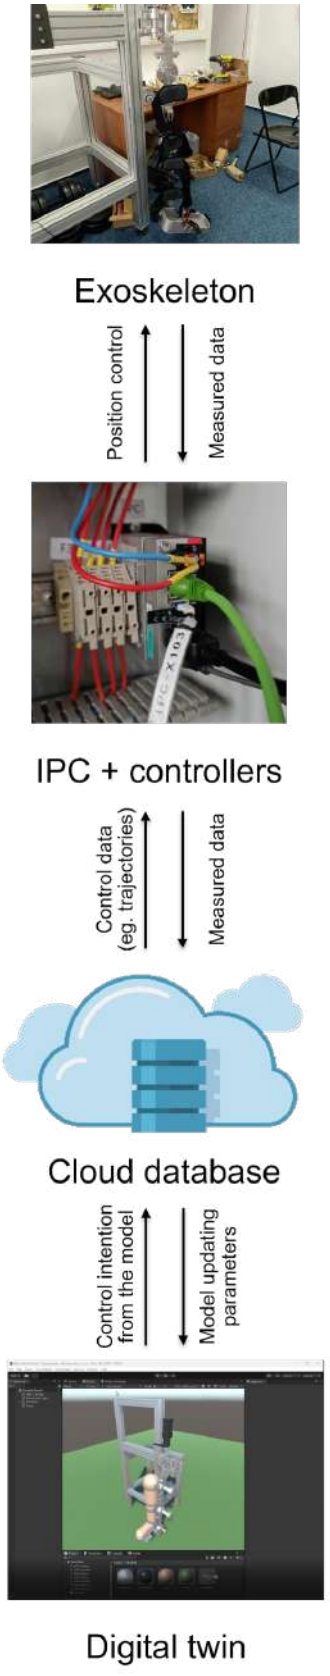

Fig. 2. Block graph of the remote control chain

sending the point by node A within the trajectory and visualizing reaching this point by node B, based on the smoothed registered trajectory. The inaccuracies values were compared based on the average square mean and the maximum absolute error.

Every trial session was repeated three times with sinusoidal trajectories of different periods (2-6 s) and amplitudes covering the whole range of joints (see Table I). The frequency of the data transfer was set to the maximum operatable by the bottleneck of the loop (typically cloud database, related to select/insert queries realisation times). The trajectories were registered at the different stages, including:

- data inserted by the digital twin to the database (Data Set 1),
- data selected by the IPC software from the database (Data Set 2).
- data recorded by the exoskeleton encoders (Data Set 3),
- data inserted to the database by the IPC software (Data Set 4),
- data selected from the database by the digital twin (Data Set 5).

An example of the registered interpolated signals is visualised in Fig. 3.

The teleoperation trials were followed with tests of additional delays for communication at the Poland-Türkiye distance. These included measuring digital twin-exoskeleton control commands execution times and assessing times for ping OS native program. Twenty series of 30-minute connection trials were carried out between Türkiye and Poland to measure delays and validate the stability of the connection.

The computer uploading data to the database directly or via the digital twin located in Turkiye was connected to the network with the tested speed parameters as below:

- Latency: 2 ms;
- Download speed: 32.9 Mb/s;
- Upload speed: 38.4 Mb/s.

III. Results and discussion

Results of the performed experiments are presented in Tables II and III. These include the times of transferring control commands from the digital twin or the database to the exoskeleton and the times for sending measurements from encoders back to the database and visualising them in the digital twin. Moreover, the times of that whole loop from control via the digital twin to visualising the desired position in the model and the loop from setting the desired position in the database to inserting information on reaching it were tested. Only flexion/extension motion was examined as being subject to gravity in passive therapy.

The latency was computed as the difference between setting a certain position and either reaching it by a physical component or getting the same value in the software. Therefore, it varies depending on the joint studied, especially while the physical object control is in the measuring cycle. The times differ mainly due to the ratios of maximum torques and velocities in the joints to the moments of inertia of the distal segments of the exoskeleton. As can be observed in Table II, the differences and times of transfer of the measured signals to the database (exoskeleton - cloud delay) are minimal. Furthermore, the differences in these can result from the order of measuring the angular positions in joints realised sequentially by IPC.

The ankle joint has the lowest delays overall, suggesting that this component is the least mechanically complex, as it is responsible for the last element in the kinematic chain. Hence, its moment of inertia is the smallest compared to the segments corresponding to medial joints. The knee joint has the highest latency in most cases, which may indicate problems with mechanical inaccuracies. That is proved in Table III, where degrees' inaccuracies are also the highest for the knee joint (0.606 deg) during teleoperation, which could be observed as visible vibrations during the experiment. Again, the lowest inaccuracies were measured for the ankle joint (0.188 deg).

The total time of the cycle from setting a position to the digital twin, through reaching it by a physical exoskeleton, to seeing it visualised in the digital twin does not exceed 211.6 ms for any joint (the highest value is for the knee joint). This does not include additional delays coming from the more distant connection, which is elaborated in the next part of the section. Therefore, compared to the values reached in the teleoperation of surgical devices (considered safe while remaining below 300 ms) [16], these are acceptable for manual control over rehabilitation devices.

Visibly, the motion inaccuracies result from the time differences between sending signals for setting a position and executing control commands based on these. These affect the smoothness of the motion process and result in small oscillations within the motion. Moreover, since the times from setting the position and obtaining it can differ for the joints, reaching the position is not possible with the accuracy of the industrial robots [17]. However, the obtained accuracy is outperforming the accuracy obtained for some rehabilitation robots accepted for practical application [18].

Fig. 3. Experimental set of registered experimental data for DOF 4

TABLE II
Average delays during teleoperation between the selected nodes of the system presented in Fig. 2 (digital twin - digital twin means a full loop from setting control via the digital twin to observing reaching the position via the digital twin; cloud - cloud means a loop from setting control via the cloud database to observing reaching the position via the cloud database)

Joint	Hip	Knee	Ankle
Digital twin - exoskeleton delay [ms]	133.14	156.95	98.94
Cloud - exoskeleton delay [ms]	74.69	98.51	40.50
Exoskeleton - cloud delay [ms]	13.66	7.09	8.65
Exoskeleton - digital twin delay [ms]	60.92	54.64	55.66
Cloud - cloud delay [ms]	88.34	105.60	49.14
Digital twin - digital twin delay [ms]	194.05	211.60	154.60

TABLE III
Average control inaccuracy during experimental trials

Joint	Hip	Knee	Ankle
Inaccuracy during PID control [deg]	0.006	0.014	0.008
Inaccuracy during teleoperation [deg]	0.462	0.606	0.188

Additional measurements of delays in communication at the Poland-Türkiye distance were performed in twenty 30-minute connection trials. The average ping value across all sessions is 51.29 ms, and the standard deviation is 1.85 ms. The device being pinged was an IPC computer (responsible for setting trajectories), and the pinging device was a laptop in Türkiye connected to the wireless network (as a representation of a digital twin device). Throughout the twenty sessions, 100% of the data packets sent were delivered, which proves the reliability and robustness of the created robotic system's network.

The observed delays are not significant and allow safe therapy, both from the patient and from a cybersecurity perspective. It can be expected that the total control process with the safe three-way handshake communication protocol should not exceed 400 ms, which is defined as acceptable but tiring for teleoperation [17]. Furthermore, continued development of the project and advancements in global technologies, such as 6G, could further improve these results, enhancing both system performance and safety.

IV. Conclusion

The performed investigation included short-distance teleoperation to assess delays occurring at the different communication stages, resulting from the performance of control systems and communication protocols. Moreover, the accuracy obtained with the exoskeleton controlled with this method was computed. These trials were followed by tests of additional delays coming from long-distance communication and assessment of such connection stability. These proved that telerehabilitation can be performed with the presented methodology. However, the delays can increase significantly while meeting safety requirements with multiple data exchange steps to send one position frame from the digital twin. For such applications, delays of up to one second can occur. With such, manual control over such a system is not possible, and the motion control system irregularity introduces vibrations.

Further investigation will focus on reducing delays and mitigating the effects of the minimum lags. Therefore, the presented trial will be repeated after the implementation of the ADS communication protocol to the system, which changes the way of communication between the IPC and the rest of the components in the network. This can improve the results by decreasing lags and providing comfortable control of the exoskeleton from Türkiye to Poland. Moreover, to ensure smoother movements, the position control will be changed into velocity control. Therefore, even the non-continued control signals will result in a continuous expected joint angle trajectory.

The presented methodology for controlling exoskeletons will be directly implemented into the SmartEx-Twin exoskeleton of the lower extremity. It will regularly operate based on pre-programmed motion routines with optimisation of treatment based on EMG and EEG tracking. However, in case of significantly improper activation of the muscular group regarding performed motions, the process will be stopped, and the physiotherapist will be able to overtake control remotely via a VR-based system. Thanks to this, the performed motion trajectories could be adjusted to the individual needs of a patient on the spot.

Nevertheless, the teleoperation methodology is applicable to other exoskeleton-based physiotherapy devices. Moreover, it can be also easily transferable to other medical devices with physical interactions with their users.

***Abstract*—Person following is a crucial feature for mobile robots, with many using 2D LiDAR-based tracking due to its cost-effectiveness. However, such methods have limitations, such as tracking only from the front or back and being prone to false positives from environmental artifacts. More advanced tracking approaches combine position and appearance information. These can be classified into two categories: 1) position-based tracking, which fuses features from RGBD cameras and LiDARs, and 2) image-based tracking, which uses deep learning to match person appearances in images and then computes position via 3D de-projection. While position-based tracking has shown to be effective for short-term tracking, it has not been tested for person following application on a real robot. Image-based methods have been deployed on real robots but have not been compared to position-based tracking of target person for person following application, where consistent tracking without ID switching is crucial. This work presents a position-based target person tracking system tested on a real robot for person following application using deep learning for person detection, multi-sensor fusion (RGBD cameras and LiDAR), and UCMCtrack algorithm. We compare this with the SORT algorithms for image-based tracking. Our results show that position-based tracking is more suitable for person following, as image-based methods are prone to ID switching due to close proximity in images but distant in 3D space.**

***Index Terms*—Person tracking and following for mobile robots, Camera and LiDAR sensor fusion, Human Robot Interaction.**

I. Introduction

Person following is crucial for mobile robots working alongside humans, enabling applications like luggage-carrying and caregiver following wheelchair. A key challenge in person following is ensuring that the robot can reliably detect and track the target person in unstructured environments. Existing approaches such as [1]–[3] do back following using 2D lidar based person detection and tracking by detecting cross section of person's leg in 2D LiDAR scans. However, they are prone to a high rate of false positives, due to environmental artefacts such as chairs being mistaken for legs. Since, lidar scan area can be restricted for back following, 2D lidar based tracking is still effective.

However, for person following by a robotics wheelchair, in order to enable caregivers to maintain proper contact with the wheelchair user, ability to follow a person from front, side or back is important. Information in 2D lidar scans is not sufficient for reliable person detection and tracking in a wider field of view. For more robust tracking, it is important to use modalities like camera image which provide much more information about target person.

Existing approaches which utilize both lidar and camera sensors for person detection can be categorized into 2 main categories 1) position-based tracking 2) image-based tracking. Position-based tracking approaches [4]–[7] fuse inputs from different sensors to get an estimate of the position of the person in 3D space at every time step and then track the person using Extended Kalman Filter based trackers. Such approaches have been shown to work well for short term person tracking where motive is to avoid the tracked person and ID switching of tracked person after a short while is acceptable. For person following application, such approaches have not been tested on a real robot. Vision or image based tracking like SORT [8], [9] derive motion cues from image observations such as detection bounding boxes, their velocity profile, IOU etc to determine current state of tracked person. Even though they have shown good tracking performance on state-of-the-art datasets and have been deployed on real robots, they tend to restrict to a single camera and all computations are done in image space.

To best of our knowledge, no studies have compared position-based and image-based tracking for person following from front, side or back application where long term consistent tracking with less ID switching is crucial.

In this work, we implement a position-based tracking approach using deep learning for person detection, multi-sensor fusion and modified UCMCtrack [10] algorithm and deploy it on a real robotic wheelchair. Our sensor fusion approach integrates camera and LiDAR detections as probability distributions, considering both position (mean) and covariance matrix, which are essential for Kalman filter-based tracking. We extend the covariance matrix to polar coordinates, enabling fusion of detections from multiple sensors in 3D space, improving person detection and reducing false positives compared to 2D LiDAR tracking. Multiple cameras with overlapping fields of view are used to ensure better track initiation and to allow the user to be detected anywhere around the robot, alongside LiDAR.

Additionally, we modify UCMCtrack [10], which efficiently tracks objects by projecting detections onto the ground plane (obtained from image) as probability distributions and applying a Kalman filter with Mapped Mahalanobis Distance

Authors are from Rehabilitation Research Institute of Singapore (RRIS), Nanyang Technological University (NTU), Singapore

(MMD) for improved tracking accuracy. By combining UCMCtrack with our sensor fusion framework, we achieve robust human tracking in 3D space using multiple sensing modalities. To compare position-based tracking approach with image-based tracking, we also implement OCSORT [8] and Hybrid SORT [9] which use wheelchair robot's RGBD cameras. Our experimental results show that position-based tracking performs much better than baseline approaches in terms of consistent ID retention, association with fewer false positives.

The rest of the paper is organized as: Section II provides related work done in person tracking. Section III introduces our position based tracking framework including sensor fusion and tracking paradigms. In section IV, we show the experiments conducted and results in comparison to baseline approaches. In Section V, provide the conclusion and future works.

II. Related Work

2D LiDAR based person tracking is a very common approach in mobile robotics that aims to provide the position and velocity of the people being tracked. Detecting people's legs in laser scan points using feature based clustering [3] and deep learning [1], [2] have shown good performance, they depend on the training data used and do not generalize well in new environments and might require retraining, which is impractical for mobile robots. These methods also suffer from high false positive rate in crowded and cluttered environments as the amount of information in 2D LiDAR clusters is very limited.

To account for the lack of semantic information in LIDAR detections, vision based approaches are combined with them. [11] proposed a fusion approach for person following but it was not reliable in multiple people scenarios [3]. [4] evaluated a combination of 2D LiDAR, RGB-D person tracking, sensor fusion approaches in a crowded environment for guiding a person. [7] proposed multimodal person tracking algorithms in crowd with the aim of avoiding them. For assistive robots, [12], [13] proposed human perception and interaction frameworks based on leg detector [3] and RGB-D based upper body detections. But [12] had to add an extra thermal camera to handle the false positives. All these approaches focused on tracking persons around the robot to guide or avoid them and didn't focus on following a target person.

For small size robot platforms with a single monocular camera [14] or single RGB-Stereo-Depth camera [15] person following algorithms have been developed that assume the target is always in front of the camera. Similar to these approaches, we combine camera and 2D LiDAR to remove false positives and use both modalities for tracking continuously. Also, in contrast, we allow for the target person to be anywhere around the robot (not restricting to back following). For this purpose, we implement a sensor fusion algorithm that can account for multiple cameras and fuse detections of camera and LiDAR.

SORT based approaches [8], [9] are popular in multi-object tracking. Traditionally, these are vision-based motion model trackers that rely on cues extracted from 2D bounding boxes, their IOU etc for association. They are viable frameworks for combining 2D motion and camera's ReID appearance features as shown by [9]. But they perform motion tracking in a 2D image plane that restricts their ability to be used for multiple cameras and sensors. In contrast, we propose to use spatial information from LiDAR and combine them with camera person detections. For person tracking and following framework, we modify the UCMCtrack to work with final set of detections in a 3D space around the wheelchair.

III. Our Proposed Tracking Framework

A. Hardware Configuration

The proposed tracking framework is implemented, tested and verified in our wheelchair prototype shown in Figure 1. Our prototype includes 3 orbbec RGB-D cameras on the top to cover a field of view of close to 200 degrees in front of the wheelchair. Also, 3 LiDARs are included to provide laser scan of the environment around the wheelchair. All required modules such as mapping, navigation and localization etc are run in ROS framework. Given this wheelchair hardware, the aim is to develop a person/target tracking system that can track the person anywhere around the wheelchair robustly. The tracking framework aims to provide the position of the target with respect to a fixed world coordinate. It is necessary for the framework to provide a consistent tracking ID for the target being followed without losing him/her

.

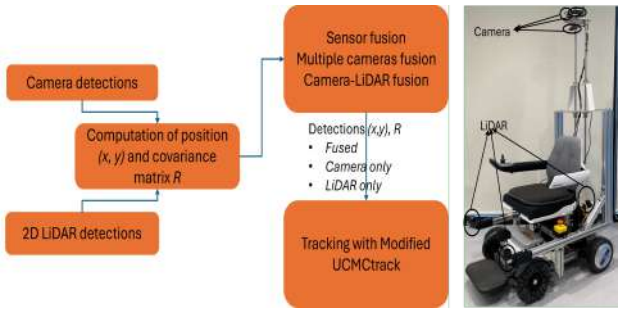

Fig. 1. (Left) Our approach computes the position and covariance matrix for both camera and 2D LiDAR detections, allowing the sensor fusion algorithm to decide whether to merge them. These fused detections are then input into a modified UCMCtrack for tracking and following a person in a wheelchair. (Right) Our Wheelchair prototype with multiple cameras and LiDARs

B. Overview of the proposed framework

As shown in Figure 1, the proposed framework could be divided into three components, namely, person detections from camera and LiDAR, sensor fusion to identify actual person and modified UCMCtrack that handles detections (fused and separate) to provide a consistent tracking ID for the people around the wheelchair.

For vision-based person detection, we use YOLO [16] to identify all persons in the cameras around the wheelchair, assigning each detection a bounding box and confidence score. Depth d_s is estimated using the bounding box coordinates in the depth frame, and the 3D world position is computed via

inverse projection using the centroid, depth, and the cameras' intrinsic and extrinsic parameters. The wheelchair's $base_link$ serves as the reference frame for the extrinsic matrix.

For LiDAR based person detection, we utilize the $leg_tracker$ package [3] which outputs the position $(x, y) \in \mathbb{R}^2$ for each detected pair of legs, a track ID and a confidence score for each detection. The position for each detection is again provided with respect to the wheelchair's $base_link$.

A key component of sensor fusion and tracking is the covariance matrix $R \in \mathbb{R}^{2\times2}$, which quantifies the uncertainty of each detection's position (x, y). Confidence scores from YOLO and $leg_tracker$ are retained for camera and LiDAR detections, respectively. Camera-camera detection association is first performed to match detections from neighboring cameras, followed by LiDAR-camera detection association.

Finally, all detections, which are represented in the form of position (x, y) in the bird's-eye view with an associated covariance matrix R defined with respect to the wheelchair's $base_link$ are provided as input to UCMCTrack. Here after, person tracking and following are performed relative to wheelchair's $base_link$. In the following subsections, we begin with the preliminaries related to representation of our fused person detections, computation of detection covariance matrices for each detections, proposed sensor fusion (camera-camera and camera-lidar), modifications within UCMCtrack.

C. Unified Representation for Person Detections

In our framework both camera and lidar detections are unified under a single representation $(x, y, R, conf, bbox : [bb_lt_x, bb_lt_y, w, h], cam_id, fuse_state_name, ID)$ that contains the position $(x, y) \in \mathbb{R}^2$ in 3D coordinates (z as height is omitted), covariance matrix $R \in \mathbb{R}^{2\times2}$, confidence score $conf \in (0, 1) \subset \mathbb{R}$, bounding box information: top left pixel coordinates $(bb_lt_x, bb_lt_y) \in \mathbb{Z}_{\geq0}$, width $w \in \mathbb{Z}_{\geq0}$, height $h \in \mathbb{Z}_{\geq0}$, camera ID $cam_id \in \mathbb{N}$ to distinguish between camera detections from different cameras, $fuse_state_name$ is the current fusion state of the detection e.g. *'camera', 'lidar', 'camera+lidar'*, and the track ID which is assigned once the detection has been through the tracker. Since the bounding box information and camera ID is applicable only to camera detections, for lidar detections, the bounding box information is filled with zeros i.e. $bbox : (0, 0, 0, 0)$ and cam_id with -1 i.e. cam_id: -1.

D. Computation of Detection Covariance Matrices

Covariances of detections are crucial for computing Mahalanobis distances which serve as the association metric employed in UCMCTrack. In the original UCMCtrack framework, the tracking is done in a single camera frame and define covariance matrices in terms of ground plane obtained from (u, v) pixel in 2D image space alone which might not be valid for the proposed use case, as we are dealing with both camera and 2D LiDAR detections.

A study on robot localization [17] observed that the pose distribution of a noisy two-wheeled robot moving in a plane follows a "banana-shaped" distribution, which is non-Gaussian in Cartesian coordinates. Most algorithms assume a Gaussian distribution in Cartesian space, leading to inconsistencies as uncertainty increases. To address this, [17] suggested using exponential coordinates (a more robust form of polar coordinates) for Gaussian fusion. Inspired by this approach, we apply a similar strategy to handle uncertainty in a person's position. For a generalized covariance matrix definition, we define a Gaussian distribution in polar coordinates that allows us to deal with both types of detection, compare their positions and fuse them if needed. Also this enables us to track in 3D space around the wheelchair.

We define the wheelchair coordinate axes $base_link$ (x', y'), with basis vectors $\hat{i}'$ and $\hat{j}'$, as the standard coordinate Cartesian coordinates (x, y), with basis vectors $\hat{i}$ and $\hat{j}$, rotated by 90^o counter-clockwise (CCW) around the z-axis. Here, the z-axis is defined as the direction perpendicular to the (x, y) plane in $\mathbb{R}^2$, corresponding to the positive z direction in a right-handed coordinate system.

Also polar coordinates (r, ϕ), with basis vectors $\hat{r}$ and $\hat{z}$ where $r \in \mathbb{R}_{\geq0}$ is the radial distance and the angle $\phi \in [-\pi, \pi] \subset \mathbb{R}$ is the angle measured from x' axis to the position vector $r\hat{r} = x'\hat{i}' + y'\hat{j}'$ positive CCW (following the right hand rule).

The covariance matrix of the Gaussian distribution can then be defined as:

$$\Sigma(r, \phi) = \begin{bmatrix} \sigma_{rr} & \sigma_{r\phi} \\ \sigma_{\phi r} & \sigma_{\phi\phi} \end{bmatrix} \in \mathbb{R}^{2\times2}$$

where

$$\sigma_{rr} = \frac{k_r}{r^2} \quad \sigma_{\phi\phi} = \frac{k_\phi^2}{r^2} \text{and} \quad \sigma_{r\phi} = \sigma_{\phi r} = \rho(\phi)\frac{\sqrt{k_r}k_\phi}{r^2}$$

$\sigma_{r\phi} = \sigma_{\phi r}$ since covariance matrices are required to be symmetric and positive definite. $k_r \in \mathbb{R}_{>0}$ and $k_\phi \in \mathbb{R}_{>0}$ are the scaling factors that affects how the radial distance r and angle ϕ are related. $\rho(\phi)$ is the correlation parameter that adjusts the covariance between variables r and ϕ.

To satisfy positive definiteness, the determinant of the covariance matrix should be greater than zero i.e. $\det\Sigma(r, \phi) > 0$. The condition,

$$\det\Sigma(r, \phi) = (1 - \rho(\phi)^2)\frac{k_r k_\phi^2}{r^4} > 0 \Rightarrow -1 < \rho(\phi) < 1$$

follows. Choosing $\rho(\phi) = \rho_0 \cos(2\phi) \in (-1, 1) \subset \mathbb{R}$, where ρ_0 being the correlation coefficient, $-1 < \rho_0 < 1$, and noting that $\cos(2\phi)$ is symmetric along the range $[-\pi, \pi]$, making it a suitable choice in consideration of the problem's geometry.

For our experiments ρ_0 is chosen to be 0.5, k_r is chosen to be 0.05 for lidar detections and 0.07 for camera detections and k_ϕ is chosen to be 0.25 for both camera and lidar detections.

As mentioned in subsection III-C, each of the detection contains position (x, y) in 3D coordinates as z (height) is omitted, which is equivalent to 2D tracking. Because tracking is done in the 2-dimensional Euclidean space $\mathbb{R}^2$, the covariance matrix should be transformed to the standard Cartesian coordinates (x, y). Given the relationship

$$x' = y, \quad y' = -x \quad \Rightarrow \quad x = -y', \quad y = x'$$

and

$$x' = r\cos\phi, \quad y' = r\sin\phi$$

the Jacobian matrix J of the transformation $(r, \phi) \rightarrow (x', y') \rightarrow (x, y)$ is given by

$$J_{x,y}(r,\phi) = J_{x,y}(x',y')J_{x',y'}(r,\phi)$$

$$= \begin{bmatrix} \frac{\partial x}{\partial x'} & \frac{\partial x}{\partial y'} \\ \frac{\partial y}{\partial x'} & \frac{\partial y}{\partial y'} \end{bmatrix} \begin{bmatrix} \frac{\partial x'}{\partial r} & \frac{\partial x'}{\partial \phi} \\ \frac{\partial y'}{\partial r} & \frac{\partial y'}{\partial \phi} \end{bmatrix} = \begin{bmatrix} -\sin\phi & -r\cos\phi \\ \cos\phi & -r\sin\phi \end{bmatrix}$$

Thus the covariance matrix $\Sigma(x, y)$ can be computed as:

$$\Sigma(x,y) = J_{x,y}(r,\phi)\Sigma(r,\phi)J_{x,y}(r,\phi)^T$$

this expression can then be calculated numerically by substituting, $r = \sqrt{x'^2 + y'^2}$ and $\phi = \text{atan2}(y', x')$

Therefore, each detection can be written as $\det \sim \mathcal{N}((x', y'), R)$, where (x', y') represents the mean and $R = \Sigma(x, y)$ denotes the covariance matrix. It is worth noting that $\Sigma(x, y)$ and $\Sigma(x', y')$ are related by a rotation about the z-axis. Specifically, $\Sigma(x, y)$ can be obtained by applying a $+\frac{\pi}{2}$ rotation to $\Sigma(x', y')$ and vice versa, $\Sigma(x', y')$ can be obtained by applying a $-\frac{\pi}{2}$ rotation to $\Sigma(x, y)$.

