Follow-Up	–	–	–	5

TABLE II: Progression of RMD metrics as well as PSQI scores throughout the study phases. The table summarizes average time spent in bed, as well as the average and standard deviation of RMD episode duration across baseline, intervention, washout, and follow-up periods, and the averaged PSQI scores.

the video camera and completion of the questionnaires. These deviations were primarily due to the complexity of the protocol and participant factors. The findings suggest that while the protocol was feasible, certain adjustments may be needed in future studies to further improve adherence, particularly for the more demanding components of the data collection process, as well as automated checks should be put into place that detect incomplete questionnaire data as early as possible.

Nonetheless, the primary limitation of this study was its single-case design, which limits the generalizability of the findings. In this regard, we also cannot draw conclusions on the effects of body-parallel versus body-orthogonal movements because the participant was free to change his lying position and frequently reoriented himself, regardless of the intended stimulation direction. Nonetheless, the individual's strong adherence to the protocol and his positive feedback indicate that the intervention is both feasible and well-tolerated, marking an important initial step toward studies with larger cohorts.

V. CONCLUSION

This pilot study demonstrates the feasibility and acceptability of using the Somnomat Casa as a therapeutic tool in a child with a diagnosis of RMD. This study also represents one of the first attempts to investigate sleep architecture using overnight PSG in a child diagnosed with RMD. The intervention showed potential in reducing peak RMD episode frequency and improving objective sleep architecture measures, particularly in enhancing deep sleep. While preliminary, these findings lay the groundwork for future research to explore the therapeutic effects of vestibular stimulation on RMD in larger cohorts. Ultimately, the Somnomat Casa may represent a novel, non-invasive, and accessible solution for managing sleep disorders, offering an alternative to pharmacological interventions.

ACKNOWLEDGMENT

The authors sincerely thank the patient and his family for their willingness to participate in this study and for their valuable contributions and feedback. The authors would like to extend their gratitude to Prof. Catherine Hill from the University of Southampton and Dr. Hasselman from the Ostschweizer Kinderspital in St. Gallen, Switzerland for their ideas and feedback in the design of this study. Deep appreciation goes to Michael Herold-Nadig and Marco Bader from ETH Zurich for their support in the development and fabrication of the Somnomat Casa. Alexander Breuss also gratefully acknowledges the financial support provided by the Promedica Foundation for supporting his research. Open access funding was provided by ETH Zurich.

Design of a Semi-Active Ankle Foot Prosthesis Using a Pneumatic and Hydraulic Hybrid for Stiffness and Energy Timing Control*

Sy Nguyen, Sepehr Ramezani, and Hwan Choi, *Member, IEEE*

***Abstract*—Lower-limb amputees require ankle-foot prostheses with adjustable stiffness and energy return timing to adapt to varying walking speeds, as well as adequate ankle push-off power to propel the body forward. Most passive prostheses utilize energy storage and return with carbon fiber blades (CFBs), but their single stiffness and early energy return timing limit their effectiveness for propulsion. Quasi-active or powered prostheses with CFBs also fail to fully utilize the energy storage and return capabilities of the CFB. As a result, many quasi-active prostheses lack precise energy return timing, while powered prostheses rely on large motors or bulky hydraulic cylinders. In this paper, we present the Pneumatic and Hydraulic Hybrid Prosthesis (PHHP), designed to adjust stiffness and energy return timing. The system leverages the compressible and incompressible properties of pneumatic and hydraulic systems to enable both stiffness adjustment and stored energy delivery timing. The PHHP includes three pneumatic chambers of varying sizes that adjust the resistance of a hydraulic cylinder by turning valves on and off, enabling variable stiffness. The hydraulic cylinder stores energy from the carbon fiber foot's deformation and releases it for push-off assistance via a hydraulic valve. Theoretical and experimental results show the PHHP's potential for push-off assistance and variable stiffness (24.3–54 N/mm), making it adaptable to different walking speeds for lower-limb amputees.**

I. Introduction

A lower limb amputation is often performed when a limb is irreparable or functionally compromised due to severe trauma, congenital deficiencies, infections, or tumors. Given the rising prevalence of diabetes, the number of lower limb amputations is expected to increase in the coming years [1]. Lower limb amputation frequently leads to biomechanical and neurological changes that reduce mobility, accelerate joint degeneration, and adversely impact quality of life. To restore essential functional movement for individuals with limb loss, numerous prosthetic feet have been developed [2-11]. Among these, the carbon fiber blade (CFB) prostheses are one of the most widely used due to its low cost, lightweight, and durability. It can return a portion of the energy stored during walking, delivering supportive and propulsive energy stored in the carbon fiber foot's deformation [2].

However, CFB prostheses provide a single level of stiffness and lack the ability to control the timing of energy release, which can lead to improper walking and increased muscular demands [3]. To enhance the efficiency of CFB prostheses, several studies have explored adjusting stiffness, commonly by using elastic beams [4,5] or spring-damper systems [6,7]. Recently, using a leaf spring with solenoid-driven linear actuators was proposed to adjust the level of stiffness [8]. Utilizing multiple linkage systems for ankle-foot prostheses represents a recent advancement in prosthetic design. For example, Gabert et al, developed a powered polycentric prosthesis using a four-bar mechanism, primary helical gear, and roller screw transmission [9]. Similarly, Rogers et al, designed a 2-DOF ankle with a U-joint and two linear actuators for a rock-climbing ankle-foot prosthesis [10]. Another approach by Lenzi et al, utilized a cam-driven ankle mechanism to design a variable stiffness prosthesis [11].

Although these prostheses can provide variable stiffness, the total amount of energy is used inefficiently to replicate the biological ankle, which generates more than 50% of the total limb power [12]. This inefficiency arises because these designs do not fully utilize the substantial amount of energy stored in the CFB, which could otherwise support push-off. Instead, the energy stored in the CFB is often released prematurely during midstance, requiring these devices to compensate with larger motors and batteries to deliver sufficient push-off power. Prior work has demonstrated that when prosthetic designs fail to control the timing of energy release effectively, they must rely on active power input to generate ankle work, leading to increased power consumption and larger motor requirements [13,14]. Semi-active prosthetic designs have been introduced to regulate the timing of energy release and improve efficiency [4,15]. Using a large motor and sophisticated mechanism fully leveraging the energy stored in the CFB remains an ongoing challenge in the field.

Using a hydraulic cylinder to capture force from a passive component, such as a CFB, is another method for adjusting stiffness. Commercially available ankle-foot prostheses, such as the OttoBock Triton Smart Ankle [16], Endolite Élan [17], and Freedom Innovations Kinnex [18], incorporate hydraulic components on the CFB to utilize the stored energy in the carbon fiber. However, the hydraulic cylinders of these prostheses are intended to absorb energy from heel strike in order to focus on delivering comfort to users. Thus, they do not contribute to energy support. Pneumatic actuators and cylinders, which behave similarly to mechanical springs, have the ability to provide adjustable stiffness in prosthesis. For example, pneumatic-driven, muscle-like actuators provide another method of control ankle prostheses [19]. Mooney et al., [20] developed the pneumatic transtibial ankle prosthesis that provides a wide range of motion for various activities. However, the size of the pneumatic chamber or hydraulic

cylinder must be carefully considered to keep the system compact and energy efficient.

Despite notable advancements in prosthetic technology, significant technical challenges remain, such as single stiffness, high energy consumption, and inefficient use of the CFB's stored energy. With these findings, we present a pneumatic and hydraulic hybrid prosthesis (PHHP) that enables customized stiffness and effective push-off work while maintaining energy efficiency. The PHHP design leverages the compressibility of air to offer variable stiffness levels through adjustable pressures, while hydraulic components control the timing of energy release via the incompressible nature of fluid. First, numerical analyses were conducted to determine the physical parameters of the hydraulic-pneumatic system. Next, a prototype was fabricated. Finally, experiments were conducted to evaluate the stiffness variation and push-off functionality of the proposed device

II. PROSTHETIC DEVICE DEVELOPMENT

A. System overview

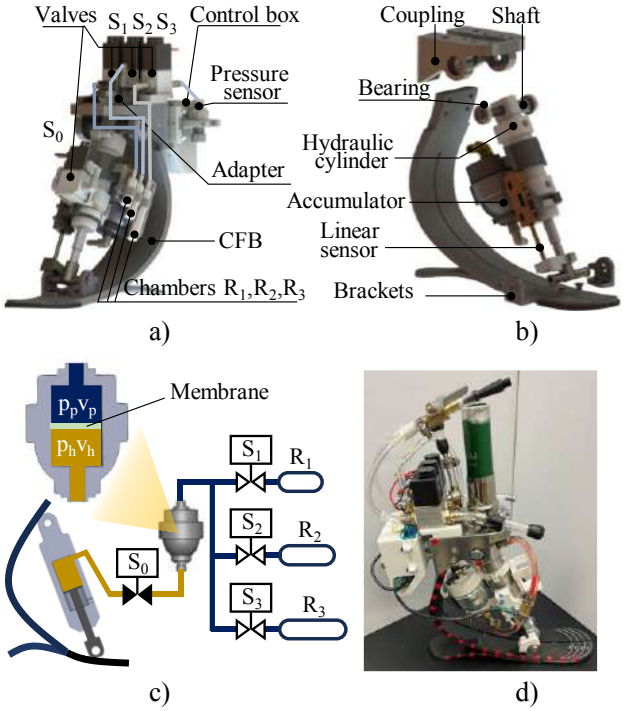

Fig. 1 The overall design of PHHP; (a) The overview of assembled prosthesis; (b) The exploded view of PHHP, (c) The pneumatic (chambers R_1, R_2, R_3 solenoids S_1, S_2, S_3) and hydraulic (solenoids S_1 and hydraulic cylinder) diagram; (d) The prototype of PHHP.

The overall design of the proposed prosthesis, incorporating a pneumatic and hydraulic hybrid system is illustrated in Fig. 1. The PHHP has a compact total dimension of L28 x H24 x W8 cm, (weight 2.7 kg) comparable to the size of a commercially available carbon fiber foot. The design comprises four main components:

1. **Carbon Fiber Blade:** Since our goal is to develop an affordable, lightweight prosthesis for commercialization, we employed a compliant CFB (Flex-Foot Cheetah, Össur, Reykjavík, Iceland) to provide the base stiffness. The CFB has been cut to create a low-profile structure, making the prosthesis compatible with various residual limb length of people with lower limb amputation. The upper part of CFB is fixed with a coupling, forming as single unit. This coupling connects to an adapter that links to the pylon, allowing anterior or posterior adjustments of CFB. It is mounted on the top of the device, enabling a custom fit for users.

2. **Hydraulic System**: Hydraulic system includes a hydraulic cylinder (DSNU-32-20-P, Festo, Esslingen, Germany), which is connected to the CFB via the coupling, an accumulator, and a hydraulic solenoid valve (12V Electric Solenoid Valve, Tailonz, China) (S_0). The S_0 valve connects to the hydraulic cylinder (HC) and the accumulator, allowing the PHHP to capture the stored energy on the deformed CFB by maintaining deformation using the incompressible of fluid. Then, S_0 valve also releases the stored energy on the CFB in an appropriate time to make efficient push-off and support during terminal stance. To achieve a low profile and a compact size, we placed the accumulator between HC and the CFB. Also, we set HC in a 65^0 of angle to effectively convey the pressurized force to the CFB and make the prosthesis fit into shoes. A pneumatic manifold is implemented directly onto the accumulator to avoid the need for piping, the design's complexity, and the risk of leakage. One end of HC can freely rotate around the shaft mounted by the coupling, while the opposite end (HC's rod) connects with a T-shape that is supported by fixed brackets on the CFB, as shown in Fig. 1b.

3. **Pneumatic System**: The pneumatic system comprises three pneumatic solenoid valves (12V Electric Solenoid Valve, Tailonz, China) (S1, S_2, and S_3) and three pneumatic chambers (R_1, R_2, and R_3) of different sizes. These components adjust the effective resistance of the HC by altering the states of S_1, S_2, and S_3, thus changing the stiffness of the entire prosthetic foot. Additionally, the system is equipped with a pressure sensor (150 Psi Pressure Sensor, AUTEX, Riverside, CA) to measure chamber pressure, a linear sensor (Sensors 9615R5, AUTEX, Riverside, CA) to monitor the displacement of the hydraulic cylinder's rod, and a control box to manage valve states during an operation.

4. **Accumulator:** An accumulator (AC 40-1/4, Hawe Hydraulic SE, Germany) is used to connects the pneumatic and hydraulic systems. As shown in Fig. 1c, the yellow line represents oil and blue line represents air. The accumulator features an elastic membrane which separates the hydraulic (yellow) and pneumatic (blue) chambers, enabling energy transfer between two sub-systems. The prototype of the proposed system is shown in Fig. 1d

B. Working principle of the PHHP

From heel strike to mid-terminal stance, the weight of the body deforms the CFB, and the total external force is distributed between the CFB and the HC. Because the level of CFB stiffness remains constant, we control the pneumatic system to provide additional stiffness on top of CFB. As shown in Fig. 1c, when the CFB is compressed by an external force (i.e., weight bearing of prosthetic user), it pushes the hydraulic piston, causing oil to flow into the accumulator. As oil flows into the accumulator, the membrane is displaced, reducing the volume of the pneumatic chamber while increasing its pressure. This process converts the energy of the external force into hydraulic energy and subsequently into

pneumatic energy, which is stored in the pneumatic chamber. Since each chamber is equipped with on/off valves, the total available volume of air can be adjusted by selecting different combinations of chambers via the three pneumatic valves. For instance, if all valves are closed, only the volume within the accumulator will be pressurized by movements in the hydraulic system and PHHP becomes stiffest. Conversely, when all valves are open, the maximum pneumatic volume is achieved, reducing the pressure to displacement changes in the hydraulic system. Additionally, once the stroke of HC reaches a maximum compressed displacement (the mid-terminal stance phase), the hydraulic valve closes, maintaining both CFB deformation and the HC position as oil is incompressible. Subsequently, the hydraulic valve opens, the stored energy of CFB and pneumatic chamber returns, and this generates a push-off force. This sequence repeats in each gait cycle.

C. *Modeling a static test*

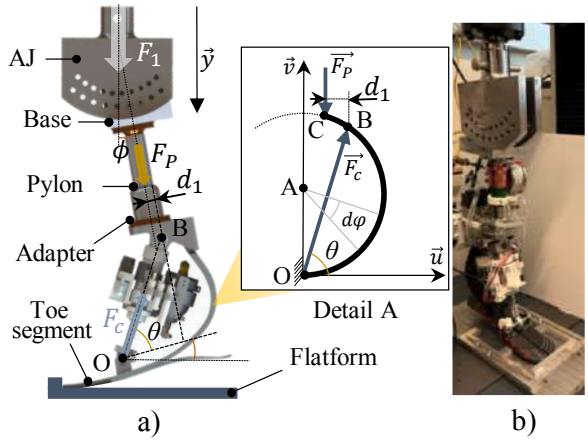

Fig. 2 Model for PHHP; (a) The 3D model of PHHP on the universal testing machine and modeling of PHHP (Detail A); (b) The experimental setup of the prototype on a universal test machine.

For the initial development of the prototype, the PHHP was installed on a universal testing machine (313 model, Test Resources, Shakopee, MN) to validate how the pneumatic system affects the overall stiffness of the prosthesis. We used an adjustable jig (AJ) and base with 5° rotational adjustment slots, allowing us to apply force in each dorsiflexion angle (Fig. 2a). We set the prosthesis in 0°, 5°, 10°, and 15° dorsiflexion and applied 950 N.

In the setup, a load representing the human weight bearing force (F_1) was applied vertically (y-direction), creating an angle ($\emptyset$) between the prosthetic pylon (or amputee's shank) and the y-axis. The load applied to the pylon is denoted as F_p, with the distance from F_p to the rotational point (B) designated as d_1, as amputee users may adjust the adapter position for comfort. L_1 represents the displacement of the HC from point B to point O when the prosthesis is under load, while F_c indicates the resistive force from the pneumatic system. Finally, θ represents the angle of the HC relative to the ground in the prosthesis's neutral position.

To determine the deformation at point B, a geometric model is derived using Castigliano's theorem [21]. In this model, point O is considered fixed, as the toe segment of the CFB contacts the ground, creating resistance in the hydraulic system through the force F_c, (Fig. 2a, detail A). We examined a curved beam fixed at one end (point O) and subjected to forces at the free end (point B). Given that the distance d_1 is small, we simplify the model by assuming the load F_p acts at a distance d_1 from the free end. Thus, the displacement of point B (γ) in the v-direction is represented in Eq. 1.

$$\gamma_{v_{F_i}} = \frac{\partial U}{\partial F_i} = U_1 + U_2 + U_3 \quad (1)$$

$$U_1 = \int_0^t \frac{1}{EI}\left(M\frac{\partial M}{\partial F_i}\right) Rd\varphi \quad (2)$$

$$U_2 = \frac{1}{EA}\int_0^t \left(N\frac{\partial N}{\partial F_i}\right) Rd\varphi \quad (3)$$

$$U_3 = \frac{2(1+\sigma)}{EA} K_x \int_0^t \left(V\frac{\partial V}{\partial F_i}\right) Rd\varphi \quad (4)$$

Where $\gamma_{v_{F_i}}$ represents the defection in direction v-direction at tip, caused by the input force F_i. U represents the deformation energy. M, N, and V refer to the normal moment, axial force (internal), and shear force (internal) contributions, respectively. R denote the radius of curvature, A is a cross-sectional area, K_x is a shear factor and σ represents is poisson's ratio. E and I refer to Young' modulus and the first moment of area, respectively. The φ represents the span angle of the beam, while t denotes angle of curvature ($\widehat{OAB}$).

Note that we primarily consider deflection in the v-direction, as deflection in the u-direction is neglected due to its minimal impact [21], which aligns with our testing conditions, where a vertical load will be applied to the prosthesis pylon on the testing machine. The input forces in our system consist of F_b and F_c; thus, the normal moment, axial force, and shear force are described in Eqs. 5, 6, and 7, respectively, while deflections in the u- and v-directions in Eqs. 8 and 9 can be achieved by substituting Eqs. 5, 6, and 7 into Eq. 1.

$$M(\varphi) = -F_P(Rs(\varphi) + d_1) + F_c s(\theta)Rs(\varphi) - F_c c(\theta)R(1 - c(\varphi)) \quad (5)$$

$$\mathrm{N}(\varphi) = -F_P s(\varphi) + F_c s(\theta)s(\varphi) - F_c c(\theta)\, c(\varphi)) \quad (6)$$

$$V(\varphi) = F_P c(\varphi) - F_c s(\theta)c(\varphi) - F_c c(\theta)\, s(\varphi)) \quad (7)$$

$$\gamma_v(\varphi) = \gamma_{v_{F_p}} + \gamma_{v_{F_c}} \quad (8)$$

$$\gamma_u(\varphi) = \gamma_{u_{F_p}} + \gamma_{u_{F_c}} \quad (9)$$

Here c and s refers to cosine and sine respectively. γ_v and γ_u represent the total deflection in v- and u-directions, while $\gamma_{v_{F_p}}$ and $\gamma_{v_{F_c}}$ are the single deflection caused by each input forces. F_c is force from hydraulic piston. Given the deflection and the angle of cylinder, we can determine the displacement of the HC stroke (L_1). Additionally, the relationship between the displacement of the cylinder rod and pressure of pneumatic system can be expressed as shown in Eq. 13.

$$F_c = P_{p1}A_c \quad (10)$$

$$P_{p1} = (P_h - \Delta P_1 - \Delta P_2)A_c \quad (11)$$

$$V_{p1} = V_{ac} + V_{cham1} + V_{cham2} + V_{cham3} \quad (12)$$

$$P_{p2} = P_{p1}\left(\frac{V_{p1}}{V_{p2}}\right)^n = P_{p1}\left(\frac{V_{p1}}{V_{p1} - \Delta V}\right)^n \quad (13)$$

Where P_{p1} and P_{p2} are the air pressure in the accumulator before and after loading. ΔP_1 and ΔP_2 denote pressure losses due to bends/turns, and different tube segments in the hydraulic system. V_{p1} and V_{p2} are the volumes of the pneumatic system before and after loading. V_{ac} and A_{cham1} , A_{cham2}, and A_{cham3} are the volumes of the accumulator and three chambers, respectively. $\Delta V = L_1 A_c$ volume change under loading, where A_c is a piston's area and n is a constant [22].

Note that the following assumptions are made for a rough estimation of the stiffness equation: (1) the stiffness of the accumulator membrane is negligible, (2) the volume change in the cylinder is equal to the volume change in the gas side of the accumulator, (3) friction within the HC is negligible, (4) the gas behaves ideally, and (5) pressure and temperature within the accumulator and chambers are homogeneous

D. Experimental setup

The first experiment aims to validate the hydraulic system's ability to provide push-off in desired time. The dorsiflexion angle at push-off is approximately 15° for unimpaired individuals. The dorsiflexion angle peaks during the late Terminal Stance phase of the gait cycle, also known as the energy storage phase, which typically occurs between 30 % and 50 % of the gait cycle. In our setup, the PHHP was tested at a dorsiflexion angle of 15°, closing the hydraulic valve at peak dorsiflexion to observe the response of the CFB's energy return timing.

The second experiment is to evaluate the variable stiffness system of the PHHP. The prototype was subjected to a static test using universal testing machine, as shown in Fig. 2a. The adjustable jig was connected to the head of the testing machine which has a load cell attached. The input is the applied load of 950 N was applied to the shank at a rate of 100 N/s, following the dorsiflexion test (ISO 10328 Standard Static Test) for a 100 kg human reference [23], and the output is the measured vertical displacement. In this experiment, shank angles (∅) of 0°, 5°, 10°, and 15° were tested under each valve condition.

For investigating the impact of varying pneumatic chamber configurations and accumulator pre-charge pressures on prosthesis stiffness, this study utilizes three pneumatic chambers with distinct volumes, labeled V_1, V_2, and V_3, alongside pre-charge pressures set at 100 kPa and 200 kPa. Initially, a pre-charge pressure of 100 kPa was applied to the pneumatic system with all pneumatic valves (S1, S2, and S3) in the open position. This configuration, termed "Open ALL," establishes a uniform system pressure of 100 kPa across the accumulator and all three pneumatic chambers. The experimental procedure then transitions to a second configuration, referred to as "Close 1," wherein valve 1 (S_1) is closed. Under this condition, the effective pneumatic volume is confined to the accumulator and pneumatic chambers 2 (V_2) and 3 (V_3). Subsequently, a third configuration, "Close 1,2," involves closing valves 1 (S_1) and 2 (S_2), effectively limiting the active pneumatic volume to the accumulator and pneumatic chamber 3 (V_3), while maintaining the initial pre-charge pressure of 100 kPa. Finally, in the fourth configuration, all three pneumatic valves are closed or "Close 1,2,3", resulting in an effective pneumatic volume that comprises only the accumulator, representing the system's minimum effective pneumatic volume. This sequence of configurations was replicated under the 200 kPa pre-charge condition to facilitate comparative analysis across different pressure levels. The symbols and its description/values of variables are summarized in Table 1.

TABLE 1. THE PARAMETERS OF PROPOSED PHHP

Symbol	Definition
θ = 65°	Initial angle of the HC relative to the ground
E = 63 Gpa	Young' Modulus [24]
I = 3.10^{-9} m^3	Moment of inertia
∅ = [0° ,5° ,10°, 15°]	Dorsiflexion angle
A_c = *8* 10^{-4} (m^2)	Piston head area
ΔP_1, ΔP_2 (Pa)	Hydraulic pressure losses
V_{ac} = *4* 10^{-7} (m^3)	Volume of accumulator
$[V_1, V_2, V_3]$ = *[4.5, 6.5, 9]*10^{-6} (m^3)	Volume of chamber 1, 2 and 3

III. RESULT AND DISCUSSION

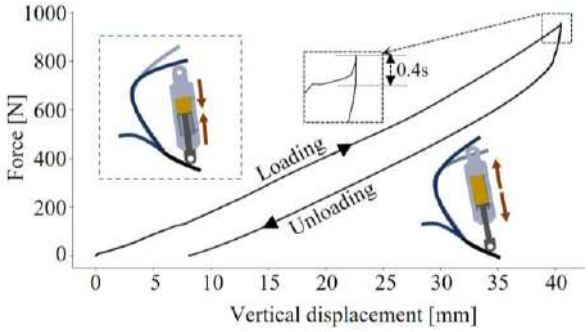

Fig. 3 CFB energy return time with hydraulic valve

In the first hydraulic valve and CFB experiment, we observed that the hydraulic valve can hold the CFB securely for approximately 0.4 seconds before losing holding force due to bubble formation and/or valve leakage, as shown in Fig. 3. The incompressible nature of oil enables PHHP to store energy and release just by turning on/off the valve. It is important to note that the holding force at peak dorsiflexion and the release of stored energy occur between 50 % and 60 % (preswing phase), which is approximately 1 millisecond for normal walking speed [25]. Based on these findings, the PHHP shows strong potential to store and deliver effective push-off work with given time during preswing phase.

In the second variable stiffness experiment, we found that the force-displacement curves follow a polynomial pattern. To simplify, a purely elastic model was used, and the linear stiffness was calculated [26]. For example, the stiffness of the prosthesis was experimentally determined to be 48.6 N/mm under the 100 kPa pre-charge condition with Open ALL, as shown in Fig. 4a. In addition, the percentage values next to the arrows in each bar indicate the discrepancy between theoretical and experimental results. An upward-pointing

arrow indicates that the theoretical result is higher than the experimental result by the specified percentage

In general, stiffness decreases as the dorsiflexion angle increases. At the neutral position, most of the load is applied to CFB, and the displacement direction of the HC aligns closely with the displacement of the CFB. Therefore, stiffness in this position primarily reflects the intrinsic stiffness of the CFB. However, as the dorsiflexion angle increases, the HC experiences more force, and the contribution of the compliant toe segment becomes more pronounced, thereby influencing the overall stiffness. The linear stiffness values increase with higher pre-charge pressure across all valve configurations and dorsiflexion angles. This effect is due to the high initial pressure in the accumulator, which enhances resistance to CFB's deformation under load (Figs. 4a, 4b). It is important to note that the pre-charge pressure can help establish a high baseline stiffness to meet the needs of individual amputees, and the variable stiffness can then be adjusted by modifying the effective pneumatic volume. We found that the linear stiffness of the proposed design is comparable to that of most commercial devices (25 N/mm to 54 N/mm) [27], indicating its potential adaptability for different users.

For 0° dorsiflexion, the discrepancy between theoretical and experimental stiffness is relatively small (approximately 4 % to 9 %), which aligns well with theoretical expectations. This is because, at neutral position, the toe segment does not significantly affect the overall stiffness. However, at higher dorsiflexion angles (5° and 10°), the toe segment of the CFB adds to stiffness, leading to a greater error. At the maximum dorsiflexion angle of 15 °, where the piston angle approaches nearly vertical alignment ($\varphi \cong 80°$), the pushing force is directed towards the HC, similar to the theoretical model. Although the toe segment still influences the initial phase of compression testing, the head of the toe segment is subjected to load rather than the body's toe segment. As a result, the toe segment experiences vertical loading instead of bending loads, such as at 5° or 10°. Consequently, the difference between theoretical and experimental results decreases as the dorsiflexion angle approaches 15°.

Although the proposed device exhibits minimal variation in total stiffness, Figs. 4a and 4b illustrate the combined stiffness of the passive CFB and the additional contribution from the pneumatic-hydraulic hybrid system, highlighting its promising performance relative to prior research. For example, the relative differences in stiffness between "Close 1", "Close 1,2", and "Close 1,2,3" configurations, compared to the baseline stiffness ("Open All") at 0° under a 200 kPa pre-charge condition, are 4.7%, 6.7%, and 7.9%, respectively. This is comparable to the increased average stiffness observed at walking speeds of 1 m/s (4.7%), 1.25 m/s (7.2%), and 1.5 m/s (13.7 %) compared to the stiffness at a 0.75 m/s speed [28]. In [29], the displacement measured during static testing was approximately 44 mm, 45.5 mm, and 48.5 mm for the compliant, stiff, and stiffest conditions, respectively, corresponding to stiffness variations of 3.4% and 10%. In [30], we observed that ankle torque during running at 2.6 m/s and 4.0 m/s differed by approximately 4%. Furthermore, from the force-displacement response, we calculated the elastic energy

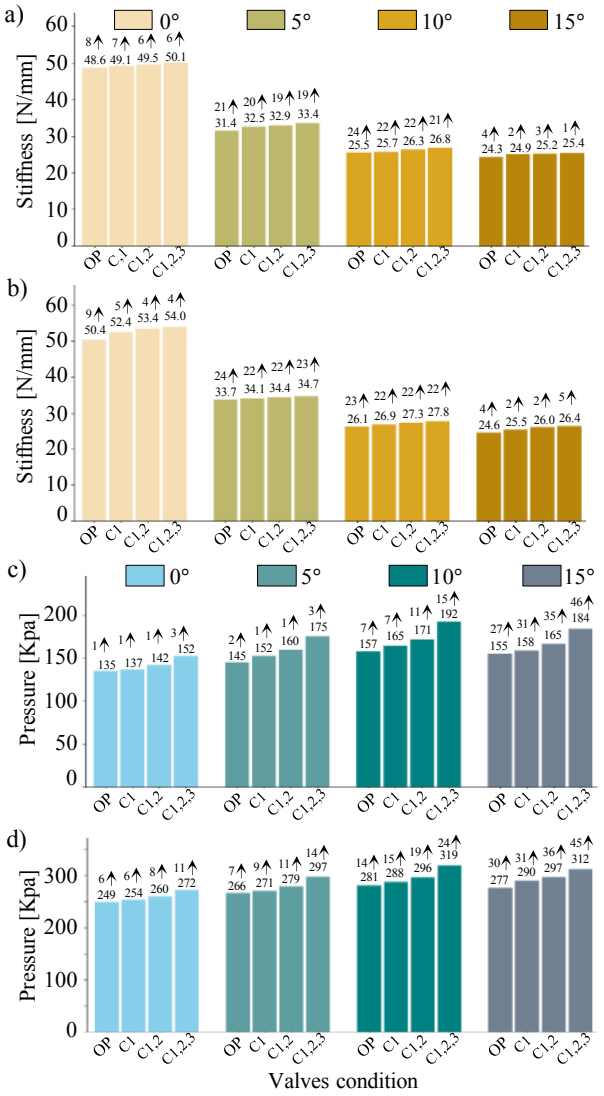

Fig. 4 Experimental and theoretical results; (a) The linear stiffness of PHHP under the 100 kPa pre-charge condition; (b) The linear stiffness of PHHP under the 200 kPa pre-charge condition; c) The pneumatic pressure under the 100 kPa pre-charge condition; (d) The pneumatic pressure under the 200 kPa pre-charge condition.

during loading and unloading. The PHHP demonstrated 72% to 84% energy return efficiency, indicating high energy effectiveness in the forefoot loading experiment [31].

Regarding pneumatic pressure, discrepancies may arise from factors such as membrane stiffness, cylinder friction, and air bubbles in the hydraulic system, as illustrated in Figs. 4c and 4d. Achieving complete oil saturation in the hydraulic tube of the prototype is challenging at this moment. Generally, we observed that the error increased with higher dorsiflexion angles. This discrepancy occurs because the model assumes that the displacement of the HC is directly proportional to changes in pneumatic volume. However, in practice, additional force is required to bend the toe segment, which reduces the HC's displacement compared to theoretical predictions. Additionally, we can see that the increased pressure provides a good amount of force for devices, leading to the big change in stiffness values. For example, as shown in Fig. 4a, the pressure reaches 135 kPa (equivalent to a force of 108.54 N acting on the piston). The additional pressure of 35

kPa (observed at OP in 0° under a 100 kPa pre-charge condition) corresponds to an extra force of 28 N on the piston, accounting for 26 % of the total force acting on the hydraulic piston compared to the pre-charge condition alone.

IV. CONCLUSION

In this study, we proposed a PHHP capable of not only providing variable stiffness but also storing energy, maintaining deformation to hold the stored energy, and releasing it at the desired time. The PHHP was modeled and validated by comparing theoretical model with experimental results. The energy transfer from the pneumatic system to the hydraulic system, facilitated by the membrane of the accumulator, enables the PHHP to generate various stiffness values, making it adaptable to different walking speeds for lower-limb amputees. Additionally, the proposed system provides push-off assistance with a simple on/off valve mechanism, resulting in a design that is both mechanically simple and energy-efficient.

For this initial investigation, we performed a feasibility analysis of the mechanism. As a next step, further refinement of the PHHP model is required, including optimization of the accumulator, tubing, and chamber dimensions to create a more compact system. The stiffness of the diaphragm in the accumulator, which affects the overall stiffness, should be considered. Finally, rather than employing three distinct sizes of pneumatic chambers, a single pneumatic cylinder and motor will be employed to alter the pneumatic volume to adjust stiffness and provide additional energy to users by actively compressing the air.

A Control Method for Transtibial Prostheses with Bilateral Leg Data

Aniket Mazumder[1], Edsko E.G. Hekman[2], and Raffaella Carloni[1]

Abstract— **Micro-controlled lower limb prosthetic devices typically employ onboard sensors on the amputated side of the user's body to generate control patterns. However, balanced ambulation in a healthy subject requires synchronized neural control to facilitate appropriate positioning and orientation of both limbs. Building upon this idea, this study introduces a control architecture that utilizes information acquired from both limbs using only two inertial measurement units (one placed on the left shank, and one placed on the right thigh) to generate the control commands for a transtibial prosthesis prototype clamped to a table-top. Multiple trials were performed with a healthy subject walking on level ground at different speeds and undertaking an obstacle avoidance task. The results of the experiments suggest that incorporating data from each side provides comprehensive information about the limb's positions and orientations, thereby enabling a controller that can handle actuation timing and assist in precise prosthesis control through an understanding of the user's gait states.**

I. INTRODUCTION

Micro-controlled lower limb prostheses incorporate sensors that provide feedback to the prosthesis' controller to regulate its actuators and mechanical properties [1].

An approach to prosthesis control is the finite state-based impedance control. This method subdivides the entire gait cycle into multiple states along with the intermediate transition strategies for walking, standing, sitting [2], [3], [4], [5]. An intent recognizer, then, determines the gait state using sensor data, classified using probabilistic models, with the end-goal of matching the joint impedance and joint angles for the prosthetic system during ground contact.

Another prominent method solving the control problem involves use of a gait phase determination algorithm (volitional control) as demonstrated in [6], [7], [8], and [9]. Here, rotation rate measuring devices (e.g., gyroscopes, potentiometers) are placed on limb segment (tibia/shank), and the integration of rate of rotation yields the segment angles relative to the gravity vector [10], [11].

An initial attempt to control a prosthesis by using information from the sound limb is the echo control method [12], where the sound limb motion is used as a reference motion profile and played back for the prosthetic side. However, this control method is usually better suited for repetitive tasks, such as level ground walking. A second method that utilized data from the sound limb is the complementary limb motion estimation method, based on the principle that the limbs of a healthy human are inherently coupled through physiological couplings. While the method can successfully estimate the gait trajectories online, due to the nature of the coupling assumed in this method, it might not prove to be efficient during obstacle avoidance steps [13].

Since balanced ambulation necessitates optimal positioning of the entire body frame, accurate control ideally requires kinematic and dynamic information from all body segments. Based on this premise, the research presented in [14], [15], [16] and [17] demonstrated a system that employed a whole-body sensory array that uses a combination of seven inertial sensors placed on leg segments on both sides and the trunk, with force sensors placed in the insole of the shoe worn on the sound limb. The objective of this arrangement was to obtain as much sensory kinematic and dynamic information as possible from the subject and to perform level ground walking. The benefits of incorporating data from both sides become more apparent when undertaking complex tasks such as walking over obstacles [18], [19]. In such scenarios, the position information from the planted foot can be utilized to ensure the maintenance of a dorsiflexed toe of the moving foot while clearing the obstacle. Similar advantages can also be achieved when ascending/descending stairs, where power must be injected once sufficient loading of the amputated leg has occurred.

Inspired by [14], [15], [17], this study proposes an architecture to control the ankle joint angle of an active transtibial prosthesis that uses data collected from both legs to detect the states and phases of gait. For this, only two wireless inertial sensor units (IMUs) are used, which are strategically positioned on either side of the body, namely one on the shank of the leg wearing the transtibial prosthesis and one on the thigh of the contralateral healthy leg. Since the main focus of this study is the control method, it has been tested in a healthy participant, where data were taken from the shank and contralateral thigh, and the control system actuates a transtibial prosthesis on a fixed test bench. The ankle joint angle of the prosthesis is controlled by fusing information obtained from the two IMUs to achieve gait state and phase state estimation.

II. CONTROL SYSTEM

The controller design process begins with an analysis of Figure 1, which depicts the angular velocity of the shank and the angle of the thigh of the opposite sides of a healthy subject during ground level walking at a preferred speed [20].

This work was funded by the European Commission's Horizon 2020 Programme as part of the project MyLeg under grant no. 780871.

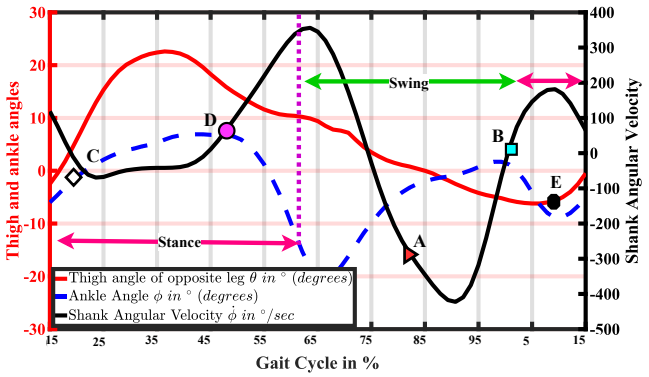

Fig. 1: Thigh angle and shank angular velocity from opposite limbs of a healthy subject during level-ground walking at a preferred speed as obtained from [20]. Point 'A', 'B','C', and 'D', are the reset step point, the step detection point, the stance rollover point and the power injection point, respectively. Point 'E' corresponds to the point where the thigh angle reaches its miniumum value. The plot has been shifted by 15% to demonstrate the linear nature of the thigh angle.

Previous research has demonstrated the existence of a relationship between the angle of the shank and shank angular velocity during walking [16], [21], [22], which allows for the generation of a gait phase variable relating both parameters that can act as an indicator for the overall progression of the gait. Conversely, the use of the angle of the thigh to derive a phase variable has been illustrated in [23], [24] and [25]. In these studies, phase relations from the same side were employed to control the prosthesis. With reference to Figure 1, several observations may be made regarding the *thigh angle* (red curve):

1) The thigh angle of the supporting leg (red curve) exhibits a linear nature with a negative slope from (35%) until (5%) into the next gait cycle.
2) A minimum in the curve, denoted by the black dot E, occurs at approximately the flat foot (7%) of the alternate leg. Then, beyond this point, the angle increases with a positive slope followed by a stance phase.
3) From rollover onward, the thigh angle continues to increase with a positive slope, and reaches its maximum value at approximately 40% of the next gait cycle.

Due to the presence of the linearity of the thigh angle along with a distinct minimum at approximately 7% of the gait cycle we argue that it is possible to utilize the thigh angle information from the contralateral side (lying at 180° out of phase) to provide an insight into the gait progression.

In contrast to the thigh angle, the *shank angular velocity* (black curve) exhibits a lesser degree of linearity. The shank angular velocity over a gait cycle can be subdivided into four sections around four control points (see Figure 1). The method for selecting these four points is as follows: i

1) A crossing of a threshold of approximately $-300^\circ/s$, corresponding to a gait progression of 80% in the plot is considered to be a 'Reset Step' point 'A'.
2) This is followed by a 'Step Detection' point 'B', corresponding to a value crossing $5^\circ/s$ around 100% of the gait cycle.
3) Subsequently, there is a 'Stance Rollover' point 'C', where the angular velocity falls below $5^\circ/s$ at approximately 20% of the gait cycle.
4) Finally, there is a 'Power Injection' point 'D', corresponding to a crossing of $70^\circ/s$ at approximately 50% of the gait cycle.

Based on these observations, we propose a controller that employs the *shank angular velocity data from the prosthetic-side* to regulate the prosthesis during level ground walking situations, while simultaneously utilizing the *thigh angle data from the contralateral side* as a supplementary tool for situations that require obstacle avoidance and for resetting the cycle and letting the controller know that a step detection point can be expected. A comprehensive description of the controller that has been designed based on the aforementioned points is presented in the following sections.

A. Controller Design

The design philosophy of the controller may be understood by considering a two part design as shown in Figure 2, with each part assigned the task of monitoring the motion of a dedicated (left/right) side of the subject. In the current application, the prosthetic side is monitored by the yellow portion in the figure, while the contralateral leg is monitored by the green portion in the figure. The combined monitoring, results in a fused signal that is used to control the overall motion of the prosthesis. The functioning of each side is explained further in the paragraphs below.

1) Monitor of the Prosthetic Side: The yellow portion of the controller in Figure 2 is always active and consists of the logic to detect the four points, namely the reset-step detection point, step detection point, stance rollover point, and the power injection points. This detection is performed by utilizing the shank angular velocity data as input and comparing it with the pre-determined thresholds (as described earlier). The thresholds in the current application were determined by taking and average of 15 trials performed overground by a test subject. The detection of each point is followed by an associated command such as 'Goto: Power Position', 'Goto: Reset Position' and 'Detect: New Step'.

To actuate the prosthesis, the actuation command accompanied by the updated desired velocity and acceleration are sent to the hardware controller. For every gait cycle, the actuation velocities and accelerations are calculated by comparing the last gait cycle time with the reference gait cycle time in [20], and are applied to the subsequent gait cycle. Thus, update to the actuation parameters happens every gait cycle. In this study, the gait cycle time is defined as the time taken between two consecutive steps, and a step is said to be detected when the condition 'B' (shown in the yellow portion of the figure) is satisfied. If no step is detected for a set period 'T', then the subject is said to be at rest, and consequently the prosthesis moves to the rest position where it only provides stationary support to the subject.

2) Monitor of the Contralateral Side: The green portion of the controller in Figure 2 is activated during instances of obstacle avoidance and uses the contralateral leg, which

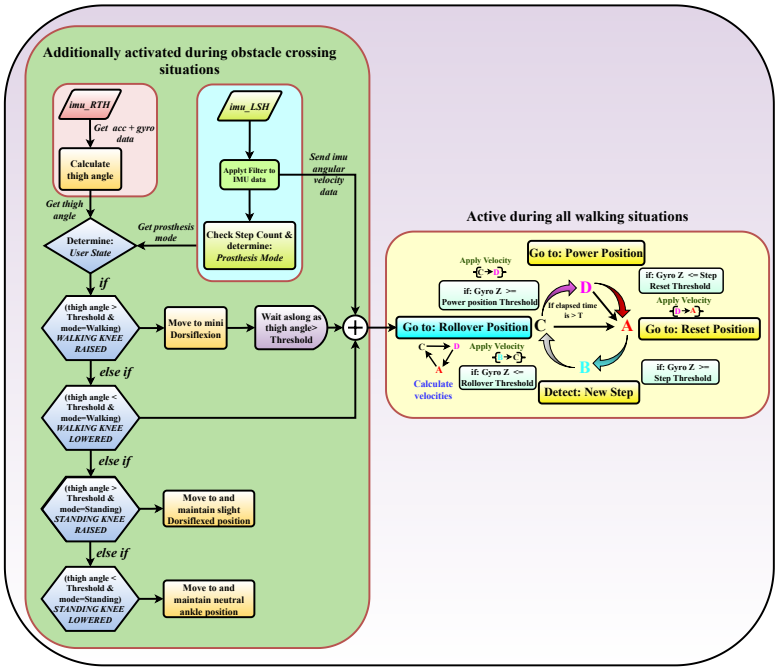

Fig. 2: Control architecture for a transtibial prosthesis, which uses data from two IMUs to generate position profiles and actuate the prosthesis. imu_RTH represents the IMU on the right thigh, whereas imu_LSH represents IMU on the left shank. The green block represents the logic where the data fusion from both IMUs occurs, whereas the yellow block shows the outcome of the decisions as applied to the prosthesis. The thigh angle threshold is set at 30°.

is continuously monitored. Data are obtained from two IMUs: imu_RTH (placed on the contralateral right thigh) and imu_LSH (placed on the amputated left shank). The acceleration and angular velocity data obtained from imu_RTH is first used to calculate the global thigh angle with respect to the direction of gravity (red box). This is accomplished by numerically integrating the gyroscope data over time using a complementary filter, as explained later. The information of the thigh angle is then utilized to determine the *'User State'*, which can either be *'Knee raised'* or *'Knee Lowered'* based on a thigh angle threshold determined to be 30° after multiple trials of raising a lowering the contralateral leg. On the other hand, the IMU data obtained from the imu_LSH is utilised to determine the number of steps taken by the prosthesis (cyan box). Based on the number of steps accumulated by the user, the *'Prosthesis Mode'*, is either set to *'Standing'* or *'Walking'*. Thus the two IMUs together consists of four possibilities viz. *'Walking knee raised'*, *'Walking knee lowered'*, *'Standing knee raised'* and *'Standing knee lowered'*. For the *'Walking knee raised'*, which happens primarily during walking over and obstacle, the prosthesis is moved to a mini dorsiflexion position and wait as long as the knee angle falls below a set threshold. This is done in order to assist the user in stepping over of the obstacle. When the knee is lowered sufficiently, normal roll-over, power pulse and reset phases follow (as explained in the yellow section). The same sequence happens for *'Walking knee lowered'*, without the intermediate waiting period. For the *'Standing knee raised'*, the prosthesis is instructed to move and maintain a dorsiflexed position, while for the *'Standing knee lowered'*, the prosthesis is instructed to move to and maintain a neutral ankle position. In both of these conditions, a supporting torque is provided to the ankle joint to aid standing.

By combining information from both sides, we are able to devise a controller that can respond to a user either undergoing level ground walking or walking over an obstacle.

B. Hardware and Control Software

The proposed control architecture has been implemented and tested on a transtibial prosthesis prototype, as shown in Figure 3 [26]. The design incorporates series-elastic springs for shock absorption, a ball screw-nut combination (Misumi BSSCK1204, Misumi Group, Europe, `de.misumi-ec.com`) for translation of rotation to linear motion, and a BLDC motor (Maxon EC-i 30, Maxon Group, Switzerland, `www.maxongroup.com`) as the prime mover. All three components are coupled using a timing belt and pulley system (Misumi S3M) around a hinge joint. This arrangement permits dorsiflexion and plantarflexion motion of the ankle around the hinge when power is applied to the motor. Clockwise rotation of the motor results in the rotation of the coupled ball screw. This rotation causes the ball-nut to slide upwards compressing the top spring (represented in green color) and pushes against the top fixture (represented in orange color), thereby moving the rear part of the mechanism upwards. This results in a plantar-flexion movement of the foot blade. A counterclockwise motor rotation unloads the springs, leading to the return of the foot to a neutral position. The details of the mechanical components used in this design are provided in [26].

The control hardware for the system comprises a Maxon EPOS4 motion controller, motor shaft encoders, and an ankle

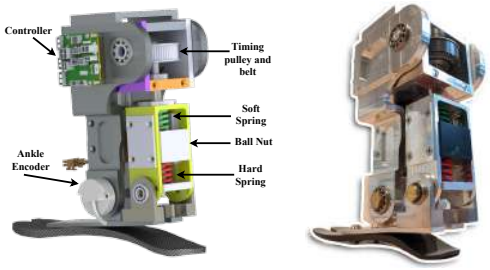

Fig. 3: Rendered image (left) of the transtibial prosthesis and the actual developed prototype (right).

joint for position feedback. Additionally, two MPU9250 IMUs capable of sensing rotation rates and accelerations are placed around the shank and thigh. These form the primary components of the control hardware. All software algorithms for the system are executed on a quad-core Raspberry Pi Zero 2W running Linux. Motion commands are transmitted to the controller from the Raspberry Pi via a USB connection. The system is powered by a 24V power supply.

III. Experiments

This section describes the experiments that have been performed on one healthy subject to validate the proposed control architecture. The subject's left leg simulated the prosthetic leg.

Multiple trials were conducted while allowing the user to self-select their gait progression speed as depicted in Figure 4[1]. Predetermined walking speeds were avoided to provide more generic values when choosing cut-off thresholds compared to when a specific speed or pattern is imposed on the subject. Initial experiments consisted of 10 calibration trials where a male subject (height 175 cm, weight 60 Kg) walked on level ground with the IMUs placed on his limbs. An average of these 10 trials were used to finalize the thresholds A, B, C, D, and E, as shown in Figure 1.

For the experiments, the IMUs were configured as shown in figure 4, with +X facing the direction of walking, +Y pointing downward towards gravity and the angular velocity of the shank about +Z (which points to the left) being used as the control signal for the prosthesis. Following this, 10 trials (divided into two parts) with the same sensor configuration and the thresholds programmed were conducted to assess the performance of the designed control algorithm. The prosthesis was secured to a table using a clamping mechanism that allowed it to perform its motion using wireless signals without being placed on the subject. The IMUs worn by the subject transmitted their data wirelessly in real-time to the prosthesis controller. The motion of the prosthesis and the shank/thigh angles were determined in real-time using an OptiTrack (Natural Point Inc,USA, `www.optitrack.com`) motion capture system.

The first part of the 15 trials consisted of the subject walking on level ground for multiple instances of gait initiation, speed maintenance, deceleration, and termination. Subsequently, obstacle avoidance tests were performed where a box-shaped obstacle measuring 10×15 cm which was placed in the subject's path. The subject was instructed to avoid the obstacle by first stepping over it with their right leg while placing their simulated prosthetic leg immediately in front of it, and then stepping over it with their other leg. The objective of this experiment was to evaluate the effectiveness of the controller in utilizing data from both limbs to set the response of the prosthesis as mentioned in Section II while the subject crossed the obstacle. The motion was executed smoothly and the response of the prosthesis along with angular calculations performed on IMU data were recorded.

We repeated this experimental procedure for multiple days over the course of a week. A video on the performed trials is provided as support material to this study.

[1]The study, under protocol number M22.298663, was evaluated and received a waiver by the Medical Ethics Review Committee of the University Medical Center Groningen (Groningen, The Netherlands) on June 9, 2022.