E. Sensor Fusion Algorithm

In this section, we brief on how we associate and merge camera-camera, camera-lidar detections using the position and covariance matrices.

1) Association of Camera-Camera Detections: From the hardware shown in Figure 1, we can clearly see that there are multiple cameras with overlapping FOV between neighboring cameras. First, we aim to associate detections of the same person, who might appear in two cameras due to the overlapping FOVs. We consider a general setup of $n \in \mathbb{N}$ cameras, $n > 1$ arranged radially facing outwards at distinct angles $\phi_k \in (-\pi, \pi)$, where k is the camera number, $k \in \{1, 2, \ldots, n\}$ and ϕ is the angle between the x'-axis and the vector resulting from the projection of camera optical axis z_c onto the 2D plane $\mathbb{R}^2$.

Now, define the sequence S of ordered pairs of consecutive camera IDs as follows:

$$S = \{(l, l+1) | l \in \{1, 2, \ldots, n-1\}\}$$

Each pair $(l, l+1) \in S$ represents the ordered pair of consecutive camera IDs in sorted order of angles ϕ of the corresponding cameras. The sequence S captures the adjacency of camera IDs in decreasing order of their angles ϕ.

The association process involves traversing the sequence S, where for each pair $(l, l+1)$, detections from camera ID l are matched with those from camera ID $l+1$ based on the position of the detection. For $n > 2$, each element $l \in \{2, 3, \ldots, n-1\}$ appears twice in S, once in $(l-1, l)$ and once in $(l, l+1)$. Thus, care must be taken when associating detections between consecutive camera IDs, as unmatched detections from $(l-1, l)$ may be matched with detections from $(l, l+1)$.

The distance metric used to construct the association cost matrix for detections between two adjacent cameras, det_a and det_b, is the Euclidean distance, $d_{\text{euclidean}}$:

$$d_{\text{euclidean}}(\text{det}_a, \text{det}_b) = \|\mu_a - \mu_b\| = \sqrt{(x_a - x_b)^2 + (y_a - y_b)^2}$$

, where (x_a, y_a) refers to a detection with $cam_id = l$ and (x_b, y_b) refers another detection with $cam_id = l + 1$. It is important to note that not all detections present in the camera pair are to be included in the association process but only detections with bounding boxes intersecting the left *or* right border of the camera image frame in the camera pair $(l, l+1)$.

2) Merging of Camera-Camera Detections: Merging of two camera detections, det_a and det_b, can be done by

$$\mu_{\text{fused}} = \left(\frac{x_a + x_b}{2}, \frac{y_a + y_b}{2}\right), \Sigma_{\text{fused}} = (R_a^{-1} + R_b^{-1})^{-1}$$

where μ_{fused} geometrically means taking the midpoint of the line segment connecting μ_a and μ_b as the combined mean. While Σ_{fused} is the covariance of the pdf resulting from the multiplication of two Gaussian pdfs.

3) Association of Camera-Lidar Detections: The resulting detections from the association of camera-camera detections (Section III-E1 and III-E2) are then used for camera-lidar detections association.

The association cost matrix for assignments of camera-lidar detections are constructed based on the expected squared distance between two Gaussian distributions. Given two Gaussian pdfs, one of camera detection $\text{det}_c \sim \mathcal{N}((x_c, y_c), R_c)$ and the other of lidar detection $\text{det}_d \sim \mathcal{N}((x_d, y_d), R_d)$ that are independent, the expected squared distance is given by

$$\begin{aligned} d_{\text{squared-distance}}(\text{det}_c, \text{det}_d) &= E(\|\text{det}_c - \text{det}_d\|^2) \\ &= \|\mu_c - \mu_d\|^2 + \text{Tr}(\Sigma_c + \Sigma_d) \\ &= \|(x_c, y_c) - (x_d, y_d)\|^2 + \text{Tr}(R_c + R_d) \end{aligned}$$

where the first term is the squared distance between the means and the second term is the trace of the sum of the covariance matrices.

4) Merging of Camera-Lidar Detections: Merging of camera and lidar detections can be performed either by using inverse-variance weighting of the pdfs of the camera and LiDAR, where the weights are modulated by its respective confidence scores, or by relying solely on the LiDAR pdf. Based on qualitative observations from our experiments, no significant difference were observed between the two approaches. Therefore, we choose to use only the LiDAR measurement, as it is also known to have higher positional accuracy compared to the camera.

F. Modified UCMCtrack

Our tracking framework utilizes fused *'camera + lidar'* as well as separate *'camera'* and *'lidar'* detections provided by sensor fusion that follow the representation in section III-C. Each detection comprises position x, y in 3D space around the wheelchair and covariance matrix R which UCMCtrack uses to compute MMD. Specifically, we have made changes in Initialization of tracks and track management.

1) Initialization of Tracks: In our implementation of UCM-CTrack, a detection is only initialized as a track when it is in the fused state or *'camera+lidar'*. This helps us to reduce the number of false positive tracks and contribute to better tracking performance in office environment where there is an abundant number of chairs. After initialization, while updating the tracks, we don't consider the $fuse_state_name$ of the detection. This is because when the person goes out of the camera frames or LiDAR range we still need to track them.

2) Track Management: Track management is an auxiliary tracker that maintains an internal list of Kalman tracks with IDs that of the output from our implementation of UCMC-Track. Its main purpose is to smoothen jaggy outputs from the tracker upstream, to manage tracks and transforming the known relative position and heading direction of the target to a fixed world coordinate for person following. The proposed method was implemented with our wheelchair prototype for successful target following.

IV. Experimental Results and Discussion

A. Dataset

For testing the efficiency of our position-based tracking framework in mobile robots, it is necessary to have a dataset that contains both multiple cameras and 2D LiDAR modalities. Also, it is required to have ground truth location of people around and actual target whom the mobile robot is following. Existing datasets [4], [6] provide multimodal data and ground truth people tracks but there is no target person that the robot follows from start to end. They were created for testing the efficiency of person tracking and for the robot to learn how to react in crowded scenarios. Existing person following dataset [15] provide only stereo depth camera images without any LiDAR information and couldn't be considered for our application. To the best of our knowledge, we couldn't find a dataset with camera, LiDAR modalities that also includes a target person. Thus, we collected our own dataset with multiple cameras and 2D LiDAR in our wheelchair prototype. For data collection, we collected rosbags with the required topics. The rosbags were recorded with various conditions like one person, multiple person and actual crowded scenarios in a university environment. The groundtruth bounding boxes were marked in each of the camera frames. During data collection, the wheelchair was manually controlled by an operator (using joystick) to follow the actual target. This was to ensure that our dataset is able to capture the person following mobile robot use case. A total $382.005596s$ of data was recorded.

B. Evaluation Metric

We employ the popular HOTA metrics [18] to evaluate the effectiveness of the proposed method. Whenever a person is available in the camera frame, the bounding box is annotated manually. HOTA [18] introduced a set of performance metrics that provided better understanding of tracker behavior in the Multi object Tracking (MOT) field. Using the metric, we can show the effectiveness of the tracking ID association and better ID retention. Specifically, we look at DetA (indicates detection performance), overall HOTA and AssA (indicates ID retention and association, important to person following use case). Also, we use false positive rate to compare our method and LiDAR-only tracking in terms of false positives.

TABLE I
Comparison of the HOTA metrics between proposed and baseline methods

Method	HOTA	DetA	AssA	False Positive Tracks
Our Method	74.753	75.537	73.977	0
LiDAR-only tracking [3]	73.643	76.039	71.323	23
OCSort	45.012	68.23	29.778	-
HybridSORT	44.566	47.765	42.787	-

C. Baseline

For baseline, we consider image based SORT approaches [8], [9] and position based LiDAR-only tracking [3]. Since, [3] deals only with LiDAR scan, we can't be directly estimate HOTA. Therefore, we perform sensor fusion with camera using the proposed method but instead of using the tracking ID provided by our method, we use the tracking ID provided by [3]. This way we would be able to test the ID association and retention capabilities of the baseline. For false positives, we just consider the tracks detected by the leg tracker [3] without any sensor fusion. We aim to provide rigorous evaluation of these approaches in person following application.

D. Results and Discussion

1) Better Tracking Performance: Table I shows that our method achieves better person tracking using both camera and 2D LiDAR. The HOTA metric [18], which evaluates trajectory alignment and penalizes mismatches, indicates superior performance compared to image-based SORT tracking approaches [8], [9]. Unlike SORT, which struggles with ID switching in crowded scenarios due to close proximity in image space, our method tracks in 3D space around the wheelchair, leading to better ID retention and association. Compared to LiDAR-only tracking [3], our method achieves higher HOTA and AssA scores, demonstrating improved ID retention while maintaining a comparable DetA. While LiDAR-only tracking reliably detects a single person despite false positives, it suffers from ID switching and target loss in crowded environments. As shown in Figure 2, our method significantly reduces ID switching, ensuring better target tracking even in dense crowds

2) Lower false positives: To evaluate false positives, we used rosbags with a single person walking in front of the wheelchair, ensuring only one valid track (for groundtruth). False positives were determined by counting extra initiated tracks. Table I shows our position-based tracking method eliminated false positives by leveraging the camera's semantic information, whereas LiDAR-only tracking detected 23 false positives due to environmental artifacts in the LiDAR scan (See Figure 3).

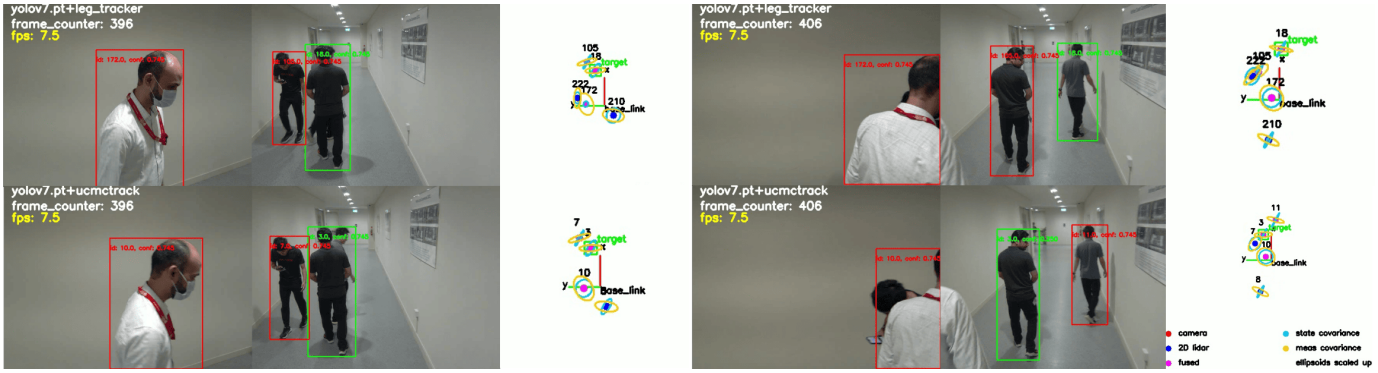

Fig. 2. Output of the target (in green) being followed using LiDAR-only tracking (top row) and proposed method (bottom row). The ID switches to another person with baseline where as the proposed method is still able track the original target with same ID.

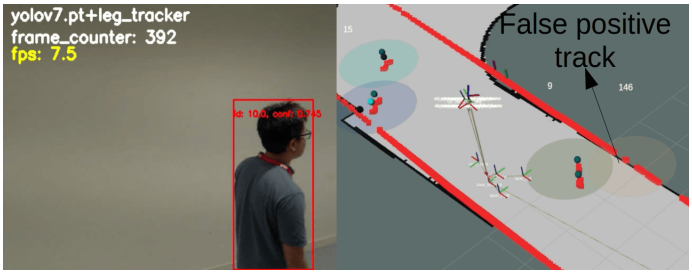

Fig. 3. False positive track detected on the wall with an assigned track ID (in white). LiDAR-only tracking detects a person's leg but also a false positive track on the wall as the pattern is very similar to legs.

V. Conclusion and Future Work

We develop a position-based person tracking framework for wheelchair robots, featuring a sensor fusion algorithm that incorporates position and covariance matrix information to integrate multiple cameras and LiDARs. By modifying the UCMCtrack framework to handle *'camera', 'lidar', 'fused'* detections, we enable person following around the wheelchair. Experimental results show position-based tracking performs better than image-based tracking for person-following applications. Also, we plan to test and collect a more diverse and bigger dataset in the future.

Acknowledgment

This research is supported by A*STAR under the National Robotics Programme (NRP) BAU grant, Assistive Robotics Programme (Award No: M22NBK0074). Also, Thanks to Mr. Neelkanth Jha and Mr. Cheng Yap for developing the wheelchair prototype and helping with testing.

Exploring Synergy Between Tactile Perception and Arm Usage

Yuhe Chen, Jonathan van Zanten, Michaël Wiertlewski, Arno Stienen[1]

***Abstract*—Stroke causes severe tactile deficiencies which affects motor control when grasping and lifting objects. Understanding the fundamental neural disorders associated with tactile deficits is crucial to developing rehabilitation and treatment plans correspondingly. Earlier studies have studied the dynamics between finger grasping behavior and arm muscle activation in stroke patients. However, the exact neuromuscular synergy of tactile perception and arm usage is left unexplored. Here we designed a comprehensive experiment platform and tested the potential synergy on 12 healthy young adults, serving as a control group to establish a foundation for future studies on stroke patients. The experimental platform consists of a lever arm on which torques can be applied to the subject's arm. The end effector is equipped with a special ultrasonic friction modulation plate that can reduce the apparent friction of the object by up to 63%, simulating real-world grasping tasks in a controlled setting. The experiments were performed under varying conditions of friction and arm usage. Results indicate significant effects of tactile stimulation on grasping force adaptation ($p < 0.05$ in 8 of 12 experimental conditions). In the meantime, arm usage did not show a significant synergy with tactile perception ($p = 0.44$ in grasping force adaptation amplitude, and $p = 0.73$ in reflex delay). These findings demonstrate that the experimental platform can provide insights into human tactile behaviors, which is critical for studying tactile sensory and motor control synergy. The results will lay the groundwork for future research on underlying pathologies and rehabilitation strategies for stroke patients.**

***Index Terms*—tactile perception, ultrasonic friction modulation, stroke, synergy**

I. Introduction

STROKE is the second-leading cause of death and the third-leading cause of disability and death combined, as a study has revealed in 2021 [1]. More than 50% stroke patients reported perceptual disorders [2], including deficiencies in somatosensation [3] and proprioception [4]. These deficiencies cause stress, loss of daily task functions, and reduction of quality of life among stroke patients [5]. Especially, impairment of tactile perception has a detrimental impact since patients have reported difficulty in sensing touch, pressure, and temperature, discriminating textures, and recognizing objects through tactile senses [6], as well as reduced or altered pain sensations [7]. To develop targeted treatment and rehabilitation strategies, it is crucial to understand the fundamental neural discrepancies associated with tactile deficits.

Tactile perception plays a fundamental role in manipulation tasks. Tasks as mundane as holding a cup or writing with a pen become tedious in the absence of touch. This is especially true when estimating the grip force necessary to securely grasp an object [8]. Stroke patients may use abnormally high forces to ensure the security of grasping, and studies have suggested that during object-lifting tasks, their grasping force fluctuates with the acceleration and deceleration of the object [9]. Accelerations and decelerations involve extensive activation of arm muscles, and the fluctuations of grasping force that occur at these moments are likely to be caused by tactile sensibility deficits [9]. Their correlation implies a neuromuscular synergy between tactile perception and arm muscle activation.

Despite increasing knowledge of the effect of friction on grasping [10], the effect of stroke on tactile functions or its effect on grasping is understudied [11]. Specifically, few studies have explored the dynamics of stroke patients' tactile perception deficits, and how they correlate with other neurological effects in complex tasks that involve the coordination of multiple neural inputs and outputs.

The absence of detailed knowledge of the impact of impaired touch on grasp is partially due to the difficulty of controlling tactile stimulation. Traditionally, changing tactile interaction is done by changing surface materials or using different gratings [12]. This method is tedious and it is often difficult to establish a general standard. But more importantly, it is impossible to study real-time responses to tactile stimulations.

In recent years, however, a new class of haptic devices, called surface haptics have emerged. These devices can modulate friction with the bare finger directly either via electroadhesive effect or using ultrasonic vibration, see [13] for a comprehensive review. Contrary to electroadhesive devices, ultrasonic friction modulation can change the coefficient of friction on a wide dynamic range. It works by physically reducing the friction between the human finger and the surface [14] and the friction coefficient can be modulated from about 1 all the way to 0 [15]. The wide dynamics range makes it ideal for simulating real-world dynamics of grasping tasks.

The ultrasonic method was first introduced in 1995 [16]. Its functional mechanism to reduce friction involves the squeeze film effect in which ultrasonic waves create an overpressure between the finger and the vibrating plate. The air between the skin and the plate is squeezed into a thin film, which slightly levitates the skin and reduces the number of asperities in contact, thus lowering friction [14, 15, 17].

We leverage ultrasonic friction modulation to study how human participants grasp objects. This marks our first attempt to understand whether stroke patients, suffering from

neurological disorders, experience a synergy between arm usage and tactile perception. This pilot study, conducted on healthy subjects as a control group, serves as a preliminary step to develop an experimental platform that can be used for future studies involving stroke patients. The results of this study, while not directly conducted with stroke patients, will provide critical baseline data for understanding how tactile perception and arm usage may interact in individuals with stroke-related deficits.

II. Materials and Methods

A. Goal

The goal of this experiment is to mimic a casual lifting task: a person grabs an object with a certain weight, lifts it slightly with their hand and wrist, with or without activating arm muscles, and holds it for a short time. The person does these all without special focus on the task itself, to reflect real-life behaviors, where people also do not pay special attention when casually grasping objects. Specifically in this experiment, the friction level of the object is changed during a trial. The subject's grasping force and the object's angle are recorded and analyzed to evaluate the response to tactile stimulation.

B. Setup

The experiment setup (Fig. 1) consists of four distinct sections:

1) Grasping Object: The grasping object (Fig. 1a) mimics a general object to be gripped in everyday life. It is able to record the subject's grasping force with two load cells. The subjects' active grasping force represents how much force they think they need to secure the grasp, reflecting how slippery they perceive the object at hand to be. The width of the object is 50 mm, and the effective grasping area is 34 mm $\times$ 25.5 mm.

2) Friction Modulation Plates: Two glass-based friction modulation plates (Fig. 1b) provide tactile stimulation on both sides of the grasping object. When activated, the actuators vibrate the plates to an ultrasonic frequency (around 23 kHz), causing a 6.21 μm and a 5.72 μm displacement amplitude on the plates' centers respectively. This ultrasonic vibration provides the squeeze-film effect, greatly reducing the plates' surface friction.

3) Constant Force System: The constant force system (Fig. 1c) uses a pulley system and an extension spring to provide a constant vertical force on the grasping object. This system is designed to provide an adjustable vertical force from - 5 N to + 5 N, adjusted by turning the black knob on the lead screw.

4) Elbow Support: The elbow support (Fig. 1d) has a rotational stiffness. When the subject flexes their elbow to an angle, they have to use their arm muscles to counter this stiffness, thus this structure can mimic the use of the arm in the object-grasping task. When the subject is instructed to flex their elbow to a fixed angle (around 30 degrees), they will need to apply approximately 4.14 N·m of torque to counter this stiffness.

C. Controls and Data Acquisitions

Grasping force from the load cells and the object's angle from an angular sensor are gathered at 100 Hz. A Labview program visualizes the data in real time and automatically executes the progressions of each trial.

D. Experimental Protocols

The main experiment studies three controlled variables: the net vertical force of the object (-0.5 N, 0 N, 0.5 N), flexion of the elbow (yes, no), and friction perturbation (high to low, low to high). Before a trial, the constant force system is adjusted to the destination force level, and the subject is asked to relax or flex their elbow to the fixed angle. Note that when the vertical force of the object is 0 N, there is no actual need to change the grasping force when there is a change in friction. This group acts as a "placebo" control to account for factors like vibration, heat, and habitual behavior, excluding the effects of friction change on the results.

The participant task includes three program-controlled phases (Fig. 2):

1) Lifting phase. This phase has no time limit. The initial friction state is applied before the start of this phase. During this phase, the subject is asked to use their hand and wrist to move the object from its beginning position to the middle (see Fig. 2), using an optimal grasp effort. The optimal effort means applying the minimal grasping force necessary while ensuring grasp stability.
2) Holding phase 1. This phase lasts for 2 seconds. It is used to establish a steady baseline of the initial grasping force. Data from the beginning of this phase are used for further analysis.
3) Holding phase 2. This phase lasts for 8 seconds. Immediately at the start of this phase, the friction state switches to the opposite as a perturbation. The subject's goal is to maintain the object's position.

Fig. 3 depicts a typical trial. During the experiment, the subject is asked to wear a pair of active noise-canceling headphones to avoid any audio cues. In the meantime, a nature documentary is played to them to divert their attention and mimic a casual grasping task.

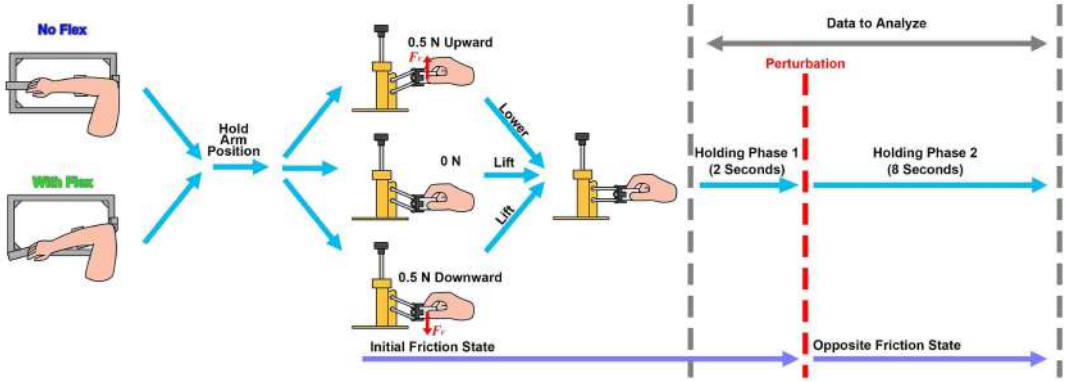

Fig. 2. Flowchart of the experimental protocol. Controlled variables are 1) Elbow position (no flex, with flex; illustrated by the elbow drawings on the left), the subject keeps their elbow position during the entirety of the trial; 2) Vertical force (0.5 N upward, 0 N, 0.5 N downward, illustrated by the hand drawings in the middle), the trial data used is the 10 seconds after they have lifted/lowered the object and stabilized; 3) Friction perturbation (high to low, low to high; shown by the purple arrows on the bottom), the initial friction state starts before the subject touches the object.

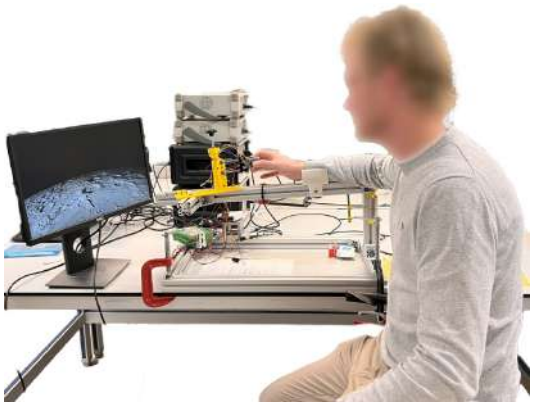

Fig. 3. A typical scene where a participant is performing the experiment. They are currently in the holding phase of a trial, not flexing their elbow, while watching the nature documentary.

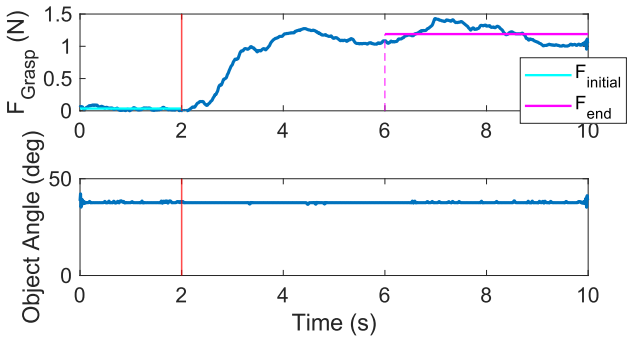

Fig. 4. A typical trial where the friction changes from high to low, and the object has a downward vertical force. The upper plot shows the grasping force over time, and the lower one shows the object's angle over time. The vertical red lines indicate the time of the friction change (2 s). The horizontal magenta lines show the initial force before the perturbation and the end force after the perturbation.

E. Friction Modulation Characterization

Before the main experiment, subjects were asked to perform a qualitative test to characterize the effectiveness of friction reduction. The object was adjusted to have a force of 0.5 N downwards. The subject would first squeeze the object with excessive force and lift it. Then, they would gradually reduce their grasping force, until the object starts to slip slowly. They were instructed to continue to release their grip until the object fully slipped from their fingers. They repeated this process with friction reduction either off (high friction) or on (low friction). Their grasping force and the object's position during the whole process were recorded and analyzed. Assuming a simple friction model, the minimum grasping force before the object slips provides a friction force equal to the object's vertical force.

F. Data Processing

1) Data Cleaning: Grasping force and object angle data were cleaned first before further analysis. First, their zero baselines were subtracted. Next, data were segmented into trials. The data acquisition rate was set to be 100 Hz; however, due to hardware limitations, the actual sampling was approximately 65 Hz, with a variable sampling rate. So, all segments were then resampled to 100 Hz by interpolation.

2) Data Exclusion: A threshold was used for detecting human errors in the trials. The value was determined by 10 times the minimum grasping force needed at the low friction condition (8.56 N in this case, as will be later shown in the results section). Further analysis excludes all trials with force exceeding this threshold. 12 trials were excluded in total among 432 trials.

3) Metric Extraction: Fig. 4 shows a typical trial where the friction changes from high to low on the two-second point (red lines), and the object has a downward vertical force. The object's position (angle) does not significantly change during a trial, and is not in the scope of this experiment, thus is not further studied.

3 metrics were extracted from each trial: the initial grasping force before the perturbation $F_{initial}$, the end force after full adaptation F_{end} (the cyan and magenta lines in Fig. 4), and the difference between them ΔF_{end}. They are calculated by:

$$\begin{cases} F_{initial} = mean(F(t < 2)) \\ F_{end} = mean(F(t > 6)) \\ \Delta F_{end} = F_{end} - F_{initial} \end{cases} \quad (1)$$

The reason F_{end} is not calculated directly after the perturbation is because there is a delay in the adaptation for grasping forces, especially in friction-increasing conditions (which will be shown in the next section). So the calculation uses the second half of the data (from 6 s to 10 s) after the perturbation.

G. Participants

This experiment recruited 12 participants, 7 males and 5 females. They are all healthy adults with no diagnosed tactile or arm usage deficiencies. Their age ranges from 24 to 30 (mean 26.4). Since the experiment setup is specifically designed for right-hand use, only right-handed individuals were recruited.

III. Results

A. Friction Modulation Effect

A paired t-test was performed for the mean values of each subject's minimum grasping force before slippage in the characterization test. It confirmed that friction modulation has a significant effect on the grasping force ($t_{12} = -3.3, p = 0.0069$). The average minimum force for the high friction condition is 0.32 N, while that of the low friction condition is 0.86 N. Assuming a simple friction model without viscosity, the ultrasonic friction effectively reduced the surface friction coefficient by 63%. Note that the actual friction model is more complex and depends on the subject [18], so this value is just for qualitative reference.

B. Data Overview

Fig. 5 plots the force data of all 12 conditions separately. The blue lines indicate when the subject does not flex their elbow, while the green lines indicate the opposite. Shaded areas are their standard deviations. The left column indicates when the friction changes from low to high, while the right one indicates otherwise. The rows from top to bottom indicate 0.5 N upward, 0 N, and 0.5 N downward force on the object respectively. Fig. 6 further illustrates the mean and standard deviations of the difference in force $\Delta\overline{F}$ over time. ΔF has a similar definition as ΔF_{end}:

$$\Delta F(t) = F(t) - F_{initial} \quad (2)$$

IV. Discussions

A. Experiment Validation

Before addressing the primary research question, it is essential to establish the validity of the experiment. This entails demonstrating that the results accurately reflect the participants' tactile perception and align with established findings in the field. Fig. 7 shows the confidence levels $(1-p)$ of paired t-tests ($N = 12$) between $\overline{F}_{initial}$ and $\overline{F}_{end}$ of each subject under different conditions. Since the confidence levels

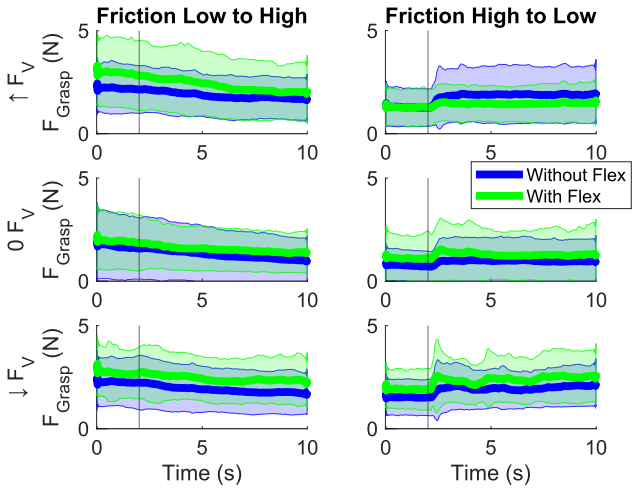

Fig. 5. Overview of the means of grasping force over time under 12 different conditions. The blue lines indicate when the subject does not flex their elbow, while the green lines indicate otherwise. Shaded areas are their standard deviations. The left column indicates when the friction changes from low to high, while the right one indicates otherwise. The rows from top to bottom indicate 0.5 N upward, 0 N, and 0.5 N downward force on the object respectively.

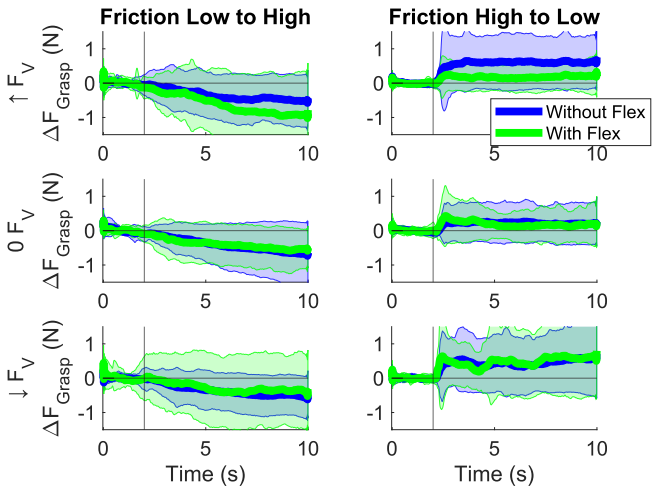

Fig. 6. Overview of the means of $\Delta\overline{F}$ over time under 12 different conditions. ΔF is the force data subtracted by $F_{initial}$. The blue lines indicate when the subject does not flex their elbow, while the green lines indicate otherwise. Shaded areas are their standard deviations. The left column indicates when the friction changes from low to high, while the right one indicates otherwise. The rows from top to bottom indicate 0.5 N upward, 0 N, and 0.5 N downward force on the object respectively.

are all above 85% and 8 out of 12 are above 95%, it is a clear indication that the friction perturbation has a significant impact on the participants' ability to regulate their grasping force.

Furthermore, there is no statistical difference when it comes to the direction of the vertical force ($t_{24} = -1.1, p = 0.3$, and $t_{24} = -0.96, p = 0.34$ for friction increasing and decreasing respectively). Thus, the upward force and downward force conditions can be combined as "with vertical force" experimental groups, with respect to "no vertical force" control groups.

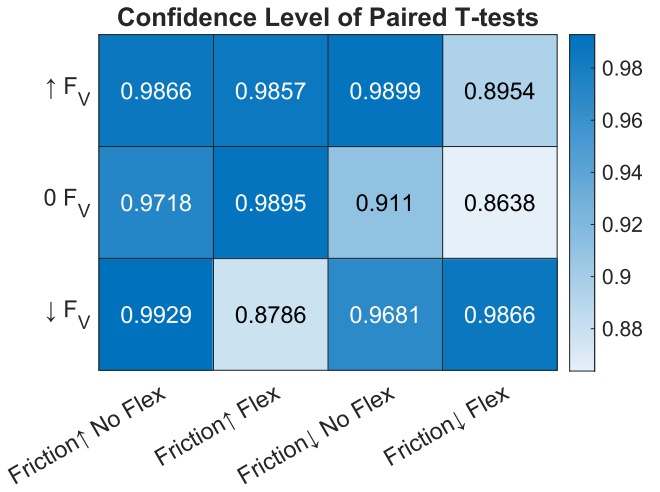

Fig. 7. Heatmap of confidence levels of paired t-tests between $\overline{F}_{initial}$ and $\overline{F}_{end}$ (as in Fig. 4) of each subject under different variable combinations. The higher the value, the deeper the color, and the more significant that the perturbation had an effect.

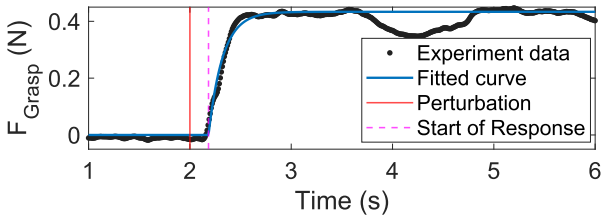

Fig. 8. Fitted curve of the mean of all trials with decreasing friction and non-zero vertical force. The black dots represent the experiment data points, while the blue line is the fitted curve. The red vertical line marks the start of the perturbation. The fitted time delay of the system is 184 ms, which is marked by the dashed magenta line.

However, it seems that the control groups (no vertical force but with friction perturbation) also demonstrated a significant effect of tactile stimulation on the grasping behaviors. So, paired t-tests of $\Delta\overline{F}_{end}$ comparing trials with and without a vertical force are performed. In these tests, all other conditions are combined except for the friction perturbation, because the difference in it affects the direction of ΔF_{end}. Results showed that there is no significant difference between the control groups and the group where friction increases ($t_{24} = 1.1, p = 0.3$). In contrast, when the friction decreases, the groups exhibit significantly larger effects ($t_{24} = -2.9, p = 0.0088$).

Taking all factors into account, it is clear that the subjects can perceive the change in friction and adapt accordingly, thus this experiment is able to reflect their tactile perceptions.

B. General Grasping Behavior

1) Decreasing Friction: Subjects increase their grasping force when the friction decreases and they sense an actual need to grip tighter. Their reactions can resemble a first-order system, where there is a small delay after the impulse (perturbation), and then the system output (grasping force) increases negative exponentially to a new steady state, as the lines on the right side of Fig. 6 suggest. In fact, the delay t_{delay} can be calculated if fitting the force curve with a piecewise function after the perturbation:

$$\begin{cases} \Delta\hat{F}(t < t_{delay}) = 0 \\ \Delta\hat{F}(t \geq t_{delay}) = A \times (1 - e^{\frac{-(t-t_{delay})}{\tau}}) \end{cases} \quad (3)$$

where A is the gain and τ is the time constant. Because individual trials often have very large deviations, the goodness of fit is not always satisfactory. As a consequence, only the average of every trial with decreasing friction and non-zero vertical force was fitted with the non-linear least squares method, as shown in Fig. 8. The resulting time delay is 184 ms. The delay is slightly larger than previous findings on friction-induced reflex response time [19], but still in the same magnitude. It is also consistent with the previous study [20]. This short delay implies that there is an intrinsic reflex pathway in humans to react to sudden grasp instability.

2) Increasing Friction: A decrease in grasping force is observed when the friction increases during a trial, but at a significantly slower rate than when friction decreases (Fig. 6). In both increasing and decreasing friction conditions, the amplitude of grasping force change is similar (comparing the left and right sides of Fig. 6). This means they adapt to the same level of friction change, no matter the direction, with the same level of grasping force change. Also, the F_{end} in increasing friction conditions is close to $F_{initial}$ in decreasing friction conditions (comparing the left and right sides of Fig. 5). This implies subjects adapted their grasping effort to their perceived optimal level. These similarities suggest that grasping forces are actively adapting to the level of friction to expend as little energy as possible while maintaining the stability of the grasp. The control groups, however, showed the same pattern of grasping force decrease as the experimental groups, despite that there is no actual need for the grasping force to change. This might be explained by: 1) Since the actual grasping forces are a lot higher than the minimum required grasping force, even in low friction conditions, the decrease in the grasping force is merely an attempt to optimize the grasping effort. 2) Since there is no actual grasping force needed in the control group, the subjects also felt the need to reduce their grasping force, as in situations where friction increases. However, the amplitude of this reduction happens to coincide with that in non-zero vertical force conditions, thus the results yield no statistical difference.

C. Effects of Arm Usage

1) Effects on Grasping Force: Fig. 5 suggests that there is a difference between the grasping force with and without arm usage, regardless of the perturbation. The control groups were not taken into account. A paired t-test between each subject's $\overline{F}_{initial}$ without and with arm usage under all other conditions confirmed there is a significant effect of arm usage on the level of force generated ($t_{48} = -3.8, p = 4.2 \times 10^{\circledast 4}$). The same test on their $\overline{F}_{end}$ yields similar results ($t_{48} = -3, p = 0.0039$), suggesting that when participants are using

their arms, they use a significantly higher grasping force both at the beginning of the grasping task and at the steady state where they have adapted to the new friction level.

2) Effects on Force Change: Since it is not confirmed that the friction-increase conditions reflect tactile perception, only friction-decrease conditions are used in this evaluation. A paired t-test between each subject's $\Delta\overline{F}_{end}$ without and with arm usage proved no significant difference ($t_{24} = 0.79, p = 0.44$). The subjects adapt to the same level of friction change with the same amplitude of force change, regardless of the usage of their arm.

3) Effects on Time Delay: Using the same function 3, response delay t_{delay} can be calculated for every subject under decreasing friction. However, due to the high deviations of each trial, this function was only successfully fitted to 8 subjects with meaningful results. A paired t-test between these subjects' t_{delay} without and with arm usage proved no significant difference ($t_{24} = -0.35, p = 0.73$). This possibly means that arm usage does not affect the time delay of response to tactile perception.

4) Is There a Synergy?: In conclusion, subjects tend to use a higher grasping force with arm usage whatever the condition; however, they respond to the same level of tactile perturbations with the same amplitude of force adaptation and likely the same level of time delay. Since several subjects reported that they involuntarily use their hand to assist in bending the elbow support (see the mechanism in Fig. 1), it is highly likely that the higher grasping force is just the additional hand pressure on the plates. With this factor accounted for, we can conclude that with healthy young adults, there is no significant neuromuscular synergy between arm usage and tactile perception.

V. Conclusions

We presented a pilot study that explores whether there is a neuromuscular synergy between humans' arm usage and their tactile perception of the object in hand. This study serves as a preliminary step, using healthy subjects as a control group, to develop an experimental platform that can be used for future research involving stroke patients. The results revealed a general grasping behavior that is consistent with earlier findings, confirming that this experiment is valid to reveal possible tactile perception discrepancies. In the end, we found no significant evidence that arm usage has a synergy with healthy subjects' tactile perception. This conclusion suggests that for healthy humans, the regulation of grasping force may function independently of general motor control. However, the findings from this study will lay the groundwork for future research on stroke patients, providing critical baseline data to explore how these dynamics interact in individuals with stroke-related deficits.

Mapping Encoder Values to Ankle Angles in a 3 DoF Parallel Ankle Exoskeleton

Miha Dežman*†, Charlotte Marquardt* and Tamim Asfour*†

***Abstract*— Accurate estimation of ankle joint angles is vital for advancing assistive technologies such as ankle exoskeletons. This study investigates whether three encoders within the parallel kinematics of a three degree of freedom (3-DoF) ankle exoskeleton can effectively estimate the three rotational movements of the ankle: plantar-/dorsiflexion (PF/DF), in-/eversion (IN/EV), and internal/external rotation (IR/ER). Performance was tested during walking, curve walking, and stair climbing with two healthy participants. Ankle motion was independently captured using a motion capture system, while encoder values from the exoskeleton were concurrently recorded. The root-mean-squared error (RMSE) for angle estimations ranged from 1° and 3°, indicating good accuracy, particularly for IN/EV and IR/ER, though challenges were noted in capturing peak dorsiflexion. The findings suggest that misalignment between the exoskeleton and the biological joint axis may have contributed to the observed inaccuracies, particularly for PF/DF, as evidenced by differing range of motion (RoM). Additionally, variability between the two participants may reflect the potential impact of individual anthropometry and alignment quality, which could inform future considerations for design and alignment protocols. Future model enhancements could incorporate dynamic effects and machine learning to generalize across diverse populations.**

I. INTRODUCTION

Exoskeletons have emerged as innovative assistive devices designed to enhance mobility, support rehabilitation, and improve the overall quality of life for individuals with various physical impairments. Among these, ankle exoskeletons specifically target the ankle joint, providing assistance to reduce the metabolic cost of walking. These systems enable users to regain or enhance movement patterns that may have been disrupted due to injury or disease [1], [2].

A critical aspect of optimizing ankle exoskeletons is the accurate estimation of ankle joint kinematics, which is essential for delivering customized assistance across the three degree of freedom (DoF) of the ankle: plantar-/dorsiflexion (PF/DF), in-/eversion (IN/EV), and internal/external rotation (IR/ER). However, determining the precise motion of the ankle joint is inherently complex due to the necessity of three-dimensional imaging techniques, which are vital for capturing the intricate movements of the ankle [3]–[5]. These imaging techniques provide valuable data but can be resource-intensive and not always accessible in all clinical or research settings.

This work has been supported by the Carl Zeiss Foundation through the JuBot project and the German Federal Ministry of Education and Research (BMBF) under the Robotics Institute Germany (RIG).

The integration of sensors into exoskeletons marks an advancement in the continuous monitoring and analysis of user data, particularly concerning motor performance [6]. These devices can provide real-time feedback, enhancing the understanding of joint kinematics and thereby improving rehabilitation protocols and performance assessments. However, most wearable exoskeleton designs primarily optimize for PF/DF motion, offering limited motion or assistance for IN/EV and IR/ER [7], [8]. A notable example is the wearable three DoF exoskeleton developed by Weerasingha et al. [9], which incorporates direct angle measurement via encoders and allows for assistance. However, this system is constrained by its considerable weight and limited torque assistance, highlighting the ongoing challenge of balancing functionality and portability in exoskeleton design. Another three DoF ankle exoskeleton mechanism by Hong et al. [10] uses a configuration of three encoders integrated into a spherical mechanism. These measure all rotations of the ankle joint. However, the proposed device does not include a method for actuation and active assistance. Lack of a rigid supportive three DoF structure requires multi-DoF measurement methods or external sensing systems to determine the accurate state of the exoskeleton. Such an example is the three DoF exoskeleton by Mooney et al. [11], which utilizes struts attached to a hiking boot for torque transmission, facilitating some IN/EV and IR/ER movements. Struts deformations were measured using motion capture (MOCAP) to estimate assistance torques, allowing for a simplified exoskeleton design but limiting its use to a laboratory setting.

Multidimensional DoF measurement of the ankle is also possible with systems exploiting magnetic fields for actuation and sensing [12]. However, the findings indicate that while magnetic fields can facilitate complex motion tracking, they require specialized calibration setups to ensure accuracy, showing the complexities involved in kinematic measurement within multi-DoF systems.

Soft exosuits allow minimally restrictive motion of user joints with structures relying on fabric materials and cables for force transmission. These exoskeletons represent a lightweight alternative with excellent adaptability to various postures and dynamic movements [13], [14]. However, their inherent compliance introduces challenges in achieving accurate kinematic assessments. This difficulty arises primarily from the non-rigid nature of their components and the lack of rigid attachment points, which complicates the use of conventional angular encoder measurements. Instead, novel sensor systems and technologies are proposed, including optoelectronic systems [15], stretchable sensors [16], and

capacitance-based bending sensors [17], to facilitate continuous monitoring of joint angles. To address these challenges, novel sensor systems and technologies have been proposed, including optoelectronic systems [15], stretchable sensors [16], and capacitance-based bending sensors [17], to facilitate continuous monitoring of joint angles despite the adaptability of exosuits. However, these novel sensors are not yet widely accessible.

Alternatively, inertial measurement unit (IMU) sensors are frequently employed for tracking motion in wearable devices, which includes both rigid and soft exoskeletons. Chapman et al. [18] validated IMU-based methods against optical MOCAP systems, demonstrating high accuracy for upper extremity movements. Similarly, Kim et al. [19] confirmed the reliability of IMU sensors in tracking ankle kinematics during running. The quality of measurements can be enhanced through sensor fusion techniques that integrate different modalities. For example, Arceo et al. [20] developed a robust system that combines force sensing resistor (FSR) and IMU sensors to measure both force myography (FMG) signals and limb motion. However, while IMU sensors offer practical solutions for motion tracking, they require extensive calibration to ensure accuracy, and there may be inherent limitations to the precision they can achieve due to factors such as drift and sensor misalignment [21], [22].

This study builds upon prior work to evaluate the feasibility of a 3-DoF ankle exoskeleton equipped with encoders for joint angle estimation [7]. The kinematic design of the ankle exoskeleton enables passive adaptation to IN/EV and IR/ER motion and assistance along PF/DF motion. It features a size adjustable frame and embedded encoders for angle measurement. Notably, the encoders are arranged in a parallel kinematics configuration, meaning that they do not directly represent the three rotations of the ankle joint. This study presents a simplified model to estimate the three ankle rotations based on the encoder values and their combinations. By testing the exoskeleton on two participants during walking, curve walking, and stair-climbing tasks, we examine the system's ability to capture 3-DoF ankle rotations and assess factors influencing its performance. The findings provide valuable insights into design and alignment improvements necessary for future iterations.

The remainder of this paper is structured as follows. Section II details the design of the exoskeleton device, the user study protocol, and the procedures for data collection, postprocessing, and optimization. Section III presents the experimental results, including an analysis of the system's performance in estimating 3-DoF ankle rotations. Section IV explores the implications of these findings, highlighting design considerations and future directions for improvement. Finally, Section V summarizes the contributions of this study and outlines potential avenues for further research.

II. METHODS

A. Exoskeleton

This paper builds on the exoskeleton presented in [7]. The exoskeleton consists of a rigid frame structure that includes a *shank* and a *foot* section, shown in Fig. 1 (left). A series of joints, including a parallelogram mechanism, link the two sections. The *shank* frame has a kinematic design that adjusts to the user's ankle movements. It incorporates 11 DoF, comprising multiple passive 1 DoF joints as well as two passive 3 DoF joints, as illustrated in Fig. 1(right). Additional

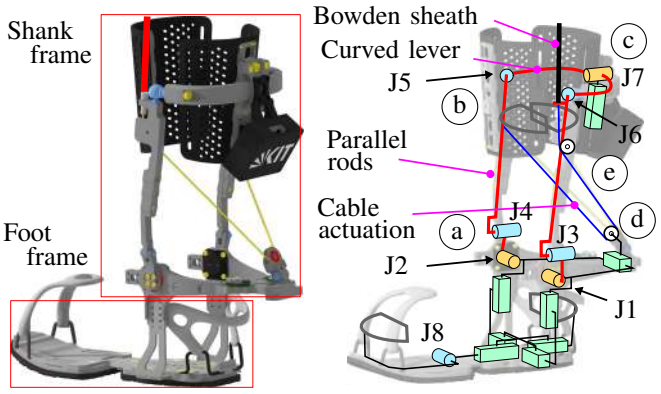

Fig. 1: Exoskeleton shown *left* and the kinematic representation shown *right*. The structure consists of several passive joints: "▭" 1 rotation DoF joint, "●" 3 DoF ball joint, "▭" 1 rotation DoF with an encoder and "▭" 1 DoF manually adjustable translation joint. (reused from [7])

aspects of the *shank* frame include: two cylindrical joints on both sides of the exoskeleton (J1, J2, J3, J4) illustrated in Fig. 1 ⓐ, are intentionally misaligned for a more compact integration of the magnetic encoder. The two ball joints (J5, J6) connect each parallel strut to the curved lever, as shown in Fig. 1 ⓑ, allowing for both IN/EV and IR/ER of the ankle. A cylindrical joint (J7) links the curved lever to the exoskeleton cuff, depicted in Fig. 1 ⓒ, and incorporates the third encoder. Altogether, three of the passive joints (J1, J2, J7) include an integrated absolute encoder (RMB20, RLS d.o.o.) to infer the ankle joint angles. The exoskeleton frame is designed to adjust in multiple dimensions for both the *shank* and *foot* frames, as illustrated in Fig. 1(right).

This passive joint configuration permits all three types of ankle rotation, as shown in Fig. 2. When joints J1 and J2 rotate in the same direction, PF/DF movement occurs. The combined rotation of joints J3 and J4 with joints J5 to J7 facilitates the IN/EV motion. Conversely, rotating joints J1 and J2 in opposite directions alongside joints J5 to J7 allows for the IR/ER. An additional foot frame DoF allows for forefoot rotation.

The *foot* frame design is rigid with one passive DoF for rotation of the forefoot, and several adjustable DoF to fit different shoe sizes. The shoe is secured using toe and heel bails adopted from crampons (Petzl, France).

B. User-study

This user study evaluates the proposed encoder model's effectiveness in estimating the three rotational movements of the ankle across three tasks. Effectiveness is assessed by comparing actual ankle motion, measured independently

TABLE I: Participant Information

Participant	Sex	Height (cm)	Weight (kg)	EU shoe size	Age (y)
pA	female	170	59	40	27
pB	male	178	65	42	22

via MOCAP technology, with ankle measurements from the exoskeleton's three encoders. Two healthy participants performed activities including straight-path walking, curved-path navigation, and stair ascent and descent. Their demographic and physical details are presented in Table I

Both participants provided written informed consent before the study, which followed the ethical guidelines of the Declaration of Helsinki. The experimental protocol was reviewed and approved by the Karlsruhe Institute of Technology (KIT) Ethics Committee as part of the JuBot project's ethical application.