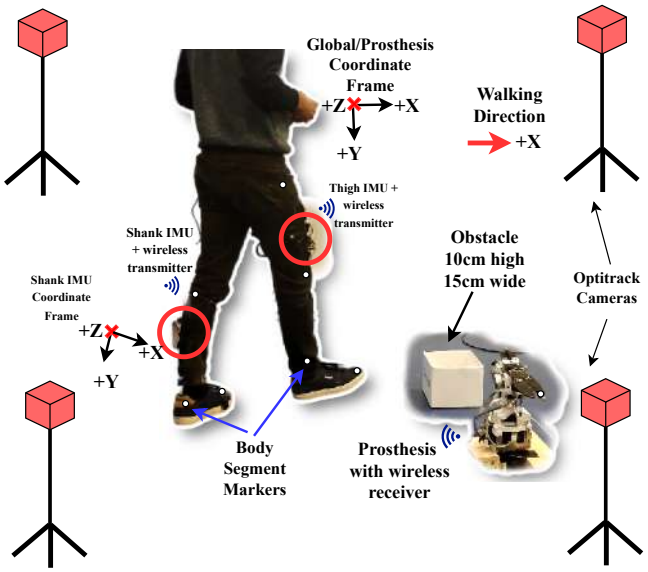

Fig. 4: The IMU on the left shank (imu_LSH) is analogous to the IMU present on the prosthesis; the imu_RTH is on the (contralateral) right thigh. The figure also shows the obstacle that the subject was asked to avoid by crossing over along with the prosthesis controlled by the algorithm. The body makers, co-ordinate systems and the optical cameras have also been shown.

IV. Results and Discussion

A. Results

Figure 5 displays the 15 gait cycle mean and standard deviation for thigh angle (in the global reference frame) during level-ground walking at preferred speed as calculated by fusing gyroscope and accelerometer data using the complementary filter described in Section II. This is compared to the angles of healthy subjects [20] and the angles measured by using the Optitrack system. One complete gait cycle in the figure lies between 0.2 s and 0.9 s of the experiment.

Figure 6 shows the prosthesis response while using the proposed control architecture that utilizes gyroscope data from the shank and the angle data from the contralateral thigh to step over an obstacle. The yellow areas represent instances where the subject is stepping over the obstacle,

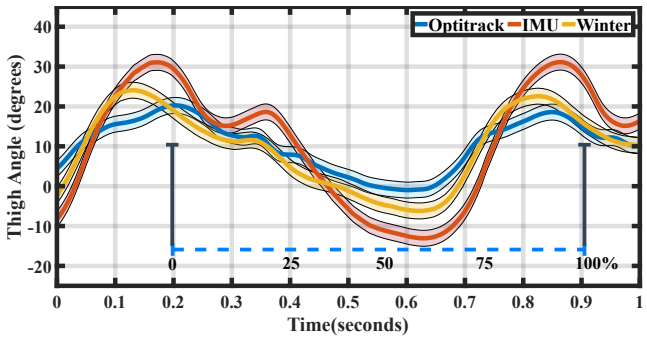

Fig. 5: Comparison between the angles(mean and standard deviation of 10 gait cycles) calculated by the control algorithm, the angles measured using the Optitrack motion capture system, and the reference angles from healthy subjects [20]. The figure shows data of more that one gait cycle. 0 to 100% grading of a single gait cycle is marked using the blue line.

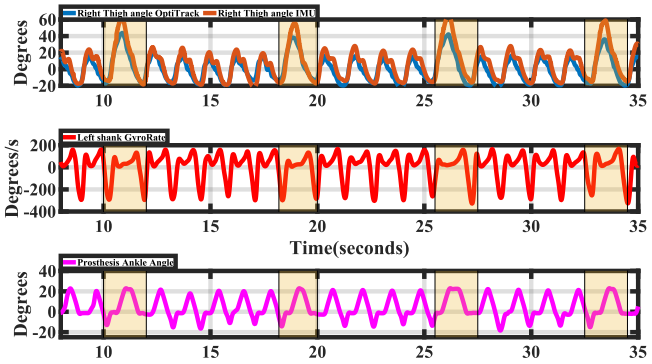

Fig. 6: Data collected during an experiment: the yellow areas represent instances where the subject is stepping over the 10×15 cm obstacle, while the white areas are when the subject walks on level ground.

while the white areas are when the subject walks on level ground. The variations in the thigh and shank as the subject moves overground, and their combined effect on the angles generated by the prosthesis can be noticed in the figure.

B. Discussion

Figure 5 shows a comparison between the thigh angle calculated with respect to vertical with the IMU, the measured angle using the Optitrack motion capture system, and the standard thigh angle as mentioned in [20]. The figure demonstrates that the thigh angle computation algorithm is able to generate angles comparable to those generated using standard optometry tools. In the figure, it is noticeable that there exits a correlation between the angle calculated using the complementary filter and the measured thigh angle. For the controller functionality, the thigh angle plot from the IMU and Optitrack shows the possibility of existence of a number of strategic control points which may be utilized as gait sub-dividing limits by the prosthesis controller. For example, the thigh angle curve has a minima at $\sim 60\%$ of the gait cycle, and a maximum at $\sim 85\%$ of gait cycle. For normal human gait, the minimum in the thigh angle signifies the end of the stance phase, whereas the maximum indicates the occurrence of a heel-contact [20].

Moreover, by tracking the thigh angle in real-time, it is also possible to indicate whether a leg has been raised beyond the normal limits for level ground walking. For example, angle values greater than the maximum for normal walking can indicate a raised leg. In the current application, we monitor the thigh angle for these abnormal values($>$30 degrees was considered as abnormal) and indicate the controller to suspend actuation and only to provide a supporting force while being fixated in a dorsiflexed position as long as the thigh angle remains higher than the threshold.

This concept has been demonstrated in Figure 6, where the yellow regions represent instances during which the contralateral knee has been raised to step over an obstacle while other regions represent normal walking on level ground. As the contralateral knee is raised, the prosthesis' response slows and a longer period is required for cycle completion. This is because, at this point, the thigh angle's threshold has been crossed and the controller then waits for the thigh to be lowered down before performing the power injection for the prosthesis plantarflexion. The left leg gait cycle also slows down but the rotation rate recorded by imu_LSH is maintained. The middle plot in Figure 6, shows the actual prosthetic angles generated on reception of the control signals. The angles generated by this method, are similar to that of a normal human ankle angle, however, for each gait cycle, the generated angles, shows a stagnation between 20% and 30% of the gait cycle. This is primarily due to the fact that a large temporal gap exists between the detection of points C and D, as shown in Figure 1. This delay in detection translates to a delay in sending motion commands to the actuator, resulting in the stagnation at $\sim 30\%$ of every gait cycle. In such a condition, a motor with higher speed than the one chosen here is required for the prosthesis to traverse the entire trajectory within a shorter time period and avoid angular deviation.

In this way, while during normal walking the angles are generated synchronously by being governed using the left shank angular velocity, during obstacle crossing with a raised leg, the angle generation deviates from the normal pattern and waits for the leg to be brought down so that the normal mode of the angle generation may resume.

C. Recommended Enhancements

Although the above results demonstrate that data from both legs can be utilized for the overall control of a transtibial prosthesis, there are areas of possible improvement.

1) 3D Orientation: In this study, we use an accelerometer and a gyroscope to get the absolute values of roll and pitch (2-DOF) of the subject. However, to accurately estimate orientation in 3D space, a magnetometer is necessary. With a complete 3D picture, it would be possible to design a more effective controller response that could account for controlling various activities of daily living. Implementations such as the Madgwick filter [27] or a Kalman filter [28] could also add to the existing capabilities of the controller.

2) Flexion/Extension of the Contralateral Leg: The controller presently employs information pertaining to the angle

of the thigh to ascertain whether the leg has been elevated to surmount an obstacle. Furthermore, this information may also be utilized to determine the degree of flexion and extension of the contralateral leg. When fused with information regarding angular velocity obtained from the prosthesis, this data may be employed to accurately establish the instant of power pulse during level ground walking. The integration of this logic into the controller could have the potential to enhance its response in cases of level ground walking.

V. Conclusions

This study presented a methodology for the control of transtibial prostheses, which utilizes wireless transmission of data from only two IMU sensors placed on both legs. The controller's performance was evaluated during level-ground walking and overstepping of an obstacle of fixed dimensions. The experiments demonstrate that the information obtained from both legs can be used by the controller to walk and to avoid obstacles, when the balancing ability of the prosthesis can be related to positioning the contralateral leg.

Augmenting the controller of a commercial prosthesis with that on a mobile phone, placed in the pocket of the contralateral side, could potentially offer a higher level of gait comprehension than what is possible using only the available onboard sensors on the prosthesis. A mobile application that can wirelessly communicate and exchange inertial information with the prosthesis in real-time could, thus, prove beneficial in providing orientation information of the contralateral leg. Such an arrangement may ultimately result in improved performance and satisfaction for transtibial prosthesis users. These tasks along with others shall be undertaken as future efforts.

Differentiable Biomechanics for Markerless Motion Capture in Upper Limb Stroke Rehabilitation: Comparison with Optical Motion Capture

Tim Unger[*,1,2], Arash Sal Moslehian[*,3], J.D. Peiffer[*,4], Johann Ullrich[1,2], Roger Gassert[2], Olivier Lambercy[2], R. James Cotton[†,4,5], Chris Awai Easthope[†,1]

***Abstract*— Marker-based Optical Motion Capture (OMC) paired with biomechanical modeling is currently considered the most precise and accurate method for measuring human movement kinematics. However, combining differentiable biomechanical modeling with Markerless Motion Capture (MMC) offers a promising approach to motion capture in clinical settings, requiring only minimal equipment, such as webcams, and minimal effort for data collection.**

This study compares key kinematic outcomes from biomechanically modeled MMC and OMC data in 15 individuals with stroke performing the drinking task, a functional task recommended for assessing upper limb movement quality.

We observed a high level of agreement in kinematic trajectories between MMC and OMC, as indicated by high correlations (median $r > 0.95$ for the majority of kinematic trajectories) and median RMSE (root mean squared error) values ranging from $2°$–$5°$ for joint angles, 0.04 m/s for end-effector velocity, and 6 mm for trunk displacement. Trial-to-trial biases between OMC and MMC were consistent within participant sessions, with interquartile ranges of bias around $1-3°$ for joint angles, $0.01m/s$ in end-effector velocity, and approximately 3 mm for trunk displacement.

Our findings indicate that our MMC for arm tracking is approaching the accuracy of marker-based methods, supporting its potential for use in clinical settings. MMC could provide valuable insights into movement rehabilitation after stroke, potentially enhancing the effectiveness of rehabilitation strategies.

I. Introduction

The increasing number of individuals affected by stroke and related neurological conditions has created an urgent need to improve the effectiveness of rehabilitation strategies [1]. Over 70% of individuals with stroke suffer from acute upper limb impairment [2], necessitating accurate and frequent assessments of upper limb movement quality to customize interventions and monitor rehabilitation progress [3]. Ideally, recovery after a stroke involves neuroplasticity, where motor functions are restored by reorganizing neural pathways [4]. Compensatory strategies, such as relying on unaffected muscles or limbs, provide short-term functional benefits but can hinder neuroplastic recovery by reinforcing maladaptive patterns [5]. As a result, after controlling for altered movement due to pain, deviation in movement quality can serve as a biomarker for limited neuroplasticity and reduced genuine recovery [6], [7].

Consensus guidelines from European stroke experts recommend incorporating an instrumented drinking task to assess upper limb movement quality in individuals with stroke [3]. The drinking task comprises several relevant movement primitives, is easily standardized, is already learned, and the movement quality measures for this task were established using optical motion capture (OMC) in several studies [8]–[10]. While OMC does not directly measure bone movement, it is widely regarded as the gold standard for biomechanical assessment [11].

Traditional biomechanical modeling with markers follows a two-stage process: first, triangulated 3D markers are used to scale a biomechanical model to a specific individual (for example bone lengths, moments of inertia). Second, this scaled model is fit to follow marker trajectories during movements of interest [12]. This process assumes fixed marker placement on known landmarks, most of which are specific bony prominences. As marker placement is highly important for accurate biomechanical reconstruction [13], collecting OMC data requires a domain expert and significant setup time, limiting its accessibility in routine clinical practice.

Recent advances in human pose estimation with computer vision now enable Markerless Motion Capture (MMC) from RGB videos, providing a potentially viable alternative to OMC [14]. Critical to these approaches are keypoint detection algorithms which are trained on large datasets to detect "virtual" markers, termed keypoints, on raw RGB images [15]. These virtual markers can be internal locations inside joints, body landmarks or surface markers [16]. As these algorithms are increasingly robust and at minimum require a smartphone camera [17], there is great potential for MMC to be utilized in clinical settings. However, a critical limitation of keypoint detection algorithms is there are no biomechanical constraints to virtual marker locations.

To address this, Cotton et al. proposed an optimization approach allowing for simultaneous optimization of biomechanical model scaling parameters and movement trajectories [18], [19]. As this approach combines the scaling and trajectory fitting steps employed in traditional two-stage pipelines, we hereafter refer to this approach as "end-to-end" MMC. While this method has been validated for internal consistency and against instrumented walkways, [18], [20], it has not yet

part of this work is funded by Digitalisierungsinitiative der Zürcher Hochschulen (DIZH)

been validated against OMC-based kinematic data.

In this study, we conduct the first comparative analysis between OMC and this novel end-to-end MMC approach. We evaluate the established drinking task movement quality measures in individuals with stroke and compare the underlying kinematic trajectories used to derive these measures. Our hypothesis is that the agreement between the two systems will be high across key kinematic trajectories, such as joint angles, end-effector velocities, and trunk displacement as well as in the established movement quality measures for the drinking task. We test this hypothesis using comparative plots for kinematic trajectories and movement quality measures as well as several comparative metrics such root mean squared error (RMSE), correlation (r), and bias to assess the agreement of movement quality measures and underlying kinematic trajectories produced by each system[1].

II. Methods

A. Participants

The study adhered to the ethical guidelines set forth by the local ethics committee (BASEC-No: 2022-00491). Individuals with stroke with mild and moderate upper limb impairment were recruited from the University Hospital Zurich Stroke Registry and the cereneo clinic. Eligible participants were invited for a single-session measurement. Inclusion criteria mandated that participants be at least 18 years old, capable of providing informed consent, and have a confirmed diagnosis of stroke. Additionally, participants were required to have at least partial ability to perform a reaching movement, and to grasp a cup unassisted using a cylindrical grip with the affected hand. Exclusion criteria consisted of pre-existing upper limb deficits, such as orthopedic impairments, and other neurological conditions. An ad-hoc sample of fifteen individuals with stroke (9 males, 6 females) was included in this study, with a mean age of 71 years (SD = 15) and an average time since stroke of 24 months. Participants had mild to moderate upper limb impairment, as indicated by a mean Fugl-Meyer Upper Limb Assessment (FMA-UE) score of 56.3 (SD = 8.4), with scores ranging from 39 to 66.

B. Data Acquisition and Preprocessing

Participants performed 40 repetitions of the standardized, seated drinking task as in [8] (standardized motor task with standardized start and end pose) with each the affected and unaffected arm while being recorded with OMC as well as five synchronized consumer-grade webcams for MMC. The OMC system operated at a sampling frequency of 100Hz, using technologies from Qualisys (8 cameras) and Optitrack (12 cameras) across different measurement setups. We applied the base marker set used by Alt Murphy et al. [8] for the drinking task and extended it with further markers for better representation of the movement (16 body markers - see Fig. 2, without finger markers). OMC data was manually gap-filled and labeled. Five synchronized consumer-grade webcams (Logitech Brio 4k) recorded the participants at 1080p and 60Hz. The five cameras were evenly distributed in a half circle around the participant with a spacing of roughly 45° (see Fig. 1). The videos were segmented into trials based on the OMC master trigger signal, resulting in a synchronized dataset composed of multiple trials, each representing a single repetition of the standardized drinking task.

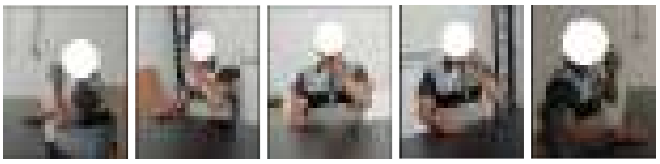

Fig. 1: Camera perspectives of the five webcams used for MMC.

C. Data Processing and Inverse Kinematics

1) Two-Stage OMC: The measured 3D markers from OMC during the initial static period of participants sitting at the table were used to scale a biomechancical model in OpenSim. The OpenSim model is based on the Rajagopal 2016 model [21], with modified ranges of motion for pronation and supination to better match the natural range of motion, as the original model constrained these motions. As the legs were stationary and occluded by the table during the drinking task, we removed all markers below the hip, effectively locking all leg degrees of freedom in the standard pose. Afterwards, inverse kinematics were calculated using the IK tool in OpenSim with the scaled model and the measured 3D marker trajectories from OMC. All calculations were performed using Python scripts, incorporating the OpenSim API to allow batch processing. Resulting kinematic trajectories of OMC were interpolated from 100Hz to 60Hz to compare directly with MMC.

2) End-to-End MMC: In contrast to two-stage approaches, previous work in MMC has simultaneously optimized body scale parameters and joint kinematic trajectories. This "end-to-end" optimization formulates model scaling, marker triangulation, and inverse kinematics as a single optimization problem [19]. Without requiring training data, this method has demonstrated improved internal consistency in biomechanical reconstructions of the lower limb [22] and upper limb [20], though it has not yet been validated against optical motion capture.

To apply this approach to the data collected here, we first used AniposeLib [23] to perform extrinsic and intrinsic calibration of cameras using a calibration recording with an A1-sized ChArUco board. Using PosePipe [24], we first extracted 87 2D keypoints from each webcam video using MeTrabs-ACAE [15] and then performed automatic person association using EasyMocap [25]. For videos where automatic person association failed, we manually performed person association.

[1]The code for the analysis is available at `https://github.com/DART-Lab-LLUI/diff-biomech-mmc-icorr-2025`

Finally, we reconstructed joint kinematics following [19]. In brief, this parameterizes the movement trajectory of a recording as an implicit function $f_\phi : t \rightarrow \theta$ mapping from time to joint angles where f_ϕ is implemented as a multi-layer perceptron. These parameters ϕ along with body scaling and marker offset parameters are jointly learned through optimization. At each optimization step, the joint angle output from the implicit function is passed through a biomechanical forward kinematic function in MuJoCo using the GPU accelerated Mjx version [26], [27] and 3D pose marker locations are projected into each camera frame using known camera extrinsics/intrinsics. This approach also employs a bilevel optimization which learns the body scale of a participant over multiple trials [28]. Since each of our participants presented here had approximately 80 trials, not all the trials could fit into our NVIDIA RTX 3080 GPU with 10GB of VRAM; thus, we performed bilevel optimization on a subset of each participant's trials, splitting them into eight batches. We used a modified version of the biomechanical model presented by Hamner et al. [29], [30] compatible with MuJoCo. We found no major differences in relevant model degrees of freedom between the models used for OMC (OpenSim) and MMC (MuJoCo).

D. System Comparison

1) Kinematic Trajectories: We exclusively included the essential kinematic trajectories (kinematic time series data, such as joint angles, displacements and velocity profiles) which are required for deriving the established movement quality measures in individuals with stroke performing the drinking task according to [8]. Specifically, these kinematic trajectories included: Shoulder Flexion, Shoulder Abduction, Elbow Flexion, Elbow Angular Velocity, Trunk Displacement, and End-Effector Velocity.

Joint angles were extracted from the inverse kinematic fits from OpenSim and MuJoCo for OMC and MMC, respectively. The end-effector velocity for OMC was computed by OpenSim based on the velocity of the center of geometry of the hand marker, while for MMC we differentiated the position of the hand keypoint. Trunk displacement was determined from the position of the trunk marker (sternum keypoint for MMC) after model fitting.

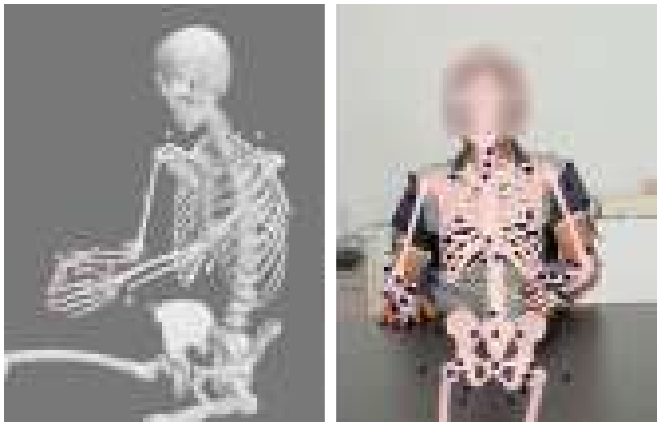

Fig. 2: Visualization of biomechnical modelling. left: OMC data with OpenSim; right: end-to-end MMC with MuJoCo.

For each trial and kinematic trajectory, we calculated the static offset between the two systems as the difference in the means of MMC and OMC trajectory. This bias (offset) was then added to the OMC signal. The static bias for each kinematic trajectory was recorded to evaluate the consistency of the offsets between the two methods across trials and participants. All further analyses of agreement were conducted with bias-removed kinematic trajectories.

To account for potential time offsets due to imperfect synchronization between the systems, we determined the optimal time lag between the two signals by shifting one kinematic trajectory over the other, up to 0.25 seconds. At each shift, we calculated the RMSE and identified the time lag that minimized this error. The resulting time lag was recorded as a measure of synchronization accuracy. Finally, we calculated the RMSE and Pearson correlation between the adjusted kinematic trajectories from OMC and MMC for each trial to assess the agreement between the two systems.

2) Movement Quality Measures: Movement quality measures for the drinking task, based on what was defined by Alt Murphy et al. [8], were derived from the kinematic trajectories of both MMC and OMC. These include: total movement time, number of movement units (smoothness), peak velocity (PV) in reaching, peak elbow angular velocity in reaching, time to peak velocity in reaching, time to first peak velocity in reaching, max elbow extension in reaching, max shoulder abduction angle in drinking / reaching, max trunk displacement during task, max shoulder flexion angle in reaching / drinking, interjoint coordination (Pearson correlation between elbow extension and shoulder flexion during reaching). Drinking task phase classification (Reaching, Forward, Drinking, Back, Returning, and Rest) for both systems was based on the end-effector velocity calculated from the OMC markers on the wrist and cup, following the approach in [8]. This eliminated any influence of difference in phase classification, thereby isolating the focus on kinematic data alone. Therefore, time to peak velocity and time to first peak velocity during reaching (in %) are not reported, as the phase duration is identical for MMC and OMC, making these measures redundant with those reported in seconds.

To evaluate alignment in the extraction of movement quality measures between the two systems, we visually assessed the measures from MMC and OMC using correlation plots. Additionally, Pearson correlations were calculated for each movement quality measure, both for individual trials (r_s) and for averaged movement measure (r_{av}) across all affected and unaffected trials per participant.

E. Data and Processing

In total 1160 trials of the drinking task of 15 participants were included with a median of 40 [39, 40] trials per affected arm and 39 [38, 41] trials per unaffected arm per participant. Trials were manually inspected, resulting in a 6% exclusion rate. Of the excluded trials, 51 were

due to incorrect movements, 13 due to end-to-end MMC reconstruction failures, and 5 due to synchronization issues between the two systems. Calculating inverse kinematics in OpenSim with cleaned OMC data required approximately 30 hours on a 13th Gen Intel® Core™ i9-13900H processor (2.60 GHz) with 32 GB of RAM. The entire end-to-end MMC process took around 12 days to complete all trials, leveraging an NVIDIA RTX 3080 GPU. The majority of this time was spent extracting 2D keypoints from a total of 5800 videos (comprising 5 cameras across 1160 trials).

III. Results

A. System comparison

1) Kinematic Trajectories: Visual inspection of the kinematic trajectories demonstrated a very high level of agreement between OMC and MMC across all kinematic trajectories (see Fig. 3).

Quantitative analysis further supported this (see Table I), with high correlation coefficients (r) observed between the two systems. Notably, shoulder flexion and elbow extension showed strong correlations ($r = 0.99$), indicating close alignment in these key movements. Among the kinematic trajectories, shoulder abduction on the unaffected side had the lowest correlation ($r = 0.88$ [0.78, 0.93]), though the RMSE remained low at $1.97°$ [$1.37°$, $2.71°$]. The lower correlation is due to the small range of motion in unaffected shoulder abduction, where slight trajectory discrepancies have a greater impact on correlation.

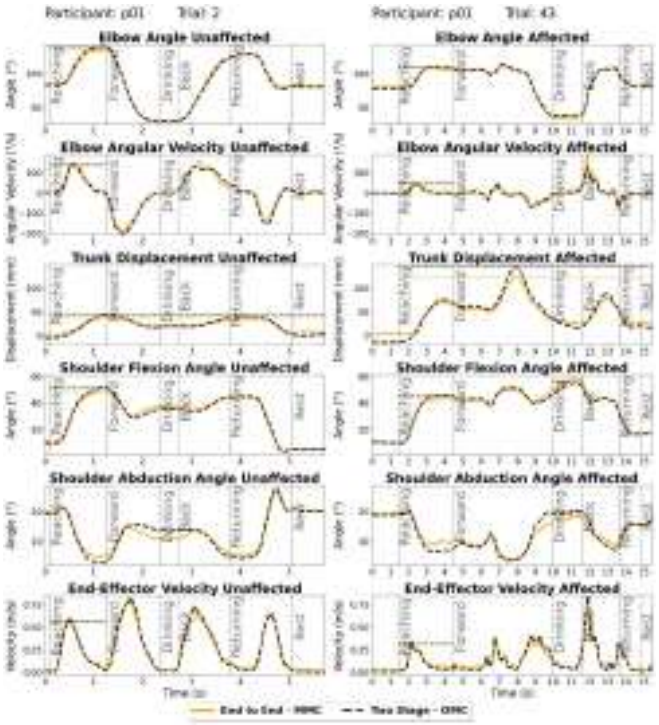

Fig. 3: Exemplary kinematic trajectories of participant p01, showing one trial each for the unaffected and affected arm (FMA-UE: 49). Horizontal lines outline the movement quality measures, and the x's on the end-effector velocity mark each movement unit.

TABLE I: Medians and [IQRs] for RMSE, r, bias, and time lag of kinematic trajectories, calculated across all patients and differentiating between the affected and unaffected arms.

Kinematic	Value	Unaffected arm	Affected arm
End-Effector Velocity	r	0.99 [0.97, 0.99]	0.99 [0.96, 0.99]
	RMSE (m/s)	0.04 [0.03, 0.07]	0.03 [0.03, 0.05]
	Bias (m/s)	0.00 [-0.01, 0.00]	0.00 [-0.01, 0.00]

Overall, RMSE values were low, particularly for shoulder flexion and shoulder abduction (both approximately $2°$). Elbow extension showed the highest RMSE among joint angle trajectories, with a median RMSE around $4°$–$5°$.

The trial-to-trial variability of bias in kinematic trajectories between OMC and MMC was low for each participant, as shown in Table II, which presents the mean variability (IQR of bias per kinematic trajectory) across participants: $< 2°$ for shoulder, $< 4°$ for elbow extension, $< 2°/s$ for elbow angular velocity, and around 3 mm for trunk displacement. However, absolute bias varied between participants, as reflected in the higher bias IQR in Table I, which shows the mean bias and IQR across participants.

Temporal alignment between systems remained consistent across all kinematic trajectories, with small discrepancies ($<$ 0.03 s) primarily in shoulder and trunk metrics.

2) Movement quality measures: We observed high correlations between systems for trial-by-trial comparisons, with improved correlations when averaging over trials ($0.91 < r_{av} < 1$, except for interjoint coordination, see Table III). Joint angle measures showed high correlations overall, with shoulder flexion ($r_s = 0.97$, $r_{av} = 0.98$), elbow extension ($r_s = 0.98$, $r_{av} = 0.99$), and shoulder abduction ($r_s = 0.93$, $r_{av} = 0.94$). Interjoint coordination had the lowest

TABLE II: Mean IQR of bias across patients, representing the average variability of bias within a patient's trials.

Kinematic	bias	Unaffected arm	Affected arm
End-Effector Velocity	$\overline{IQR}$ (m/s)	0.01	0.01
Elbow Angular Velocity	$\overline{IQR}$ (°/s)	1.83	1.57
Elbow Extension	$\overline{IQR}$ (°)	3.69	3.88
Shoulder Flexion	$\overline{IQR}$ (°)	1.34	1.14
Shoulder Abduction	$\overline{IQR}$ (°)	1.20	0.91
Trunk Displacement	$\overline{IQR}$ (mm)	2.86	3.10

correlation ($r_s = r_{av} = 0.71$) with several outliers, while elbow angular PV showed lower correlation ($r_s = 0.87$, $r_{av} = 0.93$) and broader distribution of values (see Fig. 4). End-effector velocity measures exhibited high correlations ($0.90 < r_s < 0.98$, $0.96 < r_{av} < 1$), except for the number of movement units ($r_s = 0.77$, $r_{av} = 0.91$) which also showed a broader distribution of values (see Fig. 4). Trunk displacement showed high correlation ($r_s = 0.96$, $r_{av} = 0.97$), though MMC systematically underestimated values compared to OMC at higher magnitudes (see Fig. 4).

Following [31], we tested whether the MMC system could detect subtle movement differences in patients. Using the Mann–Whitney U test ($p << 0.05$), we found a significant difference in end-effector peak velocity between the affected and unaffected arms. This difference was observed in 14 out of 15 patients, consistently across both OMC and MMC data. These results further confirm that MMC kinematic assessments reliably approximate OMC values.

IV. Discussion

This is the first study comparing biomechanics-based kinematics from OMC with the end-to-end MMC approach proposed by Cotton et al. [19]. Only a few previous studies have compared biomechanically modeled upper limb kinematics from MMC to OMC such as using the commercial THEIA3D MMC (e.g., shadow boxing in able-bodied adults [32] (10 cameras), Box and Block in able-bodied children [33] (8 cameras)). To our best knowledge, this is also the first study to compare biomechanically modeled upper limb kinematics between OMC and MMC in neurological patients.

Overall, we find a high level of agreement between the systems for the kinematic trajectories of the drinking task in individuals with stroke and a strong correlation across the majority of movement quality measures.

The end-to-end MMC approach demonstrated high robustness, with failed reconstructions in only 1.6% of trials (13 out of 1160). For end-effector velocity, the small bias and low RMSE indicate precise wrist keypoint detection and consistent scaling across methods, likely supported by bilevel optimization, enabling direct comparability of end-effector velocity between systems.

Differences in elbow angle (median RMSE around $5°$), trunk displacement (median RMSE around 6mm), and shoulder angles (median RMSE around $2°$) are small and remaining differences between OMC and MMC may reflect

TABLE III: Movement quality measures comparing OMC and end-to-end MMC: r_s represents the correlation across all trials, while r_{av} denotes the correlation for averaged participant trials per arm between the two systems.

Movement Quality Measure	r_s	r_{av}
PV [m/s]	0.90	0.96
Elbow angular PV [°/s]	0.87	0.93
Time to PV [s]	0.98	1.00
Time to first PV [s]	0.94	0.99
Number of movement units [n]	0.77	0.91
Total movement time [s]	0.98	1.00
Interjoint coordination	0.71	0.71
Trunk displacement [mm]	0.96	0.97
Shoulder flexion [°]	0.97	0.98
Elbow extension [°]	0.98	0.99
Shoulder abduction [°]	0.93	0.94
Shoulder flexion D [°]	0.95	0.97

the influence of marker placement and model variations, which can cause slight discrepancies in trajectories. The differences in kinematic trajectories between OMC and MMC fall within the session-to-session variability observed with OMC alone [13], suggesting that the end-to-end MMC is nearing the accuracy and precision of OMC. Our results are consistent with, and slightly better than, prior MMC-OMC comparisons using the commercial THEIA3D system, which reported joint angle differences with RMSE $< 6°$ between systems [33]. Comparisons of MMC and OMC in upper limb kinematics remain limited, and no studies have yet evaluated non-commercial, biomechanics-based MMC kinematics against OMC. The end-to-end MMC approach presented here demonstrates an accuracy comparable to THEIA3D while outperforming earlier custom MMC systems tested for the drinking task [34].

A key advantage of the end-to-end approach over traditional MMC methods, such as based on DeepLabCut [35], is its optimal fitting of measured data to 3D keypoints within a biomechanical model, enhancing tracking stability.

MMC shows promise as a reliable alternative to OMC, offering significantly reduced setup and manual processing times.

Temporal discrepancies between the systems were negligible, with time lags ranging from 0 to $0.03\,\mathrm{s}$, supporting the reliability of the end-to-end MMC approach in capturing temporal aspects of movement with high accuracy.

Overall, the correlation between OMC and end-to-end MMC is high across most movement quality measures, with few outlier trials observed. Averaging trials generally improves correlation (e.g., $r_{av} = 1.00$ for time to peak velocity and total movement time), aligning with recommended clinical practice for performance stability [9]. While the number of trials needed to ensure performance stability is established for OMC [9], slight adjustments may be needed for MMC to account for measurement uncertainty. Averaging also aids in outlier detection, valuable for robustness in clinical applications.

Movement quality measures based on joint angles, such as shoulder flexion ($r_s = 0.97$, $r_{av} = 0.98$) and elbow

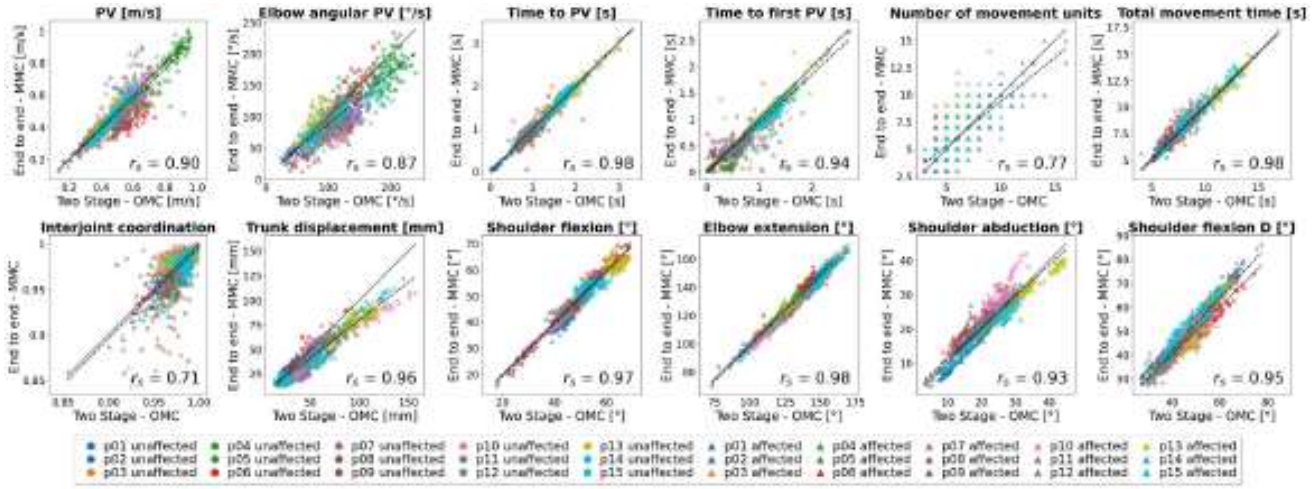

Fig. 4: Correlation plot for each measure, comparing two-stage OMC and end-to-end MMC. Each data point represents a single trial. Trials are color-coded per participant and shape-coded per arm. Solid black line: perfect correlation. Dashed grey line: observed correlation from data.

extension ($r_s = 0.98$, $r_{av} = 0.99$), as well as end-effector velocity measures like peak velocity and time to peak velocity, show strong agreement between systems, indicating high accuracy in detecting peak amplitudes in these key kinematic trajectories. Slight underestimation in trunk displacement (see Fig. 4) may result from model differences in chest marker placement, suggesting potential for model refinement.

Metrics like the number of movement units ($r_s = 0.77$, $r_{av} = 0.91$) and interjoint coordination ($r_s = r_{av} = 0.71$) show lower correlation, where small kinematic trajectory variations can produce larger discrepancies. Replacing the number of movement units with alternative smoothness metrics, such as Log Dimensionless Jerk (LDLJ) or Spectral Arc Length (SPARC) [36] , could improve the reliability of smoothness assessment.

Observed trial-to-trial biases in kinematic trajectories between OMC and MMC were consistent across trials within sessions, as evidenced by small IQR (approximately $1^\circ - 3^\circ$ for joint angles, 0.01 m/s for end-effector velocity and 3 mm for trunk displacement). This suggests a systematic bias per session, likely due to differences in marker/keypoint locations between systems (OMC anatomical landmarks vs. MMC-detected keypoints) or biomechanical model variations. The session-to-session (patient-to-patient) variation in bias may stem from variability in both OMC and MMC systems. In MMC, keypoint detection may slightly differ between individuals, while in OMC, minor differences in marker placement and registration can significantly impact inverse kinematics. Uchida and Seth [13] for example demonstrated that a 1–2 cm marker registration uncertainty can lead to a 5°–10° difference in knee flexion angles. Additionally, a prior study using the commercial THEIA3D MMC system demonstrated lower inter-session variability in MMC compared to OMC [37]. Thus, we assume that session-to-session bias variability is primarily due to OMC variability. However, definitive conclusions require further data, such as multi-session recordings of the same participants or true ground-truth bone movement data from dual-plane fluoroscopy.

Although the findings are promising, this study has several limitations. First, while OMC is generally considered the gold standard, it is not an absolute ground truth due to potential errors from marker misplacement and soft-tissue artifacts. Additionally, the used upper limb biomechanical models lack certain degrees of freedom (e.g., finger motion), which could provide a more complete assessment. For example, [20] extends the end-to-end MMC optimization approach to a full arm and hand model. The models in OpenSim for OMC and MuJoCo for end-to-end MMC are not identical, which may impact direct data comparability between the systems. Furthermore, while OMC uses a two-stage process, MMC employs an end-to-end approach; using OMC data in an end-to-end model could help better isolate the effects of marker-based versus markerless capture.

Phase classification was conducted exclusively with OMC data, meaning that MMC phase classification still requires validation for standalone application. Lastly, the study focuses on a specific patient population with mild to moderate impairment performing a single task. Results may vary with other tasks or populations, potentially introducing additional challenges and considerations for broader application.

The end-to-end MMC approach failed to reconstruct 13 trials, due to improper camera calibration, failed subject tracking, or poor initialization of the optimization. While this highlights a small limitation of the current MMC implementation, we note that OMC pipelines have undergone significantly more engineering refinement over time. As MMC methodologies continue to evolve and iterate, we expect improvements in robustness and reliability of the end-to-end approach.

Future research should focus on collecting datasets with simultaneous biplanar fluoroscopy, MMC, and OMC record-

ings to establish true ground truth for contextualizing clinical measurement uncertainty as in [38]. Additionally, research should investigate the impact of camera number and recording angles on MMC accuracy (including monocular setups [17]) and expand the analysis to encompass all upper body degrees of freedom, including fingers [20]. Additionally, studies should broaden the scope to include a more diverse neurological population. While this study focuses on measurement accuracy, future research should assess the system's usability in clinical settings, including acquisition time, the minimum required acquisitions, and reporting efficiency.

Integrating a fixed camera system into standard upper limb assessment setups in rehabilitation clinics could enable the routine collection of high-quality movement data while automating assessments, reducing therapist workload, and freeing up more time for therapy sessions. Enhanced outcome measures would not only support stroke research but also improve clinical workflows by optimizing interventions through more precise and sensitive assessments.

V. Conclusion

The end-to-end MMC accuracy and precision has improved with advanced keypoint detection and GPU-accelerated biomechanical modeling, now approaching OMC levels, as demonstrated in this study. By eliminating marker placement and reducing costs, this MMC offers a practical, low-complexity alternative using consumer-grade cameras. Our results highlight its potential to streamline clinical workflows by enabling precise movement data collection — beneficial for both clinicians and researchers — while potentially automating assessments, reducing therapists' workload, and allowing more time for therapy.

ACKNOWLEDGMENT

We sincerely thank the participants of this study.

***Abstract*— Neurological disorders, such as stroke, can affect the ability to walk and balance. Robotic rehabilitation assists in training walking and balance capabilities of patients with neurological disorders. However, not all participants are good responders when using exoskeletons. This study aims to cluster gait patterns in stroke patients to provide insights into the pathology of stroke patients. Joint angles of the affected lower limb of 45 sub-acute stroke patients from an open access database were clustered based on a principal component analyses, followed by a k-means cluster analysis. A total of eight gait pattern clusters were retrieved and clinically rearranged into four categories. The results can be used in the field of robotic devices as well as a more clinical setting. Future research should focus on validating and using the retrieved clusters as clinical indicators for selecting suitable treatments, such as robotic devices or exoskeletons, to personalize rehabilitation.**

Keywords — Hemiplegia, technology, lower extremities, Cerebrovascular accident

I. Introduction

Neurological disorders, such as stroke, can affect the ability to walk and impair dynamic balance. Around 80% of stroke survivors reported difficulties with walking [1,2]. Consequently, stroke survivors have prioritized walking difficulties and balance as an area in which further research is needed, especially older stroke survivors [3]. Younger stroke survivors have prioritized post-stroke fatigue as the main research area [3]. The use of robotic devices, such as exoskeletons, in rehabilitation has the potential to address both aspects and could improve walking and balance with less exertion in patients with neurological disorders.

Robotic devices are seen as a valuable tool in improving walking abilities and reducing disabilities resulting in a better quality of life [4]. It enables controlled, intensive, repetitive, task-oriented motor training for the affected limb(s) and dynamic balance. The use of robot-assisted training devices has been proven to have a positive effect on balance [5,6] and the chance to walk independently [6,7] in the early rehabilitation phase. However, two systematic reviews explicitly stated that not all included studies contribute to this statement [5,7]. This is in line with other studies that found that not all participants are good responders when using an exoskeleton [8]. Identification of these 'good' and 'poor' responders to exoskeletons is of great importance in both the clinical and research settings. Identifying the so-called 'recovery phenotypes' can help in recommending specifications for inclusion of participants [9].

One way to understand the responsiveness of stroke patients to exoskeletons is with clinical outcomes and demographic features [8,10]. Five key features were derived as predictors for 'good' and 'poor' improvements (i.e. initial Berg Balance Scale score [8,10], final Berg Balance Scale score [8], final Modified Ashworth Scale score [8], initial Modified Barthel index score [8] and lower age [10]). However, some of these predictors are not available until after the intervention, hindering prediction of long-term outcomes after stroke aimed at treatment selection.

A first step towards the personalization of exoskeleton-based therapy is to identify differences between patients pre-intervention, ideally based on objective data, such as gait parameters. Previous research in classifying gait patterns of stroke patients has mainly focused on supervised learning (i.e. labeled data), trying to classify the patients into severity [11] or predefined gait patterns [12,13]. However, as seen in clinical settings, gait patterns differ greatly among stroke patients (e.g. drop foot, circumduction, hip hiking and stiff knee gait) and they are not always predefined, making it an unsupervised learning problem. In order to avoid neglecting subgroups and to make the data less dependent on subjectively scored clinical scales, this study provides a first attempt to use a clustering approach based on joint kinematic data during gait without predefined/labelled subgroups of stroke patients. Therefore, the aim of the current study is to assess whether gait patterns of stroke patients can be clustered based on objective gait parameters.

II. Methods

A. Study overview

This study used data from an open source dataset that contains kinematic data of 50 sub-acute stroke patients [14]. Stroke patients were included if they had a stroke onset within

This project has received funding from the European Union's Horizon Europe program under Grant Agreement No 101120408

five months and an age between 18 and 85 years. Participants were included if they had a stroke onset within five months and an age between 18 and 85 years. Participants were asked to walk across a 12 meter-pathway at a self-selected speed. Patients were excluded if they had ≥ 20 on the trunk impairment scale, functional ambulation score of ≤ 2 and if they were not able to sit independently. All in- and exclusion criteria are explained in more detail in [14]. The trial registration for the ethical approval of the study was validated. Three stroke patients were excluded from the current study as they used a walking aid during walking. No adaptations were made to the C3D data. Two patients were excluded based on missing variables in their C3D data.

The reference data of non-disabled subjects was retrieved from the reference dataset of our lab that was collected during previous published studies and all comply with ethical requirements. The subject characteristics are presented in Table I.

B. Data analysis

The gait events were visually checked using the provided software (VICON Motion System, Oxford, U.K.). The data analysis focused on nine metrics of the affected leg associated with regular gait analysis, i.e. foot progression, ankle dorsiflexion/plantarflexion, knee flexion/extension, hip flexion/extension, hip abduction/adduction, hip external rotation/internal rotation, pelvis anterior/posterior tilt, pelvic obliquity and pelvis external rotation/internal rotation. Four kinematic metrics, i.e. ankle eversion/inversion, ankle abduction/adduction, knee abduction/adduction and knee external/internal rotation, were excluded from the study as there were signs of knee varus/valgus crosstalk and marker wobble in the data.

C. Data preprocessing

Raw data were pre-processed and analyzed using an in-house developed python script (Python 3.12). Gait cycles (GC) were defined as the first initial contact from the affected lower limb till the next initial contact of the same lower limb. The nine parameters were resampled to 101 data points per GC, representing 0% (initial contact of affected leg) to 100% (subsequent initial contact of affected leg) of the GC.

D. Statistical analysis

Data were standardized (centered and scaled around 0) before starting the statistical analysis. The analysis consisted of two stages. First, a principal component analysis (PCA) from package *Scikit* was performed to reduce dimensions for all nine metrics separately (284 GC x 101) [15]. Principal components (PCs) that explained a cumulative variability of more than 80% were retained. PC scores were then calculated for each PC.

TABLE II. PC SCORES PER KINEMATIC PARAMETER

Principal components (PC)		
Kinematics	***# PCs***	***Total Explained variance (%)***
Pelvis tilt	1	88.9
Pelvis obliquity	2	90.1
Pelvis external/internal rotation	1	87.1
Hip flexion/extension	2	88.7
Hip abduction/adduction	1	85.3
Hip external/internal rotation	1	95.2
Knee flexion	2	81.1
Ankle dorsiflexion/plantairflexion	3	86.7
Foot progression	1	87.5

A k-means++ cluster analysis from package *Scikit* was then performed on the retained PC scores [15]. K-means++ was preferred to k-means as k-means++ could improve speed and accuracy of the algorithms [16]. The package *kneed* was used to provide the knee point (i.e. point of the line with maximum curvature) of the function and therefore the optimal number of clusters [17]. Ultimately, each GC was assigned to one of the clusters based on the Euclidean distance to the centroids.

III. RESULTS

Data from 45 stroke patients were included in the current analysis (Table I, including 14 non-disabled subjects as reference). A total of 284 GC were extracted from the kinematic data to retrieve the clusters. From the nine kinematic parameters, fourteen PCs were retrieved. Table II shows the extracted PCs per metric. The knee point of the function was eight and therefore the mathematically derived optimal number of clusters was set at eight. The sum of squares error (SSE) was 1209.

Table III presents the descriptives per cluster. The number of GC assigned to the 8 clusters ranged from 14 GC in cluster 5 to 82 GC in cluster 8. The number of participants assigned to the clusters ranged from only one participant in cluster 6 to fourteen participants to cluster 8. Eight of the 284 GC (2.8%) were assigned to a different cluster than the remaining GC of an individual. From this eight GC, three participants had one GC in both cluster 2 and 8, whereas two participants had one GC in both cluster 3 and 4. In addition, one participant had all GC equally distributed over clusters 2 and 5.

The mean and standard deviation of all nine kinematic parameters for the eight clusters are presented separately in Fig. 1, along with the reference data. Each cluster will be described in more detail below.

TABLE I. SUBJECT CHARACTERISTICS FROM NON-DISABLED DATASET AND STROKE PATIENTS [14]

	PP	**Affected side**	**Gender**	**Age**	**Weight**	**Height**	**Time post stroke**	**FAC**	**Gait speed**	**Step length**	**Step time**	**Stride length**	**Stride Time**

PP = participants, n.a. = not applicable, FAC = Functional Ambulation Category

A. Characteristics per cluster

The gait pattern represented by cluster 1 consists of a slightly less dynamic and decreased knee flexion at midstance and initial swing compared to the knee angles in the sagittal plane of non-disabled individuals. The internal rotation of the hip is increased during the whole GC. The decrease in knee flexion during the swing phase could be the result of the inadequate push-off and/or the internal rotation of the hip.

Cluster 2 is seen as representing 'good' walkers. The gait pattern of cluster 2 follows the gait pattern of non-disabled, but with a slightly reduced ankle plantar flexion during the push-off phase. There is a trend towards increased hip adduction and external rotation.

Cluster 3 shows a pattern with the knee in hyperextension during the stance phase. Also, the ankle in the sagittal plane remains rigid during the whole GC. This cluster seems to stabilizes the leg through the hyperextension. The affected leg does not seem to contribute towards an efficient walking gait. The cluster starts in (hyper)extension during the stance phase. At initial swing, the pelvis moves to posterior and, together with an increased hip hike, leads to a (small) increased hip flexion that eventually moves the affected leg forward.

Cluster 4 shows a decreased anterior tilt of the pelvis and decreased flexion of the knee and ankle over the whole gait cycle. The knee remains slightly in flexion during the stance phase. The knee and ankle do not contribute (much) to a gait pattern that is seen in non-disabled individuals.

The gait pattern of cluster 5 shows an increased dorsiflexion of the ankle. This results in an increased knee flexion and therefore an increase in hip flexion. It seems that the issues are mostly on the level of the ankle. The gait pattern of cluster 5 has similar features as cluster 4, especially regarding increased flexion of the knee and hip during stance, but with a less affected gait pattern.

Cluster 6 shows an increase in flexion in the knee and hip during midstance until the end of pre-swing. The cluster lands on the forefoot and has a reversed loading response. There seems to be a passive foot drop as there is no active push-off visible in the sagittal ankle kinematics. The knee is continuously in flexion and, together with the rigid hip flexion, the question arises if there is actual foot clearance.

Cluster 7 comprises increased hip abduction during the stance phase. In combination with increased hip drop and a slightly more posterior tilt of the pelvis, it forces the knee in a more rigid position during the stance phase. This shows a hip compensation strategy during stance that is different from the hip compensation strategy in cluster 4. During the swing phase, the hip returns to neutral.

The gait pattern of cluster 8 shows no clear push-off. The hip is in increased flexion whereas the ankle has an increase in plantarflexion. There is a decrease in active ankle control, which results in gait deviations similar to clusters 4 and 5, however these deviations are larger than seen in cluster 4 and smaller than cluster 5.