The participants engaged in three distinct tasks: 1) *Normal walking*: This task involved walking along a straight path measuring 3 m in length, with two turnarounds that returned them to the starting position. 2) *Figure-eight walking*: In this task, participants maneuvered along a figure-eight path, designed to simulate slalom walking, measuring 3 m in length and 1.5 m in width, starting and ending at the center of the figure-eight. 3) *stair climbing/descending*: Participants ascended a flight of four steps, paused to turn at the top, and then descended back down the stairs before rotating to return to the starting position. These specific tasks were chosen because they represent common and functionally relevant movement patterns in daily activities and exoskeleton applications. The tasks were conducted in a randomized order, with each task repeated three times to ensure consistency in the data collection. Prior to the session, each participant underwent a 3 min familiarization phase, and resting pauses were provided between conditions and repetitions to minimize fatigue.

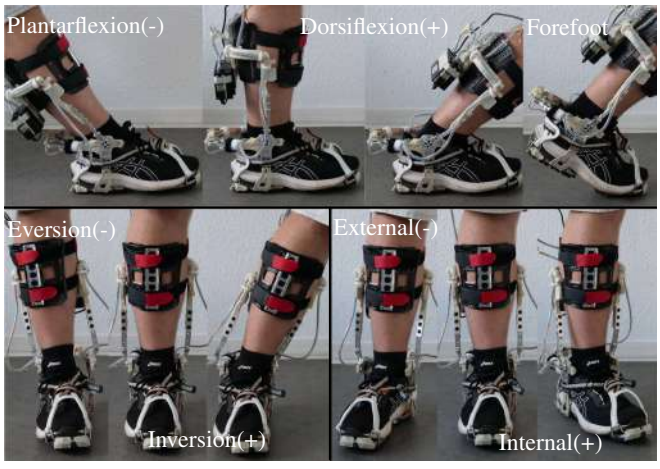

Fig. 2: A display of the exoskeleton's functionality, highlighting the three main ankle joint rotations: PF/DF, IN/EV, and IR/ER, in addition to the forefoot rotation of the foot frame. (reused from [7])

The ankle exoskeleton was fitted to the right leg of each participant and the *foot* frame was adjusted to accommodate the user's shoe size. During the donning process, the exoskeleton's PF/DF axis was aligned with the user's medial malleolus for accurate motion tracking.

The exoskeleton shank was then rotated to achieve symmetry with the sagittal plane and secured in place using adjustable straps. To account for the height of the exoskeleton's rubber sole, a separate *foot* segment was worn on the left leg, ensuring balanced support during the tasks.

C. Data Collection and Post-Processing

During the experiment, the motion of both the user and the exoskeleton was captured independently across all tasks. Passive markers were placed on the participant to track all three rotational movements of the ankle joint using an optical MOCAP system (Vicon Motion Systems, Ltd., UK). Additionally, the exoskeleton's internal sensors, including three encoders and a heel switch, were recorded on the exoskeleton side. A combined trigger signal was employed to synchronize the two data sources effectively. The encoders used are RMB14 (RLS d.o.o., Slovenia) that provide a 12-bit resolution. The MOCAP data was sampled at 100 Hz, while the exoskeleton data was collected at 200 Hz.

At the start of each recording, participants were asked to stand in a relaxed position to establish neutral marker positions and neutral positions of the encoders. After the measurements, the MOCAP data was processed to compute the ankle joint angles, as detailed in [7]. The resulting ankle angles calculated with MOCAP are henceforth named as α_{PFDF}, α_{INEV} and α_{IRER}, to denote ankle PF/DF, IN/EV and IR/ER, and present the ground truth for the subsequent analysis. In the same way, the exoskeleton encoder angles are named as $\varepsilon_{\text{LEFT}}$, $\varepsilon_{\text{RIGHT}}$ and $\varepsilon_{\text{BACK}}$, representing the encoders at position J1, J2 and J7, respectively, as shown in Fig. 1. To align with the exoskeleton's sampling frequency, α_{PFDF}, α_{INEV} and α_{IRER} were interpolated to 200 Hz using the *interp1* function in MATLAB® (R2023a, MathWorks, USA).

In all recordings, the mean of the first 100 data points from each of 6 parameters named above was used to calibrate the measurement to the neutral position. For each participant, all recordings related to a specific parameter were concatenated and used to optimize a personalized, user-specific model. To create the generalized model, recordings from all participants were combined. Finally, the distribution of all angles and encoder measurements was calculated using the MATLAB®function *ksdensity*. For visualization, the heel switch measurements marked the beginning of the right stride during straight and figure-eight walking, while MOCAP data was used to identify the start of stair steps.

D. Mathematical Model and Optimization

This section describes the mathematical model and optimization process used for estimation of ankle angles from encoder measurements. For the modeling, a 3D plane equation was used:

$$ax + by + cz = d, \tag{1}$$

where x, y and z represent the three spatial coordinates of the plane, and a, b, c and d are the plane parameters to be determined through optimization.

For easier interpretation and comparison of the plane parameters, Eq. (1) is rearranged into the following form:

$$z = -\frac{a}{c}x - \frac{b}{c}y - \frac{d}{c}. \tag{2}$$

To simplify the notation, we define the terms $-\frac{a}{c}$, $-\frac{b}{c}$, and $-\frac{d}{c}$ as P_1, P_2, and P_3, respectively. This transforms the equation into:

$$z = f_{\mathrm{i}}(x,y) = P_1 x + P_2 y + P_3, \tag{3}$$

where i is the respective plane fitting. The parameters P_1, P_2 and P_3 were optimized using the nonlinear programming solver *fmincon* in MATLAB®. An initial guess vector $x_0 = [1,1,1]$ was provided, and no bounds were imposed on the search space.

This paper assumes the following parameter relations:

$$\varepsilon_{\mathrm{DIFF}} = \varepsilon_{\mathrm{LEFT}} - \varepsilon_{\mathrm{RIGHT}}, \tag{4}$$

$$\tilde{\alpha}_{\mathrm{PFDF}} = \frac{\varepsilon_{\mathrm{LEFT}} + \varepsilon_{\mathrm{RIGHT}}}{2} + f_{\mathrm{CPFDF}}(\varepsilon_{\mathrm{BACK}}, \varepsilon_{\mathrm{DIFF}}), \tag{5}$$

$$\tilde{\alpha}_{\mathrm{INEV}} = f_{\alpha\mathrm{INEV}}(\varepsilon_{\mathrm{BACK}}, \varepsilon_{\mathrm{DIFF}}), \tag{6}$$

$$\tilde{\alpha}_{\mathrm{IRER}} = f_{\alpha\mathrm{IRER}}(\varepsilon_{\mathrm{BACK}}, \varepsilon_{\mathrm{DIFF}}), \tag{7}$$

where $f_{\mathrm{CPFDF}}(\varepsilon_{\mathrm{BACK}}, \varepsilon_{\mathrm{DIFF}})$ is a plane that estimates a correction factor to improve the $\tilde{\alpha}_{\mathrm{PFDF}}$ calculated using the average of $\varepsilon_{\mathrm{LEFT}}$ and $\varepsilon_{\mathrm{RIGHT}}$. And $\tilde{\alpha}_{\mathrm{INEV}}$ and $\tilde{\alpha}_{\mathrm{IRER}}$ are estimated directly from the corresponding planes $f_{\alpha\mathrm{INEV}}$ and $f_{\alpha\mathrm{IRER}}$, respectively.

III. Results and Analysis

A. Optimized Parameters

A simple plane fitting was conducted for both individual participants (personalized model) and for the combined data from both participants (generalized model). Table II displays the optimized parameters for the three planes: f_{CPFDF}, $f_{\alpha\mathrm{INEV}}$ and $f_{\alpha\mathrm{IRER}}$, which correspond to the ankle rotations α_{PFDF}, α_{INEV}, and α_{IRER}, respectively. While $f_{\alpha\mathrm{INEV}}$ and $f_{\alpha\mathrm{IRER}}$ directly represent the estimated ankle angles, f_{CPFDF} functions as a correction factor that is added to the average readings from the left and right encoders. This correction improves the estimation the PF/DF angle, as shown in Eq. (5).

The goodness of fit for each plane is assessed using the RMSE, with lower values indicating a closer alignment to the recorded data. Table II presents the RMSE values calculated for both the individualized models and the generalized model. The table comprises three rows: one for the individual models of participants pA and pB, and another for the generalized model (pAB). The parameters P_1, P_2, and P_3 define the orientation of each plane relative to the three axes, providing insight into how well the models represent the actual ankle movements. Normalized RMSE values from this table are presented in Table III to account for different range of motion (RoM).

Participant pB consistently demonstrates the lowest RMSE values across all three parameters (f_{CPFDF}, $f_{\alpha\mathrm{INEV}}$, $f_{\alpha\mathrm{IRER}}$), indicating the most accurate fit of the modeled planes. Notably, the RMSE values for participant pB are smaller for nearly 30% of those recorded for participant pA in both f_{CPFDF} and $f_{\alpha\mathrm{INEV}}$. This disparity suggests that participant pB's movement patterns align more closely with the modeled planes, resulting in a superior fit. In contrast, participant pA exhibits higher RMSE values for all parameters, underscoring a less precise correspondence between their motion and the fitted model.

The generalized model (pAB) yields root RMSE values that lie between those of the individual participants. This suggests that while the combined model captures overarching trends across both participants, it sacrifices some specificity achieved by the individualized models. Although the generalized model results in slightly higher RMSE values, the differences are relatively small, indicating that it could serve as a practical approximation. Nonetheless, its performance may still be enhanced through further fine-tuning for each participant to improve accuracy.

The plane parameters P_1, P_2, and P_3 provide valuable insights into the relative contributions of the encoders in estimating each plane. For f_{CPFDF}, parameters P_1 and P_2 consistently dominate across all cases, while P_3 remains close to zero, suggesting a negligible influence on the estimation. A similar pattern is observed for $f_{\alpha\mathrm{INEV}}$, where P_2 and P_3

TABLE II: Optimized Parameters for 3D Plane Fitting Across Ankle Rotations

	f_{CPFDF}				$f_{\alpha\mathrm{INEV}}$				$f_{\alpha\mathrm{IRER}}$			
Participant	P_1	P_2	P_3	RMSE	P_1	P_2	P_3	RMSE	P_1	P_2	P_3	RMSE

Entry pAB represents combined recordings. P_1, P_2, and P_3 define the 3D plane orientation, with root-mean-squared error (RMSE) measuring fit accuracy.
[1] and [2] denote RMSE values for personalized and generalized models, respectively.

TABLE III: RoM Normalized RMSE values

Partic.	f_{CPFDF} nRMSE (%)	f_{CPFDF} RoM (deg)	$f_{\alpha\text{INEV}}$ nRMSE (%)	$f_{\alpha\text{INEV}}$ RoM (deg)	$f_{\alpha\text{IRER}}$ nRMSE (%)	$f_{\alpha\text{IRER}}$ RoM (deg)
pA	4.84[1]	60.8	4.29[1]	33.4	3.88[1]	47.6
	4.86[2]	60.8	4.35[2]	33.4	3.97[2]	47.6
pB	3.39[1]	63.3	4.83[1]	20.3	3.52[1]	37.6
	3.46[2]	63.3	4.91[2]	20.3	3.64[2]	37.6
pAB	3.73	67.9	3.61	33.4	3.78	47.6

Entry pAB represents combined recordings. [1] and [2] denote RMSE values for personalized and generalized models, respectively. nRMSE (%) is normalized as RMSE/RoM × 100, using RoM from MOCAP angles and RMSE table III.

emerge as the dominant parameters. In contrast, for $f_{\alpha\text{IRER}}$, parameters P_1 and P_3 are identified as the most influential. In the $f_{\alpha\text{INEV}}$ plane, the parameter P_2 consistently hovers around 1.009 across participants, indicating a strong and stable contribution from a specific orientation in the plane fitting. Furthermore, the RMSE values for $f_{\alpha\text{INEV}}$ are relatively low, suggesting a good overall fit for this motion parameter. For $f_{\alpha\text{IRER}}$, slight variations in P_1 are observed across participants, particularly between the individual models. While the RMSE values for $f_{\alpha\text{IRER}}$ are higher than those for $f_{\alpha\text{INEV}}$, they remain moderate, reflecting a reasonable fit for this parameter.

Overall, participant pB's lower RMSE values across all parameters indicate more consistent and controlled movement patterns in relation to the exoskeleton encoders.

B. Range of Motion Analysis

For additional insights, Fig. 3 illustrates the distribution of measurement points across the RoM for the three ankle

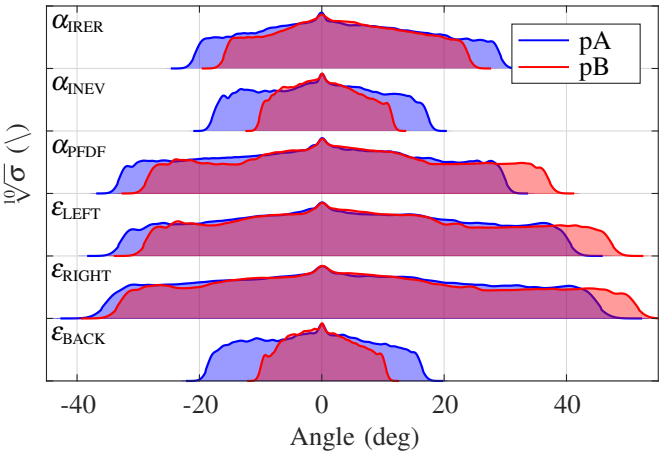

Fig. 3: Visualization of the distribution of ankle joint angles (α_{PFDF}, α_{INEV} and α_{IRER}) measured using MOCAP and exoskeleton encoder readings ($\varepsilon_{\text{LEFT}}$, $\varepsilon_{\text{RIGHT}}$ and $\varepsilon_{\text{BACK}}$) for two participants. The 10th root scaling of density values improves visualization of data distribution, especially in regions of high density.

angles (α_{PFDF}, α_{INEV} and α_{IRER}) alongside the three exoskeleton encoders ($\varepsilon_{\text{BACK}}$, $\varepsilon_{\text{LEFT}}$ and $\varepsilon_{\text{RIGHT}}$) for both participants. To improve visualization and address uneven data density, a 10th root scaling is applied to the density values. The intra-participant differences in the RoM for the α_{IRER} and α_{INEV} angles reach up to 10°. Notably, participant pB demonstrates a narrower RoM for both angles.

The RoM of α_{INEV} closely aligns with that of $\varepsilon_{\text{BACK}}$. Similarly, the RoM of the $\varepsilon_{\text{LEFT}}$ and $\varepsilon_{\text{RIGHT}}$ align with the α_{PFDF} for both participants. However, discrepancies are observed between the RoM of the $\varepsilon_{\text{LEFT}}$, $\varepsilon_{\text{RIGHT}}$, and α_{PFDF} angles.

Given the direct alignment of $\varepsilon_{\text{LEFT}}$ and $\varepsilon_{\text{RIGHT}}$ with the α_{PFDF} axis, these differences may indicate either a misalignment between the exoskeleton and the ankle joint or limitations in the MOCAP angle measurement principle described in [7] to fully capture the α_{PFDF} movement.

A notable observation in Fig. 3 and Table II is the inter-participant variation in both RoM and RMSE values. Table III addresses this by normalizing the RMSE values to RoM, aiming to reduce the impact of RoM variation. The table presents nRMSE values for the correction factor (f_{CPFDF}) and the two ankle angle estimates ($f_{\alpha\text{INEV}}$, and $f_{\alpha\text{IRER}}$) for two participants and two model types (personalized and generalized).

Participant pB demonstrates a smaller RoM for the $f_{\alpha\text{INEV}}$ and $f_{\alpha\text{IRER}}$ estimates compared to participant pA; however, the RoM for f_{CPFDF} is of similar magnitude between the two participants. Following normalization of the RMSE, participant pB exhibits lower nRMSE values for both f_{CPFDF} and $f_{\alpha\text{IRER}}$. In contrast, the nRMSE value for $f_{\alpha\text{INEV}}$ is higher in participant pB than in participant pA. The data indicate that the nRMSE values for $f_{\alpha\text{INEV}}$ and $f_{\alpha\text{IRER}}$ are much closer when accounting for the differences in RoM. Conversely, the nRMSE values for f_{CPFDF} remain distinct even after scaling by RoM, suggesting that the discrepancies in this parameter are more pronounced.

C. Ankle Rotation Estimate

This section examines the ankle joint motion of participant pA, who exhibited higher RMSE values compared to the other participant, necessitating closer analysis. Figure 4 compares MOCAP-derived measurements with encoder-based model predictions for three parameters: α_{PFDF}, α_{INEV}, and α_{IRER}. Both participant-specific (pA) and generalized (pAB) models are assessed for normal walking (left column) and stair ascending (right column).

The top row of Figure 4 shows the α_{PFDF} parameter, with three estimates compared against the MOCAP data. The first estimate is derived as a simple average of the left and right exoskeleton encoders ($\frac{\varepsilon_{\text{LEFT}}+\varepsilon_{\text{RIGHT}}}{2}$). The second incorporates a participant-specific correction factor ($f_{\text{CPFDF,pA}}$), while the third applies a generalized correction factor ($f_{\text{CPFDF,pAB}}$).

For the walking task, correction factors don't visibly improve the $\tilde{\alpha}_{\text{PFDF}}$ estimate, though slight improvements are seen during stair ascending. Discrepancies include overestimation of maximum dorsiflexion (DF) during heel touch in walking and pronounced deviation at maximum DF during

stair ascending. However, the model accurately captures minimum values in both tasks.

The $\tilde{\alpha}_{\text{INEV}}$ parameter exhibits closer alignment with the MOCAP measurements. Both walking and stair ascending tasks show well-captured trends, but also features small discrepancies. Interestingly, the results indicate no visible differences between the personalized and generalized models, suggesting comparable performance across both conditions.

For $\tilde{\alpha}_{\text{IRER}}$, the estimates demonstrate strong agreement with the MOCAP measurements during walking but show a poorer match during stair ascending. Larger deviations occur at extreme angles or during rapid transitions. Similar to $\tilde{\alpha}_{\text{INEV}}$, no visible differences are observed between the personalized and generalized models.

IV. DISCUSSION

The proposed approach successfully estimates ankle angles, with better performance for IN/EV and IR/ER compared to PF/DF, where maximum dorsiflexion was not well-captured. A major source of error presumably stems from the misalignment between the exoskeleton's axes and the user's biological joint axes. This misalignment is evidenced by the discrepancies observed between the RoM ankle PF/DF and the corresponding encoder ($\varepsilon_{\text{LEFT}}$ and $\varepsilon_{\text{RIGHT}}$) readings from the exoskeleton, as illustrated in Fig. 3. Based on the exoskeleton design, the PF/DF axis of the exoskeleton can be directly aligned with the PF/DF axis of the ankle joint. However, despite efforts to position the exoskeleton in relation to the outer malleolus of the ankle, challenges persist in achieving accurate alignment with the center of rotation of the ankle, particularly given the complexities associated with the 3 DoF design of the exoskeleton. This misalignment impacts the mapping of encoder readings to joint angles, especially for PF/DF, where precise alignment is evidently more critical than for the other two axes (IN/EV and IR/ER). Although users reported a high level of comfort while using the exoskeleton, any compliance in the shoe or attachment mechanism may have further contributed to discrepancies in alignment and motion, potentially affecting the overall effectiveness of the device.

The RMSE values reveal inter-participant variability, with participant pB demonstrating RMSE values nearly 30% lower than those of participant pA, as illustrated in Table II. Notably, RoM between the two participants exhibits visible differences, as depicted in Fig. 3. This variability suggests that individual factors, such as anthropometry and walking style, may play a large role in influencing estimation accuracy. These findings highlight the necessity for improved

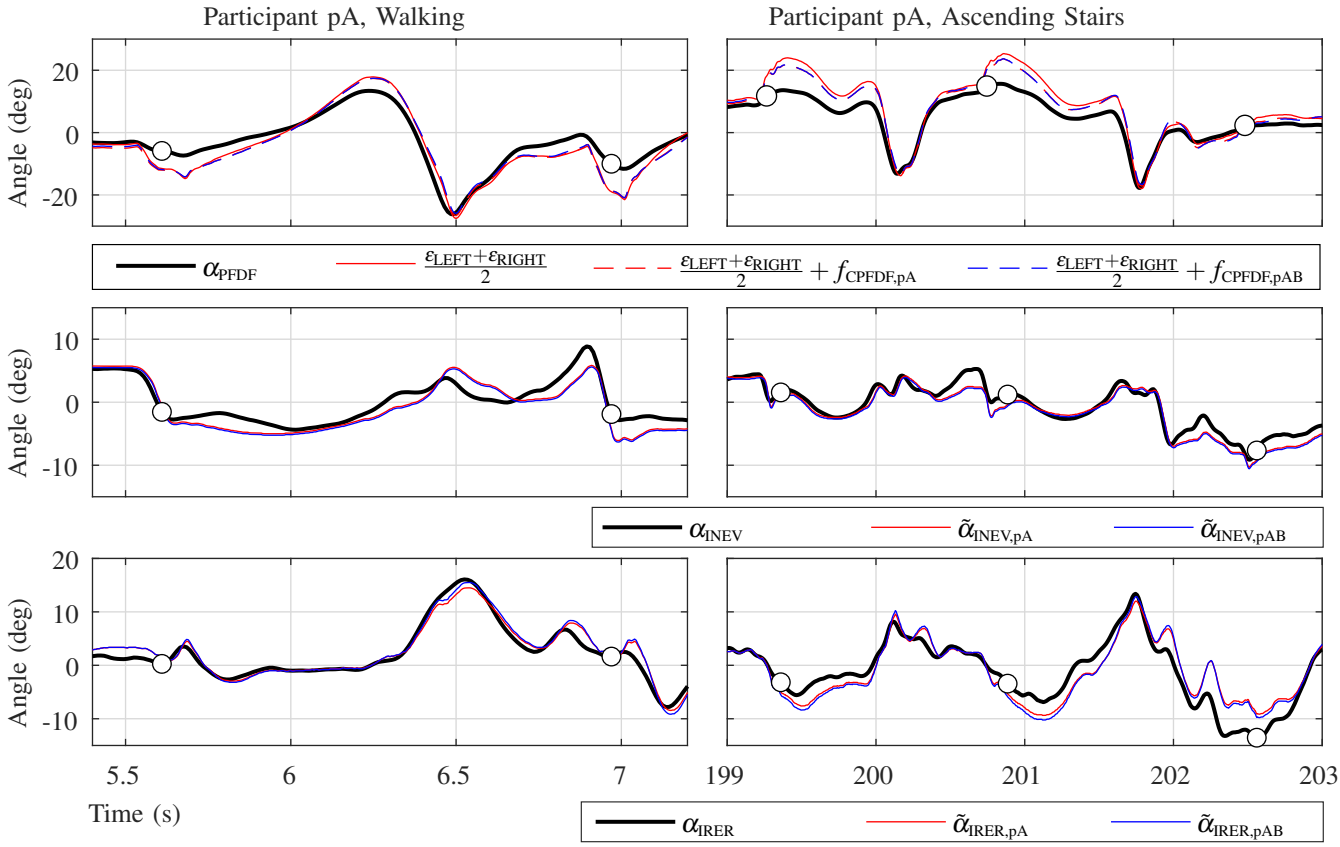

Fig. 4: Comparison of MOCAP-derived measurements (black lines) with encoder-based model predictions for f_{CPFDF}, α_{INEV}, and α_{IRER}. The participant-specific model (pA, red) and generalized model (pAB, blue) are evaluated. The top row shows the effect of correction factors on α_{PFDF}, improving alignment with MOCAP data. The middle and bottom rows illustrate the modeled values of α_{INEV} and α_{IRER}. The white point marks the stride

alignment protocols and the inclusion of larger sample sizes in future studies to enhance the generalizability of model performance. The RMSE values for PF/DF further emphasize the critical importance of achieving proper alignment along this axis to ensure accurate measurements. Consequently, future designs of exoskeletons should prioritize mechanical adjustments aimed at optimizing alignment, particularly for PF/DF, as well as implementing strategies to mitigate the effects of compliance and foot movement within the exoskeleton.

The current methodology, which evaluates each angle separately and relies on plane fitting, may limit the overall accuracy of the model. Personalizing the model yielded only marginal improvements compared to the generalized approach, showing potential for simplifications and generalization. The observed inter-participant variability underscores the necessity of a larger sample size for a robust evaluation of the model. Additionally, observed discrepancies at the peaks of motion indicate that factors such as velocity and dynamic effects, including tissue compliance, need to be integrated into future models. To address these limitations, a more unified approach that combines the assessment of multiple angles and incorporates additional parameters—potentially through machine learning techniques—could enhance both performance and generalizability.

V. CONCLUSION

This study demonstrates the potential of encoder-based models for estimating ankle angles in parallel exoskeletons, but challenges remain due to alignment issues, compliance effects, and inter-participant variability. While the current model is a step toward understanding the relationship between ankle motion and encoder readings, further research is needed to refine the approach. This includes incorporating additional parameters, testing with larger and more diverse participant pools, and exploring more advanced machine learning techniques. Ultimately, these efforts could improve the accuracy and generalizability of the model, paving the way for enhanced exoskeleton performance.

Kinematics Estimation Using a Skin-Adhesive Strain Patch for Shoulder Rehabilitation: A Preliminary Study*

Chan Beom Park, Hyeok-Jun Kwon, Seongok Chae, Su Jae Lee, Seong Hyun Kim, and Hyung-Soon Park, *Member, IEEE*

***Abstract*— Shoulder kinematics has been required to be estimated using compact sensors to provide visual feedback on joint movements for patients undergoing home rehabilitation due to musculoskeletal diseases, such as stroke. Multiple strain patches have been used for shoulder kinematics estimation, either embedded in tight shirts or attached directly to the skin. However, it is desirable to eliminate the tight shirt while minimizing the number of strain patches for convenient use in home rehabilitation. This study presents a single all-in-one skin-adhesive strain patch that enables shoulder kinematics estimation through placement optimization. At the optimal on-skin position, strains caused by flexion-extension and abduction-adduction movements were generated significantly in different directions. The fabricated all-in-one strain patch measured these strains using embedded sensors oriented accordingly. Moreover, the patch was designed to be lightweight and ultra-thin, allowing for convenient attachment to the skin. Shoulder kinematics estimation using this strain patch was preliminarily evaluated with a subject, demonstrating that shoulder joint angles could be estimated with an average error of 15.8% of the range of motion for two degrees of freedom. The placement optimization reduced the total number of strain patches required for kinematics estimation, enhancing convenience for daily use.**

I. Introduction

Compact sensor-based shoulder kinematics estimation is necessary in home rehabilitation for motion-based visual feedback. Patients with musculoskeletal diseases, such as stroke, require adjustments in muscle activation coordination of the upper limb through rehabilitation [1-3] to improve functional outcomes, which can be facilitated by providing visual feedback based on shoulder movements [4-8]. Although various contactless sensors, such as camera, have been used to estimate joint movements [9-11], the bulky cameras required for such systems are less convenient for daily use. Therefore, compact sensors have been used for shoulder kinematics estimation

S. J. Lee and S. H. Kim are with the Flexible Electronics Research Section, Electronics and Telecommunications Research Institute , Daejeon 34129, South Korea (e-mail: leesujae@etri.re.kr; kimsh@etri.re.kr).

Tight shirts can estimate shoulder kinematics from measured skin strains using embedded strain patches [12-15]; however, their tightness, required to prevent slippage between the sensors and skin, causes inconvenience. The shirts should be designed to be tight, as measuring skin strain becomes challenging when slippage occurs between the skin and the strain sensors. However, it is desirable to design sensors that avoid applying strong pressure to the skin for convenient use. Moreover, these shirts pose challenges for use in harsh conditions, such as hot weather, due to sweating. Therefore, shoulder kinematics has been estimated using skin-adhesive strain patches.

Although shoulder kinematics can be estimated using multiple skin-adhesive strain patches [16-19], the number of patches should be minimized for convenient use. To estimate shoulder kinematics using conventional strain patches, multiple patches, each comprising a single strain sensor, should be attached distantly around the shoulder in different directions. However, considering the inconvenience caused by multiple patches, it is desirable to utilize a single strain patch for estimation.

The main objective of this paper is to present a skin-adhesive all-in-one strain patch capable of estimating shoulder kinematics by optimizing its placement based on strain distribution analysis during movements, which was preliminarily verified in an experimental setup. Three strain sensors, oriented in different directions, were embedded in the patch. Moreover, the patch was designed to be stretchable and ultra-thin, allowing it to be attached to the skin without causing discomfort. By optimizing the sensor placement, it was demonstrated that shoulder kinematics in two degrees of freedom (DOFs) could be predicted using the strain patch. This study includes the procedure for placement optimization, the evaluation method, and an assessment of its significance.

II. Materials and Methods

A. Overall Procedure for Shoulder Kinematics Estimation

Shoulder kinematics in two DOFs is preliminarily estimated using a single all-in-one strain patch, with its placement determined through optimization (Fig. 1). Placement optimization identifies the optimal on-skin position where the skin strains caused by horizontal flexion/extension (F/E) and abduction/adduction (A/A) movements are decoupled in different directions (i.e., principal strain) and show significant changes corresponding to its respective shoulder movements. The location of the optimal on-skin position is determined by measuring variations in the distance between reflective markers on a marker grid placed around the

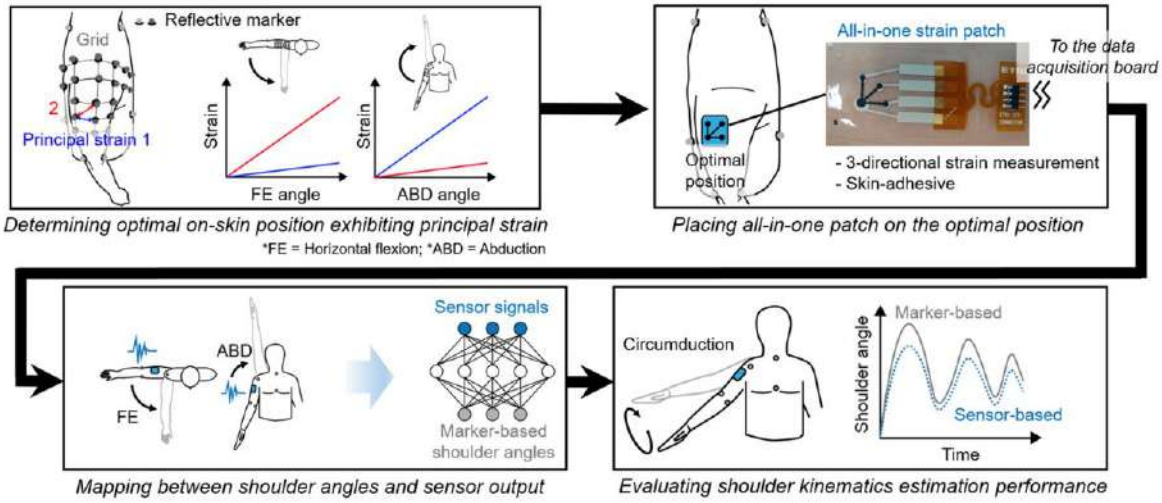

Fig. 1. Overall shoulder kinematics estimation procedure using the all-in-one strain patch through sensor placement optimization.

shoulder during F/E and A/A tasks. The all-in-one strain patch is then attached to the optimal on-skin position to measure the skin strains using embedded three strain sensors. The relationship between the sensor output and shoulder horizontal flexion (FE) and abduction (ABD) angles, measured by a marker-based setup during F/E and A/A tasks, is then established using machine learning. Using the established relationship, it is evaluated whether the single all-in-one strain patch, placed at the optimal position, can predict the targeted shoulder joint angles.

B. Subject Recruitment

A healthy 29-year-old male subject was recruited for evaluation of shoulder kinematics estimation. Exclusion criteria included subjects with limited shoulder joint range of motion (ROM) due to diseases, such as neurological impairments. This study was approved by the institutional review boards of the Korea Advanced Institute of Science and Technology (KH2022-048). The subject provided written consent before the study.

C. All-in-one Strain Patch Design

The all-in-one strain patch was designed to measure strains in different directions at the on-skin position (Fig. 2a). Graphite paste was applied to a polydimethylsiloxane (PDMS) substrate to sense strain changes in the 0°, 45°, and 90° directions. Voltage was applied to the graphite paste through silver (Ag) paste on the PDMS to measure the change in resistance (ΔR) relative to the initial resistance value (R_0), as shown in Fig. 2a. The total thickness of the all-in-one strain patch was less than 600 μm, allowing it to be easily attached to the skin. Note that a data acquisition board was used to acquire sensor resistance and transmit it to the PC via Bluetooth.

The resistance of the all-in-one strain patch showed linearity with respect to stretching (Fig. 2b). It was experimentally confirmed that the resistance linearly increases as the strain patch is stretched. Moreover, the sensitivity of the resistance variation to stretching converged to a consistent value with higher stretching cycles. However, the all-in-one strain patch exhibited non-linearity due to hysteresis (Fig. 2c) during cyclic stretching and velocity dependency.

D. Placement Optimization

The optimal on-skin position was identified based on the skin strains caused by F/E and A/A movements. All skin

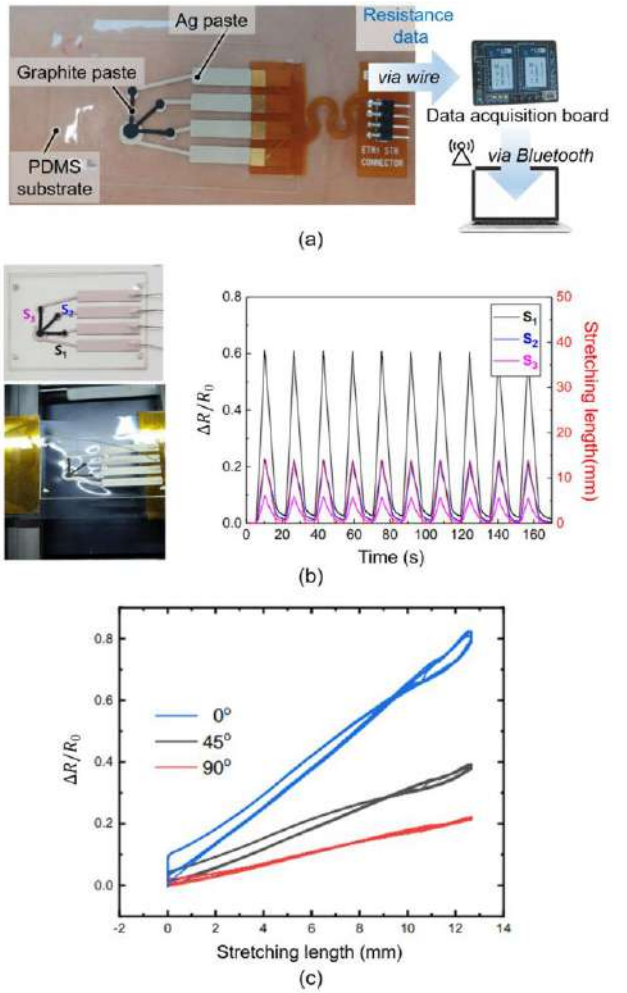

Fig. 2. Characteristics of the all-in-one strain patch. (a) Three strain sensors were embedded in the all-in-one strain patch to measure strain in different directions, (b) Resistance variation of the all-in-one strain patch by stretching, (c) Hysteresis observed in the all-in-one patch during stretching and releasing.

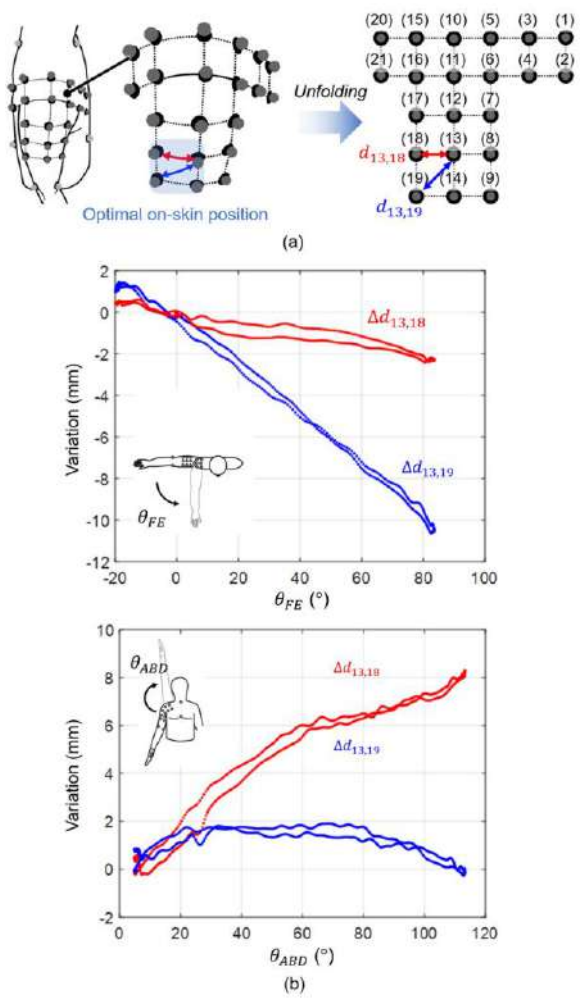

Fig. 3. Obtaining the optimal on-skin position by strain distribution analysis. (a) Identifying the optimal on-skin position where principal strains by shoulder joint movements are exhibited, (b) $d_{13,18}$ and $d_{13,19}$ were significantly changed by horizontal flexion/extension and abduction/adduction movements, respectively. Note that θ_{FE} and θ_{ABD} indicate horizontal flexion and abduction angles, respectively.

strains caused by these movements were measured using markers on a marker-grid placed around the shoulder (Fig. 3a). A marker grid was positioned around the shoulder, enabling the measurement of variations in distance between skin-to-skin positions using a motion capture system (VICON motion systems, Oxford, United Kingdom) at data acquisition frequency of 100 Hz. Note that this marker grid was designed to cover areas from the chest to the upper limb and the back. The distances between all adjacent markers within the grid were obtained during F/E and A/A tasks. Note that $d_{i,j}$ in Fig. 3a indicates the distance between the markers indexed by i and j. Thereafter, by using distance variations, the optimal on-skin position, where significant strains (i.e., principal strain) are generated by F/E and A/A movements in decoupled orientations, was determined. To find this position, two adjacent strains that significantly change due to only F/E and A/A movements, respectively, were identified among all strains by calculating their ratio during F/E and A/A movements, as follows:

$$\left\| \left(\left| \frac{\Delta d_{i,j,FE}}{\Delta d_{k,l,FE}} \right|, \left| \frac{\Delta d_{k,l,ABD}}{\Delta d_{i,j,ABD}} \right| \right) \right\|, where\ i = k\ or\ j = l \quad (1)$$

$\Delta d_{i,j,FE}$ and $\Delta d_{k,l,FE}$ indicate the distance variations between the markers indexed by i and j, and k and l, respectively, during the F/E movement. $\Delta d_{i,j,ABD}$ and $\Delta d_{k,l,ABD}$ indicate the distance variations between the markers indexed by i and j, and k and l, respectively, during the A/A movement. Note that (1) can be maximized at the optimal position due to the principal strains.

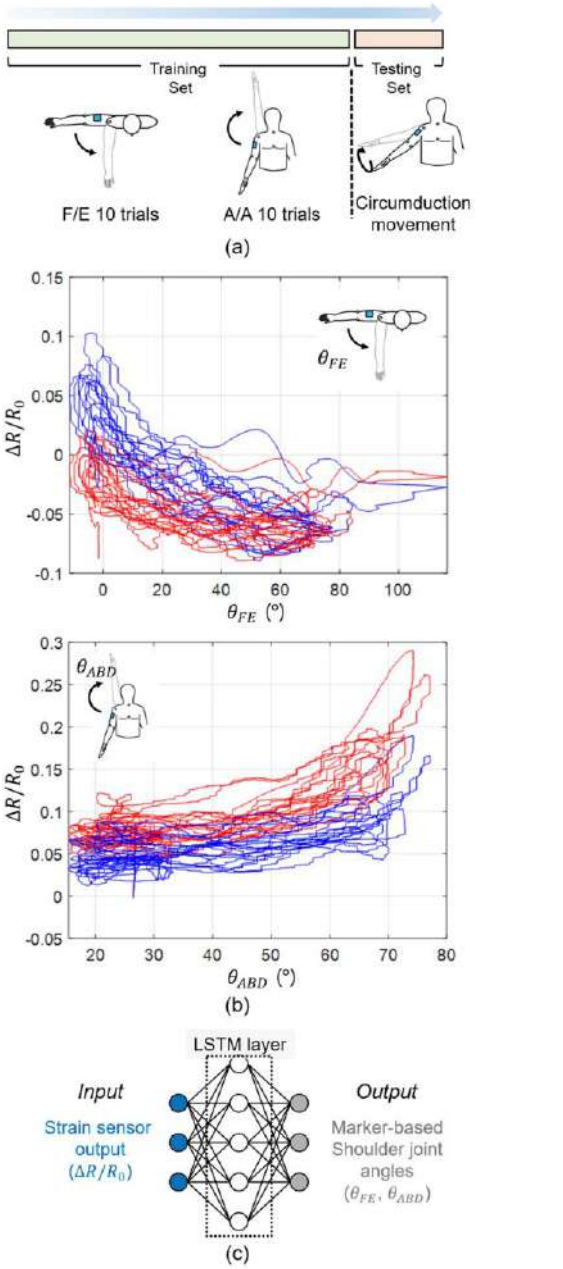

Fig. 4. Procedure to obtain relationship between sensor resistances and shoulder joint angles. (a) Sensor resistances and marker-based shoulder joint angles, measured during 10 repetitions of horizontal flexion-extension (F/E) and abduction-adduction (A/A) movements, were used for mapping. The all-in-one strain patch and reflective markers were attached for the measurement, (b) Recorded sensor resistances and shoulder joint angles. Note that θ_{FE} and θ_{ABD} indicate horizontal flexion and abduction angles, respectively, (c) Long-term short memory (LSTM) layer used to establish relationship between sensor resistances and shoulder joint angles.

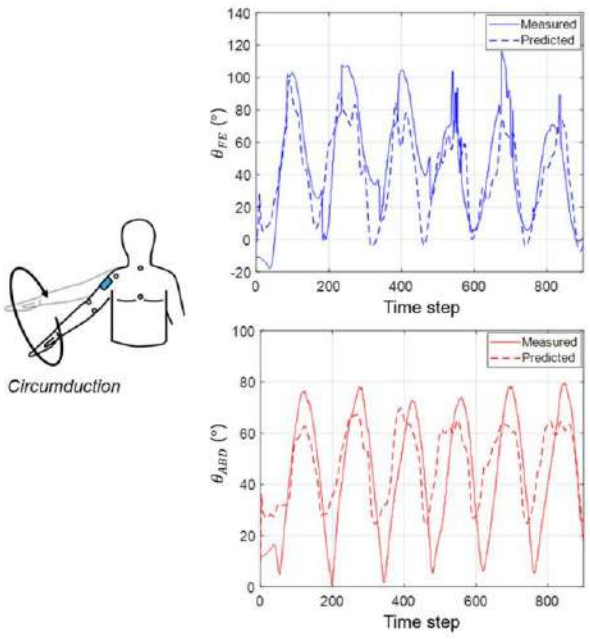

Fig. 5. Prediction results of θ_{FE} and θ_{ABD} using recorded resistance variations of the all-in-one strain patch. Note that θ_{FE} and θ_{ABD} indicate horizontal flexion and abduction angles, respectively.

The optimal skin position was found to be located at the marker indexed by 13 in Fig. 3a. Note that the principal strain (i.e., $d_{13,18}$ and $d_{13,19}$) on the optimal skin position and the corresponding shoulder joint angle exhibited a strong linear relationship (Fig. 3b).

E. Mapping between Shoulder Kinematics and Sensor Output

The relationship between the shoulder joint angle and the resistance variations of the all-in-one strain patch was established. To establish this relationship, the all-in-one patch was attached to the optimal on-skin position. Note that the reflective markers were simultaneously attached for shoulder joint angle measurement. The sensor resistances and marker trajectories were then recorded during 10 repetitions of F/E and A/A movements (Fig. 4a). Note that the sensor resistances were recorded at a frequency of 25 Hz. The subject was instructed to flex the shoulder horizontally and abduct it maximally for 2, 4, and 6 seconds, respectively. Using the recorded data (Fig. 4b), the relationship between the sensor resistances and marker-based shoulder joint angles was established using a machine learning (Fig. 4c). While the principal strain on the skin and the targeted shoulder joint angle exhibited a highly linear relationship, as shown in Fig. 3b, velocity dependency and hysteresis of the sensor led to non-linearity. Therefore, a single long short-term memory (LSTM) layer was used to establish the relationship using MATLAB software (MathWorks Inc. Natick, United States) with an Adam-based solver.

F. Evaluation Methods

1) Shoulder Kinematics Estimation: The estimation accuracy of shoulder kinematics using the all-in-one strain patch was evaluated. The subject was instructed to move the shoulder in circumduction (Fig. 4a), with the all-in-one strain patch attached to the determined optimal on-skin position. Note that reflective markers were also placed on the body to obtain marker-based shoulder joint angles (i.e., ground truth). Using the recorded sensor output, the FE and ABD angles were predicted and then compared with the ground truth.

2) Comfort: The subject was asked to mark a 10-cm-long line to indicate their satisfaction with the all-in-one strain patch in terms of comfort.

III. Results

A. Shoulder Kinematics Estimation

Shoulder kinematics could be estimated using the single all-in-one strain patch (Fig. 5). It was confirmed that the shoulder joint angle could be predicted with an error of 18.0° ± 11.7° for F/E and 14.9° ± 9.2° for A/A. These errors corresponded to 12.9% and 18.6% (15.8% on average) of their respective maximal ROM observed during the circumduction movement. The error was most significant when the shoulder joint was in a maximally flexed or abducted posture and was considered to be primarily attributed to the velocity-dependency and hysteresis of the sensor. Note that the trained LSTM layer could predict the training data set with a root mean square error (RMSE) less than 7.5°.

B. Comfort

The strain patch was rated 9.0 by the subject for comfort. The reduced score was attributed to the rigidity of the data acquisition board required to acquire the sensor output. Nonetheless, due to lightweight design of the patch (i.e., 2 g), the subject reported negligible inertia force from the sensor during shoulder movement. Additionally, no detachment of the patch from the skin was observed.

IV. Discussion

In this study, we present a skin-adhesive all-in-one strain patch capable of estimating shoulder kinematics through placement optimization based on the strain distribution analysis of skin during movements. The placement optimization enabled the single patch, where three strain sensors are embedded, to estimate shoulder kinematics by measuring skin strains generated during F/E and A/A movements. Specifically, the optimal skin position, where strains caused by F/E and A/A movements are decoupled, was identified, and the corresponding strains were measured by attaching the strain patch. Thus, by establishing the relationship between skin strains and shoulder joint angles, shoulder kinematics in two DOFs was predicted. For a single subject, it was preliminarily demonstrated that shoulder kinematics could be estimated using the single patch with optimized placement. Moreover, due to the lightweight (i.e., 2 g) and ultra-thin (i.e., < 600 μm) characteristics of the patch, the subject reported comfort while moving the shoulder with the patch attached.

The placement optimization can reduce the number of strain patches required for shoulder kinematics estimation. Shoulder kinematics have typically been estimated using a number of skin-adhesive strain patches equal to the targeted shoulder DOFs [16-18]. However, minimizing the number of

strain patches used for shoulder kinematics estimation is desirable for convenient use in daily life. Identifying the optimal on-skin position, where principal strains are generated, allows for the use of a single all-in-one strain patch to estimate shoulder joint angles. For the subject, this optimal on-skin position was found to be located on the upper limb, rather than near the shoulder. Note that the skin strains near the shoulder were influenced by both F/E and A/A movements. Additionally, the optimal on-skin position was easily accessible to the subject, allowing the all-in-one strain patch to be attached without assistance, demonstrating its potential for convenient use. This optimal on-skin position may vary between individuals due to differences in skin conditions, requiring placement optimization for each subject based on the strain distribution analysis of skin before use.

The principal strain and the corresponding shoulder joint angle show a strong linear relationship during movements, indicating the possibility of shoulder kinematics estimation without the use of machine learning. However, despite the linear relationship, machine learning was necessary due to the non-linearity between strain and sensor resistance, caused by velocity dependency and hysteresis, resulting in an error of 15.8% in kinematics estimation. This error was greater than the estimation accuracy reported with a tight shirt (i.e., 2.0% [12]) and comparable to that of multiple strain patches (i.e., 11.3% [16]). Although precise joint angle estimation using the strain patch was challenging, shoulder posture was considered sufficiently predictable, potentially allowing its application in rehabilitation games.

This study has limitations. Internal/external rotation was excluded from the kinematics estimation performed by the all-in-one strain patch. Moreover, the feasibility of using the all-in-one patch for shoulder kinematics estimation was preliminarily demonstrated only with a young subject. Further evaluation on elderly individuals is needed, as varying skin conditions may affect estimation accuracy. Additionally, the LSTM layer used in this study requires refinement to enhance shoulder kinematics estimation accuracy.

V. Conclusion

This study presents an all-in-one strain patch with optimized on-skin placement for shoulder kinematics estimation. To facilitate rehabilitation, minimizing the number of skin-adhesive strain patches required for motion feedback is essential. To achieve this, we propose a methodology to reduce the number of patches needed for the kinematics estimation. It was preliminarily demonstrated that shoulder kinematics could be predicted using the single patch at the optimal on-skin position.

In future studies, this placement optimization approach will be applied to the estimation of shoulder kinematics in 3 DOFs with more subjects. Additionally, to improve estimation accuracy, the LSTM layer will be refined by incorporating more layers and using additional sensor and shoulder joint angle data sets for training, while minimizing both the velocity dependency and hysteresis of the sensor patch through material optimization.

Comparative Analysis of Force Myography and Electromyography Signals in Isokinetic Ankle and Knee Joint Motion

Charlotte Marquardt*‡, Gunther Kurz†, Miha Dežman*, Thorsten Stein† and Tamim Asfour*‡

***Abstract*— Exoskeletons aim to enhance mobility by integrating muscle-level biomechanics and by addressing limitations like personalized control, with sensing methods such as electromyography (EMG) and force myography (FMG) to provide biofeedback. Previous comparative analyses of EMG and FMG were focused on specific classification and regression tasks without accounting for the full range of motion (RoM) of the human joints. This paper presents a descriptive analysis of both FMG and EMG signals of eight leg muscles obtained in a user study with ten participants, comparing both signals and their variations across the complete RoM of the ankle and knee joints during isokinetic motion at four different joint angular velocities. Results indicate that FMG signals exhibit higher repeatability in maximum amplitude and the corresponding joint angle, though they show higher variability in the signals' full width at half maximum. While EMG features are influenced by changes in angular velocities, FMG signals appeared to be more susceptible to cross-talk caused by opposing muscle activities. This analysis contributes to a better understanding of the relationship between FMG and EMG and their potential applications in the control of assistive wearable technologies.**

I. INTRODUCTION

Wearable robotic systems such as exoskeletons are created to aid or enhance mobility. While the primary focus of these devices has been on joint biomechanics, there is a growing interest in integrating muscle-level biomechanics for more effective interaction with the user's musculoskeletal system. Incorporating muscle-level biomechanics into the design and control of exoskeletons has the potential to address current limitations, such as the lack of personalized control. This includes the manual adjustment of control parameters for each user and monitoring user fatigue or energy expenditure [1]. Research on muscle biomechanics offers valuable data and insights for understanding human movements and joint function, thereby enhancing the effectiveness of exoskeleton control [2].