B. Kinematic differences between the clusters

From a clinical point of view, we can rearrange the eight clusters into four categories. In the first category, we can include cluster 1 and cluster 2. Both clusters showed similar gait patterns to that of non-disabled individuals. The main difference between clusters 1 and 2 is that cluster 1 is less dynamic in the knee and ankle compared to cluster 2, resulting in cluster 1 having a more affected gait pattern when compared to non-disabled walkers. This is reflected in the walking speed being the highest among all clusters, with cluster 2 showing the highest speed between the two clusters.

The second category comprises clusters 4, 5, 7 and 8. All four clusters show signs of a rigid knee as reflected in a limited range of motion across the GC. The four clusters also demonstrate a decrease in active ankle control. Clusters 4 and 7 show the most affected ankle control, and consequently most affected gait pattern, followed by cluster 8 and lastly cluster 5.

Cluster 7 shows similarities with cluster 4 regarding the ankle, knee, hip and pelvis patterns in the sagittal plane. However, this cluster seems to use another hip compensation strategy. Cluster 4 shows adduction of the hip during the stance phase, whereas cluster 7 shows abduction during stance. Furthermore, there is a simultaneous hip drop in cluster 7 whereas there is a hip hike in cluster 4. This suggests that clusters 4 and 7 are subclusters of the general pattern seen across clusters 5 and 8 in various degrees of deviation, with different hip compensation strategies to stabilize during the stance phase.

TABLE III. DESCRIPTIVES PER CLUSTER

Cluster	Counts	Affected Side[1]	Gender[1]	Age	Weight	Height	Time post stroke	FAC	Gait speed	Step length	Step time	Stride length	Stride Time

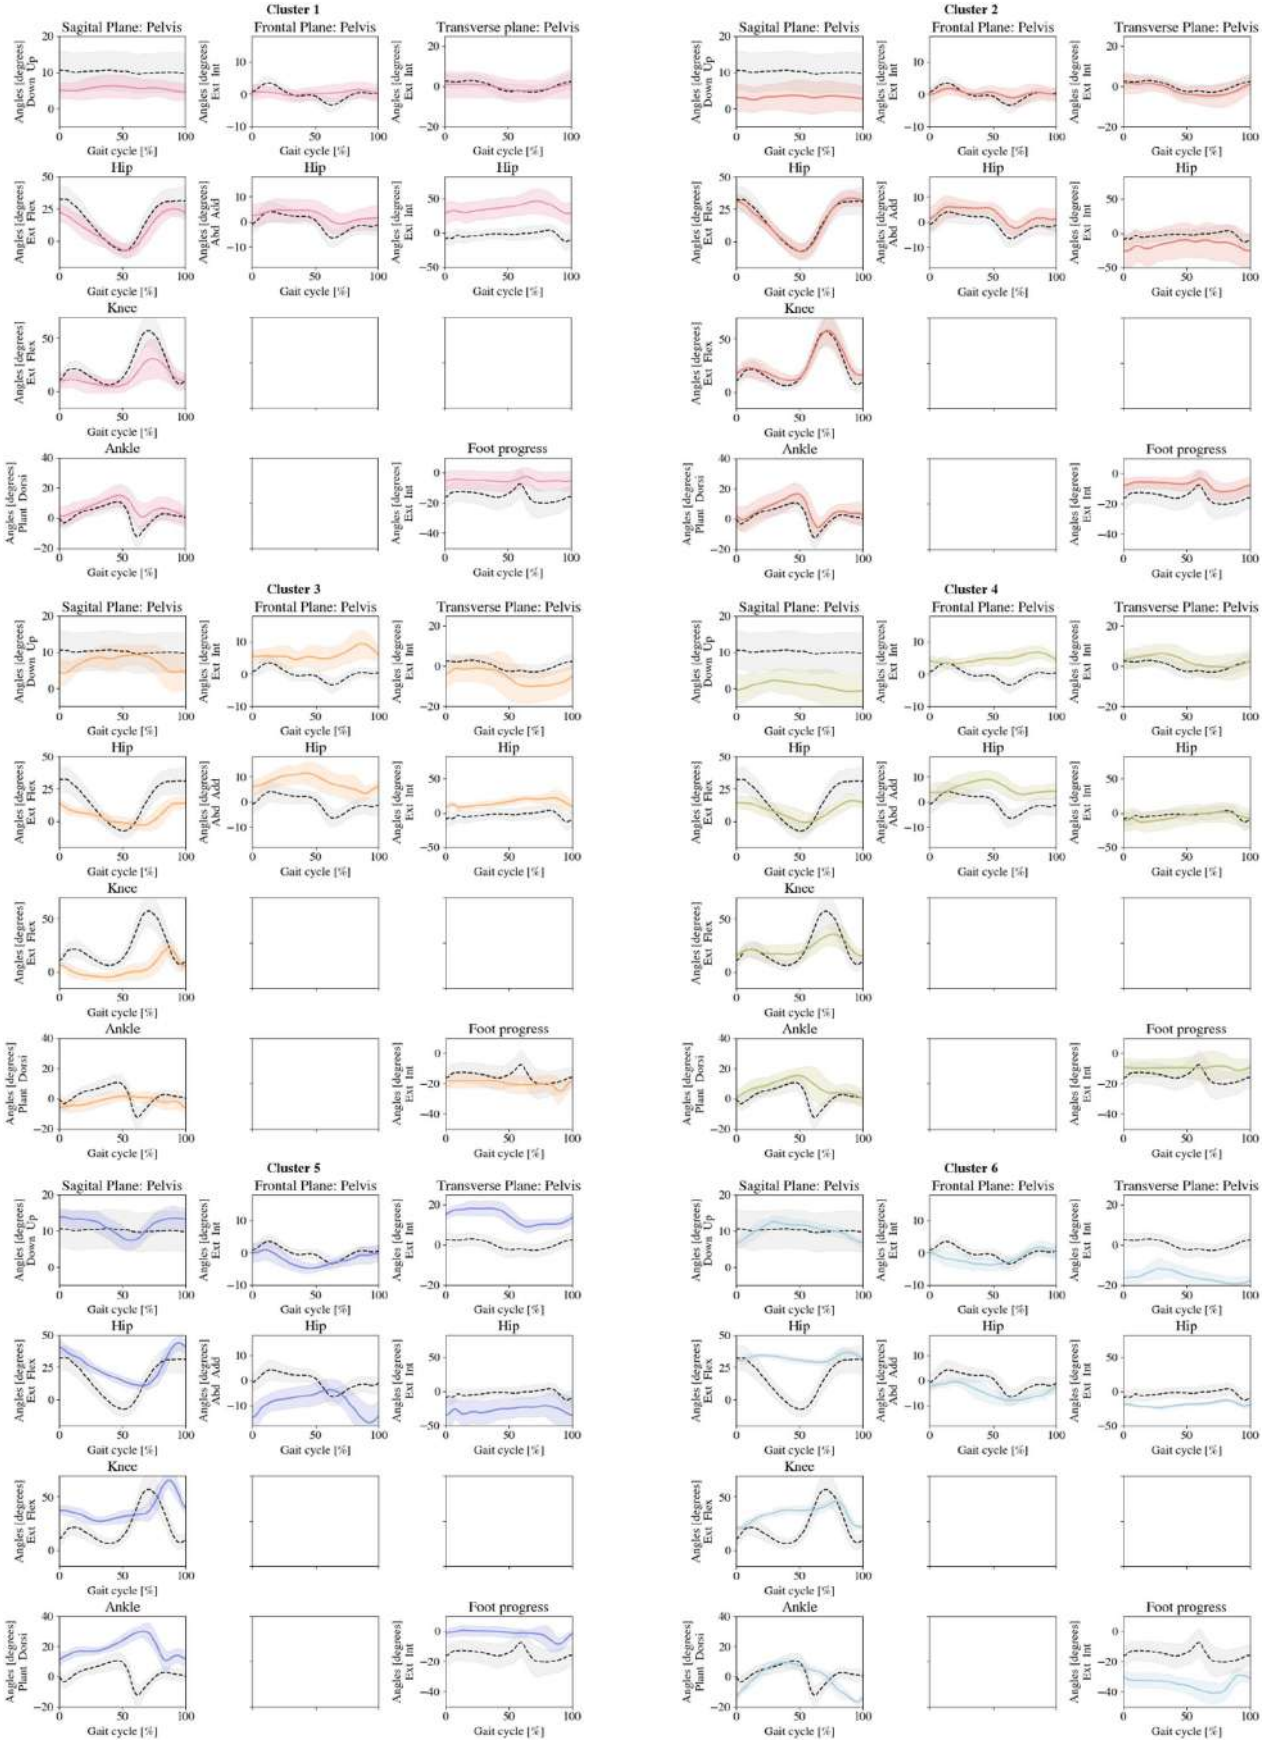

Fig. 1. Kinematic parameters for every cluster. Black dotted line represent the normal range of the angles.

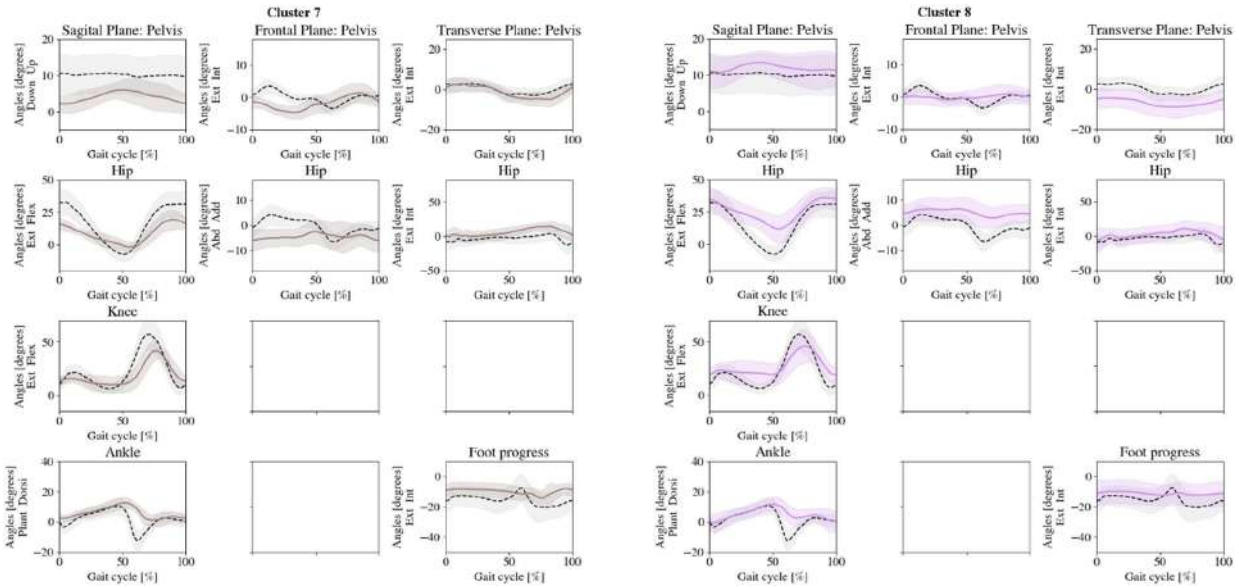

Fig. 1. Continued. Kinematic parameters in every retrieved cluster. Black dotted line represent the normal range of the angles.

The third category comprises cluster 3 and shows a knee (hyper)extension during the stance phase. The cluster also demonstrates a decrease in range of motion in the sagittal plane of the knee. This is reflected in a severely affected functional gait with very low walking speeds.

The last category consists of cluster 6 and is characterized by a (plantar) flexed position of the ankle, knee and hip. The knee is continuously in flexion and there is no variation in the hip angle. Due to the reversed loading response and no real change from dorsiflexion to plantarflexion during the pre-swing/initial swing phase, there could be a passive foot drop in this cluster. This prevents efficient walking, as reflected in the lowest walking speed among the eight clusters.

IV. Discussion

A total of eight clusters were retrieved based on nine kinematic parameters of the affected leg. These eight clusters provide insights into the various pathological gait patterns of stroke patients. These eight clusters can be rearranged into four categories from a clinical perspective.

This study used a methodology where pathological gait patterns were retrieved based on kinematic parameters and tried to translate the clusters into clinically meaningful categories as a first indication of the validity of the clustering. This is in line with the methodology of [18] in which they used almost the same approach to cluster gait patterns in growing children with Duchenne muscular dystrophy. Only one study has used the full kinematic GC to cluster and classify stroke patients simultaneously [19]. Previous research on clustering has been using spatial-temporal distance variables and discrete joint angles in stroke patients [19-21] with equinus deformity [22] and resulted in less clusters compared to the current study. The number of clusters ranged from three [20,22] to four [21] to six [19]. These clusters were mainly based on walking speed. Previous research has shown that individual's characteristic gait patterns were preserved across their range of walking speeds and were not grouped based on absolute walking speed [23]. Therefore, this study did not take walking speed into account, which might have contributed to the larger number of clusters found in the present study.

Two identified clusters should be considered with caution. Firstly, cluster 6, as all GC assigned to this cluster are from only one participant. In addition, only two participants are assigned to cluster 5 and the GC of one participant have been equally distributed over both cluster 5 and 2. Future research should investigate whether these trends are also found in other stroke patients or if these gait patterns are unique to this specific individual.

The majority of participants had all GC assigned to one cluster. Overall, only eight of 284 GC (2.8%) were assigned to a different cluster than the remaining GC of an individual. This indicates that the clustering was relatively consistent within subjects, especially in the case of stroke patients. This is in line with studies that demonstrated that there is less variation in GC within-subjects [23]. Although there are a few exceptions, the clustering consistency suggests that such unsupervised and unrestricted classification of gait patterns based on joint kinematics only is promising for further study.

Previous research on the comparison of non-disabled subjects and stroke survivors has highlighted the differences in ankle, knee and hip joints in the sagittal plane during the early stance phase and late stance to early swing phase [24]. The results of the current study demonstrated that not all clusters have deviations in the ankle (i.e. clusters 1, 7 and 8), knee (i.e. clusters 2 and 7) and hip (cluster 2) during the early stance phase and late stance to early swing phase. This indicates that research into the differences between stroke patients and non-disabled participants should be read with care as different types of gait patterns exist across stroke patients.

This study has several limitations. One of the limitations of the study is that only the affected leg is taken into account. Previous research has shown that the less-affected leg also demonstrated abnormal biomechanics variables compared to the control group [24]. This suggests

that the same approach of clustering can be executed with the less affected leg, retrieving clusters based on compensation strategies and/or a combination with the current approach. The second limitation is that the angles of the ankle and knee in frontal and transversal planes were excluded in the study as this did not comprise reliable information. Therefore, it might be that stroke patients have (additional) problems around the ankle and knee that are currently not accurately identified. Lastly, this study provides a first attempt to cluster gait patterns based on kinematic parameters. Future research is needed to validate the clusters with external databases and against clinical outcomes.

The results of this study provide insight into the gait pathology of stroke patients. The eight clusters demonstrate that there are variations among stroke patients in terms of gait kinematics of the affected leg. Ultimately, such clustering may be used by clinicians and physiotherapists to tailor rehabilitation programs based on the patients' assigned cluster. The identified clusters can also be relevant to the field of robot-assisted gait, by selecting the suitable type or amount of support. The clusters could be used as a tool to predict the outcome of specific robotic devices on the walking ability of stroke patients before the patient utilizes the device. Future research should therefore focus on the implementation of these clusters as clinical indicators for exoskeletons use, after the clustering has been validated.

V. Conclusion

This study provides a first attempt to cluster pathological gait patterns in stroke patients using principal component analysis and k-means clustering. A total of eight clusters were retrieved and rearranged into four clinically meaningful categories. The results show initial feasibility of clustering gait patterns in stroke patients. Future research should focus on validating the approach and using the clusters to identify the responsiveness of stroke patients to exoskeletons as a way to personalize rehabilitation programs.

Acknowledgment

We would like to thank the team of Van Criekinge [14] for making their dataset publicly available (used under CC-by 4.0 license). As the burden for stroke patients during activities of daily life, such as walking, is already high, the dataset is greatly appreciated.

Optimizing the Myokinetic Interface: A Finite Element Model to Predict Displacement in Amputated Muscles

Flavia Paggetti[1], Marta Gherardini[1], Alessandro Lucantonio[2], Christian Cipriani[1]

Abstract— **In recent years, a novel human-machine interface for prosthetic control has been developed: the myokinetic interface, which decodes the user intent by monitoring the displacement of implanted magnets in the muscles. Simulations and the first in-human demonstration of this interface indicate that the placement of the magnets is crucial for the range and stability of the control signals. Therefore, a preoperative estimation of individual muscle displacement is necessary to identify optimal implantation regions and generate synthetic datasets of magnet displacement. In this study, we developed a finite element model of pennate muscles, calibrated and validated using the geometries of healthy muscles and in vivo measurements from healthy subjects. The performance of the model was further assessed on three amputated muscles by comparing simulations with in vivo data from a limb-impaired individual. Overall, the simulation results aligned well with experimental data, with average errors below 0.7 mm for the healthy muscles and 1.7 mm for the amputated ones. These results suggest that this model could serve as a valuable tool for optimizing surgical procedures and control strategies prior to clinical implementation. This framework could be expanded to investigate muscle behavior in different amputee populations or individuals with neuromuscular diseases, to enhance understanding of muscle biomechanics and advance the design of personalized rehabilitation devices.**

I. Introduction

A limb amputation is a traumatic experience that profoundly impacts the quality of life of many individuals, significantly reducing their capability and independence in performing daily living activities. Despite the development of technologically advanced prostheses, the absence of human-machine interfaces capable of accurately and reliably monitor the user's intentions hinders the widespread adoption of these assistive devices. In the past years, multiple strategies to decode the user's intent have been developed. Most of these methods detect muscle activation by measuring the electromyographic signals generated during contraction [1], [2], using either surface electrodes or implantable sensors [3]. Recently, a new paradigm for decoding the user intent has emerged, based on the detection of muscle displacement. This approach can be implemented non-invasively by capturing muscle architectural changes using ultrasound probes (sonomyography) positioned on the stump [4], or by recording pressure changes on the skin surface (force myography) [5]. Another approach, the myokinetic interface [6], [7], involves tracking markers implanted within the muscle to monitor its contractile state. As multiple markers can be implanted in the muscles, the localization of their poses (position and orientation) allows to reconstruct the muscle deformation. Unlike sonomyography, this approach does not require continuous contact between the device and the skin, nor does it rely on the application of gels or moisture, which could cause skin problems with prolonged use. We developed this concept by implementing the myokinetic interface initially through laboratory studies, and eventually transitioning to clinical settings [8]. The concept has gained significant interest within the scientific community, resulting in numerous studies that underscore how muscle deformation, and consequently, the selection of implant sites, can profoundly influence the choice of control strategies, as well as the expected range of motion and signal resolution [9], [10]. This aspect was further validated during the first in-human trial involving a patient with transradial amputation: the positions of the magnets within the muscles proved to be crucial in determining the amplitude and consistency of the control signals [8]. These findings highlight the importance of preoperative planning and studying muscle deformation, focusing on the kinematics of amputated muscles.

Within this framework, preoperative estimation of muscle deformation and fiber rotation is crucial. Finite element (FE) models have the potential to provide such information, enabling to generate realistic dataset of muscle contractions. This capability can support the preoperative planning of surgical procedures, identifying the most suitable muscle regions for the magnet implantation, to maximize the range and consistency of control signals. Over the past decades numerous FE models of muscles have been developed, involving different constitutive laws to model both the passive and active components of the muscle tissue [11]. More recently, researchers have also included fiber direction in the model, demonstrating to be a key element in the muscle kinematics [12][13]. While most simulations have been applied to healthy muscles, only a limited number has focused on the behavior of amputated muscles. Among these, the majority focus on the lower limb, investigating limb-socket interactions to identify strategies for reducing discomfort and dermatological issues [14].

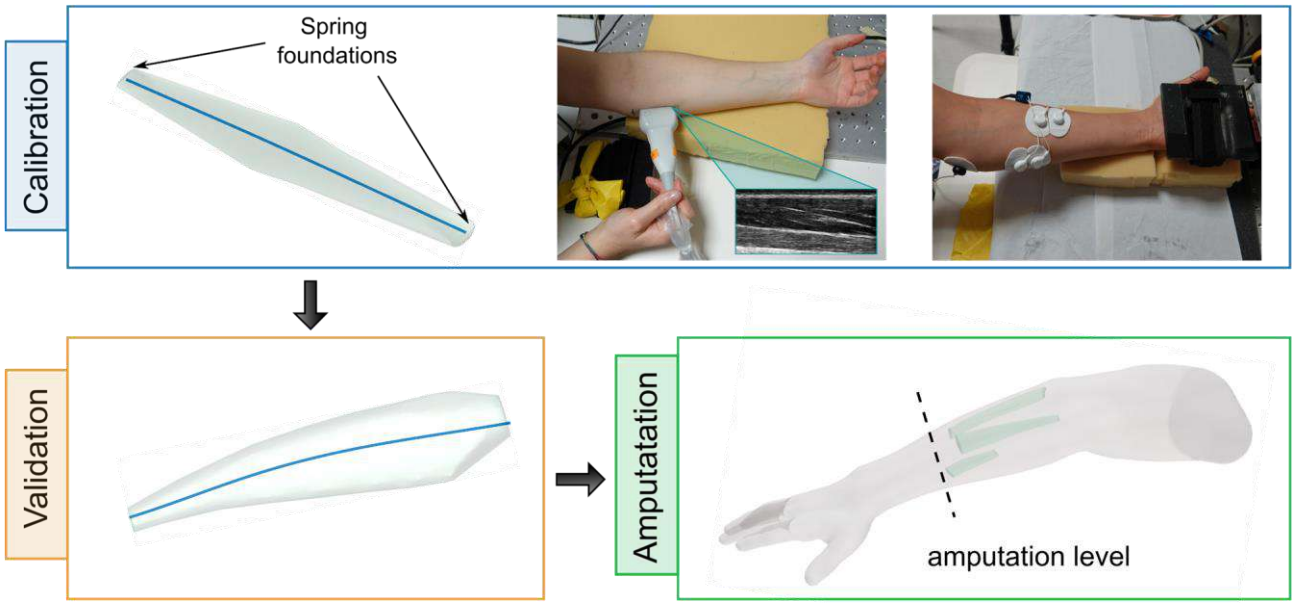

Fig 1 Block diagram showing all the steps of the experimental setup. *Calibration* was performed on the healthy geometry of the FCU muscle (on the left), with ultrasound images and EMG signals acquired to record the pennation angle and estimate force development (on the right). *Validation* was performed on the healthy geometry of the FCR muscle. Finally, *Amputation* was simulated on the geometries of three muscles (ED, FPL, FCU).

Within this framework, a finite element (FE) model of forearm amputated muscle becomes necessary to specifically address the displacement field generated during contraction. In this study, we calibrated and validated a model of muscle contraction [15] on the geometry of healthy forearm muscles, incorporating fiber direction and displacement specifically derived from in vivo measurements. Calibration was performed on a simplified geometry of the flexor carpi ulnaris (FCU) muscle to fine-tune material parameters. Subsequently, forces and displacements generated by a more realistic geometry of the flexor carpi radialis (FCR) were compared with those of healthy participants, validating the model performance. Finally, the model was applied to the geometry of three amputated muscles, and results were compared with muscle displacement data recorded from a limb-impaired participant. This work provides a preliminary development of an amputated forearm muscle model, that could potentially enable patient-specific preoperative planning and could be extended to any amputation level. This framework could be adapted to study muscle function in various groups of amputees or individuals with neuromuscular disorders, to improve understanding of muscle biomechanics and support the development of customized rehabilitation tools.

II. Materials and Methods

The FE model was implemented in Comsol Multiphysics 5.5 (COMSOL Inc. Stockholm, Sweden) and calibrated and validated through in vivo experimental measurements from 8 and 7 healthy participants, respectively (age range: 20-30 years old, two females, six males). The model was then applied to the geometry of three amputated muscles and the resulting displacement was compared with that recorded from one limb-impaired participant (Fig 1). Informed consent in accordance with the Declaration of Helsinki was obtained before conducting experiments from each participant. The studies were approved by the local ethical committee of the Scuola Superiore Sant'Anna, Pisa, Italy (Approval No. 10/2023). The methods were carried out in accordance with the approved guidelines.

A. Geometry, material and boundary conditions

The geometries of forearm muscles were extracted from a 3D model of healthy human forearm (Zygote, American Fork, US) already used in [9]. The model included muscle-tendon structures, bones, skin and vessels. Only the muscle-tendon units were retrieved and divided by transecting the distal and proximal tendons. Muscle bellies were modeled by implementing material-specific equations. As skeletal muscles are essentially incompressible and show a highly nonlinear stress-strain behavior, their passive properties can be described with hyperelastic models [16], as a combination of passive and active materials. In this work, muscle bellies were modeled according to the mixture active strain approach introduced by Riccobelli and Ambrosi [15]. The deformation gradient is multiplicatively split into an elastic (F_e) and an active (F_a) contribution. The choice of F_a is inspired by the microstructural architecture of the muscles

$$\mathbf{F} = \mathbf{F_e}\mathbf{F_a} \tag{1}$$

$$\mathbf{F_a} = (1-\gamma)\mathbf{M} + \frac{1}{\sqrt{(1-\gamma)}}(\mathbf{I}-\mathbf{M})$$

where $0 \leqslant \gamma < 1$ is a parameter that describes the microstructural degree of contraction of the muscle (0 corresponds to a relaxed state) and **M** the fiber direction. The mixture active strain approach considers the material as composed by an isotropic and an anisotropic phase. The former represents only passive constituents that do not contribute to muscle contraction, such as elastin and collagen,

whereas the latter describes the fiber contribution. The strain energy density function describing the material is the following:

$$\psi = \psi_{iso} + \psi_{ani} \tag{2}$$

$$\psi_{iso(F)} = -\mu \frac{I_{max}}{2} log\left(1 - \frac{I_1 - 3}{I_{max}}\right)$$

$$\psi_{\mathrm{ani}}(F) = \alpha\beta\left(\mathrm{I}_4^{\frac{1}{2\beta}} - 1\right)^2$$

A Gent material model has been adopted for the isotropic part, with μ being the shear modulus and I_{max} a constant setting the maximum value reachable by the first invariant I_1. The anisotropic part of the strain energy depends on the anisotropic parameter α (N/m^2), and a dimensionless constant β, which controls the stiffening behavior of the material.

The constitutive law presented in (2) was implemented in Comsol Multiphysics 5.5. The model requires as input the values of μ, I_{max}, α, β and the fiber orientation **M.** In all simulations, the shear modulus μ was set to a value comparable to human muscle shear stress (μ = 30 kPa [17]), and I_{max} to 0.41 as in Riccobelli's and Ambrosi's work. α and β were selected according to a calibration procedure described in *B*. The muscle fiber orientation was derived from ultrasound images of the muscle fibers (calibration phase) and from literature data for the validation and amputated muscle simulation. Muscles were modeled with a tetrahedral mesh (0.038 - 0.525 mm element size), while the proximal and distal tendons (when present) were represented by distributed springs (elastic modulus of 800 MPa [18]) with length equal to the tendon length.

Muscle simulations were performed by varying the degree of muscle contraction γ from 0 to 0.3 [19], with steps of 0.002. Variation in pennation angle, displacement field and force generated during different contraction intensities were monitored and compared with experimental data. Specifically, from the FE simulations, mean and standard deviation computed across the neighboring points of the muscle centerline were reported.

B. Calibration

A calibration procedure was performed to determine the optimal values of α and β. This calibration was carried out using a simplified 3D geometry of a healthy FCU muscle, selected due to its superficial location and large pennation values. Based on the 3D CAD model of the human forearm, a symmetric geometry for the FCU muscle belly was developed, preserving the original length and cross-sectional area (Fig 1). The material parameters α and β were optimized to match the measured muscle tensile force and pennation angle recorded during isometric contraction of eight healthy subjects. Specifically, the variations in pennation angle during isometric maximum voluntary contraction (MVC) were measured using B-mode ultrasound imaging. An 18 MHz linear transducer (Esaote Mylab, probe LA435) was used to capture images at the level of ~30%, ~50% and ~70% of the muscle length. The transducer was positioned in the coronal plane to detect the angle of fiber attachment relative to the tendon axis, in both relaxed and contracted states (Fig 1). The average fiber angles measured at rest were used to define the initial fiber orientation **M** in the FE model. The variation in fiber angle from resting state to maximum contraction was compared with results from the FE simulation.

The maximum force generated by the FCU was recorded by a load cell (Nano17 by ATI, SI 25-0.25), while participants were performing isometric wrist flexions to activate the FCU. Participants sat with their dominant forearm placed on the table, in a supine position and with the hand located right below the load cell. A rigid flat frame was tied on the palm of the hand, to provide a rigid interface with the measuring system, thus reducing eventual errors due to local skin deformation (Fig 1). Participants performed three maximum voluntary isometric contractions, isometrically flexing the wrist, with joint movement constrained by the load cell. Since the measured force reflected the combined contribution of both wrist flexor muscles (i.e., FCU and FCR), their electromyographic (EMG) activity was recorded to disentangle their individual contributions. Bipolar electrodes recorded activation from both muscles (Fig 1), and the signals were amplified, filtered (10–500 Hz), rectified, and low-pass filtered (15 Hz) to produce linear envelopes. Muscle contributions were estimated by comparing the amplitudes of these envelopes across trials and subjects, leveraging the established linear relationship between EMG and muscle force during isometric contractions [20] . Finally, using the known moment arms of both muscles [21] and the load, the balance of moments around the wrist joint was solved to estimate the actual contraction force developed by both muscles.

Multiple FE simulations were run by manually varying α (1 kPa -5 MPa) and β (0.8-2.5). Variation in pennation angle was evaluated as the average angle variation over a number of points along the centerline at the distal (30% muscle length), central (50%) and proximal (70%) muscle region. The force developed following maximum contraction was measured at the muscle-tendon interface of the distal extremity, by integrating the distributed spring force magnitude over the area of attachment. Finally, the values of α and β that produced FE results best matching the experimental data were identified and used in all the subsequent simulations.

C. Validation

A validation procedure assessed the generalization ability of the model towards different geometries and output variables, exploiting a realistic geometry of the healthy FCR muscle, obtained from the 3D model of human forearm (Fig 1). The muscle-tendon unit was transected distally and proximally to retain only the muscle belly, according to anthropometric data [22]. The initial pennation angle was set to 13°, in agreement with literature data [23]. The material parameters selected in the calibration phase were used to simulate contractions, again increasing γ up to 0.3.

The displacement and force developed by the FE model under different contraction intensities were compared with data from seven healthy subjects performing five isometric contractions at 20%, 50%, 70%, 90% of MVC. Ultrasound videos recorded the muscle contractions in the longitudinal plane, with the probe positioned at ~30% (proximal), ~50% and ~70% of muscle length. The displacement of visible

TABLE I. MEAN VALUES OF PENNATIN ANGLE FOR THE RELAXED AND CONTRACTED STATE, ALONG THE MUSCLE LENGTH

State	Mean pennation angle (deg)		
	20% muscle length	*50% muscle length*	*70% muscle length*
Relaxed in vivo	5.68 ± 2.04	4.56 ± 1.54	3.96 ± 0.89
Relaxed FEM	5.57	4.77	4.18
Active in vivo	8.13 ± 2.56	6.83 ± 1.80	5.47 ± 1.44
Active FEM	7.73	6.57	5.10

reference points (e.g. fiber attachment) was manually measured and compared to the FE displacement. Similarly, the force of FCR measured with the load cell during calibration was compared to the FE output.

D. Amputated muscle

The finite element model, developed through the calibration and validation phase, was used to simulate contractions in amputated muscles. Three forearm muscles have been considered, namely the extensor digitorum (ED), flexor pollicis longus (FPL) and FCU, with geometries obtained from the 3D CAD model of the human forearm (Fig 1). As in [9], the amputation was simulated by transecting the distal part of the muscle-tendon complex until the middle third. This resulted in the absence of tendon for the FPL and FCU muscle. The myodesis technique (anchoring of transected muscles directly to the bone) was simulated by applying a fixed constraint at the transected muscle end. For the ED muscle, a ~4 cm residual tendon was simulated through a spring foundation (elastic modulus of 800 MPa [18]). Finally, longitudinal ultrasound videos recorded muscle displacement at 25% and 50% of muscle length during 10 repetitions of 20%, 50%, 70% and 90% MVC. As for the validation process, the displacement of reference fibers was manually measured offline, and reported as mean and standard deviation computed over multiple contractions.

III. RESULTS

A. Calibration

The values of α and β that best matched the experimental measurements corresponded to α = 1.5 MPa and β = 1. Using these values, the simulation developed a force of 96.3 N during MVC of the FCU muscle. This result was comparable to the in vivo forces measured across subjects, which proved in the range 89.51 – 96.40 N, and was consistent with literature data [21]. Regarding the variation in pennation angle, results from the experimental session and the FE simulation are reported in Tab. I. A decreasing trend in fiber angles at rest was observed when moving distally along the muscle, consistent in both simulated and experimental data. The variation in fiber angle from relaxed to contracted state followed a similar pattern, showing a smaller increase in pennation angle distally (increment of ~2° proximally, ~1° distally), in both FE results and experimental observations. Notably, the results from the FE model consistently fell within the standard deviation of the experimental measurements, demonstrating its ability to replicate the overall trend of angle variation along the muscle (Fig 2). The maximum difference

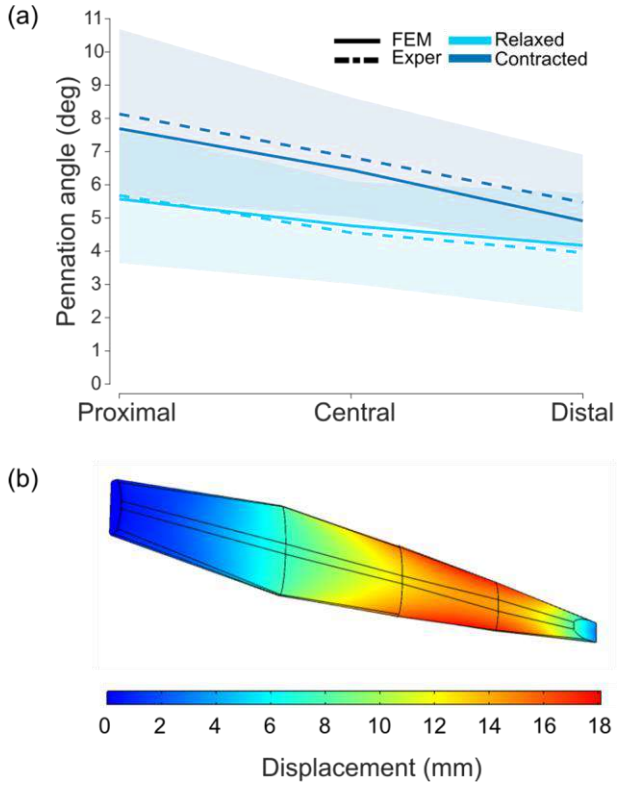

Fig 2 Calibration results. (a) Variation in pennation angle along the muscle: comparison between the FEM results (solid line) and the experimental results (dashed line) for the relaxed and contracted muscle state.

between experimental and simulated angles was always below 0.6°.

B. Validation

Overall, the displacement predicted by the FE model closely matched the experimental data across all contraction intensities (Fig 3). The discrepancy between the two profiles was consistently below 0.7 mm (17% of the maximum displacement), with the largest deviation observed at 50% of the muscle length, at 20% MVC. The maximum longitudinal displacement was observed at the highest contraction intensity and at 50% of the muscle length, with values ranging from 3.9 mm (in vivo measurements) to 4.1 mm (simulation). Both the proximal and distal regions exhibited similar displacement trends, while the central region consistently showed the largest displacement across all contraction intensities, except for the experimental data at 90% MVC (Fig 3). The force of the
FCR muscle estimated from the calibration process ranged from 91.73 N to 98.75 N during MVC. In contrast, the simulation predicted a force of 134.9N at the maximal contractile state.

C. Amputated muscle

All muscles and regions exhibited a displacement that increased with contraction intensity, though not always in a consistent manner for the in vivo measurements (Fig 4). The maximum in vivo displacement was found at 50% of the muscle length for all muscles, with values of 8.1 mm, 2.2 mm and 5.7 mm for ED, FPL and FCU, respectively. The

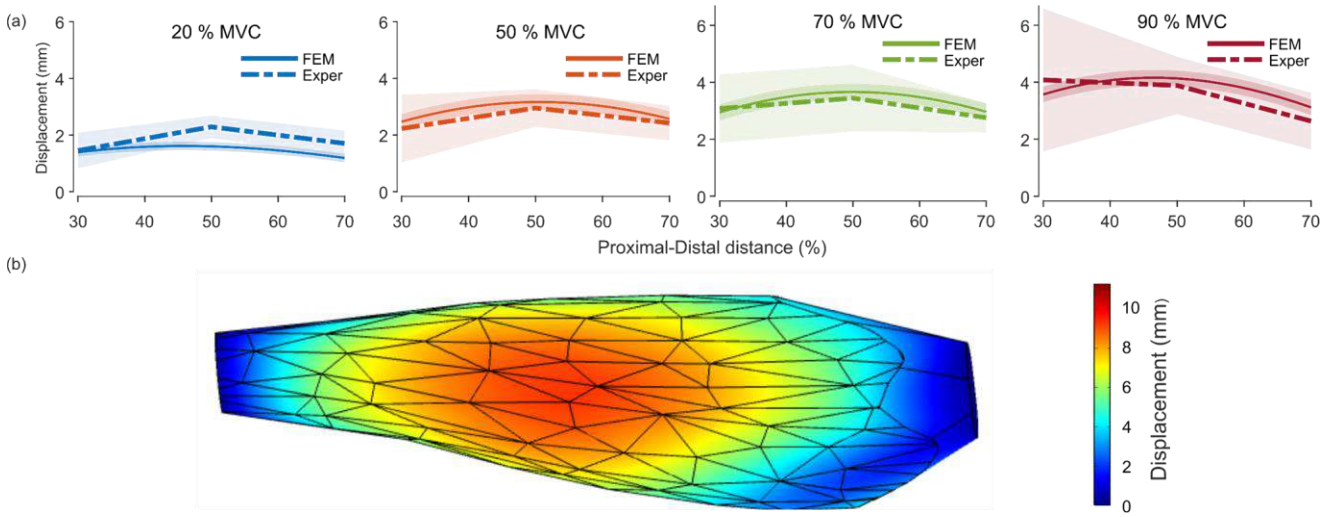

Fig 3 Validation results. (a) Displacement along the muscle for different contraction intensities: comparison between the FEM results (solid line) and the experimental results (dashed line). (b) Displacement field of FCR following maximum voluntary contraction.

discrepancy between measured and simulated displacement, averaged across contraction intensities, proved always below 1 mm for ED and FPL, and below 1.7 mm for FCU (12%, 45% and 30% of the muscle displacement, respectively). The maximum discrepancy was found in the central region of the FCU for 90% MVC, with an error of 3.5 mm (61%) with respect to the experimental data. Overall, except for the proximal region of the ED and FPL, the simulated displacement slightly underestimated the experimental one.

IV. Discussion and Conclusion

We developed a FE model of muscle, starting from a healthy configuration and then moving toward an amputated one. The model provided accurate estimates of force and displacement of healthy muscles, effectively capturing the overall dynamics and kinematics of pennate muscles. Preliminary assessments of amputated muscles demonstrated the model's capability to simulate realistic muscle contractions in amputated conditions, highlighting its potential applications for various limb amputations and related pathologies.

During the calibration phase, the distal region exhibited the largest pennation angle at rest and, unsurpisingly, showed the largest increase in pennation angle during contraction (Fig 2). These findings agree with previous studies indicating that the amount of fiber rotation highly correlates with the pennation angle at rest [24]. This aspect must be considered when planning magnet implantation, particularly if the variation in magnet orientation is a desired control signal. Indeed, a large change in pennation angle during contraction is expected to produce greater magnet rotation.

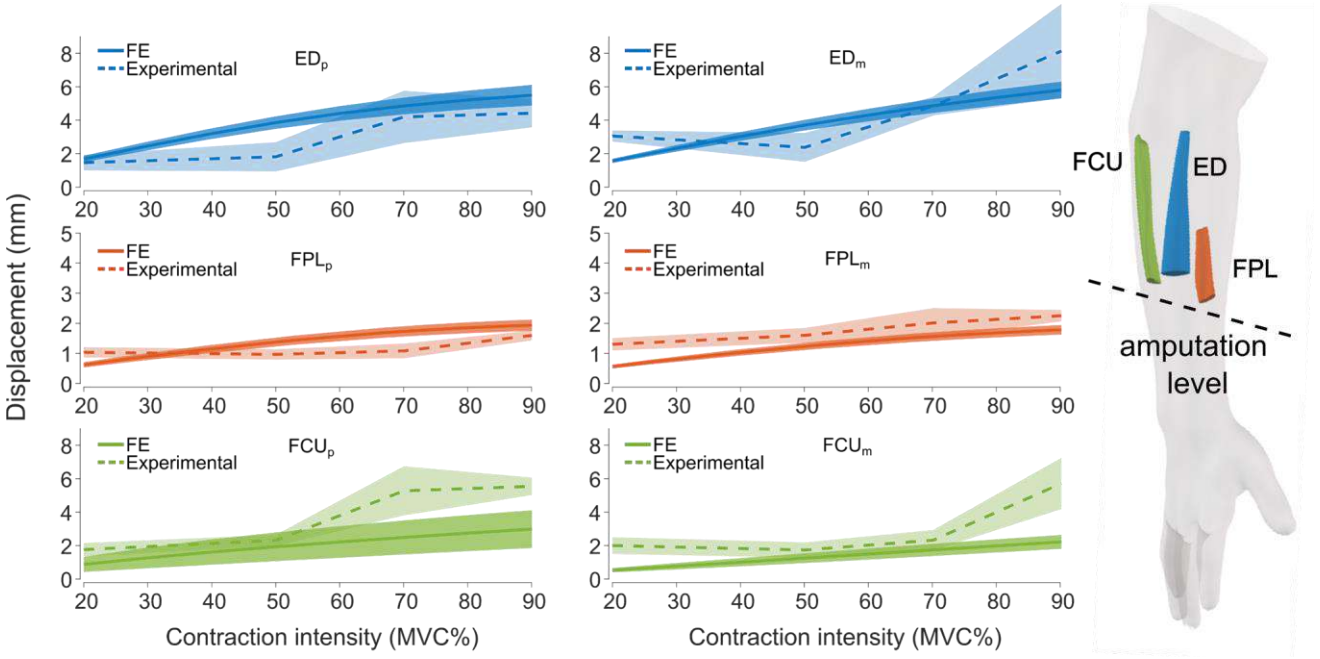

Fig 4 Amputated simulation results. Displacement as a function of contraction intensities for the three amputated muscles: comparison between the FEM results (solid line) and the experimental results (dashed line) for the proximal region (left column) and the central one (right column).

The discrepancy between the force generated by the FCR muscle in the FE model and the in vivo data is likely due to challenges in accurately visualizing the fiber angle in the ultrasound images. As a result, a literature-derived value was used instead of a subject-specific measurement. Incorporating more precise, subject-specific fiber orientation data could significantly improve force estimations, as fiber orientation is known to significantly affect force output [24].

Finally, the slightly higher discrepancy between the FE model and experimental data in the amputated configuration (Fig 4) could be attributed to several factors. First, the model parameter were calibrated and validated using a healthy muscle and were not specifically adapted for an amputated one. It is well-known that muscles in limb-impaired individuals may undergo atrophy and experience reduced volume due to decreased activity: future studies should take this into account. Additionally, the boundary conditions were modified to account for the shorter tendon length, assuming it was anchored via the myodesis technique. A different anchoring technique might explain the lower displacement estimated by the FE model compared to in vivo data. Therefore, future investigations should explore the influence of different suturing techniques on the muscle displacement, first in vivo and then by defining the appropriate boundary conditions in simulation.

Overall, these results demonstrate the feasibility of predicting the behavior of both healthy and amputated muscles, using fast in vivo measurements. Future studies should extend these findings to a larger population, by incorporating subject-specific geometries to refine the model parameters and enhance the overall accuracy. This work could be applied to estimate the muscle behavior in different amputee populations or individuals with neuromuscular diseases, paving the way for the development of novel and personalized rehabilitation strategies.

***Abstract*—This paper presents a human-machine interface designed to help individuals with upper-limb impairments select items on a screen using only head movements. The system allows users to make selections and confirm choices without requiring hand input. A study with 22 participants (11 male, 11 female, average age 23 years) evaluated its performance across three configurations. Results showed a clear learning curve, with participants achieving greater accuracy and consistency over time. Users adapted well to the system, maintaining stable mouth-opening and head-transition movements close to target values. Their range of motion in pitch and yaw also became more controlled, suggesting improved efficiency and ease of interaction. Survey responses reflected high confidence in system safety while highlighting areas for improving comfort and ease of use. These findings demonstrate the system's potential for accessible, intuitive interaction, with opportunities for further refinement to enhance user experience.**

I. Introduction

Over the last few decades, Human-Machine Interaction (HMI) has witnessed remarkable progress, this is primarily fueled by the integration of new technologies designed to enable users to communicate seamlessly with machines [1]. Researchers continue to push the boundaries of what these systems can accomplish. Despite significant advancements in assistive technologies, substantial gaps persist in meeting the diverse needs of individuals with physical impairments. The World Health Organization reports that over 2.5 billion people require one or more assistive products [2]. Upper limb impairments due to conditions such as degenerative diseases, strokes, or traumatic brain injury significantly impact an individual's ability to perform activities requiring selection and confirmation independently [3]. Furthermore, motor impairments caused by neuromuscular disorders, such as Amyotrophic Lateral Sclerosis (ALS) and cerebral palsy (CP), can severely limit fine motor control and the ability to interact with traditional HMI systems [4]. Additionally, impairments related to neurological disorders like multiple sclerosis, or Parkinson's disease can lead to tremors, muscle weakness, and involuntary movements, complicating the use of conventional devices [5]. For many individuals, these physical limitations pose great challenges in selecting and confirming choices, limiting their independence in essential tasks and daily activities [6], [7].

Traditional HMI systems are built upon various input methods, each with strengths and limitations. Joysticks have long been used for mobility aids, such as in powered wheelchairs, offering precise and proportional directional control. A proportional drive control allows the wheelchair's speed/direction to mirror the force/direction applied to the input device by the user [8]. Coltellaro emphasized that while joystick-controlled wheelchairs have evolved to become more adaptable, they still require a significant degree of upper limb coordination, presenting a barrier for those with severe motor function loss [6]. For users with neuromuscular disorders like ALS or CP, even slight upper limb movements may be difficult or impossible, further underscoring the need for more adaptable input methods [9].

Robotic assistive systems, such as feeding, use proportional (e.g., joysticks) and non-proportional (e.g., buttons, sip-and-puff) control options [8], [10]. While sip-and-puff systems allow users to control devices via breath, they may be unsuitable for those with respiratory issues or fatigue, particularly individuals with multiple sclerosis or traumatic brain injury [8], [9]. Recent innovations, including touchless sensors, still often rely on voice commands or auxiliary controls, which may not be feasible for non-verbal users or those with limited motor function [11].

Eye-tracking technology, such as Tobii Dynavox, offers an alternative for users unable to operate traditional controls [12], [13]. However, its effectiveness depends on precise calibration and controlled environments, limiting reliability in real-world settings [14]. Additionally, high costs and complexity hinder widespread adoption [15]. Voice-controlled systems, like Amazon Alexa and Google Assistant, provide hands-free interaction for individuals with upper limb impairments [16]. However, they exclude non-verbal users and those with speech disorders, such as dysarthria [17].

These limitations highlight the need for a more inclusive and intuitive control system, particularly for non-verbal individuals and those with severe upper limb impairments. While facial recognition and head tracking have been used in robotics and virtual reality, their potential as input methods in human-

machine interaction remains underexplored [18].

This work addresses the identified gaps by proposing a system that relies exclusively on head and mouth tracking to enable user selection and confirmation. The proposed system has the potential to simplify daily tasks for humans interacting with computing devices. Unlike traditional methods requiring significant hardware or extensive calibration, this approach is designed to be easily adaptable, minimizing the learning curve for users and caregivers. This ease of use is critical for individuals with upper limb impairments, as it reduces their reliance on external assistance, thereby improving independence. Jones et al. noted that user-friendly assistive technologies can substantially reduce the workload on caregivers and improve overall care efficiency [19].

Existing head-tracking systems, such as the HeadMouse Nano [20] and NuPoint [21], enable users to control on-screen cursors through head movements. These devices typically rely on dwell-based selection, requiring users to hold their head steady over a target area, which can increase fatigue and reduce efficiency over time. In contrast, our system introduces a **graph-based selection mechanism** that structures selectable items as interconnected nodes, allowing for more efficient navigation and reducing the physical demand on users. Additionally, while conventional systems rely solely on head movements for both navigation and selection, our approach leverages head movements for selection and mouth movements for confirmation, providing a more intuitive and less tiring user experience. The system can be scaled and adopted in a variety of HMI settings and applications, from home use to clinical environments. In conclusion, the development of these systems empowers individuals with disabilities to boost their engagement with assistive/computer devices, enhancing their independence while reducing the burden on caregiving resources [6], [7], [19]. To the best of the authors' knowledge, this is the first system that leverages head movements to select and mouth movements to confirm selections.

II. Method/Procedures

A. Hardware

The camera used for this research was an Intel RealSense D435i, and it was chosen due to its advanced depth-sensing capabilities and reliability in real-time 3D imaging. This camera was mounted on the wrist of the Fischer Scientific Fanuc F5 LR200ic 6DoF Robotic Arm and is used for both object detection task and facial tracking. This setup provides the flexibility needed for applications where accurate selection and confirmation are necessary, such as interacting with personal devices or assistive systems for daily activities.

The system was developed using a Linux operating system, specifically Ubuntu 22.04 LTS, and was equipped with ROS (Robot Operating System). This setup allowed for seamless integration and communication between the hardware components and the software system.