Muscle contraction is influenced by the frequency of electrical action potentials. The central nervous system activates slow muscle fibers at low frequencies and fast muscle fibers at high frequencies. Engaging more motor units, especially fast ones, during movement leads to greater force and more dynamic contractions [3]. Electromyography (EMG) gives the quantitative and objective recording of muscle function during a contraction and thus the recording of muscle activity [4]–[6]. Additionally, this facilitates the detection of changes in contraction patterns due to fatigue during prolonged exertion. Changes in EMG signals can generally be utilized to control the exoskeleton in various applications [7], [8]. Force myography (FMG) detects mechanical changes associated with muscle contraction rather than electrical effects. It measures the normal forces resulting from changes in muscle volume during contraction which is related to the muscle activity [9], [10].

To integrate muscle biomechanics into the control of exoskeletons, sensors and methods are required to acquire or approximate biosignals. Non-invasive technologies such as EMG or FMG offer the potential to measure muscle activity and integrate this information into control [1], [11]. The quality of the EMG signal is influenced by factors such as the positioning of the electrodes, tissue properties, physiological cross talk, and changes in the distance between the muscle and the electrodes due to muscle movement [12], [13]. Therefore, the recording of EMG signals involves precise preparation for data acquisition and extensive signal post-processing. On the other hand, FMG does not necessitate direct skin contact or as precise sensor placement and complex post-processing as EMG [9], [10].

Various research studies have been conducted on the performance of FMG and EMG in upper limb motion control applications. The findings suggest that FMG offers greater accuracy and repeatability compared to EMG, as well as higher stability over time, in both offline and online usability tests, particularly when there is a time gap between training and testing [9], [14]–[17]. This makes FMG more suitable

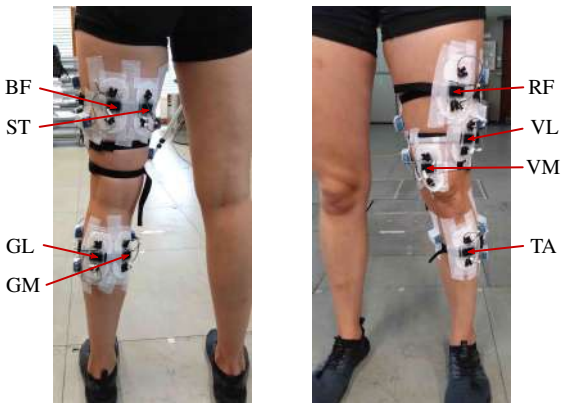
for assistive exoskeleton applications for daily activities, as it does not require users to undergo retraining after frequent use. In contrast, EMG is better suited for rehabilitation applications where continuous monitoring of muscle activity is required [14]. And while an EMG signal can indicate the onset of contraction, an FMG signal is better suited for identifying the end of contraction [18]. Overall, FMG-based methods appear to be more effective for classification and regression control in daily exoskeleton use and are preferred by users [15]. This makes FMG a promising, yet less explored technology for the control of wearable systems.

Recent studies [16], [19]–[23] indicate that combining FMG and EMG sensing enhances muscle activity analysis. This integration can benefit from their complementary strengths for a more thorough assessment of muscle function. While most co-located, sensing devices are used in forearm or hand motion recognition, Wang et al. [23] introduced a dual-mode wearable system for monitoring lower-extremity muscular activity. It utilizes a multi-channel pressure sensing matrix to map FMG in a single muscle while simultaneously capturing electrophysiological signals with a custom EMG module. Experimental results indicate that this system effectively captures both the activation and structural changes in the tibialis anterior and gastrocnemius medialis muscle. Both sensor modalities demonstrate high stability and repeatability during walking, and the measured data of muscle activity complements each other during certain gait phases, enhancing gait phase recognition accuracy.

In our previous research, we investigated the application of FMG for exoskeletons, utilizing barometric pressure-based FMG units [10] and compared it to EMG regarding its positioning. Our current work diverges from previous studies by providing a comprehensive descriptive analysis of both FMG and EMG signals gathered concurrently and collocated. This study explores the similarities and variations in signal amplitude, occurrence of maximum amplitude, and variability between these two signal modalities throughout the full range of motion (RoM) of the ankle and knee joints in isokinetic sagittal motion. By examining these parameters, we aim to enhance our understanding of the relationships between FMG and EMG signals and their dependence on joint angle and joint velocity. The findings from this analysis not only contribute to the existing knowledge of FMG and EMG but pave the way for future research focused on optimizing exoskeleton performance through customized design options and control mechanisms.



II. METHODS

This section outlines the sensor setup and the user study used for data acquisition, followed by the signal processing and feature extraction, and concluded by the analysis methods as indicated in Fig. 1.

A. Sensor Setup

The sensor unit for FMG, as explained in [10], detects the normal force resulting from alterations in the volume and stiffness of the human muscle beneath the cuff during leg movement. It contains five barometric pressure sensors on a single printed circuit board (PCB), all housed under a silicon dome. Changes in pressure identified by these sensors signify changes in the forces exerted on the silicon dome.

The muscle activity of *rectus femoris (RF)*, *biceps femoris (BF)*, *semitendinosus (ST)*, *vastus medialis (VM)*, *vastus lateralis (VL)*, *gastrocnemius medialis (GM)*, *gastrocnemius lateralis (GL)* and *tibialis anterior (TA)* was measured using eight FMG units and eight EMG electrode pairs placed at specific anatomical locations, as indicated in Fig. 2. The

(a) (b)

Fig. 2: EMG (white electrodes) and FMG (black straps) sensor positions on the back (a) and front (b) of the left leg.

placement of the sensors was determined based on recommendations from SENIAM [24] and real-time feedback from the EMG sensor. Each EMG electrode pair was positioned directly above and below the FMG sensor unit, leaving a distance of about 20 mm between the electrodes, along the muscle to ensure common measurement points. In addition, the respective angular position θ_J of the joints were recorded via the IsoMed 2000 device (Fig. 3).

B. User Study

The user study was conducted in a controlled laboratory setting using an IsoMed 2000 device. This device offers an integrated mode enabling isokinetic motion of one joint at a time in the sagittal plane (Fig. 3). In isokinetic motion, the velocity of limb movement remains constant even as muscle forces vary. Additionally, it provides a direct on-axis measurement of the true joint torque.

For this study, we analyzed ten healthy adults, their characteristics are detailed in Table I. The experimental protocol received approval from the Ethics Committee of the

TABLE I: Participant Information

Values represent the mean and standard deviations.

Karlsruhe Institute of Technology (KIT) as part of the JuBot project. All participants provided written informed consent before participating in the experiment, and all methods were conducted in accordance with the Declaration of Helsinki.

The experiment was conducted with participants seated on the IsoMed device, secured with their left leg on a foot or shank support. This enabled pure sagittal motion of the ankle or knee joint respectively (Fig. 3). Each participant had a familiarization period of up to 10 min with the IsoMed device. During this time, the alignment of the device's rotation axis with the sagittal joint axis of rotation was manually optimized using an integrated laser pointer. Additionally, the mechanical end stops of the device were adjusted to align with each user's maximum RoM within their anatomical limits. Following this, the participants performed two tasks in a random order:

- *Ankle*: The ankle joint was initially positioned at maximum dorsiflexion. The participant then performed five swing motions (Fig. 3a), including both dorsiflexion and plantarflexion, within their maximum active RoM. The five swing motions were repeated at four different angular velocities v_i: 30 °/s, 60 °/s, 90 °/s, and 120 °/s.
- *Knee*: The knee joint was first set to maximum extension for initialization. The participant then performed five swing motions (see Fig. 3b), including flexion and extension, within their maximum active RoM. These motions were executed at four different angular velocities v_i: 60 °/s, 90 °/s, 120 °/s, and 150 °/s.

(a) ankle (b) knee

Fig. 3: Participant set-up on the IsoMed 2000 device for ankle motion (a) and knee motion (b) and the corresponding definition of the joint angle θ_J.

The five swing motions of each joint were repeated three times for each velocity. For calibration, FMG was initialized before accessing the IsoMed device. This was done by standing upright and relaxing on both feet for approximately 10 seconds. Calibration measurements of the joint angle were conducted at each initial position $\theta_J = 0°$ as marked in Fig. 3.

C. Signal Processing

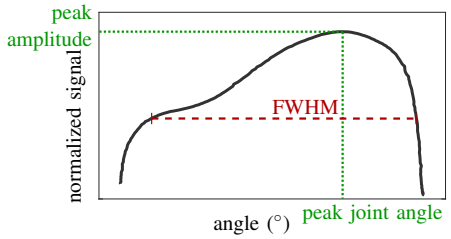
To process the EMG signals, a band-pass filter with a frequency range of 20 Hz to 500 Hz was applied, followed by rectification and a low-pass filter set at 6 Hz. All filters used were fourth-order zero-phase Butterworth filters. Outliers in the EMG signals were identified using a Hampel filter and replaced with linearly interpolated values derived from the neighboring non-outlier values. The baseline offset of the FMG was removed using the mean values obtained from the calibration measurements, no filter was applied to this signal.

The FMG sensor units have a maximum sampling rate of 200 Hz, while the EMG signals were sampled at 2000 Hz. To align and concatenate all the datasets, each dataset was linearly interpolated to achieve an equidistant number of data points. This process resulted in the down-sampling of the EMG data to match the FMG data. Both signals were normalized according to the minimum and maximum values measured for each participant and muscle after filtering.

The segmentation of each complete motion including flexion and extension of the knee joint and dorsi- and plantarflexion of the ankle joint was performed based on the joint angle and thus corresponding change in motion direction.

D. Analysis Methods

The analysis focused on the complete time-series signals during each swing motion, as well as specific features namely the peak amplitude and its corresponding joint angle, as well as the full width at half maximum (FWHM) (Fig. 4). The



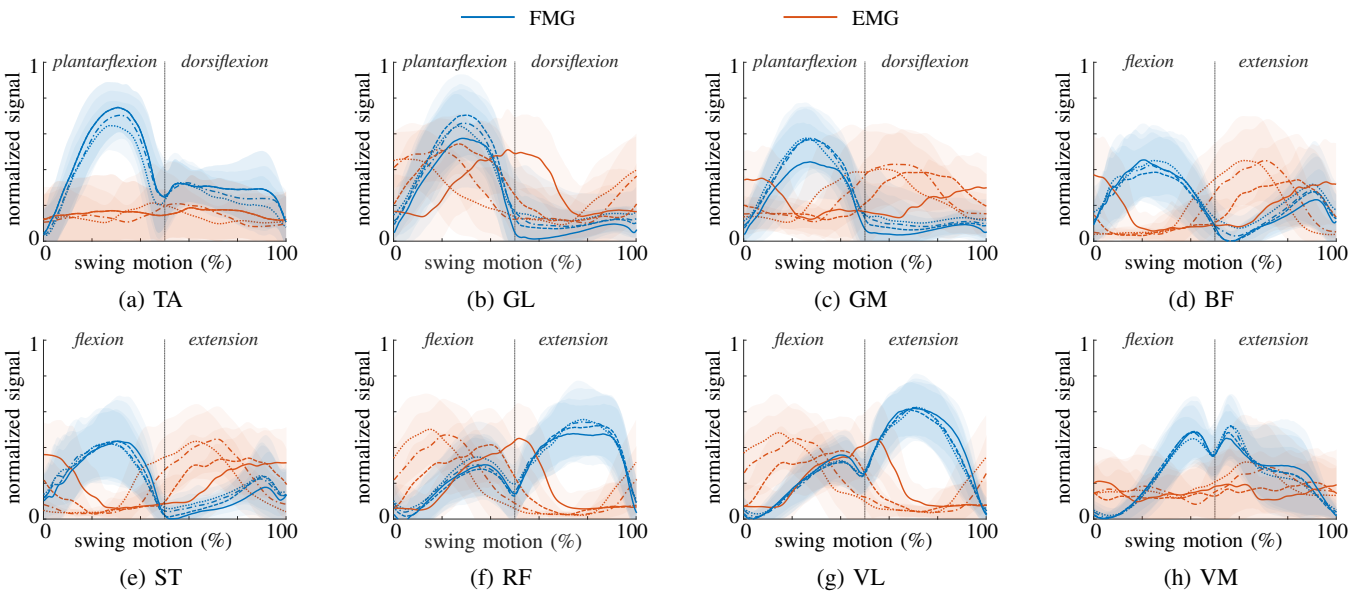


Fig. 4: Signal features analyzed in each complete swing motion over the full RoM.

peak amplitude is a distinct feature to evaluate the amount of muscular activity measured, the corresponding joint angle provides information on the amplitude distribution within the RoM and the FWHM indicates the the range of joint angles during which a muscle is active.

The variations of each feature were evaluated based on the coefficient of variation (CV), calculated for each feature over all swing motions of each participant and over all participants. The CV also known as relative or normalized standard deviation, is a standardized measure of signal variability. A lower CV corresponds to a lower variation and thus a higher repeatability of the signal. The variation analysis was conducted on the data of all four angular velocity recordings for each joint.

In a manner similar to the primary flexor and extensor muscles involved in the movement of each joint, the analysis of ankle joint motion focused on the TA (dorsiflexion), GM (plantarflexion), and GL (plantarflexion). For the knee joint motion analysis, the muscles examined included the RF (extension), VM (extension), VL (extension), BF (flexion), and ST (flexion). It's important to note that the effects of bi-articular muscles, which influence the movements of multiple joints simultaneously, were not considered in this analysis.

(e) ST (f) RF (g) VL (h) VM

Fig. 5: **Muscle signals**. Mean and standard deviation of the EMG and FMG signals over all participants. Each muscle is displayed separately for (a)-(c) ankle and (d)-(h) knee motion. Each graph includes all four velocities (v_1: solid, v_2: dashed, v_3: dash-dotted, v_4: dotted) of each EMG (orange) and FMG (blue) signal.

III. RESULTS

This chapter presents the results from the comparison between EMG and FMG signals after segmentation of all measurements to each complete swing motion, with a particular emphasis on three essential features: the maximum amplitude, the corresponding joint angle, and the FWHM, also considering each feature's variability.

Figure 5 displays the mean and standard deviation of the normalized EMG and FMG signals over one complete swing motion and across all participants. Each muscle is presented separately for both ankle and knee movements, and each graph includes data for all four angular velocities of the EMG and FMG signals. The transition between motion directions is emphasized in the middle of one swing motion by a

(a) plantarflexion (b) extension

(c) dorsiflexion (d) flexion

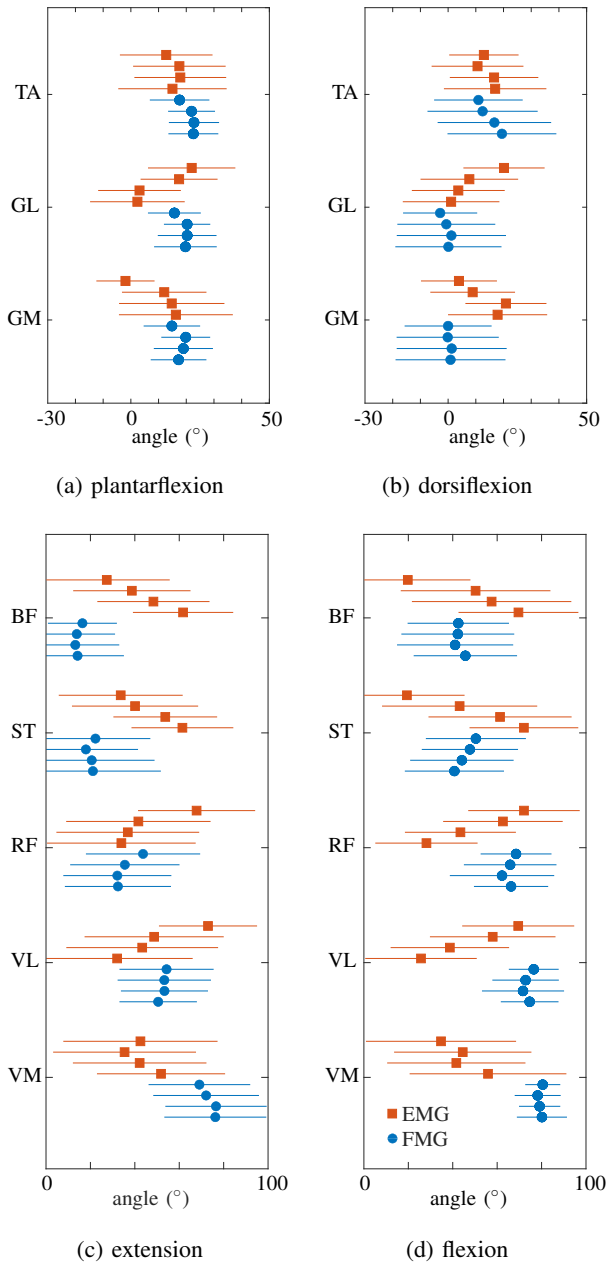

Fig. 6: **Peak signal amplitude**. Mean and standard deviation of the maximum signal amplitude for ankle (a) & (c) and knee (b) & (d) joint displayed for each motion direction. Muscle groups are categorized by the four velocities (from v_1 left to v_4 right) and by EMG (square) and FMG (circle).

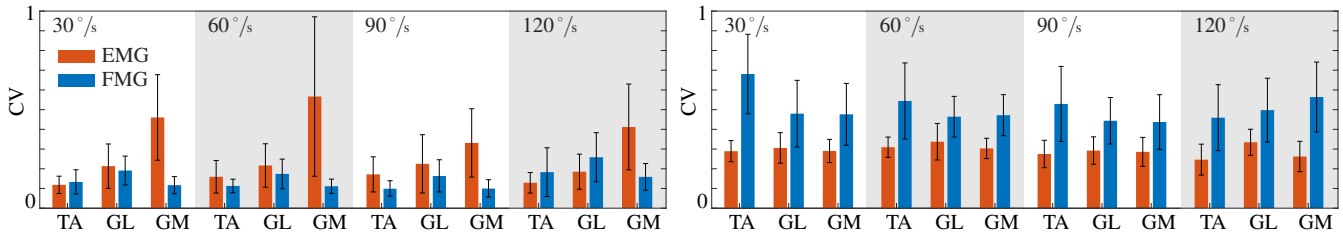
vertical line. In most muscles, the EMG signal exhibits a single prominent peak, whereas the FMG signal tendentially shows two peaks, one peak per motion direction. Notably, one of these FMG peaks is generally more pronounced than the other. In the muscles contributing to knee motion, most dominantly in BF, ST, RF and VM, the muscles tend to show contrasting activity behavior between EMG and FMG. On the other hand, the TA and the VM muscle display no peak and thus consistent activation in EMG during the complete swing motion. Furthermore, the signal FMG shows a notable drop in its signal amplitude in the middle of the swing motion, coinciding with periods in which the angular velocity of the joint is zero and the direction of motion changes. This effect is not prominently observed in the EMG data. Furthermore, the EMG activation pattern appears to shift to the left with increasing velocity. In contrast, the FMG signal maintains a consistent activation pattern across all velocities.

The mean and standard deviation of the normalized maximum amplitude observed during flexion and extension in the knee joint and plantar- and dorsiflexion in the ankle joint is shown in Fig. 6. In both joints and both, EMG and FMG signals, it can be observed that the amplitude displays a contrasting behavior in its height between the flexor and extensor muscles in both motion directions. While the BF and ST muscle show a higher activity in the FMG signal during flexion of the knee joint, the opposite can be observed for the RF, VL and VM muscle. However, an opposing effect is displayed in the EMG signal. Generally, the effect is more prominent in the knee joint than in the ankle joint and the TA displays no such effect at all. Again, the FMG signal displays a higher consistency regarding the height of the maximum amplitude than the EMG signal throughout the four angular velocities.

Figure 7 shows the mean and standard deviation of the occurrence of the maximum amplitude during flexion and extension in the knee joint and plantar- and dorsiflexion in the ankle joint, dependent on the corresponding joint angle. The FMG signal demonstrates a higher consistency in the joint angle at which the maximum amplitude occurs, while the EMG has a higher dependency on the angular velocity at which the signal was obtained. It is especially notable in the EMG signal during knee joint motion that the flexor and extensor muscles (e.g. BF and ST compared with RF and VL) display a contrasting shift of the maximum amplitude within the RoM with increasing angular velocity. This shift is more pronounced in the flexion than in the extension of the knee joint. In the ankle joint this effect is less notable though still present.



Variability was evaluated on the basis of the CV of the maximum signal amplitude and the FWHM (Figs. 8 and 9) in each muscle as the mean and standard deviation over all ten participants. The FMG generally demonstrates a lower CV for the peak signal amplitude compared to the EMG, both in terms of its mean and standard deviation. Only the TA and GL muscle demonstrate higher mean variation in FMG than in EMG at 120 °/s, RF muscle at both 120 °/s and 150 °/s. The highest variation can be observed in the EMG signal of the GM muscle in the ankle joint motion at 60 °/s and the BF muscle in the knee joint motion at 120 °/s. In contrast, the variation in the FWHM is higher for the FMG than for the EMG signal not only in its mean but also its standard deviation throughout all muscles and angular velocities. The greatest variation can be observed in the TA muscle for the FMG at 30 °/s during ankle joint motion and in the ST muscle at 120 °/s in the knee joint motion, whereas the EMG signal does not show one muscle standing out specifically.

(c) extension (d) flexion

Fig. 7: **Joint angle at peak amplitude**. Mean and standard deviation of the joint angles at the maximum signal amplitude for ankle (a)-(b) and knee (c)-(d) joint displayed for each motion direction. Muscle groups are categorized by the four velocities (from v_1 at the top to v_4 at the bottom) and by EMG (square) and FMG (circle).

(a) peak signal amplitude (b) FWHM

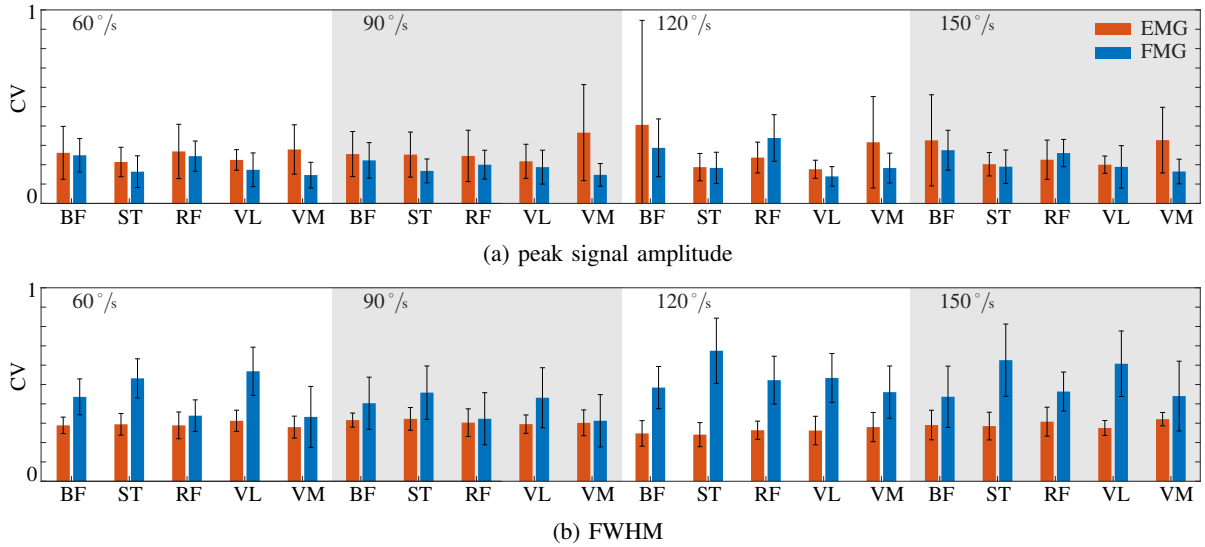

Fig. 8: **Coefficient of variation (ankle)**. Mean and standard deviation of the CV of (a) the maximum signal amplitude and (b) the FWHM of each EMG (orange, left) and FMG (blue, right) signal of each swing motion over all participants for the ankle joint.

IV. DISCUSSION

The evaluation of both FMG and EMG signals during isokinetic motion focused on maximum amplitude, the corresponding joint angle, and the FWHM. The first and last features were specifically examined for their variability. This evaluation explored the similarities and differences between these two signals throughout the RoM of the ankle and knee joints of ten participants.

Higher variations in the mean value of the maximum amplitude and the corresponding joint angle in the EMG signal (e.g. in the muscles BF and ST in Figs. 6d and 7d) suggest that EMG is more dependent on the angular velocity than FMG. The shift in the EMG signal amplitude with increasing angular velocity shown in Fig. 5 indicates a dependency on the joint angle. This observation supports the findings of Hahn et al. [25], who discovered that the excitation of all lower limb muscles measured by EMG changes based on knee flexion angles. This is also evident in the high mean values recorded for only the first angular velocity, as illustrated in Fig. 6. Notably, this includes the GL muscle during dorsiflexion, the RF and VL muscles during extension, and the BF and ST muscles during flexion, shifting them towards the opposing motion direction. On the other hand, the FMG signal exhibits a visible drop in amplitude during the transition between motion directions, as shown in Fig. 5. This occurs when the angular velocity is momentarily zero, indicating that the FMG signal is sensitive to sudden changes in angular velocity suggesting that joint acceleration has a larger influence on FMG. This supports the idea that a combination of both sensing methods could be beneficial not only in motion recognition but also in estimating kinematic and kinetic joint data.