To create modular and adaptable layouts for different user interface configurations and system validation, 3D-printed boxes in sizes of 1x1 (7.6cm x 7.6cm x 4.7cm), 1x2 (15.8cm x 7.6cm x 4.7cm), and 2x2 (15.8cm x 15.8cm x 4.7cm) were assembled. These modular components allow for various selectable options, enabling the system to be used beyond food trays – for example, for interactive selection panels for communication aids, educational tools, or rehabilitation activities. Figures 1, 2 and 3 illustrate different tray compartments configurations, showing the potential variety in the layout of selectable items. The arrows signify the movement direction between containers, one sided arrows resemble movement in 1 direction (i.e from container 5 to 1) and two sided arrows resemble movement in 2 directions (from container 1 to 3 and from container 3 to 1). The blue dashed lines are decorative and resemble the midway point in 2x1 and 2x2 containers.

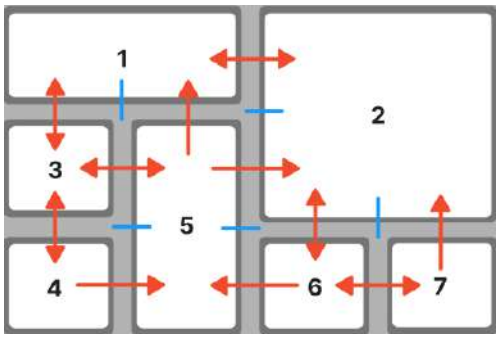

Fig. 1: Layout of Conf 1 which is comprised of four 1x1 boxes, two 2x1 boxes and one 2x2 box

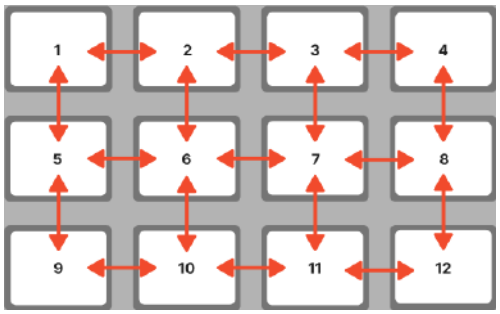

Fig. 2: Layout of Conf 2 which is comprised of twelve 1x1 boxes

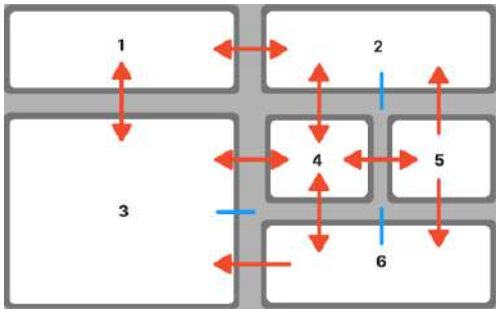

Fig. 3: Layout of Conf 3 which is comprised of two 1x1 boxes, three 2x1 boxes and one 2x2 box

B. Software

The software for this system, was developed in Python and was written as part of a bigger ROS (Robot Operating System) project. During the development process, a technique was needed that gave individuals using the system the ability to select which item/compartment they wanted to choose next from a tray of different items and configurations, without being able to use their arms. The idea was to have users choose items using only their head movements, leading to the work summarized in this paper. While the Python code developed for this system is tightly coupled with ROS's built-in publish/subscribe mechanism, the code can be generalized to be used outside of ROS for any head tracking and GUI selection system.

i. System flow

The process begins with the Intel RealSense camera, which captures an image of the arranged configured selection for the user interaction system. This image is then processed using a YOLOv9 machine-learning model that computes bounding boxes around each selectable tray box. The bounding box data is sent as a ROS message, formatted as an array of tuples containing the (x, y) coordinates of each of the four corners of each bounding box, starting with the top-left corner (x_1, y_1) and proceeding clockwise around the box (resulting in top-right (x_2, y_2), bottom-right (x_3, y_3), and bottom-left (x_4, y_4)). To determine the center point of each bounding box, the following formula is used, where x_1, y_1 represent the top-left corner and x_3, y_3 represent the bottom-right corner:

$$box_{\text{center}} = \left(\frac{x_1 + x_3}{2}, \frac{y_1 + y_3}{2} \right)$$

This center point and the bounding box coordinates are appended to the message. Once the data is received by the node responsible for handling user selection, it instantiates nodes representing each selectable box and arranges these nodes into a graph structure (refer to Figures 1, 2 and 3 for sample node configurations). The default starting node (the one initially selected for the user before any head tracking begins) is chosen randomly. Choosing a default node is application-specific and should be determined by the developers based on the intended use case. When collecting results used in this paper, the default node was always selected as the top-left node to maintain consistency between trials.

Once the graph is assembled, head tracking comes into play. A face detection node keeps track of head movement information. It computes the roll, pitch, and yaw of the user's head to determine directional intent (e.g., selecting items to the 'left', 'right', 'up', or 'down'). The system compares the current and previous directions to prevent unintended rapid movements between nodes. If the current direction matches the previous direction, no action is taken to ensure that selections occur one at a time. The system sends a message to update the active node if a new direction is detected. The system then moves the selection to the neighbouring node in the intended direction, visually highlighting the new active box/compartment to provide user feedback and confirm the successful transition.

ii. Graph Algorithm Development

The system models user navigation through selectable items using a graph structure. Nodes represent individual selectable boxes/items, while edges define allowed transitions between nodes based on spatial proximity. The algorithm constructs the graph as follows:

Algorithm 1 Graph Construction for Navigation

For each detected bounding box (node), extract corner coordinates: (x_1, y_1) (top-left), (x_2, y_2) (top-right), (x_3, y_3) (bottom-right), (x_4, y_4) (bottom-left)
for each node n_i **do**
  for each edge (left, right, top, bottom) **do**
    Generate three parallel test lines along the edge:
    - Midline: Centered on the edge
    - Offset$_+$: 50 pixels of box height above midline
    - Offset$_-$: 50 pixels of box height below midline
  end for
  for each other node n_j **do**
    if any test line from n_i intersects n_j's bounding box **then**
      Add bidirectional edge $n_i \leftrightarrow n_j$
    end if
  end for
end for

The resulting graph enables efficient traversal using head movements, with adjacency relationships corresponding to natural spatial relationships between items (as shown in Figures 1-3).

iii. Selecting choice

Selecting an option is facilitated using Python and the MediaPipe library [22]. The library tracks the head position in real-time to identify directional movements: right, left, up, and down. The system leverages facial landmark detection to compute head orientation changes and deduce the user's intended selection.

To provide immediate feedback to the user, the system includes a visual cue in the form of a green outline around the currently active node. This outline helps users understand which option is currently selected and enables them to confirm their selection with confidence.

Head pose estimation relies on algorithms such as the Rodrigues method and the Perspective-n-Point (PnP) algorithm to ensure accurate tracking of head movements [23]. The Rodrigues algorithm is used for converting rotation vectors into rotation matrices. It is known for its robust handling of facial landmark alignment, while the PnP algorithm is utilized to compute the pose of the head based on 2D-3D point correspondences. These algorithms work in tandem to translate subtle changes in roll, pitch, and yaw into corresponding movements across the graph of selectable nodes.

iv. Confirming choice

The process of confirming a selected option is based on tracking the user's mouth status (open vs. closed). This functionality is essential for ensuring that selections are deliberate and accurate. The face detection node monitors mouth movements and sends updates to the selection node whenever a change is detected.

When the system detects that the user's mouth is open, a circular status indicator begins to fill. If the mouth remains open for two continuous seconds, the indicator completes, and the selection is confirmed. During this period, the selection node halts the monitoring of head and mouth movements, effectively locking in the currently highlighted item. This step clearly indicates to the user that their choice has been successfully confirmed, represented by a green check mark appearing on the screen as shown in Figure 4.

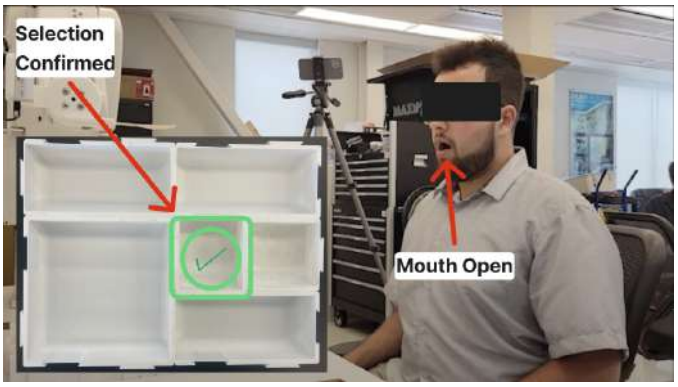

Fig. 4: Selecting and confirming user choice

The loading indicator decreases progressively if the user closes their mouth before the 2-second timer is complete. If the mouth is re-opened while the indicator is decreasing, the status resumes filling from the point where it last left off. This dynamic process ensures flexibility, allowing users to make adjustments without restarting the selection confirmation process entirely.

Visual feedback is critical for user interaction. Screenshots of the system show the status indicator in red when confirmation is not achieved, and green when the selection is successful. A red 'X' is displayed when the confirmation is interrupted, signaling that the user needs to restart the process if they wish to confirm the selection again.

This interactive mechanism ensures that selections are intentional and provides the user with a clear understanding of their interaction status. It facilitates a smooth user experience by eliminating accidental confirmations and giving users control over their choices.

C. Testing Study

To evaluate the effectiveness and user experience of the system, a testing study was conducted involving 22 healthy participants (11 males and 11 females) with an average age of approximately 23 years. Participants signed a consent form indicating that they have full control over their head and neck and they reported that they have no past medical conditions involving their upper extremities. Each participant tested the system for 30 to 45 minutes, spending approximately 12 minutes on each Config (configurations 1, 2, and 3, Figures 1, 2 and 3 respectively). The testing setup included a table with an Intel RealSense camera mounted on the Fanuc F5 Robotic Arm and a screen displaying a graphical user interface (GUI). The GUI showed a picture of the current Config and highlighted the currently selected option with a red bounding box.

Before beginning each Config, participants underwent a brief calibration step in which they were instructed to remain still for 3 seconds to establish their initial head position. During the study, participants followed pre-determined spoken commands given by the researcher. Each trial consisted of five commands involving randomized directional movements (Up, Down, Right, and Left). At the end of the fifth command in each trial, the word "Open" was spoken, prompting participants to open their mouths to confirm their selection. The commands set and order were consistent across all configurations to ensure uniform testing conditions.

Each Config involved 10 trials, with participants completing the same sequence of five commands per trial. Following each trial, participants filled out a post-trial questionnaire to rate on a Likert-scale (from 1 to 10), on how safe/comfortable/easy did the participant find using this system during the trial. This adapted instrument combined standardized Likert-scale principles [24] with context-specific modifications for HMI systems [25]. Participants were encouraged to provide their ratings immediately after the completion of the trial to capture their fresh impressions. Prior to recruiting participants and testing the system, the study was approved by the University of Guelph Research Ethics Board (protocol no. REB# 24- 07-017).

D. Performance Metrics

Four quantitative metrics were developed to evaluate system performance:

- **Head Tracking Accuracy (HTA)**: Percentage of correctly interpreted head movements relative to verbal commands. Calculated per Config as:

$$\text{HTA}_c = \left(\frac{\sum_{t=1}^{10} \text{CorrectMovements}_{t,c}}{\text{TotalCommands}_c} \right) \times 100\%$$

  Where c = Config (1-3), t = trial number, with 5 commands per trial. A movement was considered correct if the system detected user's head movement appropriately.
- **Graph Traversability Accuracy (GTA)**: Percentage of successful node transitions during command execution:

$$\text{GTA}_c = \left(\frac{\sum \text{ValidTransitions}_c}{\sum \text{AttemptedTransitions}_c} \right) \times 100\%$$

  A transition was valid only if the nodes traversed in accordance with the arrow directions outlined in Figures 1, 2 and 3.

- **Head Transition Movements (HTM)**: Average head movements per trial, normalized by:

$$\text{HTM}_c = \frac{1}{N} \sum_{t=1}^{10} \text{HeadMovementCount}_{t,c}$$

Where $N = 10$ trials per Config. The ideal HTM of 5 corresponds to the 5-command sequence per trial.

- **Mouth Opening Occurrences (MOO)**: Average count of mouth activations per trial required for confirmation:

$$\text{MOO}_c = \frac{1}{N} \sum_{t=1}^{10} \text{MouthOpenCount}_{t,c}$$

The ideal MOO = 1 reflects one intentional mouth opening for final selection confirmation per trial.

III. Results

The HTA and GTA accuracy plot in Figure 5 presents an evaluation of participant performance and system responsiveness across the configurations (Figure 1, 2, 3).

HTA results indicate a progression in accuracy across configurations. Config 1 recorded a mean HTA of 79.5% (range: 50–100%), Config 2 increased to 83.6% (range: 50–100%), and Config 3 further improved to 84.7% (range: 60–100%). GTA exhibited a similar pattern, with Config 1 achieving a mean of 85.9% (range: 40–100%), Config 2 increasing to 96.9%(range: 60–100%), and Config 3 at 92.6%(range: 70–100%). See Figure: 5, and Table: I).

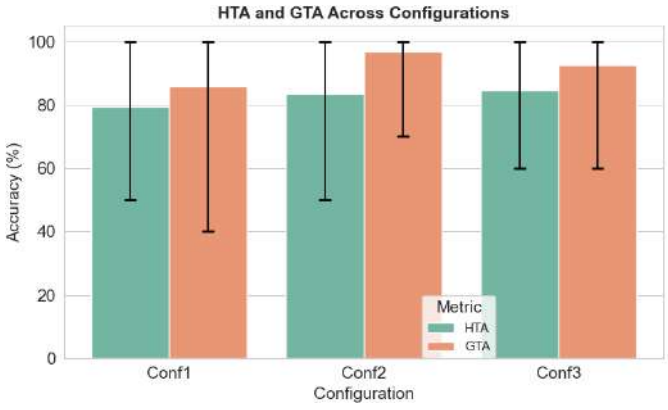

Fig. 5: Head tracking accuracy and graph tracking accuracy across three configurations

Mean MOO values remained close to the target of 1, which represents the ideal scenario where users confirm their selection with a single mouth opening per trial. Config 1 recorded **1.34** (range: 0.9–3.2), Config 2 had **1.38** (range: 1.0–2.9), and Config 3 achieved **1.23** (range: 1.0–8.5). Similarly, HTM values approached the target of 5, which corresponds to the expected number of head movements needed to traverse the interface effectively during a trial, as each trial is composed of 5 distinct head movements. Config 1 recorded a mean of **4.60** (range: 4.0–6.0), Config 2 averaged **4.39** (range: 4.0–4.7),

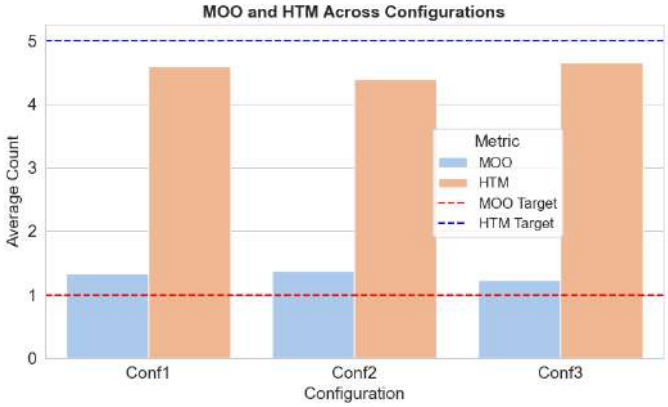

Fig. 6: MOO and HTM across three configurations. The red dashed line represents the MOO target of 1 occurrence per trial, while the blue dashed line represents the HTM target of 5 transitions per trial.

and Config 3 reached **4.65** (range: 3.4–5.0). See Figure: 6, and Table: I.

The range of motion (ROM) for pitch and yaw was computed by subtracting the minimum from the maximum ROM for each participant after normalizing to their neutral angle (calibration baseline). The system's movement thresholds were defined in absolute terms relative to this baseline, with pitch thresholds set at +2° for up and -2° for down, and yaw thresholds set at +2.5° for right and -2.5° for left. After calibration and normalization across all participants, the thresholds were computed as 19.23° (up) and 15.23° (down) for pitch (Figure 7), and 21.88° (right) and 16.88° (left) for yaw (Figure 8). These thresholds define the system's expected response limits for detecting up/down and left/right movements, serving as reference points that participants learned to align with over time.

For pitch (Figure 7), Config 1 exhibited a mean ROM of **15.8**° (range: 5.96°–42.2°), increasing slightly to **17.5**° in Config 2 (range: 9.47°–42.3°), before narrowing in Config 3 to **16.7**° (range: 13.4°–26.9°) (see Table: I).

Yaw (Figure 8) followed a similar trend, with Config 1 at **20.1**° (range: 11.6°–26.3°), decreasing to **18.9**° in Config 2 (range: 14.1°–23.6°), and further stabilizing at **19.3**° in Config 3 (range: 15.8°–22.2°) (see Table: I).

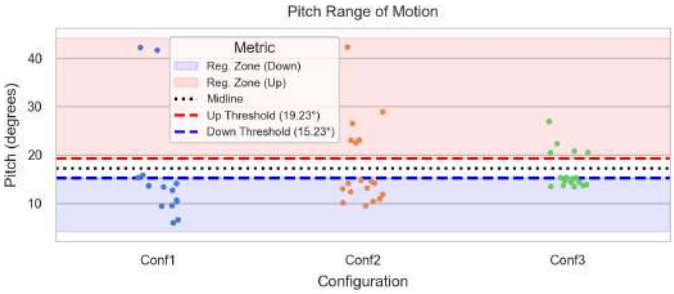

Fig. 7: Pitch range of motion across three configurations

TABLE I: Ranges and Mean Values for MOO, HTM, HTA, GTA, and Survey Responses Across Configurations

Metric	Conf1			Conf2			Conf3			Survey Ratings		
	Min	Mean	Max	Min	Mean	Max	Min	Mean	Max	Min	Mean	Max
MOO	0.9	1.34	3.2	1.0	1.38	2.9	1.0	1.23	1.85	-	-	-
HTM	4.3	4.60	6.0	4.0	4.39	4.7	3.4	4.65	5.0	-	-	-
HTA	50	79.5	100	40	83.6	100	60	84.7	100	-	-	-
GTA	40	85.9	100	60	96.9	100	70	92.6	100	-	-	-
Pitch	5.96	15.8	42.20	17.5	9.47	42.2	16.7	13.4	26.9	-	-	-
Yaw	11.59	20.1	26.25	14.14	18.9	23.6	15.8	19.3	22.2	-	-	-
Safety	-	9.69	-	-	-	-	-	-	-	7.0	9.69	10.0
Comfort	-	8.54	-	-	-	-	-	-	-	6.0	8.54	10.0
Ease of Use	-	8.59	-	-	-	-	-	-	-	5.0	8.59	10.0

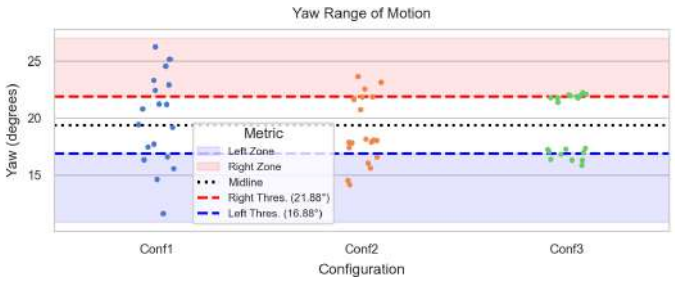

Fig. 8: Yaw range of motion across three configurations

Participants rated system safety at **9.69/10** (range: 8–10). Comfort received an average score of **8.54/10** (range: 6–10), while ease of use was rated at **8.59/10** (range: 7–10).

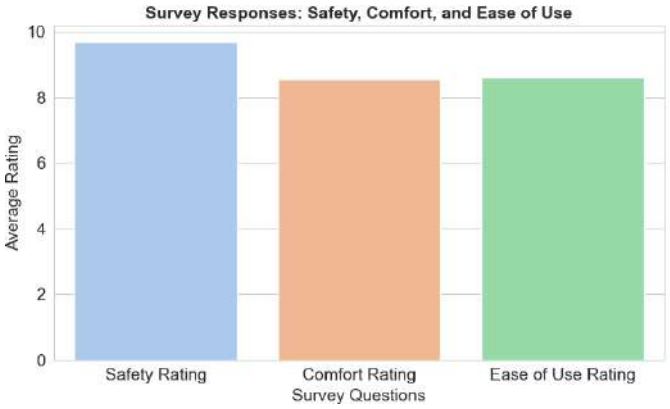

Fig. 9: Participant's survey results

IV. Discussion

HTA and GTA results suggest a learning effect, with accuracy improving progressively across configurations. The narrowing lower bounds in the latter configurations (raised from 50% in Config 1 to 60% in Config 3) indicate that participants became more consistent over time (see Figure 5, Table I). Config 1 exhibited greater variability, likely due to participants familiarizing themselves with the system's response mechanics. As they progressed to Config 2 and 3, accuracy improved, and variability decreased, implying that participants internalized movement thresholds and refined their selection strategies. The increase in mean GTA from **85.9%** in Config 1 to **96.9%** in Config 2, followed by slight stabilization in Config 3, suggests that the second Config facilitated rapid adaptation before plateauing. This aligns with motor learning principles, where repetition leads to increased precision and reduced effort [26], [27].

MOO and HTM remained stable across configurations. MOO values closely matched the target of **1** per trial, with minimal deviation. HTM values, while slightly below the target of **5** transitions per trial, showed refinement in movement execution over time. Config 1 exhibited greater variability, suggesting that participants initially explored different movement strategies. By Config 3, transitions became more consistent, indicating that participants had optimized their movements to minimize unnecessary shifts while maintaining effective interaction. These results indicate that the system facilitates intuitive adaptation, enabling participants to refine their control strategies efficiently.

ROM analysis further highlights participant adaptation. In Config 1, participants exhibited a broader ROM in both pitch and yaw, likely overcompensating to ensure input registration. The mean pitch ROM was **15.8**°, while yaw ROM averaged **20.1**°, with both showing wide variability across participants (see Figure 7, Figure 8, Table I).

As participants transitioned to Config 2, movement ranges narrowed, indicating greater control and confidence in system response. While the mean pitch ROM increased slightly to **17.5**°, the overall range decreased, suggesting improved consistency. Yaw ROM followed a different trend, with a reduced mean of **18.9**° and a tighter distribution, pointing to more refined lateral head movements.

By Config 3, ROM values closely aligned with the system's threshold lines. Pitch ROM decreased to **16.7**°, and yaw ROM stabilized at **19.3**°, with significantly reduced variability compared to earlier configurations. The tighter distribution suggests that participants had developed a precise understanding of movement registration, allowing them to execute more controlled and efficient interactions. This shift from exploratory to deliberate movement behavior is characteristic of motor learning, where repeated exposure leads to optimized motion patterns with minimal extraneous effort [28]. The continued reduction in ROM variability across configurations further

supports that participants adapted to the system's response mechanics over time, improving interaction efficiency.

Survey responses confirm strong participant confidence in system safety, with consistently high ratings. However, comfort and ease-of-use scores exhibited slightly broader variability. Most participants found the system intuitive, but some struggled with movement precision and input registration, highlighting individual differences in usability. Adjusting sensitivity and adding user-specific calibration could enhance comfort and ease of use.

Future work will evaluate the system with individuals with upper-limb impairments to assess real-world usability. Implementing user-specific calibration could enhance performance by adjusting tracking thresholds to suit different movement patterns. Additional interactive training mechanisms may further accelerate adaptation, helping new users quickly learn optimal movement strategies. Long-term studies will explore whether efficiency improvements persist over extended use and whether periodic recalibration enhances performance. These refinements aim to improve system adaptability, ensuring broader accessibility and an optimized user experience.

V. Conclusion

The analysis of participant performance and survey responses highlights the effectiveness and usability of the head-tracking system for HMI selection. Participants rated the system highly for safety (**9.69/10**), comfort (**8.54/10**), and ease of use (**8.59/10**). Performance metrics further reinforce the system's reliability, with a stable MOO value near the target of **1.0** and an HTM value approaching **4.6**/5, reinforcing that participants maintained high consistency in their interaction behavior.

A key finding is the progressive refinement in user interactions across configurations. HTA improved by **6.54%** from Config 1 to Config 3, while GTA increased by **7.80%**. Additionally, the reduction in variability of pitch and yaw movements suggests that participants adapted to the system's movement thresholds over time, this lowers the user's input effort thereby increasing comfort over time.

Lastly, the system was implemented as a modular ROS-based package, enabling seamless integration into various HMI applications. While the results demonstrate promising performance, further research is needed to evaluate its effectiveness across a more diverse user population. Expanding this evaluation will help refine movement thresholds through user-specific calibration, optimizing the system for different needs and interaction styles.

A simulation platform combining the myokinetic interface with the AMI surgery for prosthetic control

Marta Gherardini[1], Benedicta Akweley Barnor[1], Flavia Paggetti[1], and Christian Cipriani[1]

Abstract— **Amputations of the upper and lower limbs can significantly impact psychological well-being and functional independence, limiting a person's ability to perform daily tasks. Artificial limbs aim to restore lost functionality by replicating the natural limb as closely as possible. To this aim, the ideal human-machine interface (HMI) should provide seamless connection with the natural sources of control and sensory feedback. Recent advances in surgical techniques and prosthetic technologies have enhanced residual limb functionality and enabled direct connections with peripheral neural pathways. This study introduces a simulation platform integrating the agonist-antagonist myoneural interface (AMI) with a myokinetic interface based on implantable magnets, to generate synthetic data on muscle deformation and magnet displacement as potential control signals for an assistive device. A transtibial amputation was simulated, replicating the natural agonist-antagonist mechanical connection between paired muscles. The model simulated muscle contractions and magnet implantation, which displacement was tracked using a localization algorithm. Results demonstrated a combined contraction and stretching of the agonist and antagonist muscles and the feasibility of accurately tracking implanted magnets via external sensors. These findings suggest that combining the AMI with magnet implantation could contribute to more intuitive prosthetic control in the future. In this view, this simulation platform provides a valuable pre-operative planning tool to optimize magnet placement and enhance HMI performance for individual patients.**

Keywords— Agonist-antagonist myoneural interface (AMI), Myokinetic control Interface, lower-limb prosthesis, Magnetic sensors, Magnetic tracking.

I. INTRODUCTION

In Italy, around 1.2 million people have motor impairments, and among these approximately 200,000 individuals underwent lower limb amputation [1]. About 80% of these amputations affect older adults, primarily due to complications from diabetes or vascular issues, while 10% are in middle-aged adults, and another 10% in younger people, mostly due to road accidents, followed by traumatic injuries, congenital conditions, or tumors. The level of amputation often depends on the underlying cause, although the most common is below-the-knee (transtibial, 47%). To treat transtibial amputations, in recent years researchers have explored and enhanced the functionality of prosthetic ankles and feet, by imitating the natural biomechanics [2], [3]. Most are passive devices, offering simplicity, lightweight, and reduced costs, however they are unable to provide power as natural muscles do, thus limiting complex activities and augmenting the risk of compensatory movements [3]. Conversely, while limited by higher costs, weight and power consumption, powered prostheses provide net positive work, enabling the restoration of a more natural gait. Powered prostheses can be controlled using surface electromyographic (sEMG) signals, employed for over 50 years for the control of upper limb prostheses [4], but only recently applied to lower-limb prostheses for the volitional control of knee and ankle joints during non-weight-bearing conditions [5], [6]. Nevertheless, surface electrodes positioned on the skin suffer from intrinsic drawbacks including poor selectivity, filtering effects caused by subcutaneous tissues, and movement artifacts, which can compromise control reliability [7], [8]. Another aspect to consider is that amputation surgeries usually rearrange muscles cushion the bone, creating a suitable interface for a prosthetic socket, yet devoting little attention to preserving residual muscle contraction capabilities [9]. In addition, the amputation destroys the natural interplay between agonist and antagonist muscles, which activates receptors responsible for proprioceptive sensations during motion, essential to close the loop of motor control [10]. Enhancing collaboration between clinicians and engineers and developing tools to optimize surgery based on prosthetic requirements could greatly improve the usability of prosthetic devices.

This need is further emphasized by the emergence in the past decades of a new portfolio of possibilities combining surgery and technology [11]. Regarding surgical techniques, different solutions were proposed to improve the biomechanical integration of the prosthesis with the body [12], the quality of the control sources [13], as well as the sensory feedback restoration [9]. Among them, the agonist-antagonist myoneural interface (AMI) was introduced as a procedure in which a pair of muscles with antagonistic functions are mechanically coapted to restore natural dynamic muscle relationships, and allow proprioceptive signals from mechanoreceptors within both muscles to be sent to the brain [9]. The AMI procedure was successfully implemented in lower-leg amputees and demonstrated to improve control over prosthetic devices compared to traditional amputations [10], [14]. At the same time, different

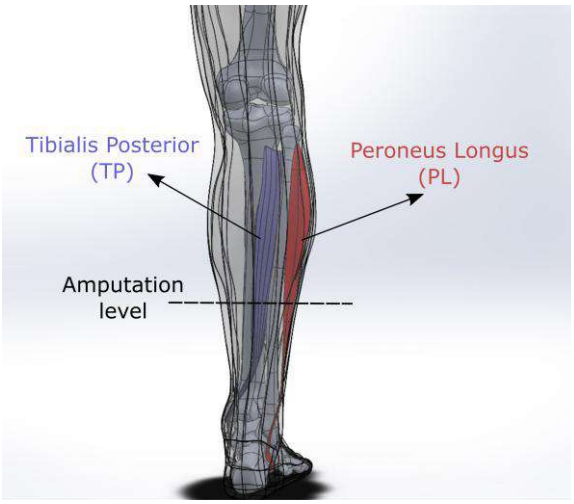

Fig. 1. 3D CAD model of the right lower-limb showing the two muscles selected for the AMI procedure (TP and PL). To simulate amputation, the two muscles were transected at the indicated level.

technologies were and are being developed to overcome the limitations of surface measurements, by recreating an intimate connection with the natural sources of control (muscles and nerves) [11]. For example invasive electromyography technology [15] demonstrated to provide better data quality than surface recordings [16]. Differently from traditional solutions measuring the electrical activity of the muscles, the myokinetic interface exploits implantable permanent magnets to monitor muscle contraction for control [17]. Specifically, small cylindrical magnets are inserted in target muscles through a minimally invasive surgical procedure, and external electronics is used to reconstruct the magnet displacement following muscle activation, with no need of percutaneous wires. The myokinetic interface was recently tested for the first time with an upper-limb amputee [18], yet its versatile architecture makes it readily transferable to other types of amputations, such as those at the lower limb.

We hypothesize that tracking magnets implanted within muscles could offer a more selective and granular measure of muscle activation compared to sEMG measurements. At the same time, control accuracy could be further enhanced by closing the feedback loop through the AMI procedure, enabling more realistic phantom motor imagery. In this study, we started to explore this possibility by developing a simulation platform that could be employed as a pre-surgical planning tool to optimize the integration of the AMI procedure with the myokinetic implant, to evaluate the potential effectiveness of such an interface. The simulated environment exploited a CAD model of lower limb muscles, and expanded a previously developed Finite Element Model (FEM) of muscle contraction [19] to simulate the AMI procedure by distally dissecting and coapting two muscles of the lower limb using a pulley-system simulating the biological tendon. Given as input the muscle degree of contraction, the model allowed to derive the corresponding deformation undergone by the muscles during contraction and elongation. FEM results were employed to simulate magnet implant and displacement according to muscle deformations, and such displacement was then reconstructed using a simulated array of magnetic field sensors and a localization algorithm.

Results showed that the FEM simulations reproduced the mechanical behavior described in the literature for muscles treated with the AMI, in which the contraction of the agonist results in a stretching of the antagonist [10]. Moreover, they showed that we could accurately track the displacement of magnets implanted in the muscles, both when the latter were contracting and being stretched. This work provides a viable tool to evaluate the usability of the myokinetic interface in combination with the AMI to control the movements of an ankle prosthesis. More in general, it introduces a versatile simulation framework that can be employed to reproduce different surgical and implant conditions and design patient-specific implantation and control strategies.

II. Materials and Methods

A. Finite Element Model of AMI and Muscle Contraction

A musculoskeletal model of the AMI was simulated using a Finite Element Model (FEM) of muscle contraction implemented in Comsol Multiphysics 5.5 (COMSOL Inc., Stockholm, Sweden), based on a mixture active strain approach proposed by Riccobelli and Ambrosi [20]. This model takes as input the muscle geometry, the fiber pennation angle and the microstructural degree of contraction γ, and outputs muscle deformation. The same model was already employed in [19], and has been experimentally validated for upper limb muscles in [21]. Muscle geometry was sourced from 3D CAD files of a healthy human lower limb comprising skin, muscles (including tendons), blood vessels and bones (Zygote, American Fork, US, Fig. 1). Only muscle-tendon units comprised between the fibula and tibial heads and the ankle joints of the right leg were considered to simulate transtibial amputation. Specifically, the muscle pair composed by the Tibialis Posterior (TP) and the Peroneus Longus (PL) was selected to simulate an AMI surgery aimed at achieving control over internal-external eversion of an ankle prosthesis. The tendons of the selected muscles were transected distally at the estimated boundary of the muscle-tendon unit [22], leaving only the muscle bellies of both muscles with an approximate length of 15 cm. Muscle distal ends were subsequently coapted to a geometry simulating a healthy tendon, which served as a biological pulley for the muscle pair as in traditional AMI. Both muscles and tendons were defined with materials that replicated biological tissue properties (see [19] for muscle parameters). Muscle fiber orientation (pennation angle, α) was defined for each muscle based on literature data, and was equal to 11° for the TP muscle and 12° for the PL muscle, respectively [22]. The distal tendon connecting the muscles was modeled as a material with a linear elastic behavior and an elastic modulus of 1 GPa [23]. A roller was applied to the central part of the tendon to simulate the synovial canal, used to provide a gliding mechanism in the AMI construction and avoid its displacement in the normal direction. At the proximal ends of the muscles, tendons were modeled as a spring (spring foundation in Comsol), considering the elastic modulus of human tendons [23]. Similarly, the muscle surfaces in contact

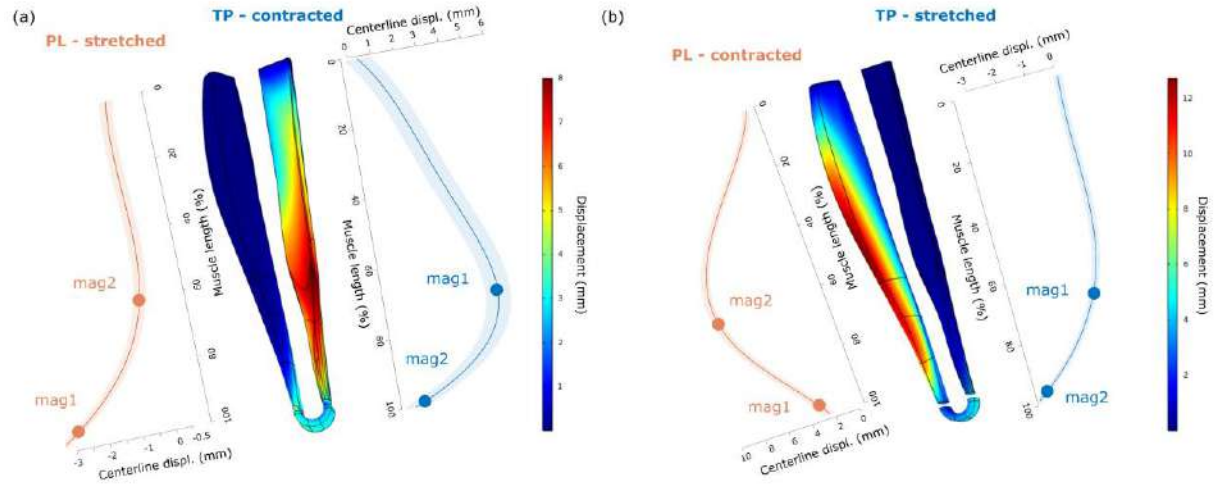

Fig. 2. FEM simulation results of muscle deformation. Color bars refer to the deformation obtained over the entire muscle volume. Specifically, mag1 was the magnet implanted in the point of maximum displacement, mag2 was implanted in the point of minimum displacement nearest to mag1. (a) The TP acted as the agonist and the PL as the antagonist muscle. Points along the TP centerline displaced along the muscle longitudinal axis according to a bell-shape curve. At the same time, the PL muscle was stretched in its distal section. Shaded areas represent the confidence interval of the muscle contraction model. (b) The PL acted as the agonist and the TP as the antagonist muscle. Points along the PL centerline displaced along the muscle longitudinal axis according to a bell-shape curve. At the same time, the TP muscle was stretched in its distal section.

with the bones were modeled through a spring foundation, considering the elastic modulus of skeletal muscles [24].

After modelling all elements, simulations were performed by alternatively contracting the agonist and antagonist muscle and deriving deformation data. Specifically, each muscle was incrementally activated by increasing the degree of contraction, γ, from 0 to 0.3 in steps of 0.005 (where 0.3 is approximately the maximum microstructural degree of contraction achieved in healthy muscles [25]). FEM simulation results were subsequently exported in Matlab (MathWorks, Natick, MA) to simulate magnet implantation and displacement. Specifically, the overall muscle deformation for different values of γ was obtained. In addition, each muscle centerline was derived from FEM simulation data by interpolating ~100 points in the center of the muscle belly. The displacement undergone by the points on the centerline along the longitudinal direction of the muscle was subsequently derived for both the agonist and antagonist muscle for $\gamma = 0.3$.

B. Magnet Implant Simulation

Two magnets were implanted in each muscle to simulate the application of the myokinetic interface exploiting differential measurements, which proved to be robust against external disturbances [19]. For both TP and PL, the longitudinal displacement of each point on the muscle centerline was used to determine potential magnet implantation sites for the magnet pairs. Specifically, the first magnet (mag1) was virtually implanted in the point undergoing maximum displacement, while the second magnet (mag2) was implanted in the nearest point to mag1 that showed almost null displacement, respecting the constraint of a minimum inter-magnet distance of 3cm [18]. This placement would allow to maximize the distance variation between the magnets, namely, the control signal of the assistive device. Candidate implantation sites were derived according to this procedure in correspondence of the maximum γ for the agonist muscle and the relative stretching for the antagonist one, and the procedure was repeated twice for the two agonist-antagonist configurations. As a results, two potential implant sites were derived for each magnet pair/each muscle. The final placement was empirically selected as the one that maximized the distance variation between the magnets both when the muscle acted as agonist and as antagonist.

Magnets were modeled as NdFeB axially magnetized cylindrical magnets (axial remanent magnetization Br = 1.27 T, radius = 2 mm, height = 2 mm). Contraction of the agonist and antagonist muscles were simulated in sequence. For each of them, magnet displacement was simulated by moving the magnets along 11-step trajectories, corresponding to equally spaced contraction degrees from 0% to 30%. A grid of 450 sensors was cylindrically arranged around the implantation site to sample the magnetic field produced by the magnets. The magnetic moment vectors of all magnets initially pointed radially (to maximize the magnetic field measured by the sensors), whereas during muscle contraction they rotated according to the fiber rotation predicted by the muscle model. The magnetic field was simulated by using an analytical model previously validated [26] and extensively employed in previous works [19]. A 4 mG white gaussian noise was added to the sensor recordings, to simulate the noise associated to actual 3-axis Hall-effect sensors in a real setup, akin to [19], [27]. Finally, sensor readings were fed to a localization algorithm which estimated the magnet poses (position and orientation) by exploiting numerical approximation methods. Extensive details on the localization algorithm can be found in previous works [17], [27]. Localization was repeated 10 times for each trajectory step by adding different random noises to the measurements, to account for variability in sensor recordings.

C. Performance Metrics

For each step of the trajectory and each repetition, the

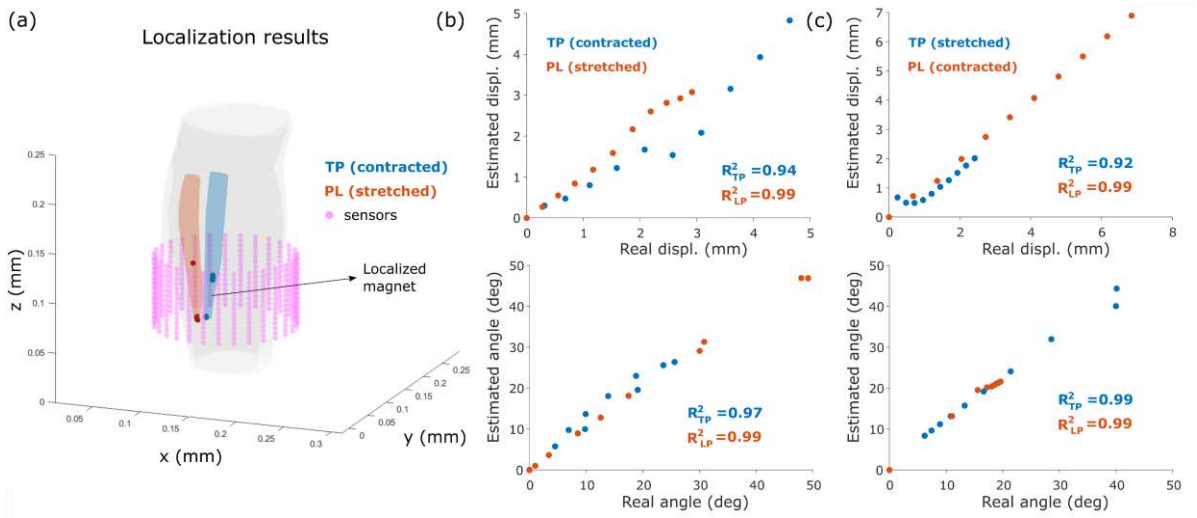

Fig. 3. Magnet localization results. (a) Results obtained when contracting the TP muscle. The figure shows the localized positions of the magnet pairs implanted in both TP and PL. An array of 450 sensors was positioned cylindrically around the implantation area to acquire the magnetic field generated by the magnets. (b) Real versus estimated displacement in terms of position (above) and orientation (below) when contracting the TP from 0 to 0.3 degree of contraction. The relationship between real and estimated displacement and angle proved linear for both magnet pairs ($R^2 \geq 0.94$, $p < 0.01$). (c) Real vs estimated displacement in terms of position (above) and orientation (below) when contracting the PL from 0 to 0.3 degree of contraction. The relationship between real and estimated displacement and angle proved linear for both magnet pairs ($R^2 \geq 0.92$, $p < 0.01$).

estimated (localized) displacement (Euclidean distance variation) and angle variation between the paired magnets with respect to their initial (rest) distance were derived. The median displacement and angle variation across repetitions were subsequently computed. The correlation between the estimated and the real value (i.e., the one set by the simulation) of the displacement/angle variation was then evaluated in terms of coefficient of determination (R^2) and associated *p* value. Finally, localization error was computed for both position and orientation. Specifically, considering the magnet pairs in TP and LG, position error was computed for each step and each repetition as the difference between the actual and estimated Euclidean distance between the magnets. Accordingly, the orientation error was derived as the difference between the actual and the estimated relative angle between the magnets.

III. Results

A. Finite Element Model of AMI and Muscle Contraction

For each agonist-antagonist muscle pair, the displacement of the points belonging to the muscle centerline along the muscle longitudinal axis for $\gamma = 0.3$ is first presented (Fig. 2a-b). Regarding the contracting (agonist) muscles, such displacement was described by a bell-shaped curve as a function of the distance from the muscle origin, with the maximum approximatively located in the middle of the muscle for PL (Fig. 2b), and more distally for TP (Fig. 2a). For the TP centerline, a maximum displacement of ~5.3 mm was derived, versus a maximum displacement of ~8.3 mm for PL. A different trend was observed for the antagonist behavior, as the displacement curves proved monotonically decreasing showing incrementally negative displacements towards the muscle distal end, corresponding to an increasing muscle stretching. Specifically, both antagonist muscles showed a maximum stretching of ~3.1 mm at the contact point with the connecting synovial canal. Such maximum stretching corresponded to a ~0.2 strain with respect to the overall muscle length. In all cases (agonist and antagonist behavior of both muscles), the displacement curves decreased towards the muscle origins, which were almost fixed.

B. Magnet Implant Simulation

Based on the derived displacement curves, mag1 was placed in TP and PL respectively in the points undergoing maximum positive and negative displacement when the TP was behaving as agonist and PL as antagonist muscle (Fig. 3a). This placement allowed to have both magnet pairs implanted towards the distal end of the muscles, with one magnet approximately in correspondence of the maximum longitudinal contraction/stretching in both the agonist and antagonist configuration (Fig. 3a-b). Specifically, mag1 was placed in TP in correspondence of 73% the total muscle length (where 0% indicates the proximal end), versus 98% for PL. Subsequently, mag2 was placed in the nearest point on the curve from the first magnet showing minimum (almost null) displacement. The latter resulted in the points corresponding to 99% the total muscle length for mag2 in TP, and 60% for mag2 in PL (Fig. 3a-b). Magnet pairs showed an initial Euclidean distance (relative angle) of 41 mm (128°) for TP, and of 58 mm (148°) for PL. Regarding magnet-to-sensor distance, mag1 and mag2 in PL showed a distance of 41.6 mm and 34.4 mm from the nearest sensor, respectively, against a distance of 55.9 mm and 51.2 mm derived for the corresponding magnets in TP.

Magnet trajectories were subsequently simulated and localization results derived for both configurations (TP contraction represented in Fig. 3a). Looking at localization results, when TP was contracting, a total displacement (angle variation) between magnet pairs of 4.8 mm (26.4°) was derived, against a real value of 4.6 mm (25.6°) (Fig. 3b). The magnets in PL showed a total displacement (angle variation)

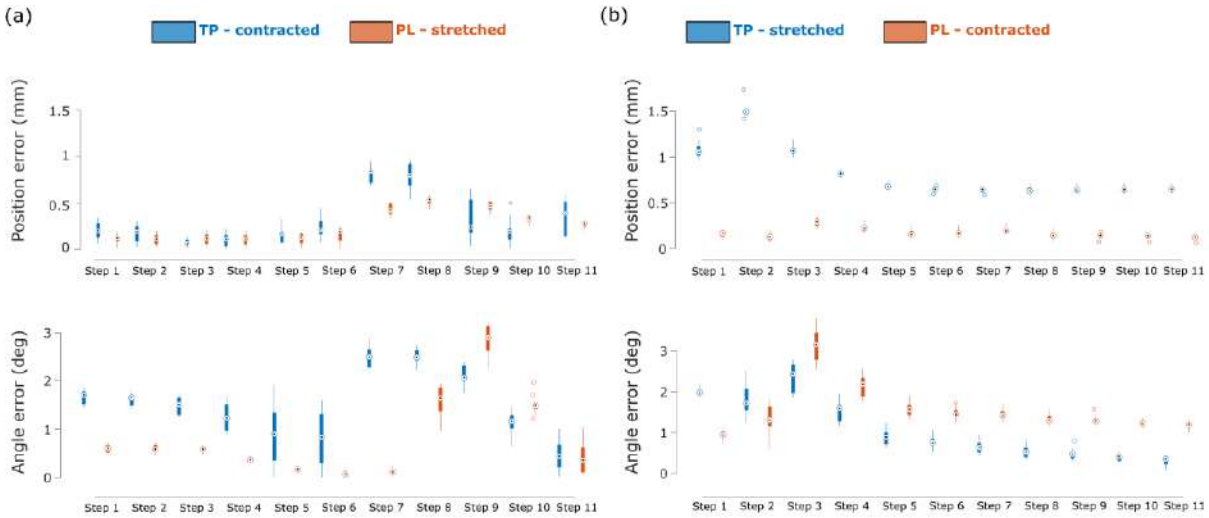

Fig. 4. Boxplots represent the localization error in terms of position (above) and orientation (below) obtained at each step (Step 1-11) of the magnet trajectory, considering all repetitions. Errors are reported both when (a) contracting the TP muscle (in blue). and stretching the PL muscle (in orange), and when (b) contracting the PL muscle (in blue). and stretching the PL muscle (in orange).

of 3.1 mm (46.9°), against a real value of 2.9 mm (49.2°). Differently, when PL was contracting, the magnets in TP showed a total displacement (angle variation) of 2 mm (44.5°), against a real value of 2.4 mm (40.0°) (Fig. 3c). The magnets in PL showed a total displacement (angle variation) of 6.9 mm (21.6°), against a real value of 6.8 mm (19.6°). In both agonist-antagonist configurations, the relationship between real and estimated displacement/relative angle proved always linear for both magnet pairs ($R^2 \geq 0.92$, $p < 0.01$) (Fig. 3b-c).

Regarding position errors along the 11-steps of the trajectories, when TP was contracting median errors proved always below 1 mm for both magnet pairs, with a maximum median error of 0.84 mm and 0.54 mm for the magnets in TP and PL, respectively. Similarly for orientation error, the magnets in TP generally showed higher error values, although a maximum median error of 2.9° was derived for magnets in PL against maximum median error of 2.5° for the magnets in TP (Fig. 4a). Similar error trends were found for position when the PL muscle was contracting (Fig. 4b). In this case, a maximum median position error of 1.49 mm and of 0.29 mm was found for the magnets in TP and PL, respectively. Conversely, regarding orientation, the magnets in PL generally showed higher errors, with a maximum median value of 3.1° versus 2.4° for the magnets in TP. Considering the agonist behavior of each muscle, the corresponding maximum median errors proved equal to 17% (9%) the total displacement (angle variation) travelled by the magnets in TP, and 4% (14%) that travelled by the magnets in PL. Overall, localization results demonstrated a good repeatability (precision) across different repetitions, with a maximum 25^{th}-75^{th} percentile range of 0.36 mm in terms of position, and of 1° in terms of orientation, both obtained during contraction of TP (Fig. 4a). These ranges respectively represented the 8% and 4% the total displacement and angle variation travelled by the corresponding magnet pair.

IV. Discussion and Conclusion

This work presented a simulation platform that allowed to reproduce the AMI surgical procedure applied to a pair of muscles, in this case muscles of the lower limb, and the subsequent implant of magnets in the muscle belly to implement a myokinetic control interface. Simulating agonist muscle contraction and combined antagonist stretching allowed to derive the amount of expected deformation in different areas of the muscles, and thus to identify potential optimal sites for magnet implantation. If combined with future work exploring a structured methodology for magnet placement, this platform could serve as a supporting tool for individualized pre-operative planning, as parameters such as muscle amputation level and contractility could be tuned to the patient's anatomy and pre-operative measurements (e.g., magnetic resonance imaging, EMG and ultrasound measurements). As a result, different magnet implantation sites and sensor arrangements could be virtually evaluated to maximize the interface efficiency for the control of an external assistive device, like an ankle prosthesis.