The EMG signals show only one prominent peak during the swing motion, as displayed in Fig. 5. In contrast, the FMG signals exhibit two distinct peaks (e.g. RF, VL, and VM), corresponding to each direction of motion or a peak where no muscle activity was expected (e.g. TA) in Fig. 5. Whereas this effect is generally, more pronounced in the knee joint compared to the ankle joint, it is most drastic in the TA muscle. Since the TA muscle acts as a flexor of the ankle

(a) peak signal amplitude

(b) FWHM

Fig. 9: **Coefficient of variation (knee)**. Mean and standard deviation of the CV of (a) the maximum signal amplitude and (b) the FWHM of each EMG (orange, left) and FMG (blue, right) signal of each swing motion over all participants for the knee joint.

joint, its peak amplitude during plantarflexion should not be as prominent. A possible explanation for this is the cross-talk produced by the muscles that are covered by the strap attaching one or more FMG sensor units to the leg. Changes in shape and volume from the antagonistic muscle can affect the pressure signals measured from the agonistic muscle, either due to its muscle being activated in parallel or due to the passive motion of the leg. The soft tissue may function as a damper with its stiffness dependent on the subject or motion [26], affecting the transfer of forces between the agonistic and antagonistic muscles within the straps. Since the lower leg generally has less soft tissue than the upper leg, and the shinbone is situated close to the surface, the cross-talk observed in the TA muscle could be more pronounced. In the future, the effect based on passive motion could be studied and potentially excluded by measuring the FMG signal obtained by leg motion while the participant is in a relaxed state. Additionally, it is important for the design of an exoskeleton to consider the sensitivity of FMG sensors to cross-talk. When these FMG sensors are integrated into the cuffs of an exoskeleton, they should be designed to be as decoupled from one another as possible.

The analysis of the EMG signals from both the TA and VM muscles reveals a generally low signal amplitude, as depicted in Fig. 5, with a slightly lesser effect observed in the VM muscle. Enhanced noise can obscure significant maxima, leading to the filtering of insufficiently pronounced peaks and complicating data interpretation. The stochastic nature of EMG signals, characterized by rapid fluctuations, contributes to challenges in post-processing, potentially resulting in undetected outliers and reduced normalization quality. Furthermore, peaks in muscle activation may occur at varying stages of the swing motion for each participant, which could lead to cancellation when calculating the mean across participants. Addressing these limitations is essential for advancing our understanding of muscle activation patterns and improving the efficacy of wearable robotic systems in clinical and rehabilitative contexts.

The signals from EMG and FMG exhibit nearly opposite behaviors with respect to their signal amplitude. This phenomenon can be observed during a complete swing motion, where the normalized maximum amplitude occurs in contrasting phases/directions of the motion, which is especially prominent in the knee joint motion. This distinction may account for the improved performance of classification methods in [19]–[23] that combine both EMG and FMG signals, as their differing features and variability provide a complementary advantage for feature-based, data-driven machine learning approaches.

The EMG signals exhibit greater variability in the activation patterns between the participants compared to the FMG signals. Specifically, the FMG signals demonstrate enhanced repeatability in terms of maximum amplitude across multiple participants, aligning with the observations reported in previous studies [16], [17]. In contrast, the duration of muscle activity, as measured by FWHM, shows greater consistency in the EMG signals, as evidenced by their lower CV. This discrepancy suggests that while FMG signals may provide more reliable peak amplitude readings, the EMG signals offer a more stable representation of the duration of muscle activation. However, no general trend regarding variations within any angular velocity can be extracted from either EMG or FMG in the peak amplitude and the FWHM.

However, it is important to note that a limited number of participants exhibited a small subset of muscles with either a markedly elevated or non-existent CV. For instance, the VM muscle in two participants displayed such outlier behavior. In particular, these outliers did not correlate with any identifiable characteristics of the participants, suggesting that external factors may play a role in these variations. One plausible explanation for this phenomenon is sensor misalignment or interference caused by the attachment of participants to the IsoMed device. The necessity for precise positioning of the IsoMed actuation levers to avoid interference with the EMG and FMG electrode locations may have inadvertently introduced variability in the signal quality. This highlights the importance of ensuring optimal electrode placement and minimizing external influences to enhance the reliability of EMG and FMG readings.

The study's findings are based on a relatively small sample size of ten participants, which may limit the statistical power necessary for rigorous hypothesis-driven analysis. Consequently, we advise that these results be interpreted as preliminary indicators that warrant further investigation. It would be beneficial to explore these findings in subsequent research with a larger and more diverse participant group to enhance the validity and generalization of the conclusions drawn. Such efforts would contribute significantly to advancing our understanding of the topic.

Although the data presented in this paper provide valuable information on both EMG and FMG, the untapped potential remains to be explored. A more in-depth examination of each specific motion direction, focusing on both agonistic and antagonistic muscles, could yield additional information. Furthermore, a closer analysis of the FWHM alongside the corresponding joint angles may reveal relevant details about the range of motion detectable by the muscular signals of each sensing method and the extent to which they can be measured. The results of this paper offer strong potential for deeper exploration, especially in highlighting the benefits and limitations of FMG compared to EMG.

V. CONCLUSION

The evaluation of FMG and EMG signals during isokinetic motion reveals that FMG signals demonstrate higher repeatability in maximum amplitude and corresponding joint angle both within and across participants compared to EMG signals, which show more consistent muscle activity duration. Although high repeatability supports the generalization of control methods for different users of wearable robots, signals with higher variability can contribute to the personalization of control, allowing for the adaptation of the controller to satisfy the particular requirements of individual users. While EMG signals appear to be more affected by

angular velocity, FMG signals seem more sensitive to sudden changes in angular velocity. The contrasting and augmenting behavior of EMG and FMG signals, particularly in signal amplitude during motion phases, suggest that combining these signals enhances their performance in application due to their complementary features and indicates their potential for comprehensive motion recognition and joint data estimation. Future research could focus on exploring these complementary strengths to develop more effective control systems for wearable robotics, while also addressing FMG's sensitivity to cross-talk and EMG's normalization challenges. Furthermore, the results underscore FMG as a promising method for the integration of biofeedback in the control of wearable robotic technologies.

ACKNOWLEDGMENT

The authors would like to thank Melina Beyerlein, Michael Herzog, and Cagla Kettner from the BioMotion Center at the Institute of Sports and Sports Sciences (KIT) for their valuable input on the variability analysis and the corresponding features.

Biomechanical Engineering, Delft University of Technology, The Netherlands

***Abstract*—To increase the quality of life of stroke patients, better diagnostics with the ability to identify the cause of motor impairment are needed. Robotic diagnostics increases the resolution of measurements, allows for tracking progress over a longer period, and can be used to evaluate new treatments. The Shoulder Elbow Perturbator (SEP) was developed to improve the diagnostics of post-stroke motor impairment. The SEP has already been tested on patients, showing promising results in identifying the cause of motor impairment, but no SEP system performance analysis has been published. To identify the joint properties of the elbow accurately, the SEP should have a bandwidth of at least 12 Hz. Furthermore, admittance and velocity control are required for various possible experimental tasks. This paper shows that the SEP performs adequately for the desired perturbations and experimental conditions for system identification of the human elbow. The SEP's performance is analysed with multisine signals to determine the bandwidth and endpoint dynamics. The velocity controller bandwidth is 50 Hz, and the admittance controller bandwidth is 65 Hz. Furthermore, the controller is stable. Thus, the SEP meets all the requirements and should be able to provide the desired perturbations and experimental conditions needed for system identification of the human elbow.**

***Index Terms*—Shoulder Elbow Perturbator, spasticity, rehabilitation robotics, stroke, (Haptic) Manipulator**

I. Introduction

Stroke survival rate has increased drastically over the last decades. Due to the increased survival rate and an ageing society, the prevalence of disability due to stroke increases [1]. Post-stroke disability greatly impacts the patient's ability to perform activities of daily living (ADL). Improving therapeutic interventions will reduce the patient's physical and mental burden, the physician's workload, and healthcare costs [2]. Stroke can cause a wide variety of motor impairments. However, diagnosing whether the cause of motor impairment is neural or non-neural is difficult as they present similar symptoms, such as paresis, synergy, co-contraction, spasticity, or viscoelastic tissue property alterations [3]. A diagnosis capable of differentiation of the causes of impairment is desired. Clinically, impairment is quantified using ordinal scales based on a physicians assessments of a patient's voluntary joint movement and resistance to passive movement. Examples are the Modified Ashworth Scale, the Modified Tardieu Scale or the Fugl-Meyer assessment [4]. The manual assessment of motor impairment after a stroke makes quantification and distinguishing between various causes of motor impairments challenging. Therefore, there is a need for objective measurements of motor impairment, with a particular focus on differentiating between non-neural and neural components [5].

Objective measurement, with the use of robotic diagnostics, increases the resolution of measurements, allows for tracking progress over a longer period, and can be used to evaluate new treatments [5]. The system identification technique, which uses robotic diagnostics, aims to objectively identify the mechanical properties of human limbs to determine the severity and cause of the patient's motor impairment [6].

There are several joint manipulators for assessing motor function for research purposes [7, 8]. The Shoulder Elbow Perturbator (SEP) (Hankamp Rehab, Enschede), shown in Fig. 1, was developed to improve post-stroke motor impairment diagnostics. The SEP has already been tested on patients, showing promising results in identifying the cause of motor impairment [6, 9]. However, the performance of the SEP, along with its control, has not been analysed in detail.

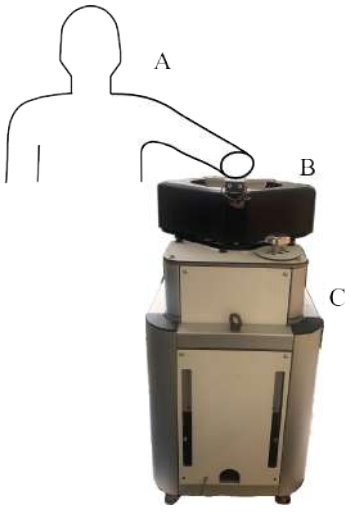

Fig. 1. The Shoulder Elbow Perturbator (SEP), with an illustration of a participant positioned in the device. The participant (A) is attached to the device with a clamp to the wrist on the ulnar and radial head. The table (B) can passively move in the vertical direction, allowing shoulder abduction and actively rotate the elbow in flexion and extension. The base (C) contains the motor and control detailed in Section II-B.

TABLE I
HARDWARE SPECIFICATIONS OF THE SEP

Component	Hardware	Parameter	Specifications
Motor	Hiwin TMS3C	Encoder resolution	4,325,376 counts/revolution
Drive	Hiwin ED1-01	Device inertia	0.043 kg m^2
Transmission	Direct drive	Torque	60 Nm (180 Nm peak)
Force sensor & signal conditioner	Futek LCM200 AIAA100	Velocity	1,800 deg/s
		Acceleration	18,000 deg/s^2
Target PC	Lenovo Ideapad (Windows)	Range of motion (R1)	160 deg
Coupler & Terminals	Beckhoff EK1100 1x EL3102, 1x EL2002, 1x EL1202	Shoulder elevation range (D1)	20 cm

For this study, the controller performance of the SEP is optimized and the control is changed from only position control to admittance and velocity control. Admittance control is primarily used in combination with a position task. The advantage of using the position task with admittance control is that the control evokes consistent human motor control by interacting with adjustable virtual dynamics [10]. Velocity control is primarily used in combination with a force or relax task. Velocity control enables precise perturbation of the participant with the desired velocities, for example, to elicit stretch reflexes or quantify limb dynamics.

To be able to do experiments needed for system identification, the SEP should be able to perturb the arm with frequencies greater than or equal to three times the eigenfrequency of the elbow [7]. For the elbow joint, the eigenfrequency is approximately 3 Hz. For this paper, the requirement was set at four times the eigenfrequency, so the bandwidth of the SEP must be at least 12 Hz, with a stable controller. This paper shows the performance of the SEP for the desired perturbations and experimental conditions needed for system identification. The current paper shows the SEP's mechanical design, control scheme and analyses the overall system performance.

II. MECHANICAL DESIGN

A. Full Setup

A schematic representation of the mechanical setup of the SEP is shown in Fig. 2. The SEP can perturb the elbow in the horizontal plane with varying shoulder support. The elbow support is used to fixate the human elbow to the SEP by placing the elbow joint in line with the axis of rotation and clamping the wrist on the ulnar and radial head. The clamp's position can be adjusted to accommodate the patients' arm lengths. The sarrus linkage uses three parallel support beams to allow vertical movement of the elbow support while restricting horizontal movements. The linkage (3) connects the elbow support to the motor. This linkage is free to rotate whilst preserving vertical movement. The spring mechanism for the upward force provides an adjustable constant force over the range of motion. Table I presents the complete overview of the components used and their specifications [9]. Multiple safety layers, including mechanical end stops, electrical end stops, software end stops, and participant and operator emergency stops, ensure the safe operation of the SEP. The end stop location can be adjusted to ensure safety for participants with various passive ranges of motion.

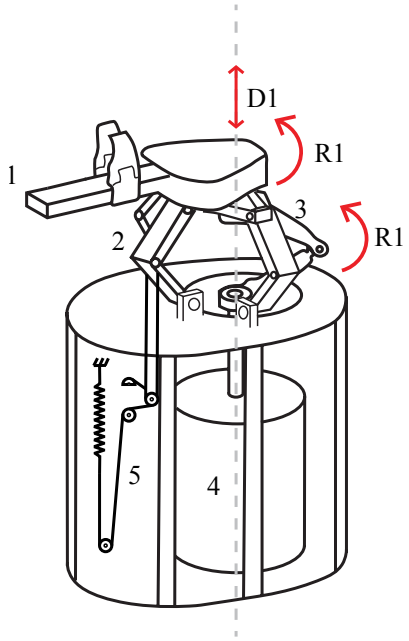

Fig. 2. Schematic representation of the SEP. The SEP contains the following parts: the elbow support (1), the Sarrus linkage, which houses the bearing for the rotation of parts 1 & 3, the linkage can not rotate or move horizontally (2), the motor-elbow support connection (3), the motor (4) and the spring mechanism exerting the constant upward force on the elbow support (5). R1 is the motor and elbow support rotation, of which the rotation axis is the grey dotted line. D1 is the possible passive vertical movement of the elbow support.

B. Hardware/Software architecture

The controller is implemented using Matlab Simulink 2024b. The Simulink model is converted to C-code and built onto the Beckhoff Twincat 3.1 software. Parameters can be controlled via Simulink in real-time. The motor driver is set to profile velocity mode. The motor driver is set to its tuneless function with the highest possible stiffness, so it follows the desired velocity to the tuneless function's maximum ability. The data used in the various control modes is transmitted back to the Simulink model from the motor and sensors. Fig. 3 shows the entire communication setup.

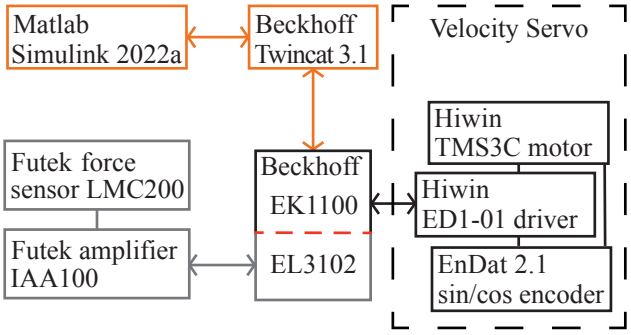

Fig. 3. Hardware/Software communication. The orange boxes represent the software running on a separate PC. The grey boxes are analogue sensors. The black boxes are digital hardware. The dotted red line represents the conversion of analogue to digital signals. The black dotted box shows the velocity servo hardware.

III. Control Scheme

The SEP has two modes of control: velocity control and admittance control. The following paragraphs explain both modes of control in detail.

A. Velocity control

In velocity control, the input is a velocity signal ($\dot{\theta}_d$) independent of the external loading in joint perturbations experiments caused by the arm and device dynamics. As mentioned in section II-B, the velocity servo is tuned to follow the input signal to its maximum ability. Thus, the motor produces the torque necessary to reach the desired velocity. The encoder measures the position (θ_m) and velocity ($\dot{\theta}_m$) of the motor used for analysis.

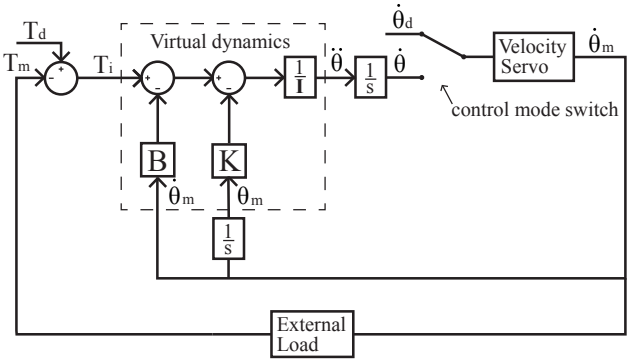

Fig. 4. Control diagram of the SEP for both modes of control. For admittance control, There is the measured torque (T_m), which is combined with a disturbance torque (T_d) to get the input for the virtual dynamics, referred to as the input torque (T_i). The virtual dynamics are the stiffness, damping and inertia, denoted with K, B and I, respectively. The output of the virtual dynamics is the desired acceleration, which is integrated to get the desired velocity. The desired velocity ($\dot{\theta}$) goes into the velocity servo, also shown in Fig. 3. The motor follows the desired velocity, resulting in a motor velocity ($\dot{\theta}_m$). The external load consists of the human and post-sensor device. The dynamics of the attached load (device + external load) on the motor create a resistance torque, the measured torque. For velocity control, there is a desired velocity ($\dot{\theta}_d$) as an input and a motor velocity ($\dot{\theta}_m$), which is the output of the driver.

B. Admittance control

In admittance control, the robotic controller's input is the external torque [11]. The controller has virtual dynamics that prescribe rotation, angular velocity, and angular acceleration in response to torque. Fig. 4 shows the admittance controller. The formula for the virtual dynamics is given in Equation 1

$$\ddot{\theta} I = T_d - T_m - B\dot{\theta}_m - K\theta_m \tag{1}$$

Where T_m is the measured torque. θ_m and $\dot{\theta}_m$ are measured the position and velocity, and T_d is the added disturbance torque for the performance analysis. Furthermore, the virtual dynamics are the stiffness, damping and inertia, denoted with K, B and I, respectively.

IV. Performance analysis

A. Perturbation signal for analysis

The perturbation signal is a multisine (i.e. a sum of sines) that excites the device over a wide frequency range of 0.1-100 Hz [12]. A wide range of perturbation frequencies helps to identify the frequency at which the servo velocity loop (H_{servo}) gain drops below -3 dB, indicating the controller bandwidth. The perturbation signal is scaled so the rotation remained within 6 degrees of the neutral position. For the experiments, the signal duration was 80 seconds. The signal was repeated four times in each trial, amounting to 320 s. Each trial was repeated five times to increase the accuracy of the performance analysis.

B. External load

The human arm introduces inertia, damping and stiffness as an external load. To ensure that the SEP functions with and without added external loads, external loading conditions were determined to mimic the extra load the human arm puts on the device. The human arm inertia was calculated by taking 2.5 kg as the weight of the arm [13], and 371 mm as the length of the forearm and hand [14] and the center of mass at 43% from its proximal end [13]. When calculating the inertia using these values, the arm inertia is 0.064 $\mathrm{kg\,m^2}$. The values are those of a large and heavy arm to get a high value for the inertia [13]. External damping is not introduced as elbow damping only makes a small contribution to the elbow joint impedance and is hard to realize. To mimic the added external stiffness of the human on the robot, two tension springs facing opposite directions are attached from the SEP to an external frame. Creating a bidirectional external stiffness of 0.84 $\mathrm{Nm/deg}$, which is in the order of magnitude of earlier identified elbow stiffness with the SEP [6]. The three external loading conditions are:

- No external load
- Added inertia (0.064 $\mathrm{kg\,m^2}$)
- Added inertia and rotational stiffness (0.064 $\mathrm{kg\,m^2}$ + 0.84 $\mathrm{Nm/deg}$)

C. Velocity control

The velocity servo's performance is tested in the velocity control mode, separately from the admittance control, to ensure that the admittance control's virtual dynamics do not suppress the high frequencies, which would create a less accurate estimate of the controllers' bandwidth.

D. Admittance control

The virtual dynamics were set to low impedance values that do not suppress too many high frequencies but maintain controller stability. The virtual dynamics were set to: $I = 0.01\ \mathrm{kg\,m^2}$, $B = 0.05\mathrm{Nm/s}$, $K = 0.5\ \mathrm{N/m}$.

E. Data processing

For the velocity control, the recorded signals during a trial were the numerically integrated input velocity (θ) and the motor position (θ_m). The frequency response function (FRF) ($\hat{H}_{velo}(f)$) is estimated in open-loop for the velocity control. For the estimation of FRFs, the power and cross-spectral densities were estimated using Welch averaging over four segments of 80 s. With these spectral densities ($\hat{S}_{output-input.}(f)$), the FRFs were estimated using the following equations:

$$\hat{H}_{velo}(f) = \frac{\hat{S}_{\theta_m\theta_d}(f)}{\hat{S}_{\theta_m\theta_m}(f)}. \tag{2}$$

Equation 3 calculates the coherence $\hat{\gamma}^2_{velo}(f)$ between the earlier defined variables (θ) and (θ_m). The coherence is a measure of the linearity and the signal-to-noise ratio. The coherence ranges from 0 to 1, with a value of 1 indicating the relationship between the input and output is linear and without noise. The coherence is estimated with the following equation:

$$\hat{\gamma}^2_{velo}(f) = \frac{|\hat{S}_{\theta_m\theta_d}(f)|^2}{\hat{S}_{\theta_m\theta_m}(f)\hat{S}_{\theta_d\theta_d}(f)}. \tag{3}$$

For the admittance control, the recorded signals during a trial were the disturbance torque (T_d), the measured torque (T_m), the input torque (T_i), the motor position (θ_m) and the numerically integrated input velocity (θ). Closed-loop estimators for the FRF were used to estimate the FRF for the virtual dynamics ($\hat{H}_{virt}(f)$), the velocity servo ($\hat{H}_{servo}(f)$), and the external load ($\hat{H}_{load}(f)$). These FRFs represent the virtual dynamics, velocity servo and external load block as defined in Fig. 4 respectively. For determining the controller stability, the open-loop FRF of the entire loop can be estimated ($\hat{H}_{loop}(f)$) with the earlier estimated FRFs. The FRFs were estimated using the following equations:

$$\hat{H}_{servo}(f) = \frac{\hat{S}_{\theta_m T_d}(f)}{\hat{S}_{\theta T_d}(f)}, \tag{4}$$

$$\hat{H}_{(f)} = \frac{\hat{S}_{\theta T_d}(f)}{\hat{S}_{T_i T_d}(f)}, \tag{5}$$

$$\hat{H}_{load}(f) = \frac{\hat{S}_{\theta_m T_d}(f)}{\hat{S}_{T_d T_m}(f)}, \tag{6}$$

$$\hat{H}_{loop}(f) = \hat{H}_{load}(f)\hat{H}_{servo}(f)\hat{H}_{virt}(f). \tag{7}$$

Finally, in addition to the FRF, the coherence $\hat{\gamma}^2_{adm}(f)$ between the disturbance torque and the output position was estimated.

$$\hat{\gamma}^2_{adm}(f) = \frac{|\hat{S}_{\theta T_d}(f)|^2}{\hat{S}_{\theta\theta}(f)\hat{S}_{T_d T_d}(f)}. \tag{8}$$

V. Results

A. Velocity control performance

Fig. 5 shows half a second of the desired- and output velocities for each loading condition, with the controller set to velocity control.

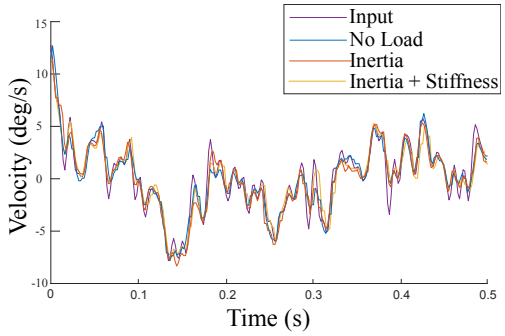

Fig. 5. Half a second of the desired- and motor velocity for each loading condition. The figure shows that the motor velocities of all external loading conditions approximate the desired velocity in this short time window.

The top two panels of Fig. 6 show the magnitude and phase of the velocity control FRF function ($\hat{H}_{velo}(f)$). The bandwidth of the velocity controller is 50 Hz. The bottom panel of Fig. 6 shows that the velocity controllers coherence $\hat{\gamma}^2_{velo}(f)$, which shows a linear behaviour throughout the required bandwidth.

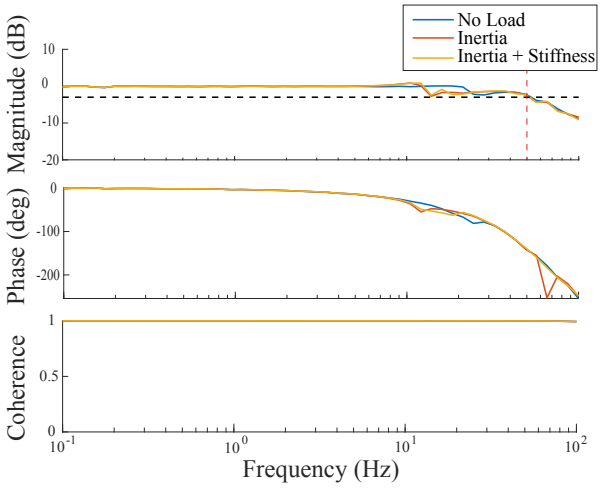

Fig. 6. The top two panels of the figure show the magnitude and phase of the FRF of the velocity controller ($\hat{H}_{velo}(f)$). The magnitude remains on the 0dB line up to 13 Hz and crosses the -3dB line at 50 Hz, shown with the red dotted line; the bottom panel shows the coherence between the actual and desired velocity $\hat{\gamma}^2_{velo}(f)$, which remains above 0.99 up to 100 Hz

B. Admittance control performance

Fig. 7 shows the FRF of the velocity servo of the admittance controller ($\hat{H}_{servo}(f)$) for the three loading conditions. The bandwidth of the ($\hat{H}_{servo}(f)$) of the admittance controller is 65 Hz when only external inertia is added and 76 Hz for the other external loading conditions.

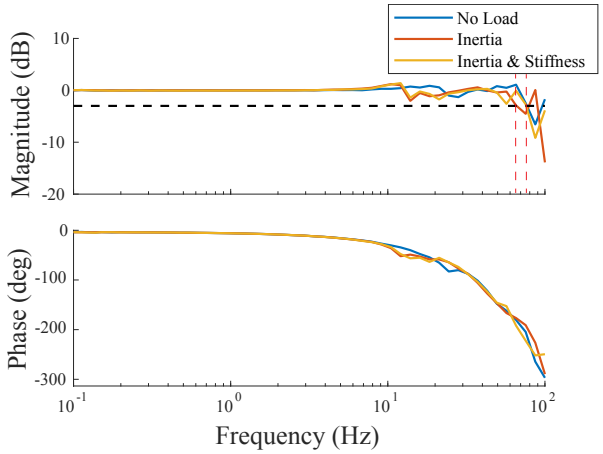

Fig. 7. Magnitude and phase plot of the FRF of the velocity servo of the admittance controller. The magnitude remains 0 dB for frequencies up to 24 Hz. The magnitude crosses the -3dB line at 65 Hz when only external inertia is added and at 76 Hz for the other external loading conditions. The magnitude crossing is shown with a red dotted line. The phase lag becomes noticeable beyond 10 Hz.

The top two panels of Fig. 8 show the magnitude and phase plots for $\hat{H}_{load}(f)$. For the frequencies between 0.3 Hz and 10 Hz the magnitude and phase plot clearly shows the dynamics of a system with only mass for the blue and orange lines and shows the dynamics of a system with mass and stiffness for the yellow line. The bottom panel of Fig. 8 shows the coherence $\hat{\gamma}^2_{adm}(f)$; the drop after 50 Hz indicates the noise becomes more prevalent than the signal.

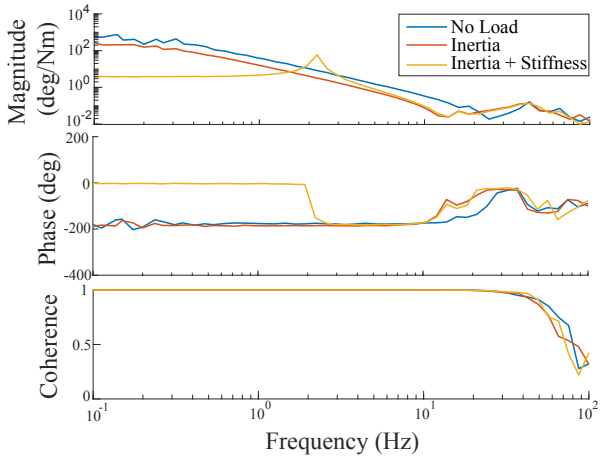

Fig. 8. The top two panels show the magnitude and phase plot of the external load $\hat{H}_{load}(f)$. The bottom panel shows the coherence $\hat{\gamma}^2_{adm}(f)$. The coherence drops below 0.9 at a frequency of 50 Hz.

From the Nyquist plot of the open-loop admittance control loop gain, the stability of a controller can be determined by checking if the (-1,0) point is encircled. The Nyquist plot of this controller showed no encirclement, so the control is stable.

VI. Discussion

This paper analysed whether the SEP performs adequately for the desired perturbations and experimental conditions needed for system identification with a stable controller. The bandwidth of the velocity servo in the admittance control mode is 65 Hz, while the same velocity servo in the velocity control mode has a bandwidth of 50 Hz. Both bandwidths are at least four times higher than the required bandwidth, so this requirement is met. The difference in bandwidth between the control modes could come from the fact that the virtual dynamics of the admittance controller suppress high frequencies, making the performance needed for the admittance controller to reach a specific bandwidth lower, explaining the higher bandwidth. For both controllers, the magnitude remains 0 up to at least 13 Hz, meaning the controller exactly follows the input. The phases of both controllers lag after a frequency of 10 Hz. Phase lag in the control system means a delay between the system's input and output, which can lead to instability. Yet, with the present phase lag, the controller is still stable. The phase lag can be reduced by increasing the sampling time of the controllers. The performance of the SEP can be compared to other robots used to identify human limb joint parameters. Schouten et al. [7] developed a robot to analyse the wrist joint. Here, the bandwidth needed for wrist parameter identification is 50Hz, which is also their controller's reached bandwidth. Another example of a robot identifying joint parameters is the ACT4D, which analyses the elbow joint. Stienen et al. [8] show a FRF that has a magnitude of 1(-) up to 40 Hz. However, their FRF does not go below 0.7 (being the -3dB line). Meaning the bandwidth of their controller is higher than 100 Hz. The performance of the shoulder elbow perturbator is somewhat lower but still meets the set requirements.

A. Limitations

One limitation is the low input velocity. A higher power of the desired velocity input asks more of the velocity servo and motor hardware, thus possibly decreasing bandwidth. This effect is also observed in the previously discussed difference between the bandwidth of the velocity and admittance control. As the current identified bandwidth is four times higher than the needed bandwidth, it is likely that the required 12 Hz bandwidth is still met with a higher input power. To ensure this is the case, further testing should be performed. A current limitation is that the data processing and collection are done at 500 Hz. A higher frequency may be needed for better performance and future controller extensions. A higher frequency will also reduce the phase lag observed in the results. Additionally, the experiment can be followed up by conducting tests on human subjects, providing us with further

insights into the SEP's comfort and usability, alongside the performance of the new controller of the SEP.

VII. Conclusion

This paper shows the performance of the SEP with velocity and admittance control. The bandwidth needed for system identification of the elbow must be higher than 12 Hz for both control modes. The bandwidth of the velocity servo of the admittance control mode is 65 Hz. The velocity controller has a bandwidth of 50 Hz. Both bandwidths are at least four times higher than the set requirement. Furthermore, the controller is stable. Lastly, the frequency response function of the external load clearly shows the dynamics introduced to the system, laying the foundation for further research. These results show that the SEP meets all the requirements, meaning it should be able to provide the desired perturbations and experimental conditions needed for system identification of the human elbow.

***Abstract*—Rhythmic Movement Disorder (RMD) is a parasomnia characterized by repetitive, rhythmic movements such as headbanging or body rocking. It typically occurs in infancy and early childhood, often disrupting sleep, and may occasionally persist into later childhood or, in rare cases, adulthood. Although its etiology remains poorly understood, RMD episodes may function as self-soothing behaviors to facilitate sleep. Current treatment options are limited, but vestibular stimulation, such as rocking, has shown potential to enhance sleep quality and reduce RMD symptoms. This study evaluated the feasibility, acceptability, and therapeutic potential of the Somnomat Casa, a robotic bed delivering vestibular stimulation, in a 14-year-old male with RMD. Over a 22-week protocol, including baseline, intervention, and washout phases, the bed applied varied frequencies (0.25 Hz and 0.30 Hz) and directions (lateral and longitudinal) of rocking. Data collection included camera recordings to quantify RMD episodes, a specific Somnomat questionnaire to assess intervention acceptability, as well as sleep quality questionnaires and polysomnographies to capture sleep quality. The intervention demonstrated high acceptability, with the participant reporting improved sleep quality and willingness to continue using the bed. Peak RMD frequency decreased by 17% during the final intervention compared to baseline, and temporal shifts in episode occurrence were observed during intervention phases. Polysomnography suggested potential changes in sleep architecture linked to vestibular stimulation. These findings support the Somnomat Casa as a promising non-pharmacological intervention for RMD, warranting further investigation in larger clinical trials.**

I. INTRODUCTION

Sleep is crucial for maintaining optimal brain function by managing changes in synaptic connection and homeostasis, enhancing brain plasticity, and regulating the encoding and storage of cognitive processes [1]–[5]. In children, sleep plays a vital role in development, as it supports the formation and consolidation of neural circuits during both critical and sensitive periods [6], [7]. Poor sleep quality in children is linked to reduced cognitive performance, negative effects on cardiometabolic health, and long-term lifestyle behaviors that may persist into adulthood [8]–[13].

Rhythmic Movement Disorder (RMD) is a type of parasomnia characterized by repetitive movements such as head banging or repeted body rocking, often accompanied by vocalizations. While RMD typically declines with age, with prevalences of around 66% for 9-month-old infants, 45% for 18-month-old toddlers and 6% for 5-year-old children [14], it can persist into adulthood in rare cases. However, these prevalence rates should be interpreted with caution as records are mainly based on parental reports [15].

Criteria to define an RMD episode were established by the American Psychiatric Association (APA) (2013) as movements occurring between $0.5\,\mathrm{Hz}$ to $2.0\,\mathrm{Hz}$ and lasting for at least four movements [16]. Polysomnography (PSG) studies have identified RMD episodes occurring before sleep onset, during transitions between sleep stages, or upon awakening [17]–[19]. However, current research fails to provide a comprehensive understanding of the sleep architecture in individuals with RMD. Furthermore, despite the prevalence of RMD being documented in infants and young children, the etiology of RMD remains poorly understood due to the absence of electrophysiological, neuroscientific, and genetic studies; a few hypotheses suggest that RMD episodes may serve as a form of self-soothing to facilitate sleep [15], [19].

Current treatments for RMD are limited and include psychological, behavioral, or pharmacological approaches. How-

*All authors contributed equally in this study.

ever, recent research highlights the potential of vestibular stimulation, such as rocking movements, to reduce RMD symptoms and improve sleep quality. Studies have shown that vestibular stimulation enhances sleep in various populations, and interventions such as hammocks have successfully reduced RMD episodes in children [20]–[24].

The Somnomat rocking beds previously developed at ETH Zurich, have demonstrated safety and efficacy across various populations in prior studies [25]–[28]. However, its specific long-term effects on RMD symptomatology and sleep architecture remain unexplored. This single-case study aims to evaluate whether long-term vestibular stimulation delivered through the Somnomat Casa (Figure 1) is an acceptable and feasible treatment option in an individual with RMD. Additionally, it presents a protocol for evaluating the therapeutic effects of these stimulations that can later be used in well-powered clinical trials to investigate the long-term effects of nocturnal vestibular stimulation in individuals with RMD. Finally, this study includes a preliminary attempt using PSG measurements to investigate sleep architecture in individuals with RMD and explore possible beneficial effects of overnight vestibular stimulation on sleep stages and, consequently, on sleep quality; if so, the exploratory protocol would reveal decreased sleep onset time and awekenings, and increased deep sleep..

II. METHODOLOGY

Fig. 1: Original version of the Somnomat Casa. It has dimensions $90\,\mathrm{cm} \times 200\,\mathrm{cm} \times 60\,\mathrm{cm}$ which are comparable to a standard-sized bed.

A. Study Participant

For this pilot study, a 14-year old male individual with a clinically confirmed diagnosis of RMD was recruited following a pre-screening and a review of his medical records. The participant and his guardian provided signed informed consent, in line with the principles outlined by the institutional ethics board. Furthermore, this study was exempted by the Cantonal Ethics Committee (BASEC Nr. Req-2023-00833) and approved by ETH Zurich's Ethics Board (EK-2023-N-329).

B. Intervention and Study Phases

The study was conducted over a 22-week period and was divided into four main phases: 1) a 3-week baseline period without intervention, 2) a 10-week intervention period where four 1-week period with varied vestibular stimulation parameters were alternated with three 2-weeks wash out periods, 3) a 2-month washout phase, and 4) 1-week period of follow-up acquisition without intervention. Depending on the intervention phase, the Somnomat Casa bed delivered two frequencies of vestibular stimulation: $0.25\,\mathrm{Hz}$ and $0.30\,\mathrm{Hz}$, once acting in longitudinal and once acting in lateral direction in comparison to the craniocaudal axis of the study participant (Table I). This would allow to study movements that are parallel and lateral to the vertical axis of the body, as suggested by previous literature [27]. Each frequency and motion configuration was planned for an equal number of nights and was separated by two-week washout phases (Figure 3), determined based on a previous study [26].

Movement Pattern	**Movement Direction**	**Frequency** (Hz)	**Acceleration** ($\mathrm{m\,s^{-2}}$)
P1	Lateral	0.25	0.25
P2	Lateral	0.30	0.35
P3	Longitudinal	0.25	0.25
P4	Longitudinal	0.30	0.35

TABLE I: Overview of the movement patterns applied in this study.

C. Required Modifications to the Somnomat Casa

As the Somnomat Casa in its original form (c.f. Figure 1) only allowed to stimulate in the longitudinal directions, hardware modifications were made. To keep the mechanical changes minimal, we added structural reinforcements to the top frame to increase stability. This allowed to widen the top frame from $90\,\mathrm{cm}$ to $180\,\mathrm{cm}$, allowing the participant to rotate 90 degrees in his bed. Furthermore, we padded the lateral extensions to cushion accidental contact with moving parts (Figure 2).

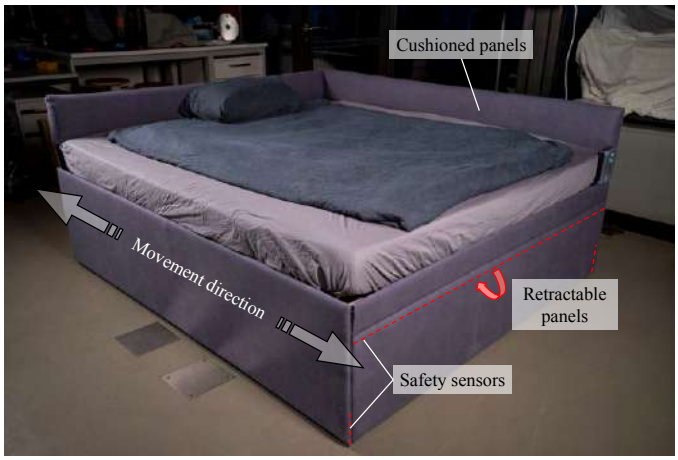

Fig. 2: Modifications performed to the Somnomat Casa. The top frame was widened, allowing the participant to rotate 90 degrees. Furthermore, cushioning was installed to reduce injury risk in case of headbanging.

D. Data Collection

Participant acceptability of the intervention was assessed through self-reported questionnaires. The participant was

Fig. 3: Schedule of the study protocol. After a 3 weeks (W) baseline period without intervention, four 1 week intervention phases (P1...P4) followed, separated by 2 weeks wash out phases (P) without any intervention. A 1-week long follow up examination (F) was carried out two months after the end of the last intervention.

asked to complete the following subjective measures at predefined intervals to monitor domains of sleep quality, comfort, and any adverse experiences related to the intervention:

- Somnomat Casa Acceptability Questionnaire: A custom questionnaire designed to evaluate the participant's perceptions of the bed's comfort, intuitiveness, noise level, and movement smoothness.
- Karolinska Sleepiness Scale (KSS): Assessed each morning to record the subjective sleepiness and observe variations in sleep quality throughout the intervention.
- Pittsburgh Sleep Quality Index (PSQI): Conducted weekly to obtain a subjective measure of sleep quality by investiganting different domains of sleep such as sleep latency, sleep duration, and sleep disturbances.
- Mini Sleep Questionnaire (MSQ): Completed weekly to assess general symptoms of sleep and wakefulness, including disturbances in daytime and nighttime functioning.
- Checklist Individual Strength (CIS): A 20-item questionnaire conducted weekly to assess various aspects of fatigue, including subjective fatigue, motivation, concentration, and physical activity.
- Modified Epworth Sleepiness Scale (M-ESS): Administered weekly to evaluate fatigue and daytime sleepiness.
- Visual Analog Scale (VAS) for pain: Used weekly to monitor neck discomfort, as the participant had previously reported neck pain associated with his significant nightly movements.

Furthermore, data collected from a night vision camera (Reolink E1, Reolink, Hong Kong) were used to determine time spent in bed, as well as bed usage duration, providing a quantitative assessment of the overall acceptability. The camera footage also enabled unobtrusive monitoring of the participant's sleep position and movements. Using 5-minute epochs, the video data were scored by a single reviewer (to minimize inter-rater variability) to document and quantify RMD episodes based on the criteria from the APA [16].

Sleep architecture assessments were performed at baseline and after the completion of the intervention using a portable PSG device (Nox A1, NOX Medical), including electroencephalograophy (EEG) and electrooculography (EOG) recordings.

Finally, participant adherence to the protocol was recorded, including any deviations from the prescribed protocol, technical issues, or adverse events. This information provided insights into the feasibility of the protocol, highlighting potential challenges and indicating how realistically participants can follow the protocol. These findings will be valuable for refining the protocol in future studies.

III. RESULTS

A. Protocol Adherence

A total of 154 nights were planned for the study, with data collection scheduled for each of these nights. For the video recordings, a total of 107 nights were planned, but the actual number of nights varied across the phases, with a total of 85 recorded nights (69%). In the baseline phase, 12 video nights were completed, while intervention and washout phases saw varying levels of adherence.

Questionnaire adherence showed some variation, with the KSS, M-ESS, CIS, VAS, and MSQ being the most consistently completed assessments, with 134 out of 154 planned nights (87%). The Somnomat acceptability questionnaire was completed in 3 out of the 4 planned nights, and the MSQ was completed 13 times. The PSQI was planned for 14 nights, with 11 nights being fully completed without missing data. Global PSQI scores, reported in Table N, were assessed from the sel-reported answers to the questionnaire as a measure of percived sleep quality. The global scores didn't show a significant change during the overall protocol (Median= 6; IQR= 2) with a maximum of 9 points on 21 both at the beginning an at the end of the protocol.

B. Acceptability

The participant completed three out of four Somnomat acceptability questionnaires (during interventions 1, 2, and 4) assessing the intervention. Overall, the participant reported a positive experience, highlighting the perceived safety and the speed of the movements, particularly during the faster movement patterns (P2 and P4, c.f. Table I). The participant noted that the bed subjectively helped him fall asleep faster and did not cause awakenings during the night. However, the participant also reported that the bed occasionally struggled to counteract his strong, violent movements, resulting in some motion disturbances. Despite this, he expressed a desire to continue using the bed and reported a subjective improvement in his condition and sleep quality.

C. Therapeutic Effect

Throughout the entire study duration, the nocturnal rhythmic movements occurred consistently, visually identifiable by an initial peak followed by four additional peaks (c.f. Figure 4). Considering the movement patterns across the entire study phase, a temporal shift is prominent, with the first peak in Intervention 4 occurring approximately one hour later compared to the baseline phase. Furthermore, a general decrease in peak rhythmic movements is notable, from 12 episodes during the baseline down to 10 episodes per 30-minute window (80th percentile) during the intervention period.

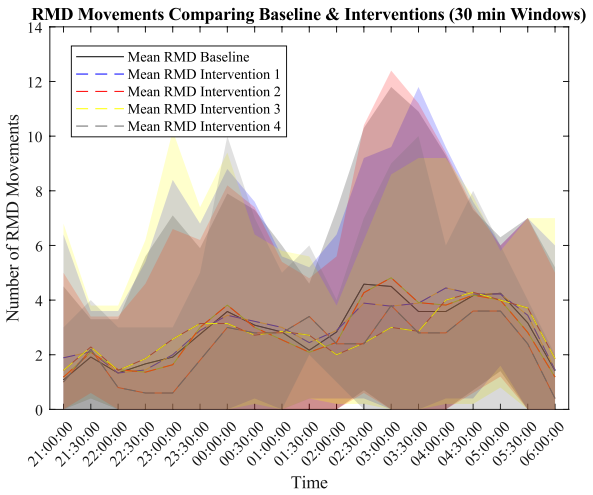

Fig. 4: Comparison of RMD episodes between baseline and intervention phases. In this figure, all nights of the respective phases are combined into a representative night defined through their mean and 80th percentile.

RMD episode percentages across phases indicate a decline in frequency during Washout 1, Intervention 2, and Washout 2 compared to Baseline. Washout 1 shows the most significant reduction, with RMD frequency less than half of Baseline levels. Figure 5 shows the normalized durations of rhythmic movements during the bed time for both Intervention Off and Intervention On periods.

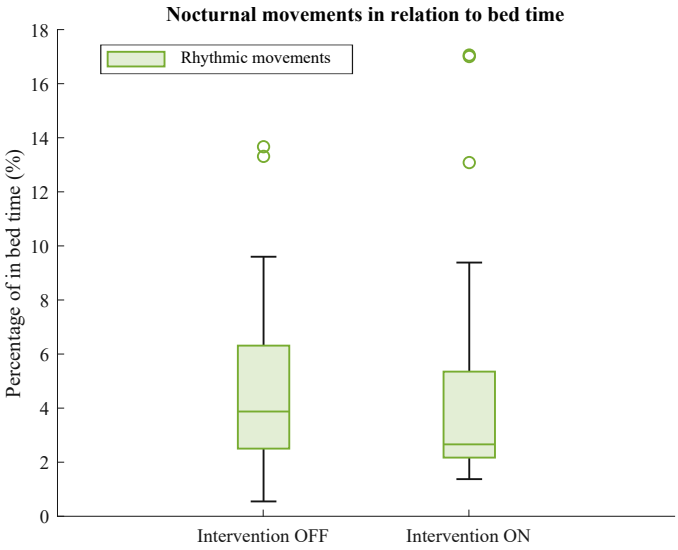

Fig. 5: Comparison of rhythmic movements between intervention-off and intervention-on periods.

Table II provides detailed data on RMD episodes and durations relative to in-bed time.

D. Sleep Architecture and Sleep Quality

Manual sleep scoring was assessed on PSG recordings by a certified sleep scorer classifying sleep stages in epoches of 30 seconds. The analysis of sleep architecture showed significant results comparing Baseline and Follow-Up, using Chi-Squared analysis of variance (Figure 6). In particular, results showed an increase of epochs spent in Non-REM Sleep 3 (NREM3) and Non-REM Sleep 2 (NREM2) ($p < 0.001$***), and a decrease of epochs classified as Wake ($p < 0.001$***). Moreover, despite an increase in sleep onset ($p < 0.001$***), the overall wake time decreased due to decreased awakenings ($p < 0.001$***). At last, it was possible to notice a significant reduction in epochs classified as movements and/or artifacts ($p < 0.001$***).

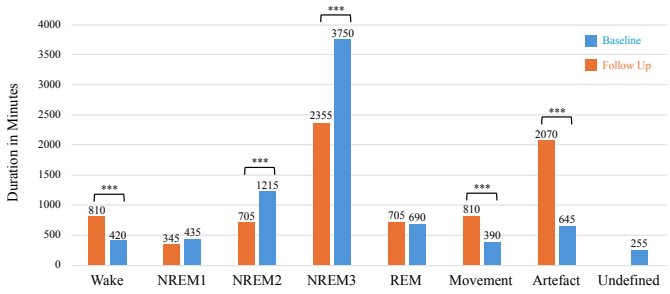

Fig. 6: Comparison on sleep stage, movement, and artifact durations between baseline and follow up. Statistical significance is indicated as *** for $p < 0.001$.

PSQI scores were explored for potential differences in sleep quality throughout the protocol but the analyses did not show a significant difference nor a trend in either a positive and negative direction (c.f. Table II).

IV. DISCUSSION

The intervention was well-tolerated, with the participant reporting improved sleep quality, reduced RMD symptoms, and willingness to continue using the bed. The participant highlighted the perceived safety, comfort, and therapeutic benefits of the bed's movements, although strong, violent movements occasionally disrupted the rocking mechanism as the output torque was limited to approximately $20\,\mathrm{N\,m}$ for safety concerns. These findings suggest that the Somnomat Casa could offer a non-invasive intervention for individuals with RMD but further adaptations to the Somnomat Casa have to be undertaken to counteract strong movements from the users.

Noticeble, the temporal shift of the first RMD episode when comparing baseline and last intervention week shows a delay in RMD symptomatology. This result might suggest that the experimental protocol might also have a positive influence on sleep patterns facilitating sleep onset and sleep quality in the first hours of bedtime.

Accordingly, the analyses of sleep architecture led to promising positive significant results with increased NREM3 and NREM2, and decreased wake time. However, these results might be biased by the number of movements and artifacts that, in turn, limit the possibility to perform a totally accurate sleep staging, which is inherent in the pathology.

Overall, the study demonstrated good adherence to the core components of the protocol, though some deviations were noted, particularly in the protocol adherence and usage of

Phase	Average Time in Bed (hh:mm)	Average RMD Episode Duration (mm:ss)	Standard deviation of RMD Episode Duration (mm:ss)	Mean PSQI Score
Baseline	8:49	00:28	00:13	6
Intervention 1	9:17	00:36	00:19	6
Washout 1	9:08	00:12	00:06	9