Results from the FEM simulations showed that, in line with literature results [10], the antagonist muscle was stretched in correspondence of a contraction of the agonist muscle (Fig. 2). A previous study evaluating two AMIs constructed between the Tibialis Anterior (TA) and the Lateral Gastrocnemius (LG) and the TP and PL of a transtibial amputee reported a fiber strain in the antagonist muscle of 0.16 (PL) and 0.8 (TA) when contracting the corresponding agonist muscles, respectively [10]. The FEM simulations implemented here resulted in a maximum strain of the antagonist muscles (both TP and PL) of 0.2 following contraction of the agonist one. Although fiber strain and muscle strain cannot be directly related, literature studies showed that length change of the muscle fibers tends to mirror that of the muscle-tendon unit if tendon compliance is poor [28], a condition that could apply to amputated muscles. Nevertheless, further clinical data are needed to comprehensively validate the developed model. Also, it

should be noted that current simulations did not consider contact in the synovial canal, thus friction was not taken into account. Future implementations should model the mechanics of tissue contact, for example by introducing a contact interface that interacts with the sliding tendon, to enhance the simulation reliability.

Localization errors generally proved higher for the magnets implanted in TP compared to those implanted in PL. These outcomes are in line with previous results from the literature which demonstrated that localization error positively correlates with magnet implantation depth [27]. Magnet-to-sensor distances obtained in the lower limb are generally larger than those obtained in the forearm, on which previous studies on the myokinetic interface were focused [17], [18]. Increasing magnet size for leg applications could be considered as an option to maximize the sensed magnetic field, thus potentially improving localization accuracy, especially for the antagonist muscles in which an overall smaller displacement is expected. Finally, in this work magnets were placed in the muscles following an empirical procedure aimed at maximizing displacement during both contraction and stretching. However, as anticipated above, we recommend investigating different placement strategies in future works to establish comprehensive guidelines based on patient-specific anatomy and placement rules, including those derived in previous works [27].

In conclusion, the simulation platform presented in this work, although open to future improvements and validations, could be effectively exploited as a testing platform to evaluate the functioning of the control interface prior to surgery, and help planning magnet implantation. Notably, it could also be readily translated to other applications, for example other level of lower-leg amputations or amputations at the upper limb.

***Abstract*—Over 1.3 billion people, about 16% of the global population, suffer significant mobility impairments as of 2024. People with mobility impairments usually struggle with performing activities of daily living (ADLs), reducing their living quality. Assistive robots are a solution to support ADLs. However, the rigid structure of current assistive robots may cause secondary injuries due to safety, comfort, and suitability challenges for delicate health conditions. To overcome these challenges, this research introduces a novel soft wheelchair-mounted assistive robot named FlexPAL (Flexible Pneumatic Actuated Linkage) to provide safer, more comfortable and user-friendly daily assistance for people with mobility impairments. FlexPAL's lightweight (3.88kg) modular design allows size adjustments for diverse user needs. Its soft design ensures users' safety through controlled and gentle assistance. Its adaptable structure integrates seamlessly into daily scenarios within its 400x400x400mm workspace, delivering precise assistance (mean error=15.95mm) for payloads up to 1kg, suitable for most ADLs. The usability was evaluated based on the user case study with one healthy participant. The results of this research illustrate the high potential of soft wheelchair-mounted assistive robotics (FlexPAL) to address the limitations of rigid systems by offering higher adaptability, safety (i.e. assistance and human-robot interaction) and user comfort, making it more effective for assistance.**

Keywords—Assistive robotics, assistive technology, soft robotics, assistance, activities of daily living

I. INTRODUCTION

Mobility impairments are common among people with neurological or orthopedic disorders, significantly affecting their life quality. Several conditions can lead to individuals experiencing mobility disability, including high-level spinal cord injury (SCI), multiple sclerosis (MS), muscular dystrophy (MD), cerebral palsy (CP) and stroke. These conditions can cause both upper and lower limb disability, significantly reducing functional independence and preventing individuals from performing activities of daily living (ADLs) such as feeding, dressing, or reaching for objects, which are essential for maintaining independence and quality of life [1, 2]. More than 1.3 billion people are suffering significant mobility impairments all over the world, and around 16.1 million people in the UK are reported as having a disability, representing 24% of the total population [3].

Due to limited medical resources, many individuals with mobility impairments may not receive adequate assistance. [2]. A wheelchair-mounted assistive robot can address people's needs by providing extended reach, dexterity, and adaptability directly integrated into the user's mobility device. These robotic devices enable users to perform tasks that would otherwise require assistance from caregivers, improving autonomy and reducing dependence on others [4]. Additionally, wheelchair-mounted robots support users at home and work, enhancing satisfaction and social inclusion by enabling active engagement [5]. With their ability to provide safe, precise, and reliable support, wheelchair-mounted assistive robots (WMAR) are a valuable solution for improving the independence and quality of life of individuals with mobility impairments.

After the most well-known WMAR, MANUS, was introduced by a Dutch collaborative in 1984 [5], the development of WMAR accelerated, leading to the development of commercialized robots like KINOVA, which offers 6 or 7 degrees of freedom (DOF) for various applications, with the price up to £34,399 (Fig. 1) [6, 7].

Fig. 1. Current commercialised wheelchair assistive robot Kinova [7]

To the authors' knowledge, there are no applications of soft-WMAR. Most of the commercialized WMAR are rigid-structured systems, which have notable limitations. One significant drawback is their safety, as rigid robots can cause injuries even with limited force due to discomfort, collision or limited adaptability to human movements. As reported by Morris et al. in 2023, the safety concerns with the use of rigid assistive robotics include primary injuries, secondary injuries and infection control issues [4]. Rigid assistive robots lack natural compliance, which can lead to excessive force being applied to the user or objects, increasing the risk of bruises, pressure injuries, or joint stress. These systems may fail to adjust dynamically during physical interaction, increasing the risk of strain or collision injuries, especially in the case of mechanical failure [8]. Another major limitation of rigid robotics is their reliance on the rigid body structure, which often requires more space for movement [9]. Due to their limited flexibility, rigid robots may struggle to perform tasks within confined or cluttered environments, such as small homes or crowded public spaces, where space for movement is limited. In many cases of daily living, especially for people who live in small apartments, these rigid robots do not have enough space to operate effectively. For example, the Kinova Gen3 robotic arm and the FlexPAL system share a similar maximum reach of approximately 890 mm. However, the footprint requirements of these systems differ considerably. Articulated robotic arms, such as the Kinova Gen3, require additional clearance near the base due to joint movements. For example, if the end-effector must reach a target within 410 mm of the mounting position, the Kinova arm's closest joint needs at least 410 mm of operational space. The metal links of rigid robots can also appear intimidating, particularly to children and the elderly, making them hesitant to engage with new devices or technologies [10, 11]. Furthermore, the risk of collisions during close human-robot interactions adds to users' concerns, highlighting the need for more adaptive and user-friendly alternatives in assistive robotics [12]. These limitations emphasize the importance of exploring softer, more flexible robots for safe and effective assistive applications.

Soft assistive robots offer superior adaptability, comfort, and safety in human interactions, making them ideal for overcoming the limitations of rigid systems. Their high curvature flexibility enables effective operation in confined spaces [13], while compliant materials enhance safety and comfort [14, 15]. Their lightweight design further supports home use, particularly in portable or wearable applications, allowing seamless integration with assistive technologies [16]. Despite rapid advancements in soft assistive robotics, most research has focused on wearable devices [17, 18], with limited attention to wheelchair-mounted solutions.

Thus, this research aims to design and develop a soft-WMAR that allows people with mobility impairments to use it at home. The structure of this paper is as follows: the *Method section* introduces the design, development and control method of a novel soft assistive robotic named FlexPAL (Flexible Pneumatic Actuated Linkage). In the same section, the functionality and usability evaluation experimental set-up are described. The functionality and usability evaluation results of FlexPAL are demonstrated and discussed in *Result and Discussion sections*. *The conclusion section* summarizes the key contributions, addressing the limitations of this research and proposing the future research direction of assistive robotics.

II. METHOD

A. Design and development of FlexPAL

As the literature identified, assistive robotics should be safe, easy to use and can support users in performing ADLs [12]. According to the user's need, a soft assistive robotics named FlexPAL was developed that can be attached to a wheelchair to provide assistance for people with disability (Fig. 2). The main body of the FlexPAL was designed and assembled using three modular arm segments, allowing customization to meet the diverse needs and preferences of different users.

The FlexPAL consists of nine off-the-shelf bellows (V6-00325 from Freudenberg), each with three parallel chambers. To counteract shear forces, the bellows have a 2 mm wall thickness with a 59 mm outer diameter. The working length for each bellow ranges from 80 mm to 220 mm

Key features include a PLA-printed hard plate on the top and bottom of the bellows and a lightweight 0.45 kg gripper mounted on the lower segment, forming the base of the end-effector. The total mass of FlexPAL is 3.88 kg, with a load capacity of 1 kg (Table I). It achieves a maximum range of 420 mm between full extension and compression and a bending angle of up to 100 degrees.

Conductive springs are used to generate inductive signals for the proprioception of FlexPAL. The extension springs were made of piano steel wire (an outer diameter of 4.0 mm, and a wire diameter of 0.4 mm), resulting in the spring with a force rate of 0.054 N/mm. Their minimal force ensures no interference with joint movement. In each segment, three springs are fix*ed to* the outer chamber ridge using fixing rings, aligning their deformation with the air chamber's movement for accurate motion representation and preventing buckling during joint movement, which reduces error during proprioception network training.

The FlexPAL system utilizes a pneumatic actuation mechanism consisting of nine independently controlled pump units. Each chamber is regulated by a dedicated YOUCHEN VN-C1 brushless pump, integrated with two 3-way, 2-position valves to enable rapid switching between extension and compression. This configuration allows real-time pressure control at frequencies of up to 50 Hz, ensuring precise and responsive actuation. The operating pressure for each chamber ranges from -80 kPa to 40 kPa, providing a low-pressure actuation scheme designed to ensure user safety. Each pump operates at a noise level of 58 dB, ensuring quiet operation, and weighs 1100 g, contributing to a total pump system weight of approximately 12 kg. This weight allows for convenient installation of the pump system under a wheelchair, enhancing portability and usability for individuals requiring assistive support.

The FlexPAL system is mounted on a wheelchair using a custom-designed bracket, 3D-printed from PLA-CF (carbon fiber-reinforced polylactic acid) for a balance of strength and lightweight properties. This mounting structure allows for

secure attachment while minimizing additional weight. The design is adaptable, enabling customization based on different wheelchair models to ensure a stable and user-specific fit.

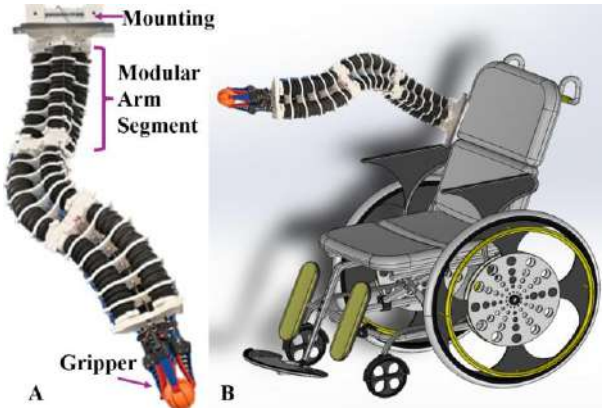

Fig. 2. Illustration of FlexPAL (A) and the assemble on a wheelchair (B) (Wheelchair copyright Mr Gean Hay)

TABLE I. SPECIFICATION OF THE FLEXPAL

Profile specification	Value
Profile size (mm)	180 x 180 x 940
Workspace (mm)	400 x 400 x 400
Elongation Range (mm/per module)	80-220
Max Bending Angle (Deg)	100
Pressure Range (Each Chamber) (kPa)	[-80, 40]
Self-Mass (kg)	3.88
Max Payload (kg)	1
Grasping Capability (Diameter-mm)	50
Manufacturing cost/per system (£)	9000

B. Perception and Control method of FlexPAL

To achieve proprioceptive feedback in FlexPAL, we adopted the method described in our previous work [19]. The proposed learning pipeline constructs the mapping function f_{smap} for proprioception through a two-stage process. First, a feedforward neural network (N_{smap}) is trained in simulation using a large dataset to capture the fundamental mapping function. Second, a lightweight network (N_{s2r}) is developed for sim-to-real transfer, trained with a smaller dataset collected from the physical environment. The datasets from the simulation and the real environment are utilized sequentially to train N_{smap} and N_{s2r}, ensuring accurate sim-to-real adaptation. This method provides precise proprioceptive feedback, facilitating robust and adaptive control of FlexPAL in dynamic and real-world conditions.

$$[T^{real}, R^{real}] = f_{smap}(s^{real}) \approx N_{s2r}\left(N_{smap}(s^{real})\right) \quad (1)$$

In this equation, s represents the spring signal with 9 dimensions. The real-world transformation (T^{real}) and rotation (R^{real}) are determined by the mapping function f_{smap}. This mapping function approximates the output of the feedforward neural network (N_{smap}), which takes as input the output of the lightweight sim-to-real transfer network (N_{s2r}) applied to the given real-world state signal (s^{real}).

During data acquisition for training, T^{real} and R^{real} are collected using a motion capture system. This system is utilized exclusively for the training phase to provide ground truth labels for real-world transformation and rotation. Once training is complete, the proprioception of the soft joints is derived solely from the spring sensor signals, utilizing the mapping function f_{smap}. This approach ensures the system remains independent of external motion capture during operation, relying entirely on the internal sensors of the FlexPAL.

The flowchart in Fig. 4 outlines the control method for FlexPAL, beginning with the desired target space, P^{ref}, which defines the desired transformation ($T^{desired}$) and rotation ($R^{desired}$) of the manipulator's end-effector (Fig. 3). The trained proprioception mapping function (f_{smap}) processes the sensor signals (s) from the geometry-based spring sensors to estimate the real-world transformation (T^{real}) and rotation (R^{real}) of the manipulator. These estimated values are compared with the desired target values to compute the errors in both transformation and rotation. The resulting error signals are then processed by a gradient control method that operates directly in the sensor space, effectively addressing discrepancies and generating sensor signals (s).

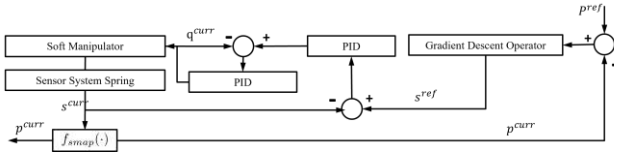

Fig. 3. Flowchart of sensor space gradient decent method for FlexPAL

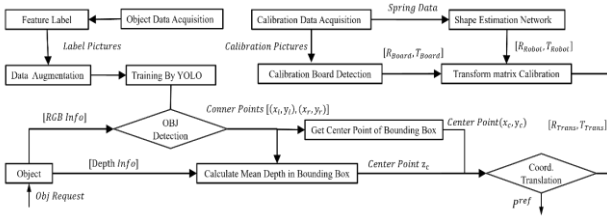

Fig. 4 Flowchart of pick and place control method for FlexPAL

Fig. 5 Data labeling and augmentation were performed using YOLO with data captured from an RGB-D camera.

The sensor signals are converted into actuation commands using a PID controller, which regulates the pressures in the soft chambers to achieve the required motion. This iterative process ensures the manipulator gradually aligns with the desired target state. The system operates within a continuous feedback loop, where updated sensor signals and error computations refine the manipulator's pose and orientation until the errors are minimized. This control strategy leverages the consistency and robustness of the sensor space for precise, adaptive manipulation.

To achieve assistance for ADLs (e.g. feeding or reaching objects), high-precision pick and place control is required. The pick and place control method for FlexPAL is illustrated in Fig. 4, comprising two key modules: ***Object Detection and Calibration.*** The Object Detection module employs a YOLO (You Only Look Once) model for real-time object detection. For example, in the experimental test for picking and placing a ball from a plate, the object detection model was trained using labelled data, as shown in Fig. 5. To enhance the model's robustness, we applied data augmentation techniques, which involve systematically altering the training images to improve the model's ability to generalize across different environments and lighting conditions. The Calibration module aligns sensor data with the robot's coordinate system through a shape estimation network and transformation matrix calculations. This process enables the conversion of object coordinates from the camera frame to the robot's coordinate system, ensuring accurate positioning for manipulation tasks

C. Evaluation experiment set up

Current assistive robots designed for individuals with mobility impairments must effectively support ADLs. Among these, feeding and dressing are the most common tasks, both of which demand high precision and safety in the robot's pick-and-place functionality. These tasks involve delicate interactions with objects and the human body, requiring the robot to adapt to various materials, positions, and user-specific needs [20]. For instance, a study on a dressing assistance robot highlights the importance of physical contact safety and the need for robots to adapt to dynamic contexts during dressing tasks [21]. Similarly, research on a robot-assisted feeding system emphasizes the necessity of comprehensive safety checks and adaptable control to cater to users with mobility impairments [22]. Ensuring safety and precision in these functions is critical to enhancing the usability and reliability of assistive robotics. In our research, functionality and usability evaluation of FlexPAL was conducted.

1) Functionality evaluation set-up

To evaluate the accuracy of FlexPAL, a two-stage experiment was conducted, encompassing random sampling and trajectory-following tests. In the first stage, random sampling was performed within the FlexPAL workspace, with over 500 random samples collected. This stage aimed to quantify the positional accuracy across the workspace. Non-parametric statistical analysis Kernel Density Estimation (KDE) was employed to analyze the system's error distribution. The KDE provided a robust visualization of the error data, facilitating an understanding of the overall consistency and precision of the FlexPAL's control system. In

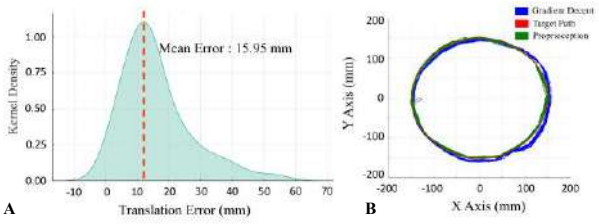

Fig. 6 Illustration of FlexPAL control accuracy through a Kernel Density Plot from a random sampling experiment (A) and trajectory tracking experiment of a circle with 150mm radius (B)

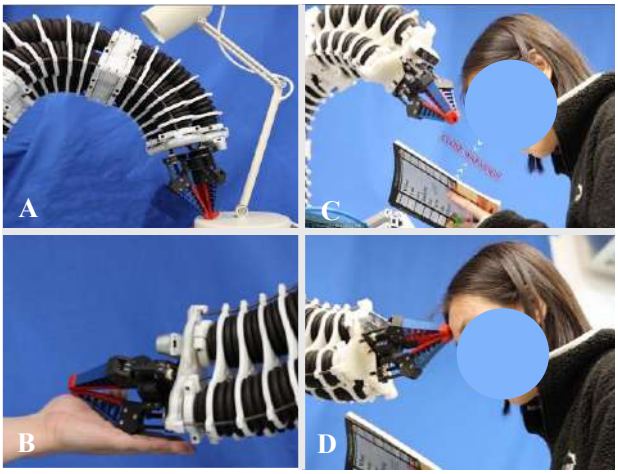

Fig. 7 Demonstration of daily assistance provided by FlexPAL (A: FlexPAL assisting a user in turning on a lamp; B : Physical interaction between FlexPAL and a human hand; C and D: FlexPAL monitoring and helping to maintain the distance between a book and the user's eyes during reading; more details can be seen in the showcase video https://www.youtube.com/watch?v=FcFkLvHGoXo)

the second stage, a trajectory-following test was conducted to evaluate its ability to perform continuous motion along a predefined path. The experiment involved following a circular trajectory with a radius of 150 mm. Target positions, current FlexPAL positions, and estimated positions were captured using a Vicon motion capture system and a proprioception network, respectively. For network training, the Adam optimizer was employed with a learning rate of 0.01 and a batch size of 128. The dataset, comprising 5000 samples from the simulator and 1000 samples from the physical setup, was divided into training, validation, and test sets.

2) Usability evaluation set-up

One healthy female from our research group participated in the usability evaluation for FlexPAL. Three user cases were conducted during this stage, including assisting users in turning on a lamp, monitoring the reading distance between the eyes and books, and evaluating physical contact between FlexPAL and the human hand to assess its ability to assist with ADLs and facilitate human-robot interaction. A focus group was conducted with one participant after identifying the user's satisfaction with FlexPAL.

According to the ethical requirement of the University of Manchester and NHS Health Research Authority, this research did not require ethical approval.

III. RESULTS

A. Functionality evaluation result: Control accuracy of FlexPAL

The KDE plot illustrates the distribution of errors observed during the random sampling experiment. The mean error was determined to be 15.59 mm, with the majority of errors tightly clustered around this value, as indicated by the sharp peak in the KDE plot (Fig. 6). This clustering highlights the consistency of the FlexPAL system, with minimal outliers, ensuring reliable positional accuracy throughout the workspace. The trajectory-following test confirmed FlexPAL's capability to handle complex motion tasks, validating its precision in real-time dynamic environments. The results demonstrated that FlexPAL maintained a smooth and continuous trajectory, closely adhering to the circular path. This capability is particularly important for tasks such as reaching, grasping, and interacting with objects in cluttered or unstructured settings, where accurate and responsive control is essential.

B. Usability evaluation results

The ability of FlexPAL to assist ADLs with safe and user-friendly human-robot interaction was demonstrated through a user case study, showcasing its practical application and effectiveness in real-world scenarios. The three different scenarios shown in Fig. 7 include assisting a user in turning on a lamp, monitoring and helping to maintain the distance between a book and the user's eyes during reading, and engaging in physical interaction between FlexPAL and a human.

IV. DISCUSSION

The results from both experiments collectively demonstrate that FlexPAL achieves a high level of positional precision, with errors well within acceptable thresholds for assistive tasks. The consistent performance across both random sampling and trajectory-following tasks highlights its suitability for assisting ADLs. These results affirm the potential of FlexPAL as a reliable and effective tool for applications requiring precision and adaptability in human-robot interaction.

Good usability is one of the most important requirements for both rehabilitation devices and assistive robotics, particularly those designed for home use [23, 24]. According to feedback from the focus group, the participants found FlexPAL to be comfortable and safe to use, attributing these qualities to its soft materials and user-friendly appearance. The modular design not only reduced physical discomfort during interaction but also minimized psychological barriers, especially for elderly users or those with limited mobility. Additionally, the participant expressed a strong willingness to use FlexPAL at home, emphasizing its lightweight design as a key factor in its integration into daily life. Furthermore, compared to currently commercialized WMAR (e.g. KINOVA up to £34,399 [7]), FlexPAL (£9,000) offers a more cost-effective solution, enhancing accessibility for people with mobility challenges and improving their quality of life.

Safety of physical human-robot interaction is one of the major requirements as well as the challenges of assistive robotics [8]. As emphasized by Bicchi et al. (2009), without proper safety measures, robots can pose significant risks during physical contact with humans [25]. This emphasizes that ensuring safety in physical human-robot interaction is paramount for the effective and responsible integration of assistive robots into environments where they interact closely with humans. Thus, assistive robotics must incorporate compliant mechanisms to ensure gentle and adaptive contact, minimizing the risk of injury during use. The common approaches to enhancing interaction safety include the use of compliant mechanisms, advanced control strategies, and biocompatible materials [26, 27]. For FlexPAL, soft biocompatible materials, specifically rubber, are used to construct the chambers, ensuring safety during physical contact with users.

In addition, unlike other WMAR, FlexPAL not only assists with ADLs but also actively monitors users' activities to help prevent the risk of injury. This dual functionality highlights FlexPAL's advanced design and adaptability. Its ability to assist with ADLs, such as reaching for objects or maintaining appropriate reading distances, ensures users can perform essential tasks independently. Meanwhile, its integrated monitoring system enhances user safety by detecting potential risks, such as improper posture or hazardous movements, and adapting its actions accordingly. This proactive approach to injury prevention sets FlexPAL apart from traditional assistive robots, emphasizing its role not only as a tool for physical assistance but also as a support for user well-being. These advantages make FlexPAL a comprehensive and user-centered solution for individuals with mobility impairments.

Additionally, customization is always the key desired feature for both rehabilitation and assistive robotics [28, 29]. Considering the varying levels of disability, the length of users' arms, and different home settings, the required size of a WMAR may vary. However, current commercialized assistive robots are designed in a generic size, making them unsuitable for diverse user needs. The participant also highlighted a preference for the modular design of FlexPAL, which enables customization to meet individual needs and enhances the accessibility of assistive devices to users.

Limitation

Despite its advantages, FlexPAL has certain limitations. The current design is not suitable for grasping objects weighing more than 1 kg, which restricts its ability to assist with a wider range of daily activities; increasing the payload capacity will be a focus for future development. Additionally, FlexPAL has yet to be evaluated by end-users, including therapists and individuals with mobility impairments. Future research will prioritize testing the system with individuals both with and without disabilities to gather feedback, refine its functionality, and ensure its effectiveness in real-world scenarios.

V. CONCLUSION

This research highlights the significant advantages of soft-WMAR, as exemplified by FlexPAL, in addressing the needs of individuals with mobility impairments. FlexPAL demonstrates its capability to provide sufficient assistance for various tasks, enhancing the independence and quality of life

for users. Its design prioritizes safety, reducing the risk of injury during human-robot interactions, particularly in scenarios where the robot works close to humans. The soft structure minimizes the risk of secondary injury, ensuring safe and gentle contact during assistance and physical contact. The high flexibility of its soft robotic structure allows it to adapt to diverse user needs and environments effectively. Additionally, the system offers superior user-friendliness, with a focus on appearance, texture, and comfort, ensuring a positive user experience. Furthermore, the modular and lightweight design of FlexPAL allows users to customize its size to accommodate different needs and adapt to various home environments. These combinations make FlexPAL a robust, adaptive, and user-centered solution in the field of WMAR.

ACKNOWLEDGMENT

This work was supported by the AMPI-The Advanced Machinery Productivity Institute [grant numbers 84646]. We sincerely thank AMPI for the essential funding and resources that facilitated the research and development in this work, as well as for their commitment to advancing scientific and industrial progress.

Evaluation of a spring-loaded lumbar occupational exoskeleton with healthcare professionals

Sara Carmosino, Lorenzo Amati, Lorenzo Grazi, Nicola Vitiello, *Member, IEEE,* Francesco Giovacchini, Tommaso Bellandi, Emilio Trigili, *Member, IEEE,* Simona Crea

***Abstract*— Work-related musculoskeletal disorders significantly impact healthcare professionals during patient-handling tasks. This work presents the results of a study that evaluated a spring-loaded lumbar exoskeleton, called SAFE-T, in reducing the physical strain for caregivers. Fifteen healthcare professionals performed patient transfer and bed repositioning tasks in three conditions, without wearing the SATE-T and with SAFE-T using two different levels of assistance. A healthy volunteer simulated a partially collaborative patient. The effect of the exoskeleton was assessed through superficial electromyographic measurements, movement kinematics, and perceived exertion. Results showed that the exoskeleton significantly reduced muscle activation across back muscles, with both assistance levels demonstrating the effectiveness of this study. Specifically, muscle activity was significantly reduced in the right lumbar erector spinae (19-29%), thoracic erector spinae (10-21%), and left erector spinae iliocostal (23-29%) muscles. The global Rated Perceived Exertion scores decreased significantly in both tasks when using the SAFE-T ($p < 0.05$). These findings highlight the potential of this device to reduce physical strain and potentially mitigate the occurrence of work-related disorders in healthcare professionals.**

I. Introduction

Work-related musculoskeletal disorders (WRMSDs) represent one of the leading causes of occupational disability in Europe [1]. Prolonged maintenance of uncomfortable postures and execution of repetitive movements are considered the main risk factors for developing these disorders, due to the biomechanical overload of the human joints [1]. WRMSDs are particularly common among healthcare professionals [2]. Manual patient handling activities, such as lifting, holding, or moving patients, apply high loads on caregivers' lower back [3]. In 2017, the rate of overexertion injuries for hospital workers was 57 per 10.000, about twice the average across all industries (30 per 10.000) [4]. The implementation of preventive measures is crucial to improve workplace ergonomic conditions and reduce WMSDs and injury risk [5] [6].

In recent years, there has been growing interest in back-support exoskeletons for preventing lower back pain among healthcare professionals and caregivers [7]. Although research efforts on exoskeletons for healthcare professionals are still in the early stages, the first studies show promising results [4].

Hwang et al. [8] assessed the effect of three passive back-assist exoskeletons (FLx ErgoSkeleton, V22 ErgoSkeleton, and Laevo V2.5) on the lower back muscle activities during simulated wheelchair-to-bed patient transfers. Results showed a reduction in lower back muscle activation. Turja et al. [9] assessed the effect of the Laevo exoskeleton (Laevo, The Netherlands) in the geriatric care setting, with initial results showing reduced physical strain on nurses during wheelchair transfers, eating, and hygiene activities. Most nurses reported that the exoskeleton reduced lower back strain when assisting the patient. Schmidbauer et al. [10] tested the CareExo Lift exoskeleton (HUNIC GmbH, Germany) for hospital care activities, including lifting and repositioning people from bed and supporting personal hygiene tasks. The caregivers perceived the exoskeleton as comfortable on the back, especially in the lumbar spine region. Lastly, Miura et al. [11] tested a powered back assist exoskeleton aimed to show a reduction in lumbar load when transferring a 60-kg patient mannequin from a seated to a standing position, and simulated the tasks with non-professional volunteers.

In this context, the present study provides a comprehensive evaluation of the effects of a novel spring-loaded occupational lumbar exoskeleton on 15 healthcare professionals in caregiving activities in long-term care facilities. The exoskeleton generates the assistive torques through a spring-loaded mechanism that mechanically encodes two torque-vs-angle profiles, making it adaptable to the different work activities of caregivers. The evaluation included instrumental measurements, namely trunk muscle electromyography (EMG) indexes and kinematics, and rated perceived exertion (RPE). Healthcare caregivers were professionals of long-term care facilities where patients with limited personal autonomy are supported in daily activities.

The study presented in this paper was promoted by the Fondazione Cassa Risparmio di Lucca within the Proximity Care project (Project No. IPROX221SN Proximity Care – prossimità, innovazione tecnologica per la rete di protezione socio-sanitaria delle aree interne nella provincia di Lucca).

The SAFE-T technology has been developed within the EU Mari4_YARD project (H2020-MG-2020-SingleStage-INEA) under Grant Agreement: 101006798.

II. Materials and Methods

A. Spring-loaded lumbar occupational exoskeleton

The exoskeleton used in this study is called SAFE-T (System for Assisting the Flexion/Extension of the Trunk, Fig. 1). It is a spring-loaded lumbar occupational exoskeleton designed and developed by IUVO Srl (a spin-off company of Scuola Superiore Sant'Anna), within the European H2020 Mari4_YARD project. The exoskeleton is a modified version of the commercial lower-back exoskeleton MATE-XB (COMAU S.p.a., Italy), designed to reduce back strain during manual material handling activities, such as repetitive load lifting. The system weighs 3.5 kg and consists of four main components.

1. *Two torque generator boxes* (one for each side) are passive, spring-loaded actuation units that store and transform the elastic energy of parallel springs into assistive torque around the hip joint (τ_{exo}).
2. *A physical Human-Robot Interface (pHRI)* secures the device to the user's waist, trunk and legs, allowing the robot to transfer the assistive torque to the trunk and the legs.
3. A *passive degree of freedom (pDOFs)* are implemented to provide increased movement flexibility. The surface area has been expanded to improve pressure distribution and enhance overall user comfort during activities and a connector links the vest to the carbon fiber back frame (thoracic pDOF).
4. *Three size regulations* at the trunk, chest, and pelvis level allow the exoskeleton to be adapted to users with different anthropometries.

The peculiar characteristic of the present exoskeleton lies in the possibility for the user of selecting the most appropriate assistive profile for the specific task. A manual knob on each actuation unit allows the user to enable and disable the assistive torque or to choose between two different assistance profiles (ASS1 and ASS2). ASS1 can provide up to 30 Nm, while ASS2 up to 60 Nm, resulting in total peak torque at the lumbosacral joint of 60 Nm and 120 Nm, respectively. The two assistive profiles are designed to potentially support different job tasks, namely tasks involving relatively high trunk bending angle (such as transferring a patient from the bed to a chair or vice versa), or activities that require maintaining postures for extended periods with a relatively low trunk bending angle (such as caregiving tasks performed

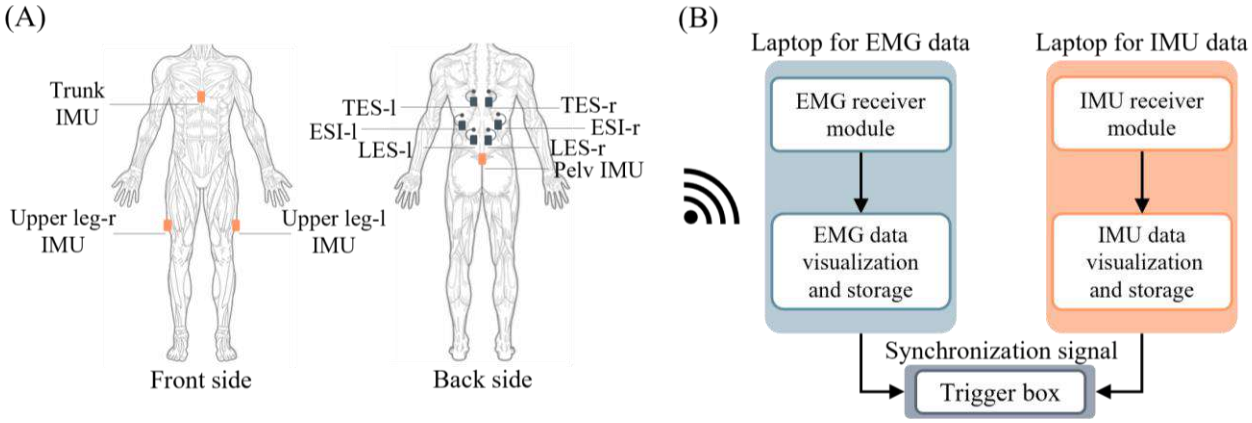

Fig. 2 Sensing system. (A) Schematic representation of the placement of EMG electrodes and IMUs sensors on the user's body. (B) Schematic representation in a block diagram of the measurement systems integration and communication.

on bedridden patients, including dressing or hygiene assistance).

B. Sensing system

A wireless EMG system (FREEEMG 1000, BT Bioengineering, Italy) was utilized to measure the activation of the participants' back muscles. Surface EMG probes were placed on the following muscles: left lumbar erector spinae (LES-l), right lumbar erector spinae (LES-r); left thoracic erector spinae (TES-l); right thoracic erector spinae (TES-r); left iliocostal erector spinae (ESI-l); right iliocostal erector spinae (ESI-r). The Xsens MTw motion capture system (XSens, The Netherlands) was utilized to measure the participant's movements (i.e., trunk flexion-extension and hip flexion-extension angles). Four inertial measurement units (IMUs) were placed on the following anatomical district: sternum; pelvis; upper left leg; and upper right leg. A FREEEMG Trigger Box (BTS Bioengineering, Italy) was used to synchronize the EMG and kinematic data offline. Fig. 2 shows the sEMG probes and IMUs placement and the network architecture of the acquisition system.

III. EXPERIMENTAL PROCEDURES

A. Participants and ethics approval

The project was supported by the management of the local health authority. Introductory meetings with caregivers and trial tests were conducted before the experimental sessions. These preliminary activities allowed for the organization of the experimental setup, following a participatory ergonomics approach, which was essential for the effectiveness of interventions aimed at improving workers' health [12]. The experiments took place at Hospice Villetta, RSA "Le Piane" (Castelnuovo in Garfagnana, Lucca, Italy) and at RSA "Paoli Puccetti" (Gallicano, Lucca, Italy). Fifteen caregivers were recruited to take part in the study (14 females, 1 male, age: 50.2 ± 12.1 years, height: 165.1 ± 6.2 cm, weight: 65.2 ± 14.1 kg). Participants did not report work limitations due to trunk or limbs musculoskeletal diseases. The study was approved by the Ethics Committee of Scuola Superiore Sant'Anna (approval n.24/2024) and followed the principles stated in the Declaration of Helsinki.

B. Experimental Protocol

Upon arrival, the participants received information about the study and the procedures and signed the written informed consent. With the help of the experimenters, the participants donned the exoskeleton and all size regulators were adjusted to ensure fit and comfort. The participants familiarized with the device for about 5 minutes, by performing free movements (such as trunk flexion and extension movements, with and without lifting objects), and simulating the subsequent experimental tasks. Before starting the experiments, commercial Ag/AgCl bipolar surface electrodes were placed on the muscles under their regular working clothes. Electrodes were placed following the SENIAM guidelines [13] and secured to the participant's skin using medical tape. The participants were asked to perform an isometric maximum voluntary contraction (MVCs) in three 5-second-long repetitions for each muscle, to be able to normalize EMG data and allow inter-condition and inter-subject comparison. The MVC was measured with the participants in a prone position following the procedures explained in [14]. IMU sensors were secured to the body segments of interest with the aid of elastic bands.

The experimental protocol (Fig. 3) consisted of a one-day testing session designed to simulate two fundamental caregiving tasks commonly performed in healthcare settings that do not require the use of mechanical lifts mandatorily. The first task, namely Patient Transfer Task (task #1), simulated a bed-to-chair transfer sequence and vice versa. The second task, namely Bed Repositioning Task (task #2), simulated patient repositioning procedures typically performed during daily hygiene care. In both tasks, a healthy volunteer acted as a patient with partial motor autonomy to ensure trial consistency. In particular, task #1 consisted of three distinct phases: (i) transfer from bed to chair, (ii) maintenance of a standing rest position, and (iii) transfer from chair back to bed. To maintain repetitive conditions, the bed height was adjusted to ensure maximum patient comfort and support during the task and remained constant among all participants. The chair was positioned at a 90° angle relative to the bed. Instead, task #2 involved simulating lateral patient movement, which required transferring the simulated patient

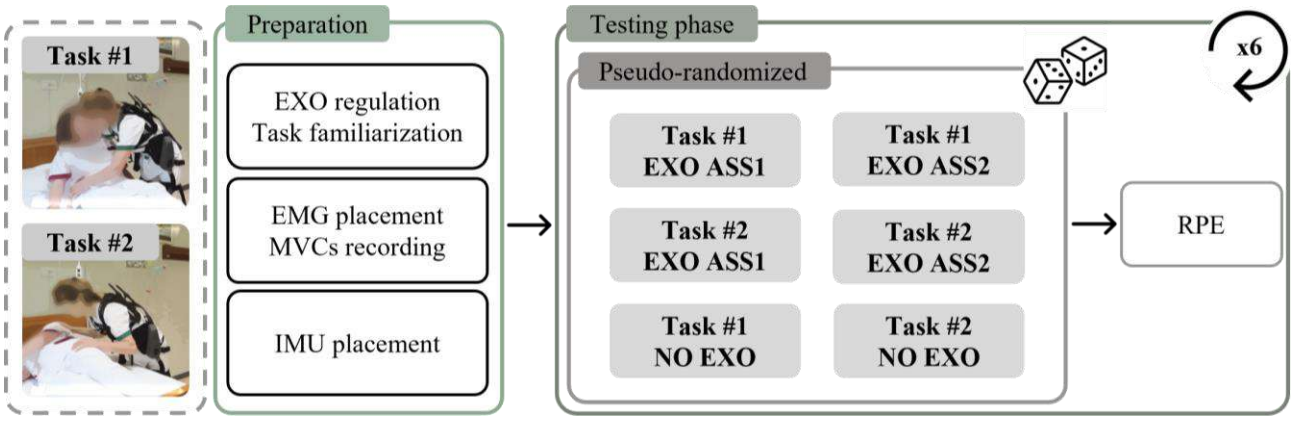

Fig. 3 Experimental protocol overview. The preparation phase includes exoskeleton regulation and familiarization, and placement of EMG and IMU sensors. During the testing phase, participants perform the task #1 and the task #2 in three different conditions (NOEXO, EXO ASS1, and EXO ASS2). At the end of each condition, participants complete questionnaires to assess effort (RPE).

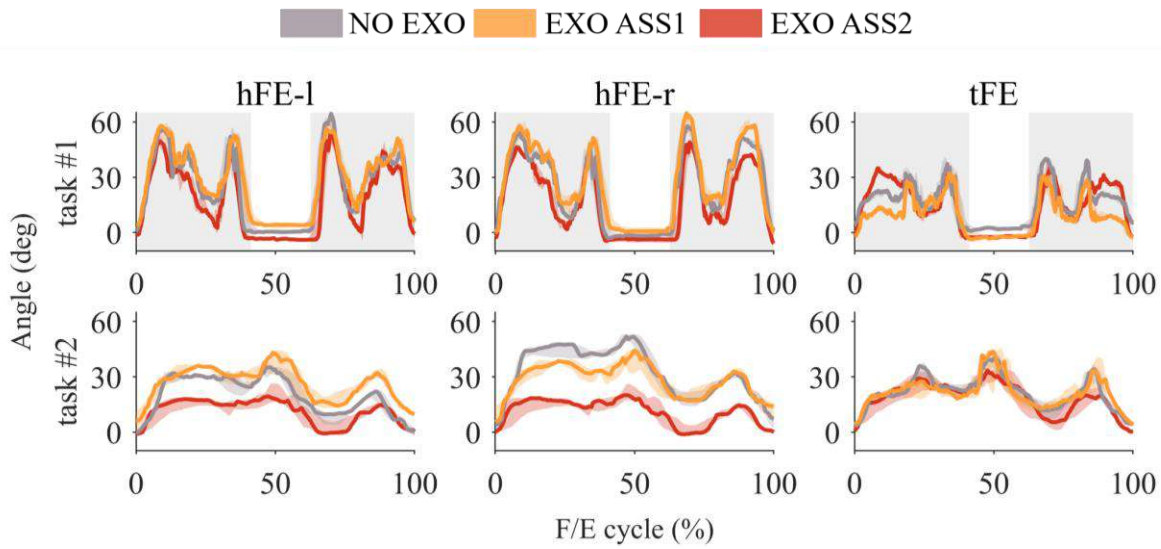

Fig. 4 Hip and trunk angles for task #1 and task #2. The two different phases of task #1 are indicated with a grey background: from left to right, the first phase is bed-to-chair, and the second phase is chair-to-bed.

across the bed surface, alternating between left and right positions. The bed was adjusted to its maximum height to optimize caregiver biomechanics during the task, consistently with ergonomic best practices in patient handling.

To assess the effect of the exoskeleton, each task was repeated five times in three different conditions: i) without wearing the exoskeleton (NO EXO), ii) wearing the exoskeleton with the assistance level set to EXO ASS1, and iii) wearing the exoskeleton with the assistance level set to EXO ASS2. The order of the three conditions was pseudo-randomized to avoid order bias: the NO EXO condition was always tested the first or last. At the end of each condition, the Rated Perceived Exertion (RPE) test [15] was used to assess the subjective perceptions. RPE scores were obtained using the Borg CR10 scale and evaluated the global and local effort perceived in four specific anatomical areas: upper back, middle back, lower back, and abdomen. The experimental session lasted about 90 minutes.

C. Data Analysis

Data analysis was performed offline using custom MATLAB R2022b (The MathWorks, Natick, MA, USA) routines. Raw EMG data were collected at 1 kHz. To obtain the linear envelope, the EMG data were processed with a band-pass filter (4th order Butterworth filter, filter range: 20–400 Hz) to remove high-frequency noise, and a notch filter (4th order Butterworth filter, cut-off frequencies 50 Hz and its harmonics) to remove AC interference. Then, the signal was rectified and low-pass filtered using a 100 ms moving average. The trunk flexion-extension (tFE) angles, the hip flexion-extension left (hFE-l) angles, and the hip flexion-extension right (hFE-r) angles were derived from IMU data, sampled at 100 Hz: from the rotation quaternions, the Euler angles of the trunk and the hip were derived, which represent the tFE and hFE angles respectively. For task#1, the EMG envelopes were manually segmented into two separate groups, according to the kinematics data, namely the bed-chair phase and the chair-bed phase. For task#2, the full cycle was considered. Representative profiles of hFE-l, hFE-r, and tFE angles are shown in Fig. 4. For each repetition of the tasks, the integrated EMG (*iEMG*) value was computed, following this equation:

$$iEMG = \int_{t1}^{t2} \frac{EMGenvelope(\tau)}{t2-t1} d\tau \qquad (1)$$

where *t1* and *t2* correspond to the beginning and the end of the considered time interval. Then, for each subject, muscle and condition, the *iEMG* values were normalized by the corresponding MVC value.

D. Statistical analysis

Statistical analysis was performed to evaluate differences in the three experimental conditions for two different tasks. All statistical analyses were conducted in MATLAB R2022b using a significance threshold $\alpha = 0.05$. Normality of the computed metrics' distributions was verified through the Shapiro-Wilk test and parametric or non-parametric statistical tests were applied accordingly. Since *iEMG* data was normally distributed, the effects of tasks and conditions on *iEMG* data were analyzed using a two-way repeated-measures ANOVA, and the assumption of sphericity was tested and verified using Mauchly's test. Separate analyses were conducted for each muscle. When the condition main effect was deemed to be significant, post-hoc pairwise comparisons were conducted to compare the EXO assistance conditions with the NO EXO condition, applying the Bonferroni correction to control for multiple comparisons. For the RPE score, the Friedman test was applied to compare with the NO EXO condition. Then, the Dunn-Sidak test was used for post-hoc comparison.

IV. RESULTS

Results on muscular and angular profiles and rated perceived exertion are reported in this section. During the experiments, two healthy volunteers alternated in simulating the patient (weight: 62 kg and 50 kg, respectively). They were experienced physical therapists who simulated the behavior of partially collaborative patients, ensuring that the testing

conditions reflected scenarios where the use of the automatic elevator was not mandatory.

A. *Muscular Activity Reduction*

The results related to the effects on back muscle activation are reported in Fig. 5. The analysis highlighted the observed differences in iEMG value as statistically significant for most of the muscles, for both the ANOVA main effects of task (all muscles $p < 0.001$) and condition (LES-r, TES-l and TES-r $p < 0.001$, ESI-l $p < 0.05$, LES-l $p < 0.01$), as well as for the ANOVA interaction effect (TES-l and TES-r $p < 0.001$, LES-r and ESI-l $p < 0.05$).

Post-hoc comparisons revealed statistically significant differences in *iEMGs* for both tasks. The median percentual variations in Fig. 5 are all reported in comparison to the NO EXO condition.

In task #1, the EXO ASS1 condition was found to reduce the muscle activity by 14%-23%, while the EXO ASS2 condition induced reductions ranging from 10% up to 29%. In task #2, the EXO ASS1 condition determined a reduction of 6%, while the EXO ASS2 condition showed significant reductions from 6% up to 15%.

B. *Reduced Perceived Effort*

Results of the RPE questionnaires are comprehensively reported in Fig. 6. The median RPE variations are all reported in comparison to the NO EXO condition. For task #1, the global RPE index and the local RPE indices for upper back and middle back were all reduced from 4 to 2 points by using the exoskeleton in EXO ASS1. For task #2, the global RPE scores were reduced from 3 to 2 points in EXO ASS1 condition and from 3 to 1 points in EXO ASS2 condition, while the local RPE scores were reduced in EXO ASS2 condition from 3 to 2 points for the upper back and middle back, and from 4 to 2 points for the lower back.

V. DISCUSSION

The results of this study suggest that the use of the lumbar exoskeleton with EXO ASS1 and EXO ASS2 can reduce physical strain during the Patient Transfer Task (task #1) and the Bed Repositioning Task (task #2). For task #1**,** both assistance levels of the exoskeleton demonstrated significant reductions in muscle activity. Specifically, the results revealed significant effects of the exoskeleton on the *iEMG* indexes within both phases of task #1. Reductions were more evident in the thoracic muscle (up to 24%) and in the lumbar muscle (up to 29%). These results suggest that the exoskeleton is effective in reducing lower back muscle activity in task #1, which requires substantial hip and trunk flexion effort. For task #2, EXO ASS2 demonstrated a more comprehensive and effective muscular activity reduction compared to EXO ASS1. The reduced muscle activations reported in this study are quantitatively in line with the results of other state-of-the-art studies during patient-handling tasks with professional caregivers ([8] [16]) and with university students [17] in laboratory settings. For example, in [8], the muscle activity of the erector spinae was significantly reduced by up to 11.2%, while in [16] it decreased by 7.78%–10.95%.

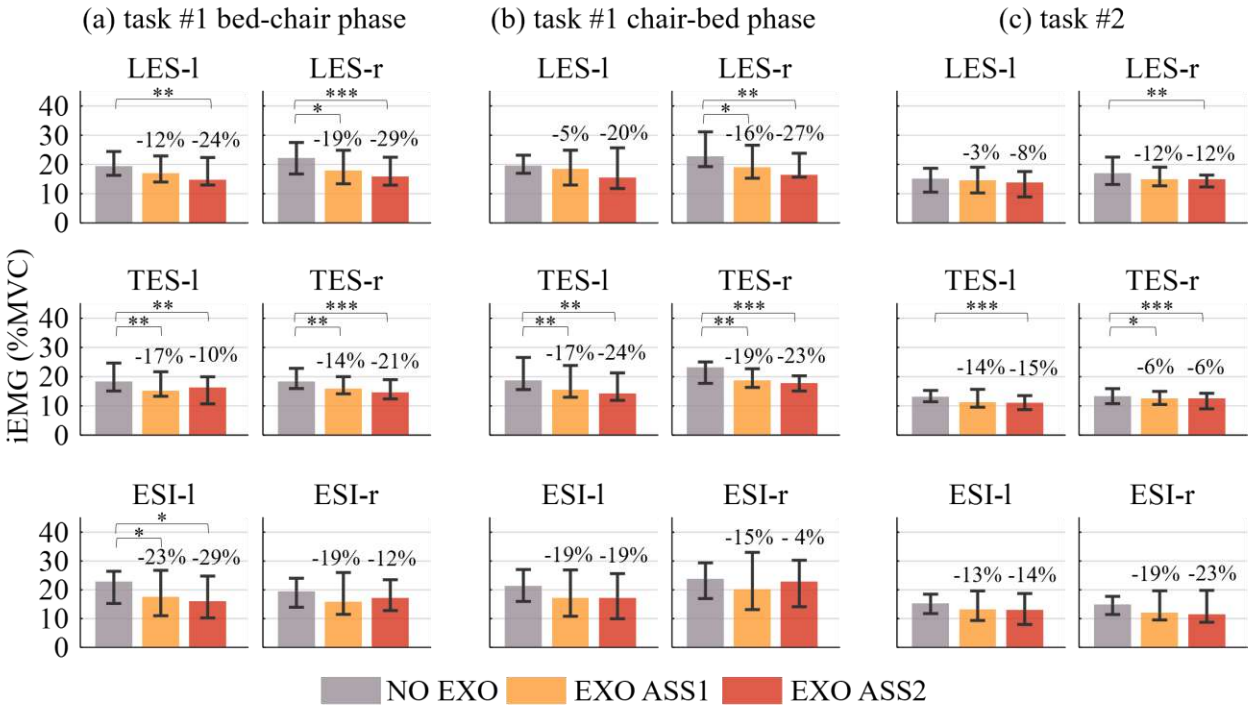

*Fig. 5 Average EMG results for the task #1 bed-chair phase, task #1 chair-bed phase and task #2. EMG results are shown for left lumbar erector spinae (LES-l), right lumbar erector spinae (LES-r), left thoracic erector spinae (TES-l), right thoracic erector spinae (TES-r), left iliocostal erector spinae (ESI-l), right iliocostal erector spinae (ESI-r). Bars represent median iEMG values expressed as percentage of the MVC, while the lower and upper end of the error bars represent the 25th and 75th percentile respectively. Median percentage variations with respect to the NO EXO condition are shown in correspondence of each bar. Asterisks indicated statistical significance due to the main effect of the intervention (*p<0.05, **p<0.01, ***p<0.001).*

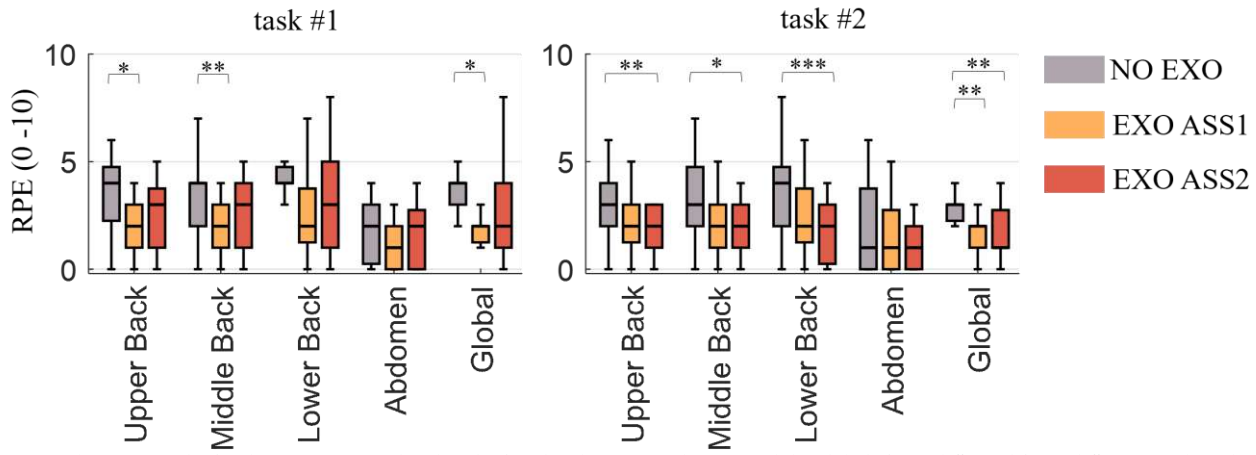

*Fig. 6 Subjective results for the RPE scores related to the four local anatomical areas and the global: for task #1 and for task #2. Asterisks indicated statistical significance due to the main effect of the intervention (*p<0.05, **p<0.01, ***p<0.001).*

Notably, the results of the present study may have reflected variability in the experimental conditions, which could have partially mitigated the observed effects. In particular, the use of a "simulated patient," who did not ensure consistent cooperation across repetitions and conditions, may have increased *iEMG* variability. Additionally, the reduction in iEMG activity of the LES muscles appears more pronounced on the right side. The higher LES muscle activity on the right side in the NOEXO condition, coupled with the greater reduction in the two assistive conditions, may be attributed to the sidedness of task #1, which required preferential turning from the right side of the bed thus likely influenced muscle activation patterns differently on the left and right sides. Finally, the slight differences in how the subjects performed the tasks may have contributed to the variability in the *iEMG* data.

Significant results were found regarding the effect of the exoskeleton on global RPE during task #1 using the EXO ASS1. Regarding the effect of the exoskeleton on global RPE during task #2, significant results were found using EXO ASS1 and EXO ASS2, with EXO ASS2 showing particular effectiveness in reducing lower back strain. These findings align with caregivers' subjective assessments, who preferred the use of the lower assistance during patient handling. This result may be due to the fact that with lower assistance, caregivers could perform movements while maintaining the same kinematics as when not wearing the exoskeleton. The higher assistance was perceived as more limiting for movement but was evaluated positively in task #2, which requires less mobility while benefiting from increased lumbar support.

Although no clear difference in effectiveness can be inferred between the EXO ASS1 and EXO ASS2 conditions, the presence of multiple assistance types seems justified by the results of subjective assessments. These evaluations highlight different user preferences, suggesting that offering both options could be an advantage to favor device subjective acceptance.

While field tests are inherently more challenging to control than laboratory studies, and the equipment available for monitoring and assessing exoskeleton efficacy in such settings is typically limited and less precise [18] [19] this study offered qualitative insights into the exoskeleton's efficacy under real-world conditions and was successful in capturing the operators' perceptions of use.

Finally, although evaluating the autonomous use of the exoskeleton was not an objective of this study, future research could adopt a more pragmatic approach to assess its usability, including autonomous use. Notably, an experienced user can don the exoskeleton in under 1 minute, suggesting that the device could be worn and removed multiple times throughout a shift, particularly during periods of more intense and repetitive tasks.

VI. CONCLUSIONS

This study examined the effect of SAFE-T on back muscles' activity and the subjective perception of effort. The results showed significant reductions in back muscles' activity. Additionally, the RPE scores were significantly reduced when using the exoskeleton. These preliminary findings highlight the potential benefits of using an exoskeleton for caregivers and further research is needed to fully assess its effectiveness and impact. Future studies will focus on investigating the long-term impact of the exoskeleton on caregivers during their daily patient-handling task.

ACKNOWLEDGMENT

The authors acknowledge the contribution of the research team from the Interdisciplinary Research Center for Health Science at the Sant'Anna School of Advanced Studies, as well as the professionals from the AUSL Toscana Nord Ovest Health Authority. ***Abstract*— Providing assistance in wearable robots based on exertion levels enables targeted and energy-efficient support. Traditional fatigue estimators, such as surface electromyography (sEMG) are predominantly reactive, identifying fatigue only after it has occurred. Near-Infrared Spectroscopy (NIRS) offers a complementary approach by providing early insights into muscle oxygenation, with oxygen depletion strongly correlating with muscle fatigue, thereby enabling proactive monitoring.**

This study integrates chip-based NIRS sensors into a physical interface to monitor muscle oxygen saturation during both static and dynamic conditions. The experimental protocol included an occlusion test, a low-intensity walking trial, and a high-intensity cycling trial to evaluate the sensor's performance under varying levels of exhaustion. Preliminary results demonstrate the sensor's sensitivity to oxygenation changes, underscoring its potential for fatigue-adaptive assistance in wearable devices.

Index Terms — Fatigue, NIRS, Physical Interface, Wearable Robots.

I. INTRODUCTION

Real-time monitoring of muscle oxygenation offers a novel approach to enhancing wearable exoskeleton functionality by providing targeted assistance tailored to the user's physiological needs. Oxygenation data reflects trends in muscle fatigue and oxidative capacity, making it particularly valuable for applications like rehabilitation and elderly assistance [1]. Personalized support can adapt to a user's functional ability, such as providing less assistance when muscles are rested and more as fatigue sets in, encouraging activity and reducing risks of chronic conditions like hypertension, osteoarthritis, and sarcopenia [2].

Sensorized physical interfaces, which form the attachment points between the exoskeleton and the body, provide a promising solution for integrating oxygenation monitoring. Due to their close interaction with the user, these interfaces can incorporate sensors to meet various requirements. One critical requirement is developing more symbiotic interaction strategies that efficiently capture user intent, enabling more intuitive control. Current sensors for this purpose primarily rely on surface electromyography (sEMG) to measure muscle activation [3], [4] or inertial measurement units (IMUs) for kinematic estimation [5]. Another crucial requirement is ensuring comfort and safety, as uncontrolled or non-ergonomic force application can cause pain or injury [6]. To address this, force and pressure sensors are often integrated into physical interfaces to prevent excessive loading on the skin [7], [8]. Oxygenation monitoring complements these technologies by providing insights into oxidative capacity a critical marker of muscle performance and health that reflects the muscle's ability to extract and utilize oxygen. Unlike metrics that respond to immediate changes, oxidative capacity evolves over longer timescales, offering valuable information for understanding sustained muscle activity and recovery [9].

Near-Infrared Spectroscopy (NIRS) enables non-invasive, real-time monitoring of muscle oxygenation by measuring the balance of oxygenated and deoxygenated hemoglobin in tissue [10]. While NIRS is established in sports science and rehabilitation, its adoption in exoskeletons remains limited due to the size and complexity of existing devices, such as the Moxy Monitor and Portamon. Although some studies have explored NIRS for fatigue monitoring in exoskeletons [11], no work has integrated NIRS directly into physical interfaces for real-time control. Furthermore, many exoskeleton applications require multiple sensors to track oxygenation in several muscle groups or body segments, and the cost and proprietary algorithms or firmware of existing commercial devices such as Portamon and Moxy Monitor make them often impractical to deploy for muscle fatigue monitoring in exoskeletons.

This study addresses these gaps by integrating a chip-based NIRS sensor into a sensorized cuff for measuring oxygenation in the muscle belly of rectus femoris muscle. By using the chip-based NIRS sensor, we aim for complete control over optical geometry, data access, and integration with the mechanical design of a wearable robot. The paper reviews the theoretical background of NIRS, describes the sensor integration, and presents validation through occlusion and activity trials, including low-intensity walking and high-intensity cycling. Finally, the performance of the proposed sensor is compared to a commercially available muscle oximeter Moxy Monitor (see Figure 1).

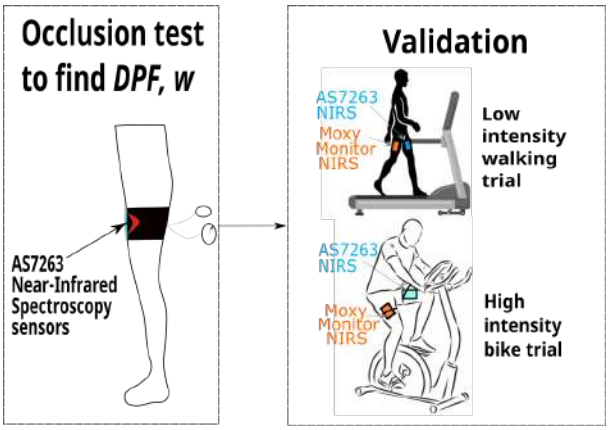

Fig. 1. Purpose of the study. The AS7263 NIRS sensors were integrated into a physical interface and subjected to an arterial occlusion test to derive the Differential Path Length Factor DPF and weighting parameter w, necessary for the Modified Beer-Lambert Law equation. The derived parameters were validated through a low intensity walking trial and a high intensity exercise trial, during which the proposed sensor's performance was compared to a gold-standard muscle oximeter.

II. Methods

A. Near-Infrared Spectroscopy: Working principle

Near-Infrared Spectroscopy (NIRS) non-invasively monitors the concentrations of oxyhemoglobin [HbO_2] and deoxyhemoglobin [Hb] in tissue, providing insights into oxygen supply and consumption [12]. In highly scattering media, the Beer-Lambert law must be modified by a differential pathlength factor (DPF) to account for the extended photon path, yielding the Modified Beer-Lambert Law:

$$\begin{cases} \Delta A_{770nm} = (\epsilon_{770nmHbO_2} * \Delta[HbO_2] + \\ \epsilon_{770nmHb} * \Delta[Hb]) * L * DPF \\ \Delta A_{850nm} = (\epsilon_{850nmHbO_2} * \Delta[HbO_2] + \\ \epsilon_{850nmHb} * \Delta[Hb]) * L * DPF \end{cases} \quad (1)$$

where ΔA_λ is the change in absorbance at wavelength λ, L is the emitter-detector distance, and ϵ_λ are the molar extinction coefficients.

Spatially Resolved Spectroscopy (SRS) reduces skin and adipose interference by placing multiple detectors at different distances (see Figure 2). The corrected absorbance ΔA_c is obtained by subtracting a weighted contribution (w) from the proximal detector (ΔA_p) from that of the distal detector (ΔA_d):

$$\begin{cases} \Delta A_{770nm,c} = \Delta A_{770nm,d} - w * \Delta A_{770nm,p} \\ \Delta A_{850nm,c} = \Delta A_{850nm,d} - w * \Delta A_{850nm,p} \end{cases} \quad (2)$$

From these corrected values, one can derive the muscle oxygen saturation S_{mO_2}, representing the fraction of oxygenated hemoglobin relative to total hemoglobin in the sampled muscle volume.

B. Experimental protocol

1) ***Materials****:* To assess accuracy relative to the Moxy Monitor, we employed 8-bit AS7263 NIRS sensors (SparkFun, USA, 3.3 V) covering wavelengths from 610–860 nm ($\pm$5 nm). Each sensor integrated a 3 mm through-hole LED emitting at 770 nm (MTE1077M3A-R, Marktech) for deoxyhemoglobin and 850 nm (SFH 4350, ams-OSRAM) for oxyhemoglobin. These were configured on two chip boards for Spatially Resolved Spectroscopy (SRS), spaced 35 mm apart along the muscle fibers to balance light penetration and minimize interference between LED sources. A custom thigh cuff (S-FIT-70-004-R3, Moovartes) with a 9 mm neoprene padding layer ensured comfort and alignment (see Figure 2). The AS7263-based cuff and the Moxy Monitor were placed on opposite legs to reduce motion artifacts, aligning with evidence that symmetrical tasks yield comparable relative bilateral oxygenation readings [13], [14].

Tests were performed on a single healthy male participant (26 years old, 1.68 m, 63 kg). The participant gave informed consent before starting the experiment and the protocol was approved by the institutional medical ethics committee of UZ Brussel and Vrije Universiteit Brussel (Belgium, B.U.N. 1432024000256).

2) ***Occlusion test****:* An occlusion test was conducted to evaluate the proposed spectrometer's sensitivity to oxygen deprivation in the muscle under static conditions. This arterial occlusion is a known method to temporarily restricts blood flow to a limb using a cuff, such as a sphygmomanometer, creating a controlled ischemic condition to monitor oxygen saturation changes and subsequent hyperemia upon release [15].

The primary objective was to identify time-sensitive events, such as oxygenation depletion and recovery, and estimate key parameters for the Modified Beer-Lambert Law, including the differential pathlength factor (DPF) and weighting factor (w), calculated using Equations 1 and 2. These parameters were optimized to improve correlation with the commercial oximeter.

For this test, an occlusion cuff was positioned proximally on the participant's thigh, with the Moxy Monitor and sensorized cuff placed just below it. The 4-minute test included a 2-minute occlusion period during which blood flow was restricted followed by the release of the occlusion. Three trials using AS7263 NIRS and Moxy monitor were performed with removal of the cuff between trials, which allows muscle reperfusion to baseline before the next measurement.

3) ***Validation****:* Following the occlusion test, two dynamic trials were conducted to evaluate oxygen saturation trends during low-intensity walking and high-intensity cycling. The walking trial, simulating an activity of daily living, lasted 20 minutes at 4 km/h on a standard treadmill. Four trials were performed using both the AS7263 and Moxy monitor, with removal of the cuff between trials. The bike trial, designed to induce muscle fatigue, lasted 7 minutes and included three phases: baseline at 60 W, 2 minutes of high resistance at 200 W, and 2 minutes of recovery at 60 W. The participant maintained a steady cadence of 75 rpm using a resistance-adjustable bike (Cyclus 2, Trek, Leipzig, Germany). The 200 W resistance level was chosen to ensure a challenging but feasible workload.

For both trials, the sensorized cuff and the Moxy Monitor

Fig. 2. Integration of Near-Infrared Sensors. The chip-based AS7263 NIRS sensor, integrated into the cuff, includes an embedded detector capable of detecting wavelengths between 610 nm and 860 nm and a custom through-hole near-infrared LED. The sensors are positioned to enable Spatially Resolved Spectroscopy (SRS) on the muscle belly of rectus femoris muscle (see right panel). In the diagram, I_0 represents the initial light source intensity, d_1 indicates the proximal detector, and d_2 represents the distal detector. This arrangement facilitates the subtraction of light absorption by skin and fat layers from the measured signal. Both the AS7263 sensor and the Moxy Monitor, used as the gold standard in this study, were placed on opposite legs to monitor oxygenation trends in the rectus femoris muscle.

were placed on opposite legs, just above the muscle belly of rectus femoris muscle, to monitor oxygenation levels.

C. Data processing

Data were collected via a Teensy 4.1 microcontroller (PJRC, USA) over I^2C and stored as .csv files. MATLAB R2021b (Mathworks, Natick, MA) handled processing, with oxygenation values normalized to $[0, 1]$ to mitigate hardware and optical-path discrepancies. Indeed, absolute oxygenation values can vary between devices due to differences in hardware design, optical paths, and signal processing algorithms. Normalization mitigates these discrepancies by focusing on relative trends in oxygenation changes rather than absolute values, ensuring that depletion and recovery dynamics remain comparable across sensors. Both the Moxy Monitor and AS7263 sampled at $0.5\,\text{Hz}$, and a $0.25\,\text{Hz}$ low-pass filter reduced high-frequency noise. Linear interpolation was applied to model key events (e.g., occlusion start/end, resistance phases). For multiple trials, mean and standard deviation of the AS7263 data were compared to normalized Moxy data, assessing consistency via coefficient of determination (R^2) and root-mean-square error (RMSE).

III. Results

A. Occlusion

As shown in Figure 3, muscle oxygen saturation declined after the occlusion onset (dashed line at 1 min), reflecting restricted blood flow and ischemia. Both the Moxy Monitor and AS7263 exhibited parallel downward trends, differing slightly in amplitude. In the first trial, the differential path-length factor (DPF) was 1.4 (proximal) and 5.59 (distal), and the weighting factor w was 0.2. Linear interpolations for both sensors illustrate the depletion phase, with slopes and R^2 values detailed in Table I.

Around 3 min, releasing the occlusion triggered post-occlusion hyperemia [15], a transient overshoot driven by vascular dilation. Both sensors showed steep recoveries, returning near baseline within similar timeframes (see Figure 3 and Table I). On average, depletion and recovery slopes across trials differed by 0.06 and 0.15 in normalized scale, respectively.

Figure 5 compares the mean AS7263 data to Moxy across all trials. Their correlation yielded $R^2 = 79\%$ and an RMSE of 11%, indicating strong agreement in oxygenation trends.

TABLE I

Depletion and recovery slopes of normalized oxygenation during the occlusion trial. Slopes and corresponding R^2 values are shown for both the Moxy Monitor and AS7263 trials, including individual trials and the mean of all AS7263 trials.

	Depletion[$\frac{1}{min}$]	Recovery [$\frac{1}{min}$]
Moxy Monitor	-0.32; R^2 = 99%	3.05; R^2 = 98%
AS7263 1st trial	-0.24; R^2 = 95%	2.49; R^2 = 95%
AS7263 2nd trial	-0.20; R^2 = 98%	3.19; R^2 = 90%
AS7263 3rd trial	-0.35; R^2 = 86%	2.95; R^2 = 85 %
AS7263 Mean trials	-0.26; R^2 = 96%	2.90; R^2 = 93 %

B. Low intensity walking trial

Figure 4 presents muscle oxygen saturation measurements from multiple trials using the AS7263 sensor and the Moxy Monitor during the walking trial. Both devices demonstrate a steadily increasing trend in oxygen saturation throughout the experiment, following a similar pattern. Unlike the occlusion test, the walking trial involved low-intensity activity, during which oxygen delivery exceeded consumption. This is because the muscles were not subjected to sustained high contractions that could compress blood vessels and restrict oxygen supply, as seen in ischemic conditions.

Figure 6 further illustrates the correlation between the normalized muscle oxygen saturation values obtained from the mean AS7263 sensor measurements and the Moxy Monitor. The linear interpolation, derived from the mean across all trials, highlights the agreement between the two devices. The coefficient of determination R-square between the devices was 89%, with a root mean square error (RMSE) of 9%, indicating the AS7263 sensor's reliability in tracking oxygenation dynamics during steady-state walking.

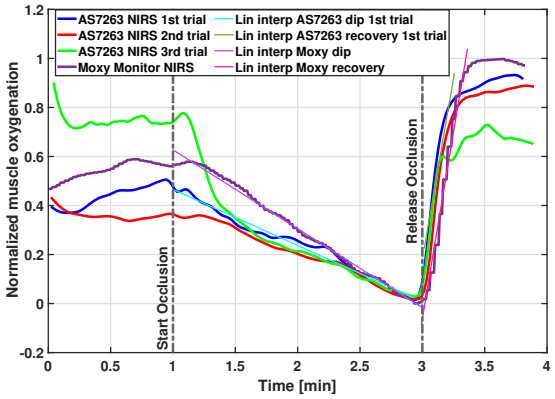

Fig. 3. **Occlusion Trial Over Time**. Muscle oxygen saturation measurements from both the AS7263 sensor and the Moxy Monitor during the occlusion trial. Dashed lines indicate the beginning and release of the occlusion. A gradual decline in oxygen saturation is observed during the occlusion phase due to restricted blood flow and ongoing oxygen consumption. Linear interpolations illustrate the depletion (dip) and recovery phases for both sensors. Upon release, a rapid increase in oxygen saturation reflects restored blood flow and oxygen supply, demonstrating the sensors' ability to capture real-time oxygen replenishment.

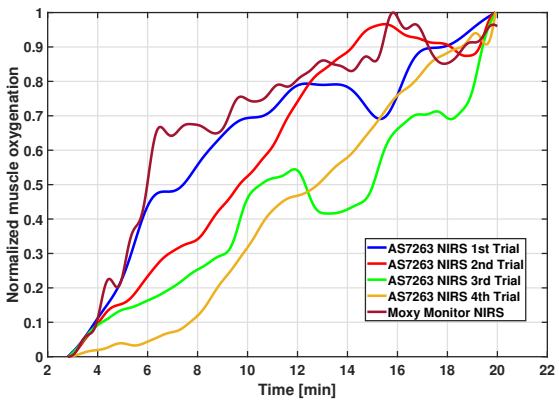

Fig. 4. **Low Intensity Walking Trial Over Time**. Normalized muscle oxygenation measured by the AS7263 sensor and the Moxy Monitor during a 20-minute walking trial. Both sensors show an increasing trend in oxygen saturation over time, indicating that the oxygen supply exceeds the demand during the activity. This occurs because the muscles did not experience prolonged intense contractions capable of compressing blood vessels and limiting oxygen flow, as observed in ischemic conditions.

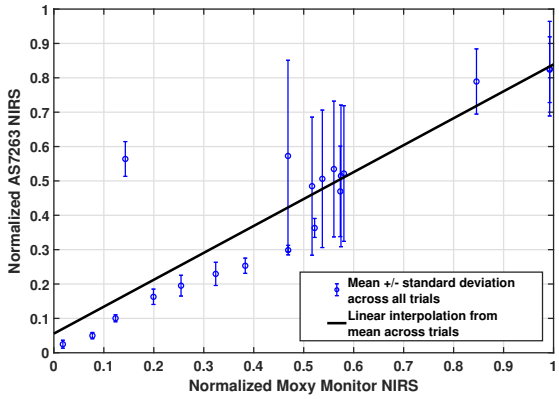

Fig. 5. **Normalized AS7263 NIRS against Normalized Moxy Monitor NIRS during Occlusion Test.** Normalized muscle oxygen saturation data from the AS7263 sensor (y-axis) and the Moxy Monitor (x-axis) are compared across three trials. The mean values are represented by blue dots with their corresponding standard deviations, while a black line depicts the linear interpolation of the mean. The coefficient of determination (R^2 = 79%) and root mean square error (RMSE = 11%) indicate strong agreement between the two sensors.

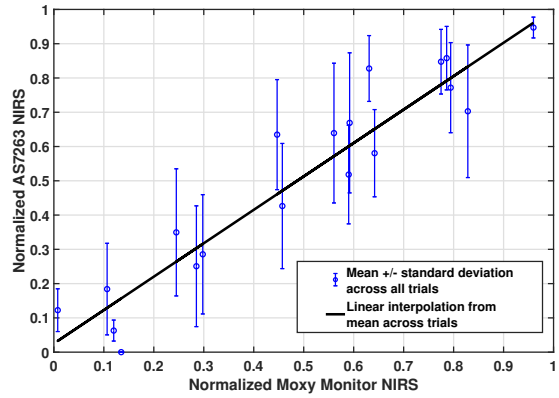

Fig. 6. **Normalized AS7263 NIRS against Normalized Moxy Monitor NIRS during Low-Intensity Walking.** Normalized muscle oxygen saturation from the AS7263 sensor (y-axis) is compared against the Moxy Monitor (x-axis) across four trials. Blue dots represent the mean values, and the black line shows the linear interpolation of the mean. The AS7263 sensor demonstrates trends comparable to the Moxy Monitor, with a coefficient of determination (R^2) of 89% and a root mean square error (RMSE) of 9%.

C. High intensity bike trial

Figure 7 shows the normalized muscle oxygen saturation from both the AS7263 sensor and the Moxy Monitor during baseline, a high-resistance phase at 200 W (starting at 3 min), and a recovery phase (beginning at 5 min). Both sensors recorded stable oxygenation at baseline, then a marked decrease under high load, reflecting increased metabolic demand. The Moxy Monitor and AS7263 showed depletion slopes of -0.47 [1/min] (R^2 = 93%) and -0.49 [1/min] (R^2 = 92%), respectively. When resistance returned to baseline at 5 min, both exhibited rapid recovery: 0.7 [1/min] (R^2 = 96%) for Moxy and 0.46 [1/min] (R^2 = 98%) for AS7263. This restoration of oxygenation arises from reduced oxygen consumption and lower intramuscular pressure, allowing blood flow to return to baseline levels.

Figure 8 compares the normalized data from both sensors, showing a lower R^2 of 32% than in other trials. The elliptical data distribution suggests a temporal misalignment, likely due to sensor response-time differences and possible motion artifacts affecting the AS7263.

IV. Discussion

The results from the AS7263-based NIRS sensor and the Moxy Monitor demonstrate comparable trends in muscle oxygen saturation during the depletion and recovery phases of the occlusion, low-intensity walking, and high-intensity bike trials. For the occlusion test, a coefficient of determination (R^2) of 79% and a root mean square error (RMSE) of

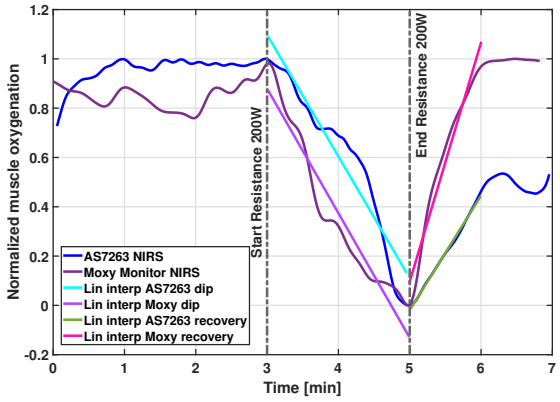

Fig. 7. **High Intensity Bike Trial Over Time.** Normalized muscle oxygen saturation data from the AS7263 sensor and the Moxy Monitor during a dynamic trial involving resistance changes on a bike. The dashed lines indicate the beginning and end of the high-resistance phase (200 W). Both sensors exhibit a decrease in oxygen saturation during the high-resistance phase, with similar slopes, reflecting the increased metabolic demand. When resistance is reduced to the baseline level, oxygenation increases as the oxygen supply surpasses the demand. Linear interpolations for both the depletion and recovery phases are shown, highlighting the sensors' ability to capture real-time oxygenation dynamics under varying resistance conditions.

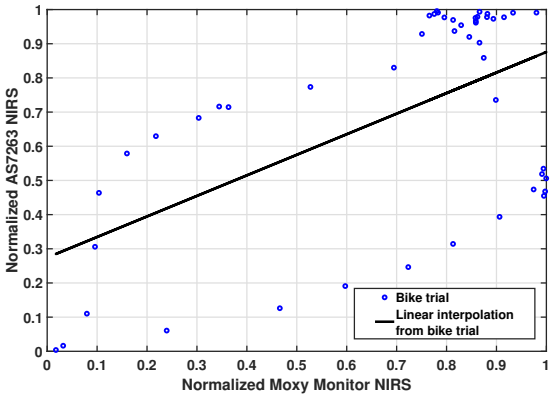

Fig. 8. **Normalized AS7263 NIRS against Normalized Moxy Monitor NIRS during High-Intensity Bike Trial.** Normalized muscle oxygen saturation from the AS7263 sensor (y-axis) is compared with the Moxy Monitor (x-axis), shown as blue dots. The linear interpolation yields a coefficient of determination(R^2) of 33% and an RMSE of 27%, highlighting challenges from motion artifacts and sensor differences during dynamic trials.

11% were observed, while the walking trial showed an R^2 of 89% with an RMSE of 9%. However, the bike trial exhibited a lower R^2 of 33% and an RMSE of 27%, indicating reduced agreement between the two sensors during high-intensity dynamic activity. The linear trendline was used as a simplified model to assess overall correlation, similar to the occlusion and walking trials, where both sensors showed strong agreement. The elliptical distribution of data points suggests that a temporal misalignment between the two sensors, possibly caused by response time differences, may have contributed to the reduced correlation. Future work will investigate temporal alignment and refine the AS7263's dynamic response for real-time monitoring.

Notably, the high variability across trials could also be attributed to differences in sensor placement. NIRS provides a localized assessment of oxygen saturation, and the heterogeneous activation of muscles can contribute to variability in the results [16]. This is particularly relevant for real-world applications, where relative motion and muscle heterogeneity can affect measurement reliability. Mitigating motion artifacts through secure, adjustable attachment mechanisms or motion compensation algorithms could enhance data stability. Despite variability, the bike trial demonstrated the AS7263 sensor's sensitivity to resistance changes, showing a 0.02 slope difference in oxygen depletion compared to the Moxy Monitor. This highlights the sensor's ability to capture real-time oxygenation changes under varying resistance conditions, reinforcing its potential for monitoring exhaustion in wearable robots using near-infrared spectroscopy.

Beyond validating the AS7263 sensor's ability to track muscle oxygenation, it remains unknown whether these measurements can inform exoskeleton control. Unlike biomechanical signals, which require high-frequency updates, muscle oxygenation changes occur over longer timescales and would be sampled less frequently (e.g., every 1 second) to track gradual trends rather than instantaneous fluctuations. In an exoskeleton framework, this data could modulate assistance dynamically, increasing support when sustained deoxygenation is detected and reducing it as oxygenation recovers to encourage active engagement. By combining oxygenation trends with faster biomechanical signals, a hybrid control strategy could use oxygenation as a longer-timescale fatigue indicator. Future work will focus on defining oxygenation thresholds for adaptive control and evaluating their impact on exoskeleton performance.

Differences in the attachment methods of the sensors could also influence measurements. The Moxy Monitor uses adhesive tape for direct skin application, whereas the AS7263 sensor is mounted within a cuff that encloses the thigh. Tightening the cuff excessively could create a pre-occlusion effect, altering blood flow dynamics and impacting oxygenation measurements. As a mitigation strategy, rather than maintaining perfectly constant pressure in future experiments, we plan to integrate secondary sensors such as pressure sensors that monitor cuff tension in real time. This will allow our algorithm to adjust for pressure variations and better isolate genuine physiological signals from artifacts. Moreover, the underlying algorithms play a significant role in the observed differences. The Moxy Monitor employs a Monte Carlo simulation-based algorithm, providing precise modeling of light scattering and absorption in complex tissue structures [17]. In contrast, the AS7263 sensor uses simpler model equations, which, while computationally efficient, lack the ability to account for intricate tissue-light interactions. Algorithmic enhancements, such as incorporating advanced tissue-light interaction modeling, could significantly improve the AS7263 sensor's performance under dynamic conditions. Additionally, the Moxy Monitor utilizes multiple wavelengths for oxygenation calculations, further enhancing its

accuracy compared to the AS7263 sensor, which relies on only two wavelengths.

Another important factor influencing muscle oxygenation measurements is the differential path length factor (DPF) and its associated weighting parameter. In this study, these parameters were fixed based on model assumptions, yet they are known to vary with changes in muscle contraction, relaxation, and adipose tissue thickness [18]. Variability in adipose tissue thickness, especially in populations such as the older or sarcopenic individuals, can affect light penetration depth and scattering properties, potentially reducing measurement accuracy. Integrating additional sensors, such as pressure sensors to detect muscle contraction, could allow real-time adjustments to DPF and weighting, compensating for tissue property variations and improving measurement precision.

Lastly, this study was conducted with a single healthy participant, and further validation across diverse populations is essential. Expanding to include more participants, particularly older and sarcopenic individuals, key candidates for exoskeletons, is crucial as their distinct physiological traits, such as increased adipose tissue thickness, reduced muscle mass, and peripheral vascular changes, may influence sensor performance. Testing these groups will enable further calibration and optimization of the sensor to address the specific needs of users reliant on exoskeletons. Additionally, systematic experimental protocols involving various activities of daily living could offer valuable insights into optimizing exoskeleton control strategies tailored to exhaustion and fatigue levels.

V. CONCLUSION

This study provides preliminary evidence that the AS7263-based NIRS sensor, integrated into a physical interface for exoskeletons, can monitor muscle oxygenation trends comparable to the Moxy Monitor. The occlusion test achieved a coefficient of determination of 79%, enabling the estimation of key parameters (DPF and w), while dynamic trials yielded 89% for low-intensity walking and 33% for high-intensity cycling, with comparable oxygen depletion and recovery trends observed. These results highlight the sensor's potential for monitoring oxygen depletion, a critical marker of muscle fatigue, and identify challenges like motion artifacts during high-intensity activities.

Based on findings from a single participant, further validation with diverse populations, including older and sarcopenic individuals, is essential. Future work should integrate advanced tissue-light interaction models and complementary sensors to improve robustness against motion artifacts and account for tissue variability. This study establishes a foundation for real-time muscle oxygenation monitoring, paving the way for fatigue-adaptive assistance in wearable assistive devices.

Multi-Channel EMS-based Interface for Perceptual Sharing of Joint Stiffness in Telerehabilitation

Yoshiori Fujii[1], Yasuhiro Suzuki[2], Modar Hassan[2] and Kenji Suzuki[2]

***Abstract*— In recent years, the demand for telerehabilitation has been increasing, and its effectiveness has been verified for various diseases and injuries. However, especially in the field of physical rehabilitation, manual assessment is commonly used, and the therapist cannot touch the patient remotely. Therefore, we developed an interface using multi-channel electrical muscle stimulation (EMS) for the evaluation of joint stiffness, which is difficult to judge visually. The performance evaluation showed that the elbow joint drag force tended to increase as the stimulation intensity of the EMS increased. In the perceptual study, the proposed method significantly improved discrimination performance compared to the video meeting system for the individuals without disabilities (p=0.0051, the Wilcoxon signed-rank test). The results suggest that the proposed method can be applied to clinical practice by establishing a calibration method that is tailored to the individual characteristics of the users.**

I. Introduction

Telerehabilitation (TR) is a subgroup of telemedicine, which refers to the implementation of rehabilitation remotely via information and communication technology[1], [2]. TR is a generic term for medical rehabilitation services including "evaluation, assessment, monitoring, prevention, intervention, supervision, education, consultation, and coaching"[3]. TR has attracted attention as an effort to reduce barriers of travel distance, time, and cost, and also the need for TR has increased due to the COVID-19 pandemic[4], [5].

Especially in neurological diseases such as stroke, cerebral palsy, and spinal cord injury, the emphasis is on evaluation and treatment by physical therapists using manual methods. During rehabilitation, if joint stiffness, such as spasticity and contracture, is not properly assessed, it will not be possible to demonstrate therapeutic efficacy and can be a major limiting factor in a patient's daily life. However there are challenges in transitioning to TR since a therapist cannot touch a patient.

Computer vision and robotic systems have been studied to assist therapists in monitoring patient status and guiding exercise in a TR environment. Pathirana et al.[6] proposed a real-time bio-kinematics tracking system using Kinect. Their system can monitor kinematics, but evaluation of joint stiffness without displacement is not feasible. Lai et al.[7] developed a hand exoskeleton robot to assess muscle spasticity. Still, installing a robotic system for a specific body part in each patient's home is not cost-effective.

[1]Yoshiori Fujii is with the Doctoral Program in Empowerment Informatics, Graduate School of Science and Technology, University of Tsukuba, Japan yoshiori@ai.iit.tsukuba.ac.jp

[2]Yasuhiro Suzuki, Modar Hassan, and Kenji Suzuki are with the Institute of Systems and Information Engineering, University of Tsukuba, Japan yasuhiro@ai.iit.tsukuba.ac.jp, modar@iit.tsukuba.ac.jp, kenji@ieee.org

Therapists relying on manual methods are reluctant to implement complex systems such as those described above because they perform rehabilitation based on their own sensory perception[8]. Liu et al.[9] and Sommerhalder et al.[10] showed the effectiveness of a robotic interface focused on the remote interaction of the therapist with the patient. Although there have been many studies of remote interfaces using mechanical actuators, there have been few studies of simple, cost-effective devices that can be used in each patient's home.

The motivation of this study is to develop a cost-effective joint stiffness evaluation support system that is easy to implement in each patient's home and can be used sensibly by therapists. The realization of such a system would facilitate the transition to TR and reduce the geographic time and cost burden on both patients and therapists.

In this study, we propose a wearable patient-therapist sensory-sharing interface that does not require an mechanical actuator. Aiming at the application of joint stiffness evaluation we focused on communication by bio-signals. We developed an interface that enables the therapist to directly perceive changes in the joint stiffness of the patient by applying electrical muscle stimulation (EMS) to the therapist's muscles based on the electromyography (EMG) signals obtained from the patient's muscles. The purpose of this study is to verify the perceptual characteristics of joint stiffness changes induced by Multi-channel EMS and to explore the feasibility of adapting the interface to TR.

II. Related Works

A. Joint Stiffness Estimation by EMG

Many studies have been conducted to estimate joint stiffness based on multi-channel EMG. Wang et al.[11] shows a potential method for assessing elbow spasticity based on 2 channels EMG of the biceps and triceps brachii muscles. We attempted to measure EMG in 2 channels, biceps brachii and triceps brachii, which is the minimum number of channels, to obtain changes in elbow joint stiffness.

B. Perception Sharing Device

BioSync[12] is a perception-sharing device in which the timing of wrist muscle exertion can be synchronized between device users without using visual or acoustic information using EMS based on EMG measurement. It provides a shared sense of human motion. However, it targets only a single channel muscle, and it is unlikely to share changes in joint stiffness. We hypothesized that by extending this technology to multi-channel EMS, we could share the sensation of changes in human joint stiffness with others.

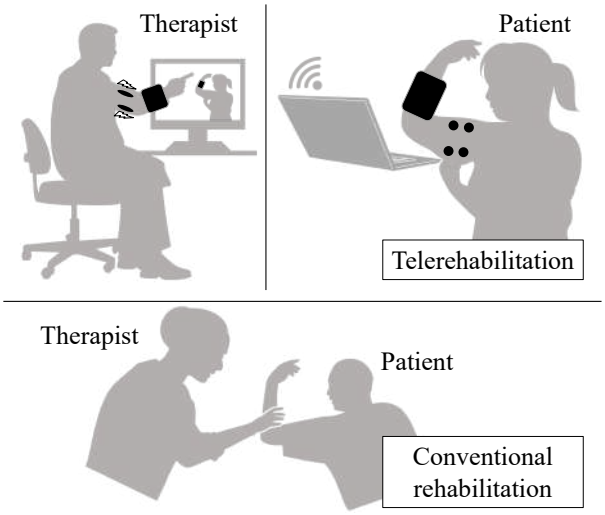

Fig. 1. The conceptional figure of an interface that can share elbow joint stiffness change using the proposal method in telerehabilitation

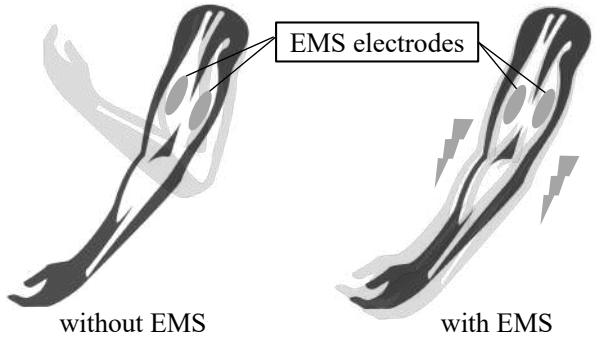

Fig. 2. Modulation of elbow joint stiffness by multi-channel EMS

III. Methodology

A. Proposed Approach

The proposed approach to improve the remote interaction of the therapist with the patient is a multi-channel EMS-based interface based on EMG inspired by BioSync[12]. Nishida et al.[13] evaluated shared wrist joint stiffness with multi-channel EMS based on EMG and showed a linear relationship between applied EMS intensity and joint stiffness with four levels of discrimination performance. In this study, we evaluate a more practical scenario in TR. Since the modified Ashworth scale (MAS) uses a 5-lebel discrimination method, we investigate the 5-level discrimination performance and compare it with the video meeting systems used in a conventional telerehabilitation setting. The elbow joint was chosen as the subject of this experiment because many stroke patients develop muscle spasticity and it is easy to perform in a chair in front of a desk for use in TR.

B. Concept for Perceptual Sharing of Joint Stiffness

Fig.1 shows the conceptional figure of an interface that can share elbow joint stiffness changes using the proposed method in TR. The therapist usually uses palpation to assess the patient's muscle condition, range of motion, and joint stiffness in conventional rehabilitation. In TR, patients and therapists are expected to communicate using a videophone

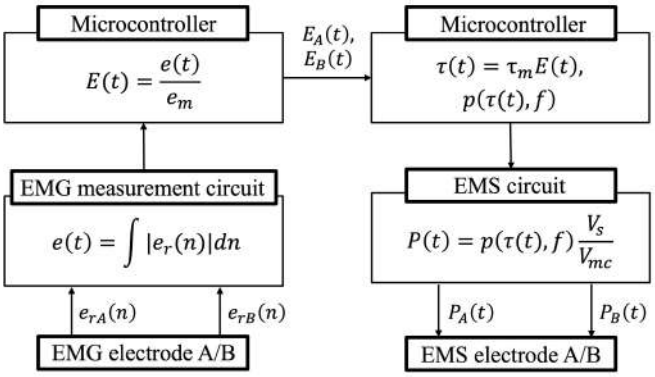

Fig. 3. The signal process from the EMG measurement device to the EMS device

or video meeting system on a PC or tablet device. We propose a wearable haptic interface that does not require mechanical actuators and can be easily integrated into conventional telecommunications equipment. The patient wears a device for measurement and the therapist wears a device for EMS. EMG signals measured from the patient are processed and sent to the therapist's device as bioelectrical signals. Based on the received signals at the therapist's side, multi-channel EMS is applied to the therapist to share the perception of joint stiffness changes. This does not replicate the conventional MAS, but allows the therapist to perceive the patient's joint condition as a force sensation.

C. Modulation of Joint Stiffness by Multi-Channel EMS

Fig.2 shows a conceptual diagram of the mechanism of elbow joint stiffness augmentation by multi-channel EMS. Functional electrical stimulation (FES) is one type of EMS technology that communicates control signals from an external device to the neuromuscular system for assisting or restoring motor functions[14]. When FES is applied to the biceps brachii, the elbow joint moves in the direction of flexion, and when FES is applied to the triceps brachii, the elbow joint moves in the direction of extension. Therefore, involuntary simultaneous contraction of the biceps and triceps muscles, which are the muscle antagonist pair to the elbow joint, makes it difficult to move the elbow joint. In this paper, joint stiffness is defined as the difficulty in moving the joint due to simultaneous contraction of the muscle antagonist pair, and changes in joint stiffness are promoted by changing the level of muscle contraction by EMS.

D. EMS Signal Model based on EMG

Fig. 3 shows the signal processing block diagram of the proposed method. A and B in the figure represent different muscle sites. $e_r(n)$ are the EMG signals amplified in the EMG measurement circuit based on the biopotential signals of muscles measured at discrete time n. The signals are absolutized and smoothed to express the magnitude of muscle contraction per constant time t. The smoothed signal $e(t)$ is expressed by the following equation (1).

$$e(t) = \int |e_r(n)|dn \tag{1}$$

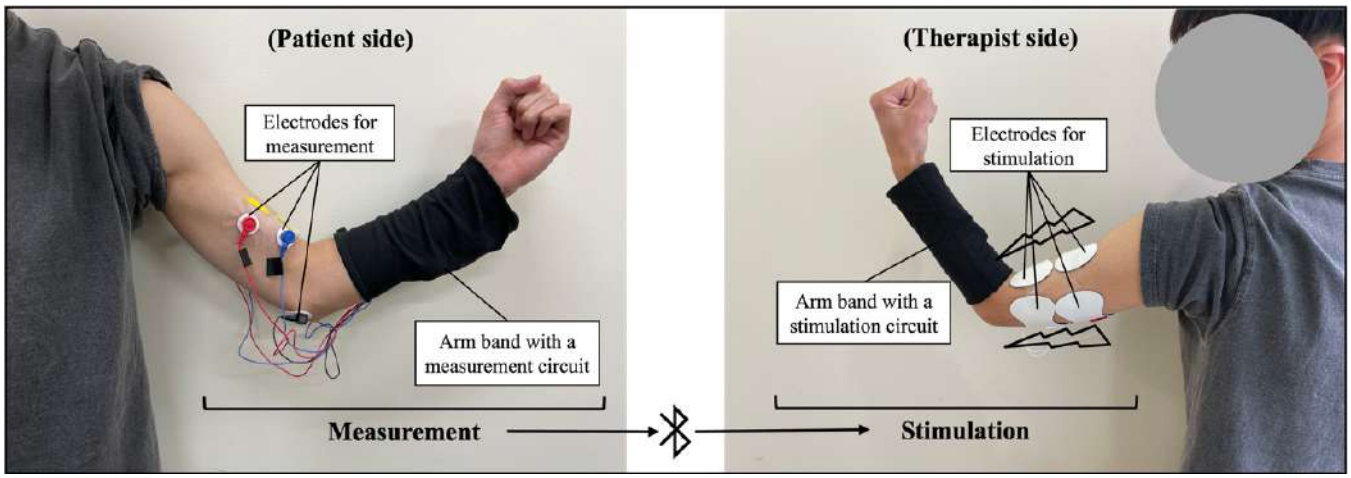

Fig. 4. System configuration

Each time the user wears the electrodes, the user voluntarily contracts the target muscle isometrically as much as possible, and the maximum value of the EMG signal e_m at that time is measured as the maximum voluntary contraction (MVC). The measured EMG signal $e(t)$ is normalized using e_m to obtain the voluntary contraction rate $E(t)$, which is expressed by the following equation (2).

$$E(t) = \frac{e(t)}{e_m} \tag{2}$$

In the device for EMS, the parameters of the square wave pulse signal for EMS are defined. When the frequency of the square wave pulse signal is f, the maximum pulse width is $\tau_m (0 \leq \tau_m < 1/f)$, and the pulse width $\tau(t)$ is expressed by the following equation (3).

$$\tau(t) = \tau_m E(t) \tag{3}$$

The square wave pulse signal function $p(\tau, f)$ is determined using the frequency f and $\tau(t)$ by the following equation (4).

$$p(\tau, f) = \begin{cases} V_{mc} & (0 \leq t < \tau) \\ 0 & (\tau \leq t < \frac{1}{f}) \end{cases} \tag{4}$$

Since the output voltage V_{mc} from the microcontroller is not sufficient for EMS, an external power supply is used in the EMS circuit to amplify V_{mc} to obtain the stimulation voltage V_s. The square wave pulse signals $P(t)$ are used as the output signal for EMS by the following equation (5).

$$P(t) = p(\tau, f)\frac{V_s}{V_{mc}} \tag{5}$$

IV. System configuration

A. EMG Measurement Unit

The EMG measurement unit is used for the patient's device. The microcontroller that controls the entire circuit is an ESP32-WROOM-32E, which sends signals from the EMG sensor to the EMS circuit. MyoWare is a module for EMG measurement and is equipped with a bandpass filter circuit, an amplification circuit, and an absolute value processing and smoothing circuit. A snap-button cable is used to connect the electrodes, allowing selective use of wet electrodes or conductive fabrics that conduct with the snap buttons.

B. EMS Unit

The EMS unit is used for the therapist's device. The microcontroller, ESP32-WROOM-32E, generates square pulse wave signals and receives data from the EMG measurement circuit. A photo coupler (PC817) is used as a relay element to electrically isolate the pulse wave control signal for EMS and the input potential to the stimulating electrode to prevent damage to the control circuit. A DC/DC converter (LM2733) is used to boost the voltage from a lithium-ion polymer battery rated at 3.7 V as an external power supply for muscle stimulation. A 10 mA constant current diode (S-103T) is inserted before the stimulating electrode connector to limit the current to avoid risk to the human body. An audio minijack is used as a connector for the stimulating electrode so that a conductive cable with an audio minijack can be easily connected and disconnected. The other end of the conductive cable can be connected to a snap button as with the EMG measurement circuit. The amplitude of the square-wave pulse signal for EMS is 10-40 V, the frequency is 1-200 Hz, and the maximum pulse width can be changed in the interval of 0-1000 µs. In this study, the maximum pulse width was set at 400 µs, which is less likely to cause pain or discomfort to the user due to EMS[15].

C. Attachment and Connection

Fig.4 shows how to wear the devices and connect each device to the other. The main body of the device can be worn to improve usability so that it does not interfere with the user's movement. The EMG measurement circuit or the EMS circuit is stored in the armband with a pocket, and only the snap-button cable is removed to connect to the electrodes. The microcontrollers can connected to other microcontrollers or PC via wired serial, Bluetooth, or Wi-Fi connection. In this study, we used Bluetooth connection, which is a wireless communication method and has stable communication. When introducing the system to TR, it is possible to switch to a Wi-Fi connection and realize communication via the Internet.

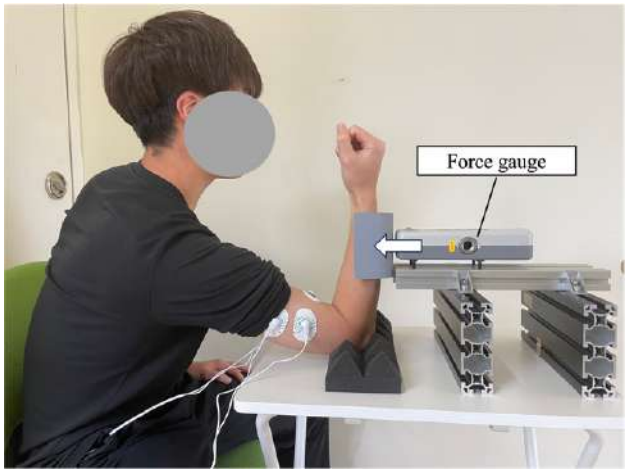

Fig. 5. The setup of the drag force measurement

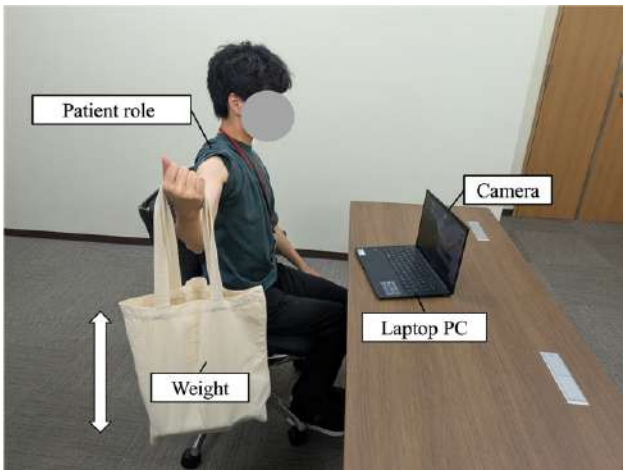

Fig. 6. The setup of the visual condition

V. Experiments

A. Performance Evaluation for EMS System

In this experiment, we aimed to validate joint stiffness modulation through the intensity of multi-channel EMS. We measured the drag force produced by displacement from the same joint angle and evaluated its characteristics. All participants in the experiment were tested at the same stimulus intensity to obtain individual characteristics.

The experiment setup is shown in Fig.5. The electrodes were attached to the biceps brachii and triceps brachii muscles, respectively, and the elbow was placed on a tabletop. A digital force gauge (ZTA-50N, Imada Corporation) was pressed horizontally against the forearm in a vertical position to move the joint, and the maximum drag force was measured at the right before the movement started. The participants were instructed to relax their arms and not to resist when the digital force gauge was pressed. The stimulation voltage was 30 V, the frequency of the stimulation signal was 40 Hz, and the pulse widths were 0, 100, 200, 300, and 400 µs and same values for both biceps brachii and triceps brachii muscles. A pulse width of 400 µs or less, which is less likely to cause pain or discomfort to the users due to EMS, was used to examine the characteristics in this experiment. The current was limited to 10 mA so as not to endanger the human body. The drag force was measured 3 times each and the average value was calculated.

4 male participants (Age: 23.25 $\pm$ 0.5) from our local organization with no history of neurological or musculoskeletal disorders participated in a total of 60 trials (4 participants $\times$ 5 stimulus strengths $\times$ 3 times).

B. Perceptual Study

The objective of this experiment was to evaluate the subjective discrimination performance of changes in elbow joint stiffness induced by multi-channel EMS under static conditions that do not cause angular displacement of the joint. No mapping to the true MAS score was performed, but we verified if there are 5 levels of discrimination performance.

The participant who is the patient role and the participant who is the therapist role were made visible to each other using a video meeting system (Zoom) in an online setting. The sound is muted to limit the transmission of information through the auditory sense. Fig.6 shows the setup of the visual condition in the experiment. In the visual condition, the patient maintains a 90-degree elbow joint angle and lifts a 0, 2, 4, 6, and 8 kg weight one time each. The weights are kept out of the camera's angle of view so that the therapist can only see the patient's upper arm muscles. The patient lifts the weights one time each in random order, and the therapist responds to the presented task by discriminating the relative stiffness of the joints in 5 levels. 2 different patient roles presented the visual conditions for participants P1-5 and P6-10. The therapist role is informed in advance that the mass of the weights are 0, 2, 4, 6, and 8 kg. In the haptic condition, the camera of the video meeting system is turned off so that the therapist role cannot see the patient role's upper arm muscles. The patient role then applies the stimuli one time each in random order at different intensities, and the therapist role then responds by discriminating the relative stiffness of the joints at each of the 5 levels. For the EMS to the therapist role, the stimulation voltage was 30 V, the frequency of the stimulation signal was 40 Hz, and the pulse widths were 0, 100, 200, 300, and 400 µs as 5 levels of joint stiffness and same values for both biceps brachii and triceps brachii muscles. Both conditions consisted of one familiarization session at each level, followed by 3 sets of recorded sessions.

The experiment was conducted on 10 non-expert male and female participants (Age: 22.9 $\pm$ 0.74) as the therapist role and two male participants (Age: 23.5 $\pm$ 0.71) as the patient role from our local organization. All participants in both roles had no upper limb motor impairment.

Both experiments were approved by the Research Ethics Committee of the Institute of Systems and Information Engineering, University of Tsukuba (No. 2024R874), and conducted with the informed consent of the participants.

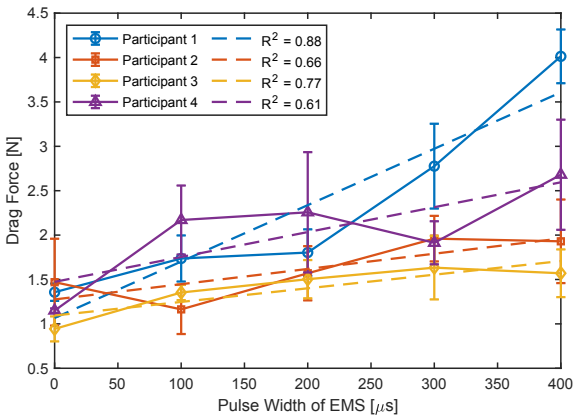

Fig. 7. The drag force measurement results

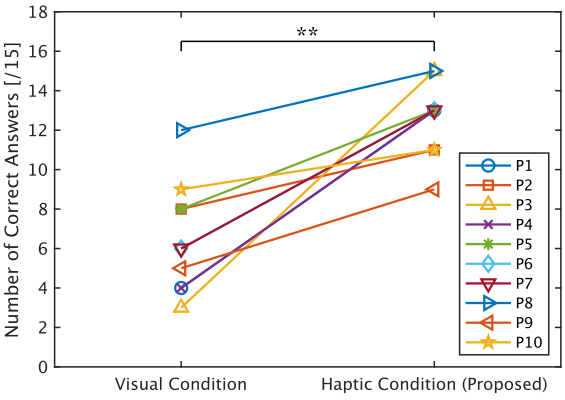

Fig. 8. Discrimination results of the perceptional study

VI. Experimental Results

A. Performance Evaluation for EMS System

Fig. 7 shows the average force obtained for each stimulus pulse width of each participant. The measured drag force tended to increase with increasing pulse width for each participant ($R^2 > 0.6$). However, the measured drag force decreased with increasing pulse width for pulse widths from 0 to 100 µs in participant 2 and from 200 to 300 µs in participant 4. It was also observed that the change in drag with increasing pulse width was not linear. These results suggest that differences in the physical characteristics of each participant can result in different thresholds of stimulus intensity at which a joint begins to move.

B. Perceptual Study

Fig. 8 and Table I show the discrimination results of the perception experiment of elbow joint stiffness change under static conditions. The numbers in the table indicate the percentage of correct responses for a total of 15 trials (5 levels, 3 sets). For all participants, the percentage of correct responses in the haptic condition was higher than in the visual condition, with an average of 6.1 points more correct responses. In the visual condition, the average correct response rate was 43.3%, whereas in the haptic condition, the average correct response rate was 84.0%. The Wilcoxon signed-rank test showed a significant difference in the number of correct responses between visual condition (Mdn = 6) and haptic condition (Mdn = 13), $W = 0$, $p = 0.0051 < 0.01$.

TABLE I
Discrimination results of the perceptional study

Participant	Visual condition	Haptic condition	Difference
P1	4/15	13/15	+9
P2	8/15	11/15	+3
P3	3/15	15/15	+12
P4	4/15	13/15	+9
P5	8/15	13/15	+5
P6	6/15	13/15	+7
P7	6/15	13/15	+7
P8	12/15	15/15	+3
P9	5/15	9/15	+4
P10	9/15	11/15	+2
Average[/15]	6.5 ± 2.76	12.6 ± 1.65	+6.1
Average[%]	43.3	84.0	+41.7

VII. Discussion

A. Performance Evaluation for EMS System

We measured and evaluated the elbow joint drag force during EMS to confirm that joint stiffness changes as the intensity of multi-channel EMS modulation. In all participants, the measured drag force tended to increase as the applied stimulus intensity increased. However, the regression analysis showed that the R^2 value was less than 0.9, indicating that the linear relationship between the measured drag force and pulse widths was lower than the results of Nishida et al.[13]. We applied the same stimulus intensity to all participants with EMS output pulse widths ranging from 0 to 400 µs to check for differences in individual characteristics. The stimulus intensity that Nishida et al.[13] used may be significantly higher than our maximum stimulus intensity because they determined the maximum stimulus intensity based on individual EMG measurements. The range of stimulus intensities that we applied was considered to have a threshold at which joint motion begins to be produced by EMS, thus more individualized features were obtained.

B. Perceptual Study

Since the TR systems currently in practical use are video meeting systems, we compared the discrimination performance between a video meeting system and the proposed method using multi-channel EMS for untrained participants. The discrimination performance of the proposed method was better than the visual condition for all participants, and the average number of correct answers was 6.1 points higher. It suggests the usefulness of the proposed method for TR by presenting force perception using multi-channel EMS.

The low average correct response rate of 43.3% in the visual condition was attributed to the difficulty of judging muscle contraction only visually within a limited angle of view when trying to discriminate joint stiffness. The fact that a certain number of correct responses were obtained even in the visual condition can indicate that the participants were able to visually confirm the muscle protuberance during muscle contraction. However, it is considered extremely

difficult to discriminate between the five levels of strength. In addition, the variability of correct responses across individuals in the visual condition (SD=2.76) was greater than that in the haptic condition (SD=1.65). It suggests that the visual condition is likely to depend on the perceptual ability of each individual. It should be noted that the results of the visual condition could be improved if experienced experts participated since this study was conducted with untrained participants.

On the other hand, the proposed method using multi-channel EMS can discriminate an average of 84.0%. It is considered superior in identifying different levels of muscle contraction, even during intense contractions near MVC. However, it is not always possible to obtain sufficient discrimination performance with EMG signals generated from the muscles of patients with different levels of paralysis, and this is an issue that should be considered in future studies.

The correct response rate for each participant in the EMS condition ranged from 60 to 100%. The results suggest that if changes in joint stiffness can be appropriately presented with the stimulus intensity calibrated for each person, the discrimination performance by force presentation is enough to be useful for understanding the modulation of joint stiffness of others.

C. Limitations and Future Works

The device we have developed treats human muscle activity as a relative value, which is highly dependent on individual characteristics, and it is impossible to obtain joint stiffness as an absolute value and simulate real spasticity. However, since spasticity is a state in which the antagonist muscles contract involuntarily[16], this method can be described as the presentation of a spastic state. We believe that this device can be used in clinical practice because relative evaluation based on MVC and manual evaluation based on the therapist's sensation are commonly used in the field of rehabilitation. We would like to establish a calibration method that is tailored to individual characteristics and improve performance.

In addition, since we have not been able to compare this experiment with the visual EMG feedback, we would like to clarify in future studies the effect of multi-channel EMS.

VIII. Conclusion

In this paper, we developed a remote interface between therapist and patient using multi-channel EMS for application to joint stiffness evaluation in TR. The device is wearable with adjustable settings and can be configured for wireless communication. In the performance evaluation, the measured elbow joint drag force tended to increase as the stimulation pulse width increased, and differences in characteristics between individuals in the low stimulation intensity range below 400 µs were confirmed. In the perceptual experiment, the haptic condition showed higher discrimination performance than the visual condition ($p = 0.0051$, the Wilcoxon signed-rank test), with an average discrimination performance of 84.0% for all participants. Although we could not obtain a five-step discrimination performance that could replace the MAS in clinical practice, we expect to improve the performance by calibrating the output signal parameters according to individual characteristics in the future. The method using multi-channel EMS has better discrimination performance than vision and is easier to implement than robotic systems. This suggests that it can be useful as part of a future TR system.

Acknowledgments

We sincerely thank Professor Dai Karasuno for his insightful recommendations on physical therapy practices and the experimental methods used in this research.

Causal inference predicts that muscle excitation is both a contributor and response to frontal plane dynamic balance during gait of older individuals with and without transtibial amputation

Arianna S. Monteiro, Matthew J. Major, and Nicholas P. Fey, *Member, IEEE*

Abstract— **More than 50% of individuals with lower-limb amputations and ~40% of older individuals (over 65 years old) fall each year. To optimize prosthetic intervention for fall prevention, it is important to understand the neuromotor control of balance. We use a data-driven approach, Convergent Cross Mapping, to determine the relationships between lower-limb muscle excitation and whole-body and segmental angular momentum in the frontal plane. These relationships were determined for 10 able-bodied older individuals and 13 older individuals with transtibial amputations at normal and fast walking speeds. The results suggest that there were several group and group-speed interaction differences, especially in the medial hamstrings of the intact and amputated legs at normal speeds, which exhibited stronger relationships between muscle activity and momentum of the whole-body, trunk and arms relative to control subjects. Difference between the subject group interlimb coupling was also observed by the stronger contribution of the gastrocnemius in the intact limb to frontal-plane momentum of the contralateral arm for persons with limb loss. Nearly equal numbers of relationships at both speeds showed muscle activities of the lower extremity were most predictive of subsequent (i.e., future), current or previous states of angular momentum, suggesting that muscle activity is responsible for generation, regulation and likely a response of/to dynamic balance in the frontal plane, respectively. Finally, this approach analyzes the functional outcomes of prosthetic intervention and how amputation alters the neuromotor control of gait in older individuals. This analysis can be applied at the individual level to study effects of prosthesis selection.**

I. Introduction

Around 2.3 million people in the United States currently live with limb loss, where 91% of these cases result from lower-limb amputations (LLA) [1]. A major concern for individuals with LLA is the risk of falling, as around 52% of the population falls at least one time each year [2]. Falling not only compromises the quality of life but has also been associated with a decline in physical activity and social activities in older individuals as well as limb fracture and decreased prosthesis use in individuals with amputations [3], [4, 5]. Along with an increase in falls, individuals with LLA often develop secondary musculoskeletal conditions such as lower back pain and osteoarthritis, which may result from aberrant gait dynamics from compensatory mechanisms [6]. To better inform prosthetic designs that help reduce falls and secondary conditions from gait compensations, it is important to understand the neural control of balance and how it is regulated in individuals with and without LLA.

To quantify dynamic balance in older individuals with lower-limb amputations, the biomechanical measure of angular momentum (H), both whole-body and segmental, can be studied. H is a laboratory-based measure that is used to quantify rotations in three cardinal planes relative to the whole-body center-of-mass (COM) and has previously been associated with an increased risk of falling in individuals with LLA [7]. In this study, we are investigating H in the frontal plane, as older individuals have shown frontal plane instability after perturbations [8]. The consequences of falling laterally have also been associated with hip fractures and can severely impact the quality of life of older individuals with and without amputation [9]. However, the whole-body H alone does not provide a holistic view of the regulation of balance, especially in older individuals with lower-limb amputations. By studying the contribution of coordinated segments to the changes in the net whole-body H, researchers can gain insight into how balance strategies change in the absence of key lower-limb muscle groups. Previous literature has found that the trunk frontal-plane H increases during unanticipated transitions in able-bodied (AB) individuals [10]. These changes in trunk segmental H were also found in our previous study of older individuals with transtibial amputation (TTA); however, we found that these individuals also have an altered segmental H in the non-dominant leg/residual leg and in both arms during residual limb braking [11].

Although segmental H gives insight into differences in balance, it does not fully reveal the unique control mechanisms used by older individuals with lower-limb amputations to maintain dynamic balance. To gain insight into the control mechanisms used to generate H, muscle excitation can be studied through electromyography (EMG). Previous studies have found differences in muscle activation during braking of the residual leg bicep femoris, vastus lateralis, and rectus femoris of individuals with LLA compared to AB subjects [12]. We previously found similar results in the non-dominant/residual medial hamstrings during braking when comparing older individuals with and without TTA [11].

Since muscle forces create changes in H, simulations have been used to determine the relationship between muscle excitations and whole-body H in AB individuals. In the frontal plane, muscles like the vasti and adductor magnus contributed

towards rotations during early stance, and the gluteus medius, soleus, and gastrocnemius contributed to rotations during late stance [13]. However, since it is difficult to model aging pathologies, to understand these relationships in older individuals with TTA, we previously correlated muscle excitations with whole-body and segmental *H* [11]. The main findings highlighted that generally muscle excitation was positively correlated with *H*; however, in older individuals with TTA, a higher residual medial hamstring excitation was negatively correlated with whole-body *H*.

Though previous results demonstrate trends of muscle excitation to changes in whole-body and segmental *H* over the entire gait cycle, they do not define causal predictive relationships. In this study, we utilize Convergent Cross Mapping (CCM), a novel data-driven approach that uncovers causal interactions of dynamical systems, in its first application to gait analysis [14]. The goal of this study was to determine how transtibial amputation and speed conditions change the causal relationships between muscle excitation and *H* in older individuals during over-ground walking. We hypothesized that these relationships would change between subject groups and would be speed-dependent.

II. Methods

A. Subjects and Protocol

We collected data from 10 AB older individuals (5 males, 5 females; 72±4 years; 168±6 cm; 77±8 kg) and 13 individuals with transtibial amputations (10 males, 3 females; 71±4 years; 176±9 cm; 86±14 kg), where the etiology of the amputations was due to trauma (n=10), infection (n=1), cancer (n=1), and vascular complications (n=1). All participants were instructed to walk back and forth along a 10-meter walkway at two self-selected speeds, comfortable normal and fast to capture a minimum of 11 gait cycles for analysis. For the individuals with and without TTAs, the normal speed corresponds to 1.07 (0.18) m/s and 1.14 (0.21) m/s, respectively. At the fast speed, the individuals with and without TTAs walked at speeds of 1.38 (0.19) m/s and 1.53 (0.24) m/s, respectively. The participants were instructed to "walk normally and comfortably as if walking in the community" and "at a brisk pace without breaking out into a jog" for the normal and fast speed conditions, respectively. Our previous study demonstrated that the walking speeds were not significantly different between subject groups, so we considered the speed-associated differences of each group the same [11]. During the trials, the group with TTAs wore their clinically prescribed prostheses. Ethical approval was granted by the Jesse Brown VA Medical Center IRB and participants provided written informed consent.

B. Data Collection and Processing

The whole-body kinematic data were recorded using a 12-camera Vicon motion capture system (120 Hz). The individuals were instrumented with a modified Helen Hayes marker set. The kinetic data were measured using ground reaction force plates (960 Hz) and were exported into Visual3D (C-Motion), where a 4th-order low-pass Butterworth filter with a 6 Hz cut-off frequency was applied. Then, a 12-segment model was applied to each participant, where the residual limb of the model applied to individuals with TTAs was adjusted according to mass and center of mass properties [15]. Then, laboratory-based measures of whole-body and segmental angular momentum (*H*) were calculated in the frontal plane. The *H* was calculated for each participant and speed condition, which was then normalized by body mass, height, and speed. In the analyses, the dominant leg in the AB group was compared to the intact leg of the group with TTAs. EMG data were recorded (960 Hz) using Delsys sensors on the tibialis anterior (TA), medial gastrocnemius (GAS), rectus femoris (RF), medial hamstring (HAM), and gluteus medius (GMED) on both legs, as appropriate and was synchronized with the *H* data. A band-pass filter (cut-off frequency 30-350 Hz) was applied to the EMG signals [16, 17]. After filtering, the signals were rectified, and a linear envelope was applied using a moving RMS (window size of 100 ms). The gait events labels which determined the start and end of a gait cycle were identified manually based on the motion of the heel and toe marker.

C. Data Analysis

Causal inference relationships were determined by the extended version of Convergent Cross-Mapping (CCM) [14, 18]. CCM is based on Takens' Theorem, which states the unobserved dynamics of a system can be reconstructed using time delays of a single observed variable in the system. Thus, if X causally influences Y, then X leaves information in Y [14]. Therefore, information about the hidden causal variable can be recovered given observations of the caused variable. This means that the response variable (Y) can be used to determine past values of the causal variable (X). Prior to performing CCM, the optimal embedding dimension, or the number of interacting variables, was determined to be 3 using Simplex projection [19]. Then, a 3-dimensional time delay embedding (τ=1) was computed for each EMG channel, whole-body *H*, and segmental *H* time series. These embeddings were then cross-mapped to the other variable. For example, if the whole-body *H* embedding (Y) can be used to predict the behavior of an EMG (X), then it is said that y cross-maps x (X causes Y). To determine the strength of the causal influence, this cross-mapped variable is Pearson correlated with the original signal (α=0.05). For example, the cross-mapped estimated whole-body *H* (using the EMG embedding) is Pearson correlated with the original whole-body *H* signal. If the correlation coefficient converges as the number of randomly sampled points increases, then it can be concluded that the two variables are causally related. The overall strength of the causal relationship is determined by the "skill" (ρ) value that it converges to. The ρ of the cross-map is computed as the average of the latest convergent correlation coefficients.

To understand if the causal variable acts on the response variable with a time delay, we used the extended CCM and performed cross-mapping with time lags (τ) -4 to 4, where each time lag is 1% of the stride [18]. This time lag range represents a temporally distributed sampling strategy where a window is repeatedly sampled across the entire gait cycle. A negative τ signifies a lag in the response to the causal variable and a positive τ means that the causal variable precedes changes in the response variable, indicating a lead. The more negative τ is, the larger the forward prediction. The ρ at each time lag was also computed for each participant and was

averaged across strides, then the average and standard deviation were computed for each subject group.

To fully capture the temporal behavior of physiological processes from the initial muscle excitation, muscle force production, and the subsequent change in velocity of body segments which contribute to changes in angular momentum, we conducted time lag analysis. These time lags account for 58 ms and 48 ms during comfortable normal and fast walking, respectively, which fully captures the natural occurrence of the activation and deactivation of muscles as well as electromechanical delay [20-22].

D. Statistical Analysis

Each participant's average ρ for each whole-body and segmental *H* v. EMG was used to compute group and group-speed interaction significances. To determine these significant differences, we used linear mixed modeling. We defined the subject groups (AB and individuals with TTAs) and the speed conditions (normal and fast walking) as the fixed effects and the participants as the random effect. We computed this statistical test in MATLAB for each time lag and highlighted significant group and group-speed interactions (α=0.05).

III. Results

The relationships between muscle activation and whole-body and segmental *H* were dependent on the group as well as the speed conditions (Fig. 1).

A. Subject Group Differences

There were significant subject group differences between the dominant TA and the whole-body *H* (τ: -4 to 4 as well as the trunk *H* (τ: 1 to 4), shown in Fig. 1 (blue or green) and Table I (in bold). The intact TA was more predictive of *H* for the group with TTAs compared to those without. These group differences were present in the dominant GAS and the non-dominant arm (τ: -4 to 4) where the group with TTAs had a higher prediction of *H*. The dominant RF had group differences in the dominant arm contributions to *H* (τ: -4 to 4) where the group with TTAs had better normal walking prediction of *H* compared to the AB group. In the non-dominant RF, there were significant group differences with the whole-body *H* (τ: -4 to 4) and the non-dominant leg *H* (τ: -3 to 4). In this comparison, the residual RF was more predictive of whole-body *H* but less predictive of non-dominant leg *H* for individuals with TTA compared to the AB individuals. Compared to the other EMG group differences, the dominant and non-dominant HAM had the most significant subject group differences with *H*. Specifically, the dominant HAM had significant group differences between the whole-body *H* (τ: -4 to 4), the trunk *H* (τ: -4 to 3), the non-dominant leg *H* (τ: -4 to 2), the dominant arm *H* (τ: -4 to 4), and the non-dominant arm *H* (τ: -3 to 2). In all of these relationships, the group with TTAs was better at predicting changes in *H*, except for the non-dominant leg *H*. Similarly, the non-dominant HAM had significant group differences with the whole-body *H* (τ: -4 to 4), the trunk *H* (τ: -4 to 0), and the dominant arm *H* (τ: -4 to 3). For this muscle, the group with TTAs was more predictive of *H* compared to the AB group. Lastly, only the dominant GMED had group differences with the trunk *H* (τ: -4 to 4), the dominant arm *H* (τ: -4 to 4), and the non-dominant arm *H* (τ: -4 to 4), where the group with TTAs had a stronger predictive relationship to *H*.

B. Subject Group-Speed Differences

Table I indicates that there is a significant group-speed difference in the relationship between the dominant TA and the whole-body *H* (COM) during fast walking. The strongest causal relationship (ρ) was found to be at τ=-1, therefore, according to CCM, the dominant TA is predictive of future changes in the whole-body *H*.

Table I. Maximum ρ values and time lags (% stride) for each causal relationship between an EMG and the whole-body or segmental *H*. The time lag at which the max ρ is found is the time of the strongest causal relationship where the muscle acts on the *H*. The more negative the τ is, the better the forward prediction. WN and WF denote normal and fast walking speeds, respectively and the COM denotes whole-body *H*. The values in bold in the WN and WF sections are significant group differences and significant group-speed differences, respectively.

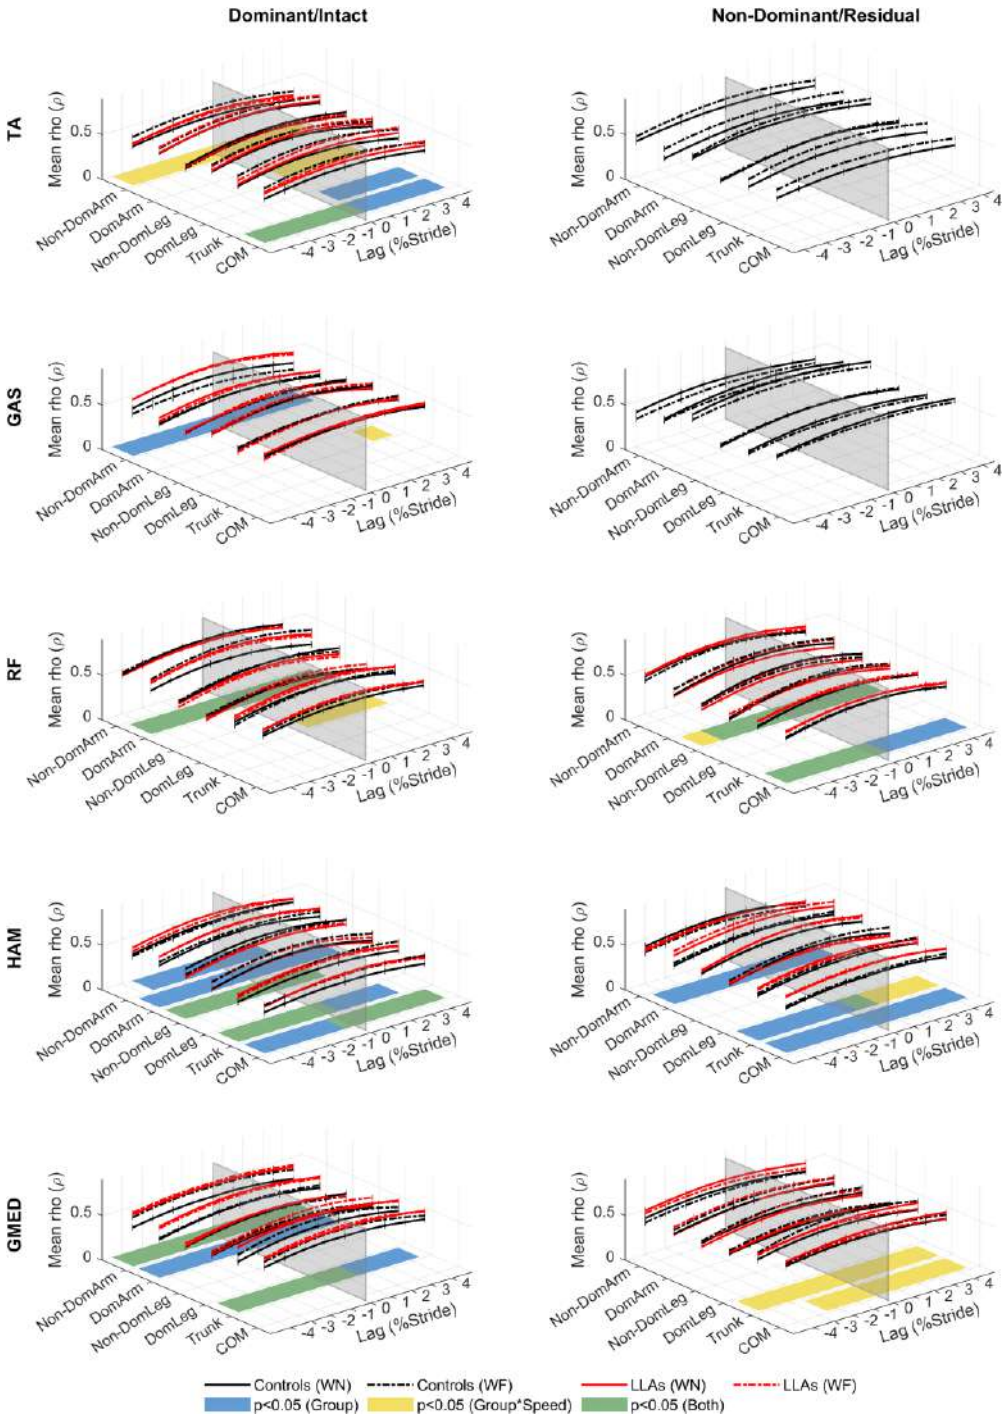

Figure 1. 3D plot of mean and 95% confidence intervals of the observed rho (ρ) vs. lag (% stride) vs. segmental *H*. WN and WF are normal and fast self-selected walking, respectively and COM is denoted as the whole-body *H*. The AB controls are labeled in black and the group with TTAs are in red. The ρ values signify the converged value of the correlation coefficient between the EMG cross-mapping the *H* and the true *H*-value. Higher red ρ values compared to black ρ values are interpreted as a stronger muscle to *H* causal inference relationship in older individuals with TTAs compared to those without. The shading underneath the curves signifies group and/or group*speed differences.

There were significant group-speed differences between the dominant TA and the whole-body *H* (τ: -4 to 0) and the non-dominant arm *H* (τ: -4 to 4). With the dominant TA, the prediction of whole-body *H* increased drastically at fast speeds in the AB group but remained similar in the group with TTAs. However, in the non-dominant arm *H,* the predictability decreased at fast speeds for the group with TTAs but increased in the AB group. The dominant GAS did not have any forward prediction causal relationships with *H*. The dominant RF had group-speed differences between the dominant leg *H* (τ: 1 to 4) and the dominant arm (τ: -4 to 4). The dominant RF predictability of the dominant leg *H* increased at fast speeds in the group with TTA; however, the opposite relationship occurred with the dominant arm *H*. The non-dominant RF had group-speed differences in the whole-body *H* (τ: -4 to 0) and the non-dominant leg *H* (τ: -3 to 4).

The predictability of the whole-body *H* and non-dominant leg *H* increased at higher speeds in the AB group and the group with TTAs, respectively. The dominant HAM had group-speed differences with the whole-body *H* (τ: 0 to 4), trunk *H* (τ: -4 to 0), and the non-dominant leg *H* (τ: -4 to 2). For this muscle, the predictability of the whole-body and trunk *H* increased at fast speeds in the AB group. There were group-speed differences in the dominant GMED and the trunk *H* (τ: -4 to 1) and the non-dominant arm *H* (τ: -4 to 4) as well as in the non-dominant GMED and the whole-body *H* (τ: -2 to 4) and trunk *H* (τ: -4 to 4), where the predictability increases at fast speeds in the AB group.

IV. Discussion

The goal of this study was to determine how TTAs and walking speed affects the forward prediction of causal relationships between muscle excitation and *H* in older individuals during over-ground walking. We accepted our hypothesis that these relationships would be subject group-dependent and would vary depending on walking speed.

We implemented a novel data-driven model to investigate the causal influence of muscle excitation on whole-body and segmental dynamic balance of the frontal plane. Interestingly, CCM has previously been used to determine the causal influence of the center of pressure on the center of mass in handstands [23]. However, previous analyses lacked information about the time-varying relationships between the two dynamical data. In this study, we apply time-dependent causal interaction analysis in its first application to gait to investigate how time changes the strength of these causal relationships. This method is beneficial in understanding the dynamic complexities of the relationships between lower-limb amputation and balance.

The most consistent findings in support of our hypothesis related to group differences were shown in the dominant and non-dominant HAM. The HAMs are often related to the generation of sagittal hip extensor moments during early stance to accelerate the leg as well as during braking in late swing [24]. However, these contributions to hip extension and the acceleration of the leg also demonstrate changes in the frontal plane. Previous studies have hypothesized that in individuals with TTAs, the residual leg HAM muscle activity increases to compensate for the lack of ankle plantar- and dorsi-flexors [12]. Fig. 1 shows that both the intact and residual HAM of the individuals with TTAs have a higher causal inference of whole-body and segmental contributions to *H* compared to the AB individuals. The only exception to this result is between the HAM and the contralateral leg *H*. In these cases, the HAM was a better causal predictor of the contralateral leg *H* in the AB group, which may be related to their more symmetrical gait pattern. Overall, the intact and residual HAM in the group with TTAs was a contributor to changes in *H* as there were more negative optimal time lags; however, in the AB group, the dominant and non-dominant HAM was a response, which was demonstrated by the positive optimal time lags.

Another significant finding that confirms previous literature is the group and group-speed differences seen between the residual RF and the whole-body *H*. The RF functions mostly to transfer energy from the leg to the torso during transition from load bearing to swing in the sagittal plane [25]. Our findings relate the non-dominant/residual leg RF activity to the frontal plane changes in *H*. Previous studies have described that the residual RF is more active during braking in individuals with TTAs and that the RF activity changed depending on speed [12]. We found that the residual RF in individuals with TTAs had a stronger predictive causal inference on whole-body *H* compared to AB individuals. This may suggest compensatory mechanisms used by these individuals to aid with braking and/or leg swing in the absence of the TA and GAS [7]. Both subject groups had more negative optimal time lags, suggesting that the RF is contributor to changes in *H*.

The TA and GMED demonstrate predictive causal differences between subject groups and group-speed interactions with the whole-body and trunk *H*. In all of these relationships, the group with TTAs demonstrated better causal relationships with *H*. The GMED's role in maintaining pelvic tilt is supported by the causal relationships in Fig. 1 [26]. Surprisingly, the group with TTAs had a stronger causal relationship between the GMED and the trunk, even though the residual GMED has been seen to have smaller abduction moment arms compared to AB group [27]. This may suggest the adoption of altered motor control strategies in individuals with TTAs in the absence of the TA and GAS, which is reflective of the distal to proximal redistribution of work.

Our findings also relate lower-limb muscle excitation to changes in upper-limb segmental *H*. These relationships indicate that the intact leg GAS was more predictive of the contralateral arm *H* in the group with TTAs. This may indicate that interlimb coupling changes in individuals with TTAs and suggests that a unique control mechanism may be used to compensate during the propulsion and braking of their residual limb [11]. One limitation of our study is that we also only investigate muscle activation causing changes in *H*. However, it is beneficial to study the opposite relationships to determine if there is an external driving factor that influences both muscle activation and *H*. In future applications, we also hope to analyze these causal predictive relationships in all three planes.

Our analyses could extend to applications in prosthesis selection. While the prosthesis across participants in the TTA group was not standardized and this may be considered a study limitation, our analysis characterized individual neuromotor signatures which accounted for the effects of each unique prosthesis and captured generalized differences between subject groups. Therefore, determining the causal prediction of muscle excitation to changes in *H* could help inform our understanding of how prostheses can be optimized to maximize dynamic balance for a person, which is particularly important for older individuals. These relationships could also guide prosthetic control systems. While current prosthetic technology frequently optimizes for factors like comfort or efficiency, many designs struggle to account for the detailed nature of how the user regulates their movement around the constraints of their prosthesis [28]. The data-driven modeling of muscle excitation can be used to inform intent recognition or the prediction of *H* that drives adaptive prostheses and exoskeletons. Recent studies show promising ubiquitous exoskeleton assistance through instantaneous estimates of lower-limb biological joint moments [29]. These

instantaneous estimates could be made for the relationships with an optimal time lag of 0, as shown in Table I. With these known muscle and *H* relationships, it could be possible to create balance-assistive devices for example. Previous studies also highlight the need for a fast reaction time of assistive devices to improve standing balance [30]. However, this need for the device reaction to precede physiological responses is even more important for dynamic balance during gait which relies on rapid responses to support postural control. By investigating optical time lags that occur at values less than 0, our applied method of CCM helps to inform the development of devices that forwardly react to postural disruptions to restore balance during gait and subsequently avoid a fall.

V. Conclusions

The results highlight that the causal predictive relationships between muscle excitation and dynamic balance are affected by the limb loss and walking speed. Between subject groups, the strength of relationships gives us insight into possible compensatory mechanisms used by individuals with lower-limb amputations and highlights how neuromuscular control changes at faster walking speeds. Also, the time-varying conditions demonstrate the role of muscles as a potential contributor, regulator and response to dynamic balance during gait. By determining the causal relationships and the time or phase-dependent delays at which they generate changes in angular momentum, we seek to utilize the user's control mechanisms to inform the development of prosthetic technology that can optimize behavior to maximize dynamic balance for preventing falls and secondary impairments.

Muscle Network Analysis of a Dynamic Bilateral Task With an Upper Limb Exoskeleton

Vladimiro Suglia, Cristian Camardella, Gianluca Rinaldi, Domenico Chiaradia, Domenico Buongiorno, Hui Zhou, Antonio Frisoli, Daniele Leonardis, Vitoantonio Bevilacqua

***Abstract*—The coordination between muscles during the execution of a bilateral task can be analyzed by recurring to functional muscle networks, which indicates how human muscles are mutually synchronized - i.e., share an oscillatory common input - during the motor task. So far, no studies have studied the impact of an assistive exoskeleton on the neural substrates of human muscles. This work addresses this question by extracting functional muscle networks of healthy individuals during the execution of a bilateral dynamic task without and with the support of a shoulder exoskeleton. The outcomes have revealed a global stationarity of these networks, together with a slight change of synergies' shape, reflecting how the employed assistive device can change physiological patterns from both temporal and frequency domains. Despite the limited sample size, the authors claim the potential of functional connectivity analysis as an additional tool for the evaluation of inter-muscular coordination for such clinical purposes as rehabilitation robotics.**

***Index Terms*—Electromyography, Muscle Network, Muscle Synergies, Wearable Devices, Robotics, Exoskeleton, Rehabilitation, Assistance.**

I. Introduction

The shoulder joint plays an important role in various activities of daily living (ADLs), such as donning and doffing [1], drinking or eating [2]. However, the execution of such bilateral tasks involving shoulder flexion may be difficult to accomplish in case of impairments due to either a a neuromotor disorder [3] or the acute phase of post-surgery recovery [1]. Hence, shoulder movements should be assisted to prevent impaired people - e.g., post-stroke survivors in the acute phase [4] - from exploiting compensatory strategies to perform bilateral ADLs.

Robotic exoskeleton can be designed to support motor tasks entailing the shoulder joint for either healthy [5] and pathological subjects [3]. Nevertheless, such non-physiological patterns as the altered activity of non-assisted muscles are hypothesized to occur when performing motor tasks supported by an exoskeleton [6].

Functional muscle networks indicates how muscles are reciprocally synchronized [7] and allows to investigate inter-muscular coordination during the execution of a motor task by highlighting its neural substrates in the frequency domain [8]. Three frequency bands, which are the alpha, the beta, and the gamma (or Piper) bands, can be used to arrange muscle networks.

Functional muscle networks have been employed to analyze many bilateral tasks involving lower limbs, such as running [9] and walking [10], as well as postural control [8]. A few works employed functional connectivity analysis to study upper-limb motor tasks, which were mainly focused on the investigation of fatigue onset in healthy subjects [11] or isometric force generation in post-stroke patients [4]. Cancrini and colleagues used muscle synergy analysis to compare the execution of reaching tasks by both stroke and healthy participants in terms of inter-muscular coordination [12].

This work applies functional muscle networks to study the influence of an exoskeleton on the motor features exhibited by humans while performing a bilateral upper-limb task that mainly involve the shoulder flexion. The presented study contributes to the state-of-art through a functional connectivity analysis of the execution of a bilateral dynamic task by healthy people with and without an upper-limb shoulder exoskeleton [13]. Therefore, this work compares muscle networks and the corresponding metrics in the two conditions of free-execution and robot-assistance.

The article is structured as follows: Section II describes the exoskeleton, the experimental setup and protocol employed for data acquisition, and the methodology necessary to determine muscle networks; Section III reports and discusses the outcomes of the data analysis; ultimately, Section IV draws final remarks about the conducted study.

II. Methodology

A. Participants

Experiments have been performed on nine healthy subjects (27.64 ± 2.46 years old, all males, all right-handed except for one), who have neither a former familiarity with occupational exoskeletons nor any neuromotor disorders and gave informed consent before the experiments. The experimental sessions conformed to the standards of the Declaration of Helsinki and have been ethically approved by the Scuola Superiore Sant'Anna Ethical Review Board, ID 152021.

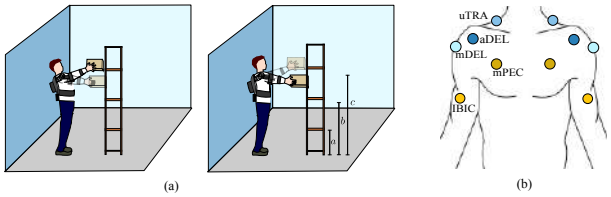

Fig. 2. Experimental setup. (a) The workspace used for the experiments encompasses a shelving unit with three heights (*a*, *b*, and *c*) from which the subject picks up a box and to which they shelve the object. (b) Placement of the EMG sensors on the human body.

B. Experimental Setup

1) Exoskeleton: Flexos is a light exoskeleton prototype that actively supports the shoulder flexion. The remaining passive shoulder degree of freedom is implemented by means of a kinematic structure; hence, torques can be transmitted from the active joint and the exoskeleton links can adapt to the body posture. The exoskeleton is made up of soft interfaces that are hand sewn to 3D-printed rigid parts. The subsystems of this robotic device are depicted in Fig. 1.

The exoskeleton is linked to the human body by a rigid interface positioned at the back, and by two links, fastened at the arms through Velcro straps. An underactuated kinematic chain, which is in parallel to the human arm, connects those two human-robot contact points: while one side of the chain is linked to the back interface, the other extremity is fixed to a series elastic actuator (SEA). This actuator is made up of a brushless DC motor (Motor AK80-9), which may transmit a maximum torque of torque of 9 Nm for assisting shoulder flexion.

Flexos is ensured to be portable thanks to a backpack, which embeds the communication and electronic control units, together with the energy storage, which is a LiFePO4 battery with a mass of 1 kg, a current of 10 Ah, and a voltage of 24 V.

The electronics communicates with three inertial measurement units (IMUs), which are placed on the two arm interfaces and at the back interface, and reads angular displacement from the SEA. It supports 500 Hz Ethernet communication with a 1 kHz control loop and an external PC. A previous work provides additional details about the electronics implementation [13].

A closed-loop torque control is integrated to partially compensate the gravity torque connected with a system to be lifted, which may be either integral to an additional object or the only arm.

The supporting torque comes from the combination between a gravity compensation control law u, which relies on a PID controller tuned according to the Ziegler-Nichols method, and a joint torque, which is used as a feedforward contribution and is estimated by the SEA according to Eq. 1:

$$\tau_j = k_j \sin\left(\frac{\gamma}{2}\right) \tag{1}$$

where k_j is the first-order joint stiffness, which was experimentally measured in [14], and γ is the angular displacement. This control law τ_m, which gives the motor torque command, is converted in a current value for the motors. The structural integrity of the exoskeleton is pursued by limiting the delivered torque to 5 Nm.

The reference torque τ_{des} is computed as follows:

$$\tau_{des} = \tau_{max} \sin(q - \phi) + K_{imu}\dot{q} \tag{2}$$

where $K_{imu}\dot{q}$ is a feedforward contribution depending on the velocity and allowing to consider the user's intentions, τ_{max} is the maximum output torque, and $\tau_{max} \sin(q-\phi)$ is the contribution related to the gravity compensation. Furthermore, the arm angle q is the difference between the series elastic joint angular displacement γ and the motor angular position θ.

This exoskeleton was originally designed for power-augmentation applications, but it is used to investigate the outcomes of muscle network analysis during a bilateral dynamic task, which recruits the shoulder motion in such ADLs as reaching overhead positions [15].

2) Motion tracking: Kinematic data are collected by means of a motion tracking system that entails three trackers (VIVE Tracker 3.0), which are placed at each subject's wrist and the target box, and four base stations (HTC SteamVR Base Station 2.0), which are located at the four sides of the experiments room. Kinematic measures (i.e., linear and angular positions and speeds) are transmitted at 250 Hz with the UDP protocol from each tracker to the PC. A SteamVR application is run on an external PC to manage trackers and base stations with a Python script.

3) Electromyography: A Trigno Wireless Biofeedback System (Delsys, Natick Massachusetts, USA) is used to measure the electromyography (EMG) activity of five upper-limb muscles that are biceps brachii (lBIC), anterior deltoid (aDEL), medial deltoid (mDEL), pectoralis major (mPEC), and upper trapezius (uTRA). For each body side, a Trigno Avanti and a Trigno Quattro EMG Sensor are comprised in the setup (Fig. 2c) and the SENIAM guidelines are followed to place each sensor uniton the human body [16]. The Delsys Trigger Module is utilized to synchronize the EMG recordings with those of the exoskeleton and the trackers.

4) Experimental Protocol: The experimental protocol comprises a dynamic task, in which the participant is asked to stay in front of the shelving unit with three shelves at a reference distance of 70 cm from the unit before starting the task execution. This shelving unit is the same for all subjects and has the characteristics reported in Table I; nonetheless,

TABLE I
DIMENSIONS CHARACTERIZING THE SHELVING UNIT.

Parameter		Value [m]
Shelving unit, *middle* shelf height	b	1.20
Shelving unit, *top* shelf height	c	1.59

it has not been modified since the height does not differ too much across subjects (183.4 ± 3.1) cm.

The dynamic task has a maximum duration of 2 minutes and is divided into the following motor actions:

1) *Upwards motion*: The participant bilaterally grabs an object placed at the *middle* shelf and move it onto the *top* shelf; then, both arms are brought back in the resting position - parallel to the trunk.
2) *Downwards motion*: The participant picks up the box with both hands from the *top* shelf and shelves it back onto the *middle* shelf: afterwards, both arms are brought back to the resting position.

Two subsequent beats of a metronome set at 20 bpm defines the pace at which subjects' are asked to perform each transition (i.e., up, down, rest). The dynamic task is executed in two conditions, which are without (w.o. Exo) and with the exoskeleton (w. Exo) with the torque controller activated, and only with a box of mass of 3 kg to prevent the individual from being affected by fatigue. Such conditions are presented in pseudo-randomized order such that a bias connected with possible learning effects is minimized. The participant are told to wait for ten minutes before the next task execution for the sake of muscle relaxation, thus preventing the subject from excessively accumulating fatigue [17].

C. Data processing

EMG signals are preprocessed in different ways depending on whether functional muscle networks or muscle synergies are computed.

1) Functional muscle network: Raw EMG data are first band-pass filtered (5-500 Hz) and then full-wave rectified by means of a Hilbert transform [18] to remove artifacts and preserve the neural oscillatory modulations in the frequencies of interest ($<$100Hz), [19]. Subsequently, EMG data are normalized by each subject's maximum voluntary contraction (MVC) and segmented by visually inspecting the object linear position.

The matching between muscle activations is quantified with the inter-muscular coherence (IMC), which is computed by extracting coherence matrices. These matrices are first averaged across trials and subjects and then decomposed with the non-negative matrix factorization (NNMF) [20], thus determining the matrix H of coherence patterns and the matrix W of edge weights according to the following formula:

$$IMC_{f*n} = (W_{f*r} \cdot H_{r*n}) + E_{f*n} \tag{3}$$

where f is the frequency, r is the number of frequency components (i.e., the rank of the matrix), n is the number of muscle pairs, and E is the residual error matrix of the NNMF. The variance accounted for (VAF), which is computed with the Frobenius norm of matrices E and IMC, is employed to minimize the coherence patterns explaining the total variance of the IMC with a threshold of 90%. As a result, this method optimized the number of muscle networks, namely frequency components (C1 and C2).

After normalizing the matrix W such that unit vectors are achieved for each component, adjacency matrices are computed by binarizing with a threshold-based method such that only the top 30% of the weights are included. Functional muscle networks are graphically depicted with a set of nodes (i.e., the muscles) and edges (i.e., inter-muscular connections) which are represented by a different thickness depending on whether the weight value lies in a range of 0%-33%, 34%-66%, or 67%-100% of the maximum of the adjacency matrix.

2) Muscle synergies: Raw EMG signals are first notch-filtered (50 Hz), band-pass filtered (5-500 Hz) and full-wave rectified, before being low-pass filtered (8 Hz) to determine the envelope [21], [22]. Afterwards, EMG data are normalized by each subject's MVC and segmented by using the object linear position as a visual reference.

Ultimately, each processed EMG matrix is decomposed with the NNMF, thus attaining two matrices of synergies and activation patterns [8]. Muscle synergies, whose number is determined with the VAF criterion to explain the 90% of the variance [23], are then reordered by similarity [8].

D. Metrics and statistics

The potential influence of the exoskeleton on motor patterns during the dynamic task is evaluated by comparing the w. Exo and w.o. Exo conditions through different metrics.

At first, the Pearson correlation coefficient is exploited to compute the similarity between the corresponding muscle synergies in w.o. Exo and w. Exo conditions [24]. Secondly, the activation intensity in the muscular coherence is quantified by computing the RMS of the activation matrix H - namely IMCfreq - for the three frequency bands of interest, which are the α-band (1Hz-10Hz), the β-band (10Hz-30Hz), and the γ-band (30Hz-60Hz).

Two network metrics derived from graph theory are extracted from the adjacency matrices: the clustering coefficient (CC) indicates how the neighbors of one node are neighbors among themselves as well, whilst the betweenness centrality (BC) quantifies the centrality of one node within the network [25]. These indexes are locally computed for each node and can be used to determine a global measure by averaging the values of BC and CC across nodes; in doing so, a scalar value is obtained for each subject, condition, and frequency component. The Brain Connectivity Toolbox is exploited to compute the above-mentioned network metrics [25].

The normality distribution of the metrics is verified with a Shapiro-Wilk test with a significance level of $\alpha = 0.05$. A statistical comparison between the index values in the w. Exo and w.o. Exo conditions is performed by means of a non-parametric Wilcoxon signed-rank test for non-normally distributed sets and with a paired t-test ($\alpha = 0.05$) for normally

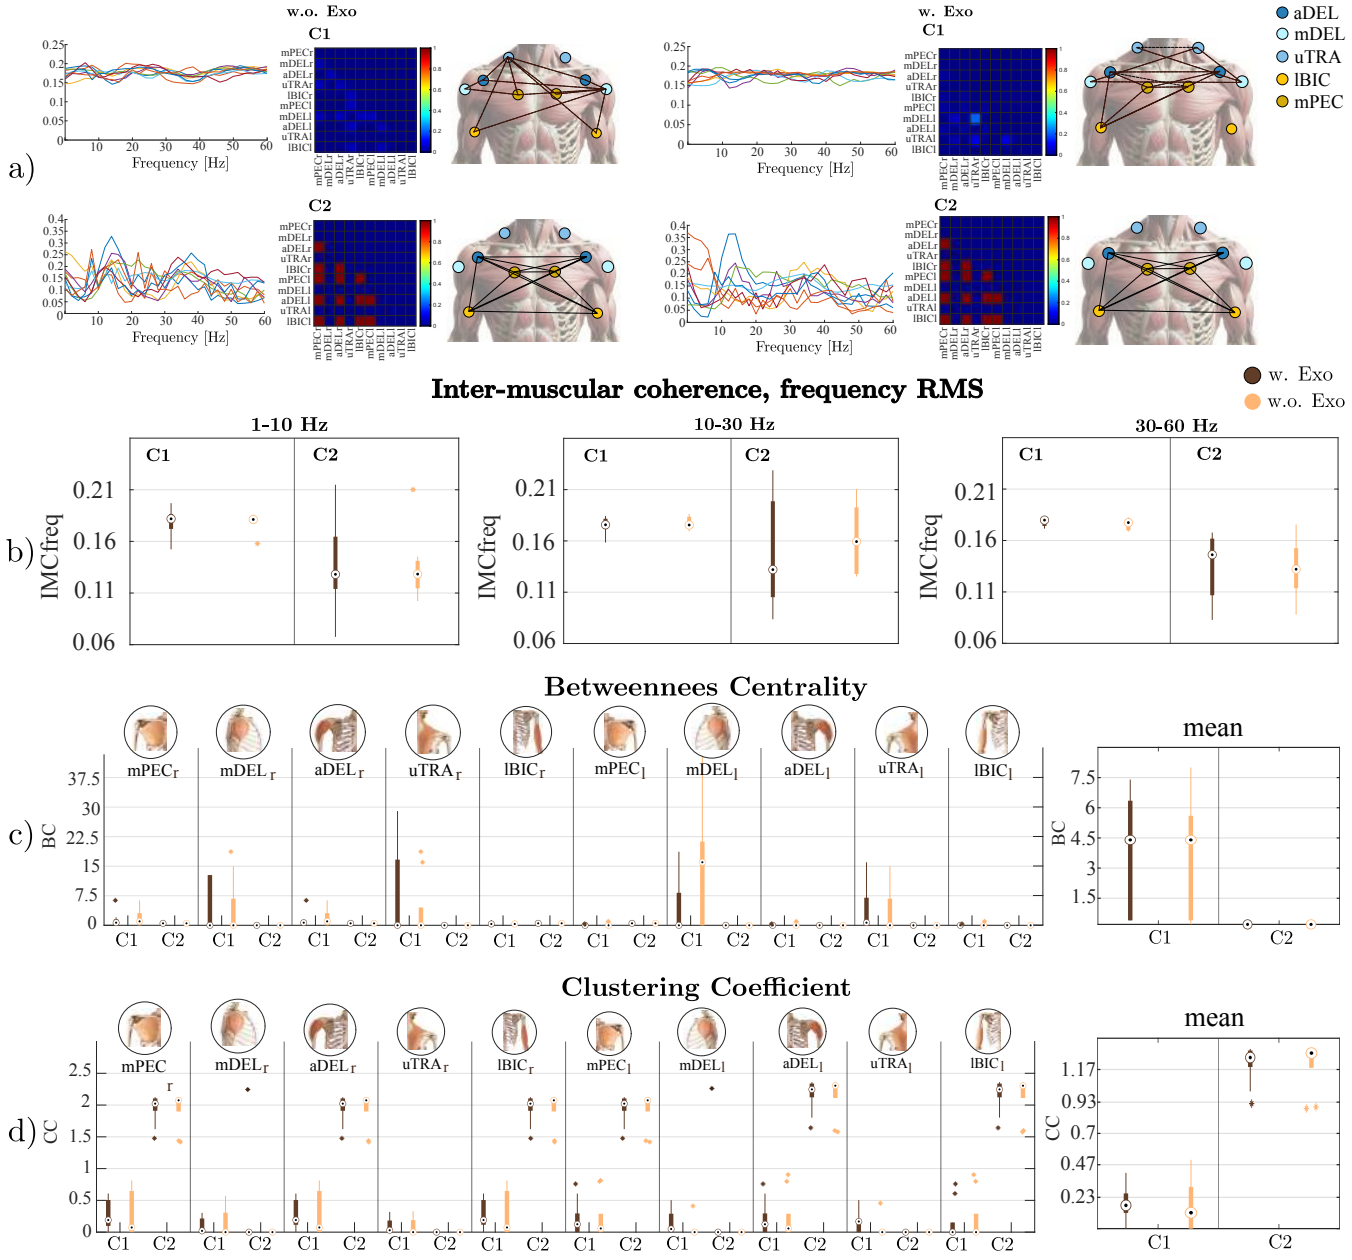

Fig. 3. Muscle network analysis outcomes of the dynamic task reported for both w.o. Exo and w. Exo conditions and both frequency components (C1 and C2). There can be found: a) the frequency components, the adjacency matrices, and the correspondent muscle networks; b) the RMS of the activation matrix H for the α-band (1Hz-10Hz), the β-band (10Hz-30Hz), and the γ-band (30Hz-60Hz); c) the betweenness centrality (BC) and d) clustering coefficient (CC), which are both computed for each muscle and averaged across muscles.

distributed ones. All the data analysis has been conducted using MATLAB 2022b and its toolboxes.

III. Results and Discussion

Functional connectivity analysis has allowed to determine muscle networks of the dynamic task, which are depicted in Figure 3 for both w.o. Exo and w. Exo conditions and both frequency components (C1 and C2) - see Subsection II-C.

As for Figure 3a, during a dynamic task the activation function oscillates in a limited range, which is larger in the second component than in the first one, and increases on average passing from the α-band (1Hz-10Hz) to the γ-band (30Hz-60Hz). However, for each component this frequency behavior is stable regardless of the condition - i.e., wearing the exoskeleton or not. The IMCfreq in the two conditions (Figure 3b) neither exhibits any statistically significant differences. For each condition, the network structure consists in bilateral connections that mainly involves shoulder flexors (e.g., aDEL, mPEC, lBIC) in the second component; on the other hand, the first component appears as a "support" for the lifting task, since such upper-limb muscles as uTRA and mDEL are more involved.

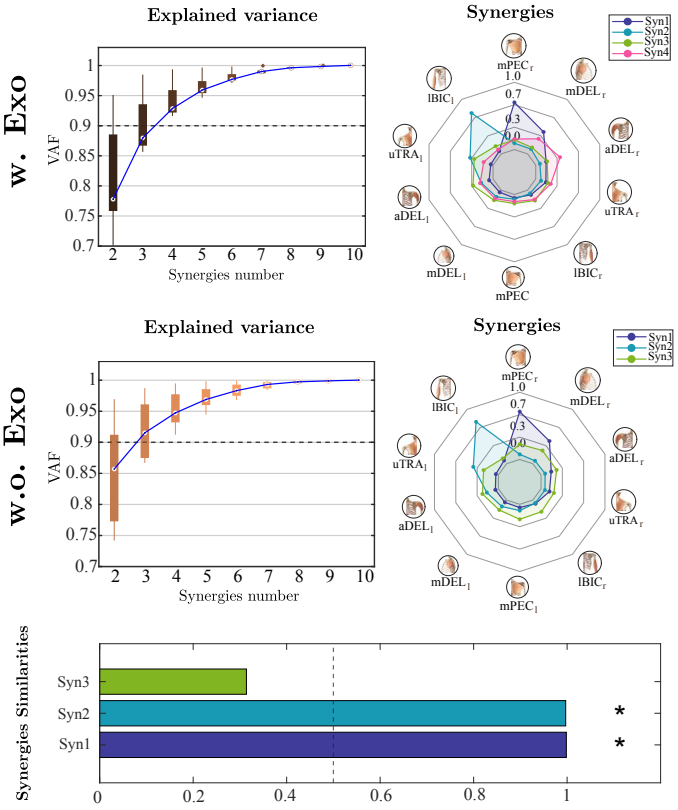

Fig. 4. Muscle synergies analysis outcomes of the dynamic task and for both w.o. Exo and w. Exo conditions. From the left side to the right side of the image there are: the cumulative of the variance explained for each number of synergies; the muscle synergies extracted with the NNMF algorithm; the similarity between the synergies related to the w.o. Exo and w. Exo conditions, where * represents a statistically significant correlation with $p < .05$.

The network topology, which is represented in Figure 3a, slightly changes between the two conditions in the first component. More in detail, the number of links between ipsilateral muscles is higher in the w.o. Exo condition than in the w. Exo condition, whereas the number of contralateral connections is lower in the former than in the latter condition; however, these inter-muscular connections are weak in both cases. In addition, the left uTRA and lBIC are isolated in the w.o. Exo and w. Exo conditions, respectively. On the other hand, the network structure is the same for the second component either wearing the exoskeleton or not. More specifically, in both conditions there are a few connections between muscles at the same side of the human body, whereas contralateral muscles are linked most of times. Furthermore, the trapezii and the medial deltoids are isolated, whilst the right mPEC, aDEL, and lBIC act as bridges allowing for direct connections between the two sides of the human body.

Accordingly, both network metrics BC and CC, which are respectively reported in Figure 3c and Figure 3d, change in the two components. Remarkably, considering the pectorales majores, the anterior deltoids and the biceps, the CC in the second component is higher (almost doubled) than the CC in the first component for each condition. Complementarily, the BC in the second component is lower than the one in the first component for the medial deltoids and the upper trapezii. Notwithstanding, no statistically significant differences can be found in terms of CC between the w.o. Exo and w. Exo conditions. The global measures of BC and CC follows the same pattern observed in the local counterpart.

The CC of one muscle reflects how the drives of its neighbors are synchronized among themselves as well, thus forming a cluster or not [25]. The complementary outcomes between the BC and CC, whether local or global, confirm that the network is more clustered in the second component than in the first one, in which case the segregated muscles are more central. Hence, a compensation strategy is arguably pursued to accomplish the dynamic task by recruiting the central nodes in the first component (upper trapezii and medial deltoids) to support the aggregated muscles in the second component (shoulder flexors).

The outcomes of muscle synergy analysis are depicted in Figure 4, which reports muscle synergies themselves and their number derived from the VAF-criterion, together with the similarity between the corresponding synergies in the w.o. Exo and w. Exo conditions. The minimum number of synergies describing the 90% of the variance differs with the condition, since it is 3 and 4 when wearing the exoskeleton or not, respectively. The first two synergies are almost the same and, accordingly, their similarity is statistically significant ($p < .05$). On the other hand, the third synergy exhibits the highest difference, as proved by the corresponding low similarity score. Wearing the exoskeleton led to the introduction of a fourth synergy that arguably contributes in a complementary way with respect to the third one: the synergy values are higher for the muscles at the right and left sides in the fourth and third synergies, respectively; nonetheless, they seem the decomposition of the third synergy extracted from the EMGs related to the w.o. Exo condition. Therefore, upper-limb muscles are mutually coordinated in a globally similar manner in terms of temporal motor pattern. The slight difference between the two conditions may be attributed to a higher difficulty of the task [26], which could have led to compensation strategies associated with the introduction of the exoskeleton acting as an external perturbation [15]. Such outcomes is analogous to other works in which either the patterns or the numbers of synergies are modified when an exoskeleton is worn [27]. It should be noted that an almost negligible alteration of muscle synergies should be pursued in the rehabilitative intervention aided by robotic devices, since motor performance should improve without altering natural muscular coordination patterns [15].

IV. Conclusion

In this work, functional connectivity between upper-limb muscles has been analyzed to investigate whether and how a shoulder exoskeleton influences the execution of a bilateral dynamic task in terms of muscular synchronization. The robotic support has kept muscle coherence globally unaltered,

while slightly but not excessively modifying the synergistic pattern, thus making functional connectivity and muscle synergy analyses two viewpoints on the overall investigation. In spite of the small sample size, the outcomes are in line with other studies evaluating robot-aided training oriented to rehabilitative purposes. Hence, the conducted method based on muscle network is claimed to be a valuable tool for assessing the motor recovery in clinical scenarios.

Design and Application of Vibrotactile Feedback to Influence Gait Symmetry*

Aileen C. Naef[1,2,†], Mathilde L. Legrand[1,2,†], Zoé Jungi[1], Roger Gassert[2], Olivier Lambercy[2], and Chris Easthope Awai[1]

***Abstract*— Recovering gait is crucial for improving independence and quality of life after neurological injuries. While conventional gait therapies are beneficial, biofeedback is gaining interest for its potential to enhance motor learning and personalize training. It was established in previous work that visual feedback, which typically engages explicit motor learning mechanisms, was able to induce changes to stance time symmetry ratio and overall gait. Therefore, the goal of this study was to examine if vibrotactile feedback, which typically engages implicit motor learning techniques, can also induce such changes. To examine this, fifteen neurologically intact participants walked on a treadmill with vibrotactile feedback being provided at the level of the left ankle, knee, and hip, aimed at inducing a 20% gait asymmetry. Results revealed that participants could use biofeedback to adapt their gait, although several did not reach the target asymmetry. Additionally, there was an average Gait Deviation Index decrease of 12.8 points, representing just over one standard deviation away from the control mean, with fair correlations observed between stance time symmetry ratio and both push-off force (r = 0.45) and vertical ground reaction force (r = 0.40) symmetry ratios. These findings suggest that vibrotactile feedback can effectively help modify temporal gait parameters while also impacting kinematic and kinetic parameters.**

I. Introduction

Stroke and Parkinson's disease are among the most common causes of gait disorders worldwide [1]. Given that gait is essential for functional independence and quality of life, addressing these impairments is a central focus in neurorehabilitation settings [2], [3]. This is often done by means of repetitive practice, a fundamental principle of motor learning [4], [5]. In conventional therapies, this process is unfortunately often hindered, as feedback on performance, a fundamental component for motor learning, is only provided verbally by the therapist [6], [7]; as such, it lacks specificity in the timing, frequency, and content as it remains subjective in nature.

One possible solution to overcome this limitation is the use of biofeedback in the rehabilitation process [8], [9]. For this purpose, biofeedback is defined as the addition of an external stimulus (e.g., visual, auditory, haptic) delivered to an individual on the basis of physiological or motor performance data, acting as an information feedback system [10]. This process is thought to enhance motor learning in both healthy and post-stroke patients as the information gained from the biofeedback can be used to detect errors in performance by comparing executed actions to expected goals, and provide information so that subsequent attempts can be adapted [11]. Multiple studies in the field have already reported that visual, auditory, and haptic biofeedback can have beneficial effects on gait in post-stroke patients [12], [13], [14], [15], [16], [17]. However, while effective, all biofeedback modalities for gait training typically target a single parameter at a time, which fails to capture the interconnected nature of gait [18]. Consequently, it is still unclear how biofeedback targeting a single gait parameter might influence non-targeted parameters, as well as the overall gait quality. Moreover, identifying the optimal sensory modality remains a challenge.

To address these uncertainties, we conducted a feasibility study in previous work [19], investigating the influence of visual real-time biofeedback on stance time symmetry ratio and gait as a whole. It is well established in the field of motor learning that various techniques can be employed for this purpose [20], [21]. Visual feedback, for instance, provides learning with information about performance outcomes through visual cues. An example of this is an individual observing a bar approaching a target value as their stance time increases, indicating proximity to their goal [19]. This process is attributed to explicit learning as it requires conscious observation and interpretation to achieve the desired movement [22]. Explicit motor learning typically engages higher cognitive processes, supported by various brain regions [20], [21].

Conversely, implicit learning occurs without the need for explicit cognitive focus on external cues [22], [23]. Mechanisms for implicit learning might involve tactile or kinesthetic cues, such as vibrations, pressure, or force, which engage somatosensory pathways [22], [23]. Legrand et al., demonstrated that visual feedback could provide information that influenced changes in stance time symmetry ratio [19]. This finding raises the question of whether similar outcomes could be achieved using vibrotactile feedback, which is more commonly associated with implicit motor learning mechanisms [24].

Therefore, using similar methods as those explained by Legrand et al. [19], this study explored the evolution of the stance time symmetry ratio between natural walking and

walking with vibrotactile feedback. As neurologically intact individuals typically do not present gait asymmetries, the ability of the vibrotactile feedback to influence the stance time towards an asymmetric symmetry ratio was examined. This was done by examining the change in the Gait Deviation Index (GDI), a clinically meaningful metric of the overall gait pathology [25]. Additionally, the correlation between stance time symmetry ratio and the symmetry ratio of other spatiotemporal, kinetic, and kinematic gait parameters was examined. It is hypothesized that the neurologically intact participants of this study will be able to use the vibrotactile biofeedback in order to learn to walk with an asymmetric stance time. Moreover, it was expected that the change would not occur in isolation, thus decreasing the GDI while maintaining correlations with specific gait parameters such as the swing time symmetry ratio.

II. Methods

A. Participants

A total of 15 neurologically intact individuals (7 = female, 8 = male) participated in this study and ranged in age between 23 and 60 years of age (mean age = 35 ± 13.8 years). Participants provided their written informed consent after having the study information explained to them. The main inclusion criteria were a minimum age of 18 years, no identified sensory impairment (self-reported ability to feel the tactor vibration prior to study start), no acute or chronical musculoskeletal conditions or neurological disorders, and no reported gait impairments. Exclusion criteria included a history of neurological diseases, orthopedic diseases, rheumatologic diseases, epilepsy, or self-diagnosed acute or chronic psychiatric disorders. The study was approved by the ETH Zurich ethics committee (No. 2022-N-41) and carried out in accordance with the current version of the Declaration of Helsinki.

B. Study Design and Procedure

This study was conducted in a Computer Assisted Rehabilitation Environment (CAREN, Motek Medical), which includes a ten-camera motion capture system (Vicon Motion Systems Ltd), a split-belt treadmill with integrated force plates, and a handrail. Upon their arrival to the study room, participants were equipped with optical motion capture markers on 26 anatomical landmarks as defined by the Human Body Model 2 (HBM2) [26]. Using this system, gait parameters were computed in real-time and used as input for the vibrotactile biofeedback system. The setup used six of the nine available tactors of the commercially available Elitac Wearable Science Suit (Elitac B. V.) to provide the vibrotactile biofeedback. To simplify the vibration pattern and avoid restricting the walking movement due to the cabled connection of the tactors, two tactors were placed at each the ankle, knee, and hip joints on the left leg only; the control unit was worn at the hip (Fig. 1). While precise placement was not required, placing the tactors on tendons was avoided so as not to induce tendon vibration, which in turn could activate the muscle spindle afferents and initiate a muscle contraction as a result of the tonic vibration reflex [27]. Two tactors were placed as close together as possible at each location and used simultaneously to generate greater vibration intensity, with the activation of the two tactors being perceived as one due to their proximity.

For this study, the first step was to determine the preferred gait velocity for each participant. This was done using the self-pace mode of the treadmill meaning that the treadmill adapted to the users' walking speed following a one-minute period of walking at 1.3 m/s. The mean speed from two-minutes of self-paced walking was defined as the preferred gait velocity. Subsequently, participants completed a five-minute baseline measurement at their preferred gait velocity followed by a feedback phase of 11-minutes (Fig. 2). During the feedback phase participants walked at 80% of their preferred gait velocity to ensure they had enough time to react to the vibrotactile biofeedback and adapt their walking pattern. Data collected for minutes two, three, and four of the baseline walking were used to calculate the baseline symmetry ratio (see subsection II.C for more information).

During the feedback phase, participants were tasked with adapting their stance time. The feedback phase, which participants completed once, started with one-minute of natural walking, followed by three-minutes of feedback (FB) during which the participant was asked to react and modify

Fig. 2. Schematic outlining the experimental protocol. Abbreviations: FB, feedback; No FB, no feedback; Min, minutes; PGV, preferred gait velocity.

their gait according to the vibration of the tactors. Next, was a one-minute no feedback block (No FB), followed again by a three-minute FB block and a three-minute No FB block. The participants were instructed to try to retain the altered gait pattern also in the No FB blocks. This was done to prevent over-reliance on the feedback, which is important to ensure that the learned behavior can persist beyond the training period [11].

C. Symmetry Ratio for Biofeedback

As many post-stroke patients exhibit asymmetric gait, the aim of this feedback in the patient population would be to help train and induce gait symmetry [28]. However, this pilot study was conducted on neurologically intact individuals who did not suffer gait asymmetries. For this reason, the goal of the vibrotactile biofeedback was to induce gait asymmetry in the participants as a simple way to test the potential of our approach to influence gait symmetry. To achieve this, the vibration pattern of the feedback gave information about the current value of a left gait parameter with respect to a target value to be reached. The gait parameters computed included: stance time, swing time, step length, step width, angular plantarflexion at toe off, maximum knee flexion, mean vertical ground reaction force during stance phase, and push off force (antero-posterior ground reaction force at toe off). Per gait parameter, the target value was defined to achieve a specific asymmetry ratio defined as a measure of symmetry as in (1):

$$SR = (\text{left parameter value})/(\text{right parameter value}) \quad (1)$$

Therefore, the target value for the left leg could then be calculated as seen in (2), using data from the right leg as a reference. To reduce the variability over consecutive steps, the mean was taken over the last three gait cycles. Finally, the mean was multiplied by the target symmetry ratio (80% of the baseline walking symmetry ratio). The target was set to be in line with a pre-study conducted on the topic, and aligns with a change sufficient to represent pathological gait [29].

$$Target = 0.8 \times BSR \times \left(\frac{right_0 + right_{-1} + right_{-2}}{3}\right) \quad (2)$$

where Target represents the left target value, BSR corresponds to the baseline symmetry ratio of the gait parameter of interest, and $right_0$, $right_{-1}$, and $right_{-2}$ stand for the right parameter value in the current, last, and second last gait cycle, respectively.

The calculated symmetry ratio and target value was compared with the actual value of the current step. The feedback was subsequently given at the left toe off based on the deviation of the actual value achieved by the left leg (see subsection II.D). In other words, the target value for the left side was defined as being 80% of the symmetry ratio recorded during baseline walking.

Before beginning the feedback phase, participants were provided with the following information: i) that the side to be adapted based on the provided feedback was the left side; ii) the parameter targeted by the feedback was explained (i.e., what is stance time); and iii) how to interpret the vibration pattern (see subsection II.D). No information was provided to the participants about the gait pattern they should achieve (i.e., no information about symmetry being influenced). No other feedback (e.g., visual information about performance) was provided during the study.

D. Terminal Feedback Design

The vibration pattern used for this study was referred to as terminal feedback, meaning the feedback was provided directly after the motor task execution (i.e., after each step during the FB blocks) [8]. The terminal feedback was designed to vibrate for a fixed 0.4s starting at the toe off event of the left leg. Subsequently, based on the participant's performance with respect to the target value, a different tactor location vibrated (i.e., ankle, knee, or hip). When the targeted stance time was properly achieved (margin of ±5% based on a pre-study), the knee tactors vibrated, indicating to the participant that they did not need to adapt anything. If the vibrations were felt at the ankle or the hip it indicated that the stance time was too low or high, respectively, to correspond to the target value. The duration of the vibration felt at the hip or ankle also provided additional information, whereby the further away the current value was from the desired target value, the longer the vibration was. It was then up to the participant to interpret the meaning of the vibration and make real-time adaptations to their gait pattern. The intensity of the vibration was set to the highest possible setting for this device; this was deemed necessary in a pre-study assessment to ensure that the vibration of the treadmill did not interfere with the tactor vibration.

E. Data Analysis

Pre-processing of the motion data was performed using Vicon NexusTM (Vicon Motion Systems Ltd UK) and a python library, Gaitalytics, before being exported and analyzed using Python 3 (Python Software Foundation) [30]. Spatiotemporal and kinetic data were retrieved directly from Gaitalytics using the motion capture data, while kinematic parameters were retrieved from the D-Flow software (Motek Medical B. V.).

To evaluate the effectiveness of the vibrotactile biofeedback in modifying stance time, the symmetry ratio between the natural walking phase and the last minute of the second FB block was compared. A Linear Mixed Model was implemented in R (R Core Team) with the natural walking and the last minute of the second FB block as the fixed effects. The participant IDs were considered random effects. A significance level of 0.05 was defined. The scaled GDI, as defined in Schwartz et al. [25], was also computed for the natural walking and second FB block to assess the evolution of the overall gait pattern.

Additionally, Spearman's rank (ρ) coefficient was calculated to study the monotonic relationship between the stance time and the additional gait metrics [31]. For the computation of these coefficients, the symmetry ratio of the natural walking phase and the last minute of the second FB block were used. No statistical comparison was conducted due to the naturally high correlation between gait cycles.

III. Results

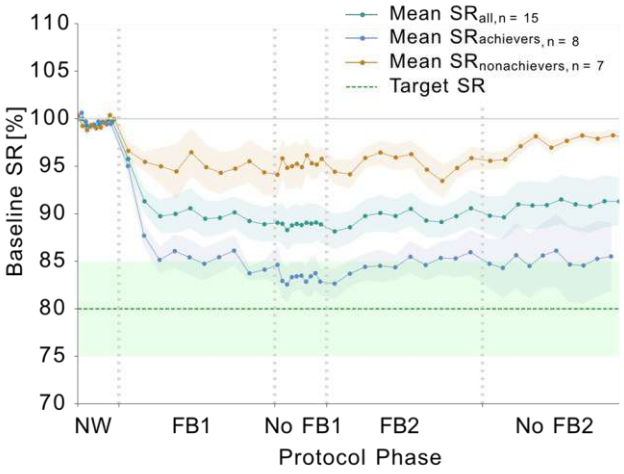

Fig. 3. Evolution of stance time symmetry ratio. Mean symmetry ratio of all participants and the split into *achievers* (blue) and *non-achievers* (orange). Abbreviations: FB, feedback; No FB, no feedback; NW, natural walking; SR, symmetry ratio.

A. Gait Symmetry

When examining the evolution of the stance time symmetry ratio over the course of the feedback phase, an ability to adapt the stance time towards the target could be seen (Fig. 3). Results from the Linear Mixed Effect model showed a statistically significant difference between the stance time at the end of the second FB block compared to during the natural walking ($p < 0.001$; CI = [-0.130, -0.057]). However, at the group level, while all participants responded to the feedback resulting in their stance time symmetry ratio becoming pathologic, the symmetry ratio did not decrease enough in all participants to reach the target value. Upon visual inspection, two separate groups could be distinguished based on their symmetry ratio during stance time; specifically, it was seen that only half the participants managed to adapt and maintain their stance time symmetry ratio to fall close to or within the target value margins (Fig. 3). Those that were able to reach the target margins were considered to be *achievers*, versus *non-achievers* who did not reach the target margins. It could also be seen visually that participants were able to maintain the altered symmetry ratio during the No FB blocks. Compared to the natural walking block, all changes were found to be significant in the second No FB block (all: $t = 3.66$, $p = .003$; *achievers*: $t = 3.99$, $p = .005$; *non-achievers*: $t = 6.06$, $p < .001$).

In addition to the stance time symmetry ratio, the symmetry ratios of the swing time ($t = 4.64$) and mean ground reaction force ($t = -5.32$) at the end of the second FB block were found to be significantly different from the symmetry ratios during natural walking ($p < 0.001$). The symmetry ratios of the push off force ($t = -1.19$, $p = 0.256$), step width ($t = 0.294$, $p = 0.773$), and step height ($t = 1.04$, $p = 0.315$) were not found to be statistically different at the end of the second FB block compared to natural walking .

B. Gait Deviation Index

The GDI is z-scaled, with a reference value of 100 set for the control group mean. The scaled GDI was calculated as the mean across all participants during natural walking and the last FB block. The stance time GDI during natural walking was found to be 100.4 and decreased to 87.6 (left leg = 84.2; right leg = 91.0) during the second FB block. These results were found to be statistically significant based on a paired t-test (combined: $t = 4.90$, $p < .001$; left: $t = 6.77$, $p < .001$; right: $t = 3.03$, $p = .009$). As explained in previous work, a GDI value of 100 indicates a gait that is absent of any pathology (i.e., there is no gait abnormality present) [25]. Every 10 points below 100 represents one standard deviation away from the control gait with no abnormality present. This indicates that the GDI achieved during the second FB block was approximately one standard deviation away from the control gait when both the left and right legs were averaged. However, when examining the legs separately it can be seen that there was a greater decrease in GDI on the left leg (i.e., the side the feedback was applied to) compared to the right.

C. Correlation Between Gait Parameters

The Spearman's rank correlation was computed to assess the monotonic relationship between the stance time symmetry ratio and the symmetry ratio of additional gait parameters (Table 1). The correlation found a negative relationship between the stance and swing time symmetry ratios. A positive correlation with the stance time could also be noted for both the push off force and mean ground reaction force. No other correlations of note were present.

IV. Discussion

The primary objective of this study was to assess whether vibrotactile biofeedback could be used to influence stance time symmetry ratio, specifically to enforce gait asymmetry in neurologically intact individuals. The results indicate that participants were able to quickly adapt their gait to achieve an altered, namely asymmetric, stance time. This shift occurred rapidly, within the first three-minute FB block, supporting the hypothesis that biofeedback can induce changes in gait. Additionally, this alteration in stance time symmetry ratio did not occur in isolation; it was accompanied by a reduction in the GDI and correlated with changes in the symmetry ratio of other gait parameters. These are important considerations for the potential use of biofeedback for the implementation of more personalized gait rehabilitation.

However, in line with the findings of Legrand et al. individual responses to the feedback varied, with only a subset of participants closely approaching target asymmetry [19]. A closer analysis of stance time evolution showed that

TABLE 1. SPEARMAN'S RANK CORRELATION COEFFICIENT BETWEEN THE SYMMETRY RATIOS OF STANCE TIME AND ADDITIONAL GAIT PARAMETERS.

	Swing Time	Push Off Force	Ankle Plantarflexion	Step Length	Step Width	Step Height	Mean GRFz[a]	Knee Flexion
Spearman (Rho)	-0.76	0.45	0.15	-0.12	-0.05	0.05	0.40	-0.02

[a]Vertical ground reaction force (z axis)

although a group of participants (*non-achievers*) did not reach the 20% target asymmetry shift, they did achieve an approximately 5% asymmetry shift. This amount of asymmetry could still be interpreted as a pathological gait pattern, in line with the study's aim [29]. Despite potential challenges in fully comprehending the feedback, non-*achievers* still adapted their gait towards asymmetry. It was noted that these participants adjusted both their left and right foot stance times almost equally, thus maintaining a balanced symmetry ratio despite altering their gait. Because the target symmetry ratio was calculated based on values from both feet (equation 1), these participants were unable to achieve the target asymmetry. This division into *achievers* and *non-achievers* suggests that identical feedback may not be intuitively interpreted by all individuals, hence indicating an individual variability. Providing participants with additional guidance on the symmetry ratio target, or providing the biofeedback on both legs, might have reduced the number of *non-achievers*. However, in this study, symmetry ratio information was intentionally withheld to allow participants to explore the feedback themselves. It is of course also possible that there are inherent limitations in the presentation of the biofeedback that made it less suitable for stance time feedback versus another potential target gait parameter.

When focusing on stance time symmetry ratio, noticeable alterations in gait patterns could be observed, as reflected by a decrease in the GDI during the feedback phase relative to natural walking. Since the GDI only incorporates spatial parameters (e.g., step length, step width) we know that these findings (i.e., decrease in GDI representing a global change in gait quality) come only from kinematic changes in the gait. This implies that even a targeted adjustment to stance time symmetry ratio can affect kinematic parameters (e.g., joint angles, velocities, accelerations) [25]. This result is promising, as it suggests that targeting a single gait parameter may influence overall gait, potentially benefiting rehabilitation. However, there is a caveat: this approach could also pose a risk, as it could lead to unintended maladaptive movements in patient populations. Since compensatory movements were not specifically examined, it is unclear whether they occurred. Changes in the GDI and correlations between the symmetry ratio of stance time and other gait parameters suggest a global shift in gait patterns. However, as healthy participants were deliberately pushed toward asymmetry, it is uncertain whether these changes reflect compensatory movements due to the lack of a reference point for distinguishing adaptive responses from maladaptive compensation. These observations should be kept in mind in view of implemented biofeedback on selected parameters for clinical applications.

Our correlation analysis sheds further light on the observed gait changes. As anticipated, a negative correlation was observed between the stance time symmetry ratio and the swing time symmetry ratio. This inverse relationship aligns with previous findings, reflecting the natural interaction between stance and swing time at a constant walking speed [19], [32]. Additionally, stance time symmetry ratio was positively correlated with push off force symmetry ratio and vertical ground reaction force symmetry ratio. These findings are consistent with the interconnectedness of stance time and these parameters, which may have an even more important role in post-stroke patients who often exhibit reduced stance time and force on the paretic side [33]. Legrand et al. found similar correlations in their study on visual biofeedback, specifically between stance time, swing time, push off force, and vertical ground reaction force [19]. Notably, while the knee flexion symmetry ratio correlated with the stance time symmetry ratio under visual feedback conditions, this association was absent with vibrotactile biofeedback. Neither this study, nor that of Legrand et al., found correlations between stance time (i.e., temporal parameter) and spatial parameters [19]. This suggests that alternative approaches may be necessary to explore how spatial symmetry can be influenced.

Moreover, while our findings apply only to neurotypical individuals, limiting their clinical interpretation, this limitation could be addressed by expanding the study to include neurologically impaired individuals. Together, our results and those of Legrand et al., reinforce the idea that modifications in a single gait parameter are rarely isolated [19], [34]. However, the broader implications of these changes, such as potential compensatory movements affecting other gait parameters, remains unclear. Another relevant limitation identified in this study would be the vibration intensity of the tactors. Some participants reported difficulty perceiving the feedback, with two participants only feeling the vibrations when actively pressing the tactor against their hip. This would be important to further examine to determine the optimal tactor attachment method, and what clothing should be worn during the measurements as these may both play a role in the vibration intensity felt by the participant. The ability to perceive the feedback may be particularly relevant for post-stroke patients, who often experience sensory deficits and may require a higher vibration intensity for effective feedback [35]. As the maximum vibration intensity of the Elitac Wearable Science Suit was already used for this study, this would need to be considered in future work.

While this study focused on the influence of vibrotactile biofeedback on stance time symmetry ratio, a spatiotemporal parameter, future research could explore the effects on kinetic and kinematic parameters. Additionally, comparing vibrotactile biofeedback with other biofeedback modalities, such as auditory or visual feedback, may provide insights into the most effective strategies for inducing gait changes as well as aspects such as the familiarization and adaptation time required for each.

V. Conclusion

This study found that terminal vibrotactile biofeedback was successfully able to influence gait symmetry in neurologically intact individuals. This change did not occur in isolation, with the change in stance time symmetry ratio generally influencing not only kinematic parameters, but also kinetic parameters as indicated by the decreased GDI and correlated gait parameters. These findings emphasize the importance of taking into consideration how using biofeedback to target a single gait parameter will most certainly also influence gait as a whole, and that care should be taken to not induce maladaptive movements.

Hybrid Brain Computer Interface-based rehabilitation addressing post-stroke maladaptive movement patterns

J. Toppi, *Member, IEEE*, G. Savina, E. Colamarino, V. de Seta, F. Patarini, F. Cincotti, F. Pichiorri, and D. Mattia

***Abstract*— Hybrid Brain-Computer Interfaces (hBCI) integrate brain and muscle signals to enhance motor rehabilitation of stroke survivors, by closing the loop between the lesioned brain and the paretic limb. To date, little attention has been devoted to their potential efficacy in managing the maladaptive movement patterns that afflict post-stroke motor outcome (unwanted abnormal co-contrations, spasticity). This study proposes a comparison of Cortico-Muscular Coherence (CMC) patterns assessed in stroke patients before and after a 1-month rehabilitation intervention based on a hBCI-controlled Functional Electrical Stimulation (FES) treatment, which included a module to monitor non-physiological movement patterns. Results demonstrated the efficacy of this type of assistive technology for post-stroke rehabilitation, addressing patient-tailored interventions able to reduce the maladaptive mechanisms.**

I. Introduction

Stroke is a major cause of adult disability. Upper limb motor impairment is often persistent after the acute event and is a crucial limiting factor that determines the patient's capability to regain social and work position [1]. Stroke modifies the connectivity between brain and periphery, resulting in impaired motor function with respect to physiological conditions [2] and is characterized by features related to maladaptive plasticity in terms of both compensatory and mirror movements, which should be monitored and discouraged during rehabilitation [3]. Several technological aids have been proposed to address upper limb motor recovery, and among those Electroencephalography (EEG)-based Brain-Computer Interface (BCI) systems [4]. BCIs rely on the reinforcement of motor related brain activity to boost post stroke plasticity underlying favorable motor outcome [5], [6]. Such reinforcement is provided within the closed-loop paradigm that is peculiar to the BCI approach, in which the patient receives instant feedback based on their own mental activity; such feedback can be visual or enriched with sensorimotor content as if provided by a Functional Electrical Stimulator (FES). The FES has been applied in stroke rehabilitation with beneficial effects on motor outcome in terms reducing spasticity and improving motor function and even muscle strengthening [4], [7]. Worth of note that electrical stimulation of muscle contraction needs to be synchronized with intended movement to restore motor function in paralysis condition. Hybrid BCIs (hBCI) are defined as systems that employ signals other than those derived from the brain, such as the muscular activity recorded via surface Electromyography (EMG).

Recently, Cortico-Muscular Coherence (CMC), an intrinsically hybrid feature encoding EEG-EMG coupling during voluntary motor actions [8], has been employed in BCIs for the real-time detection of different hand movements with high classification performances [9], [10] and proved to be a valid objective measure for the upper limb motor deficit assessment in stroke survivors [11]. Providing more complete and synergistic information could actually confirm the CMC as a valid measure to better identify and even monitor maladaptive plasticity effects than using same nature biosignals, e.g. EEG or EMG alone [12]. Specifically, in [11] we have identified CMC features related to unwanted co-contractions in a population of stroke patients and implemented their detection within a novel hBCI system in order to discourage them during hBCI-based FES training of upper limb.

The aim of this study is to evaluate the restoration of aphysiological brain-muscle communication in a convenience sample of post-stroke patients who underwent a rehabilitation training with such novel system, that is able to efficiently trigger the FES intervention and at the same time discourage dysfunctional movements.

II. Material and Methods

A. Participants

Five stroke participants recruited within the inpatients and outpatients services of Fondazione Santa Lucia, IRCCS, Rome, Italy, participated in the study. Demographic and clinical details were reported in Table I. The inclusion criteria consisted in i) first-ever unilateral, cortical, subcortical, or mixed stroke, caused by ischemia or hemorrhage, ii) upper limb hemiparesis that was caused by the stroke; and iii) age between 18 and 80 years. The exclusion criteria were the presence of (i) neuropsychological deficits preventing the ability to understand the instructions related to the experiment; (ii) concomitant diseases affecting the upper limb

motor function (i.e., orthopedic injuries or other neurologic diseases affecting reaching or grasping); (iii) spasticity of each segment of the upper limb scored higher than 4 on the Modified Ashworth Scale (MAS [13]); (iv) presence of any contraindication to FES (such as pregnancy, proneness to faint, epilepsy, compromised integrity of the stimulated limb, compromised sensation). The study was approved by the local ethics board at Fondazione Santa Lucia, IRCCS, Rome, Italy (CE PROG.752/2019) and all the participants signed an informed consent.

B. Study Design

All the patients underwent a 1-month rehabilitation intervention (three days per week for four weeks - 12 sessions) based on the hBCI-controlled Functional Electrical Stimulation (FES) treatment (described in section II.E) in addition to the standard rehabilitation program (usual care). At study entry (PRE) and at the end of the entire rehabilitation program (POST) all patients underwent a clinical/functional (section II.C) and neurophysiological (section II.D) screening to assess the effect of hBCI-FES-based rehabilitation training. Data collected in PRE session were also used to identify control features for the hBCI-FES system (section II.F).

C. PRE/POST Clinical/Functional evaluation

In PRE and POST sessions all patients were screened by means of the following clinical scales: i) the upper extremity section of the Fugl-Meyer Assessment scale (FMA), comprising the four sub-scales "Upper Limb", "Wrist", "Hand", "Coordination and Velocity" to describe the paretic upper limb residual function [14], ii) the Manual Muscle Test (MMT) to assess strength in the paretic upper limb testing shoulder abduction, elbow flexion/ extension and wrist flexion/extension [15] and iii) the MAS scale to assess spasticity of shoulder, elbow and wrist muscles [13]. For the purpose of this study, we considered only the FMA scale since it provides an overall measure of the motor function that we managed to restore.

D. PRE/POST Neurophysiological evaluation

The neurophysiological assessment consisted in the simultaneous collection of high-density EEG (61 electrodes at 1 kHz) and EMG (16 upper limbs muscles - 8 per side - at 2 kHz) signals during hand extension collected separately with the unaffected and affected hand (UH and AH, respectively) according to a block design approach. Each of the 2 per hand administered blocks consisted of 40 trials: 20 task trials of 8s each during which patients were asked to perform/attempt the extension (EXT) of UH/AH (4s of preparation and 4s of execution/attempt) and 20 rest trials of 4s each. The order of presentation for both i) trials within blocks and ii) blocks was randomly assigned and different for all the patients included in order to ensure as uniform as possible experimental conditions by preventing any learning, fatigue or expectancy effects which could influence the results beyond our aim.

EEG was recorded from the scalp by means of active electrodes (Brain Products GmbH, Germany) arranged according to an extension of 10–20 International System (reference on left mastoid and ground on right mastoid). Surface bipolar EMG signals were recorded by means of Pico EMG sensors (Cometa S.r.l., Italy) from the following 16 muscles: extensor digitorum (ED), flexor digitorum superficialis (FD), lateral head of the triceps muscle (TRI), long head of the biceps brachii muscle (BIC), pectoralis major (PEC), lateral deltoid (Lat_DELT), anterior deltoid (Ant_DELT) and upper trapezius (TRAP) of both sides (AH: and UH). EEG signals were band-pass filtered [3-60]Hz and Independent Component Analysis was used to remove ocular artifacts. EMG signals were downsampled to 1000Hz, band-pass filtered [3-500]Hz and the electrocardiographic component was rejected through template matching. A notch filter at 50Hz was applied to remove power-line artifacts on both signals and data were segmented according to the different experimental conditions. The EEG edge electrodes (Fpz, Fp2, AF8, F8, FT8, T8, TP8, P8, PO8, O2, Oz, O1, PO7, P7, TP7, T7, FT7, F7, AF7, Fp1) were excluded from the analysis to avoid synchronization between the EEG and EMG signal due to residual muscular component in the first one.

CMC was estimated as in [11] for each movement (EXT_AH, EXT_UH) and frequency band (Alpha [8-12] Hz, Beta [13-30] Hz) in both PRE and POST assessment sessions for each patient. We computed statistical CMC patterns at single-subject level by comparing (independent samples t-test, alpha=0.05) CMC values obtained for each band and EEG-EMG pair between task and rest conditions. In order to quantify the CMC patterns properties in each condition and describe their changes induced by the intervention we extracted objective indices measuring specific properties useful for describing the effect of hBCI-FES training over the patients' brain-muscles communication. In particular we computed the following indices for each patient and frequency band in PRE and POST sessions, which have already been proved to be valid CMC metrics for our purpose in a previous study [11]: i) CMC weight defined as the average strength of the connections linking the target muscle (ED in affected limb) and all the EEG electrodes considered in the study; ii) two indices related to network density describing in terms of total number of existing connections the dysfunctional involvement of proximal muscles (BIC, TRI, Lat_DELT, Ant_DELT) in affected limb or mirror movements (ED or FD) in unaffected limb.

E. Description of the hybrid Brain-Computer Interface system used in the study

The hBCI-FES device is a hBCI system that controls FES of upper limb muscles: the patient is asked to attempt simple upper limb movements (e.g., extension of fingers); the device recognizes (in correct trials) close-to-normal EEG-EMG co-

activation (see section II.G for details) and initiates FES of extensor muscles in the forearm. The hBCI-FES includes the following hardware components: i) an EEG and an EMG acquisition system used to record simultaneously brain and muscular activity; ii) a laptop where the hBCI software runs; iii) a FES stimulator (RehaMOVE2 system - Hasomed GmbH, Germany) used to deliver the stimulation to the patient. FIAB4 fully gelled electrodes are used for neurostimulation.

F. Experimental protocol used during the hBCI-FES-based rehabilitation session

The hBCI-assisted paradigm was designed as driven by the therapist and consists in several trials/repetitions of the rehabilitative exercise: at the beginning of each trial a beep sound is delivered informing the patient to get ready to attempt the movement, after 3s an acoustic cue "GO" invites the patient to start the task. The stimulation is delivered to the patient when a physiological movement is detected, without the need to continue attempting it. The target muscle is stimulated for 4s, after which the therapist's interface makes the therapist wait at least 8s before the next trial (duty cycle: 1:2 to preserve muscle fatigue development). After 4s from the acoustic cue, if no physiological movement is detected the trial ends with a "time out".

G. Extraction of control features for hBCI-FES system

EEG and EMG data acquired during the PRE neurophysiological assessment were used to select 2 hBCI-FES control features (CMC values obtained for two EEG-EMG pairs where the EMG channel is the target muscle - ED) [10] and, if present, 2 different features identifying the undesired involvement of muscles not directly related to the requested movement and that should be discouraged. FES is activated only when the BCI correctly classifies the movement attempt by means of the two control features, but at the same time, the CMC values obtained for the two discouraged features remained below a null-case statistical threshold of activation tailored for each patient. During the online BCI sessions, the EEG and EMG signals of the electrodes chosen during the feature selection were acquired, the attempted motor task was predicted and the EEG-EMG pairs to discourage were monitored along the rehabilitative exercise. FES parameters were set specifically for each patient at every session according to standard guidelines [16] to achieve full movement to avoid any kind of discomfort for them. Such parameters were identified stimulating in an open-loop modality the target muscle.

III. RESULTS

A. Clinical outcome evaluation

In Table I we reported for each patient the FMA scores collected at the enrollment and at the end of the rehabilitation programme. Worth of note is that all patients showed a trend of improvement, more evident in 3 out of them.

B. hBCI-FES system control features

A list of all the control and discouraged features selected for each patient is reported in Table II. In particular, the control features involving EEG channels contralateral to the hand involved in the movement in all the 5 patients were included. As for the discouraged features, in 3 out of the 5 patients we set a control for mirror movements (P02, P03, P04), while in P05 we control only for the involvement of proximal muscles of the affected limb. Only in P01 we discouraged movements involving both distal muscles of unaffected limb and proximal muscles of affected limb.

TABLE II. FEATURES SET IN THE HBCI-FES SYSTEM FOR EACH PATIENT

ID	Control Features	Discouraged Features
P01	FC5-EDR C1-EDR	P5-Lat_DELTR P6-FDL
P02	C1-EDR CP1-EDR	FC3-EDL
P03	C6-EDL P6-EDL	C3-EDR
P04	CP2-EDL C2-EDL	C3-EDR
P05	P5-EDR CP3-EDR	C3-BICR

C. Reinforcement of CMC patterns induced by hBCI-FES training

In Fig. 1 we compared the values obtained for CMC weight index extracted from CMC patterns in alpha and beta bands related to the extension of affected (panel a) and unaffected (panel b) hand in PRE and POST sessions. It is interesting to notice how, when patients attempted to execute the extension of their affected hand, the CMC value of the connections involving target muscle (ED of affected limb) increased after the hBCI-FES training in both frequency bands. Instead, during the execution of the extension of the unaffected hand the weights of CMC connections involving the ED of unaffected limb remained almost comparable between PRE and POST sessions. Together with an increase of this index involving particularly the target muscle (i.e., ED

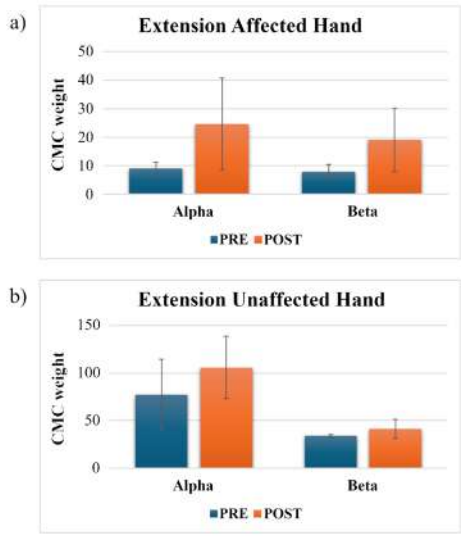

Figure 1. Barplot comparing grand average CMC weight index (average N=5 ± standard deviation) extracted from CMC patterns obtained in alpha and beta bands during the extension of affected (panel a) and unaffected (panel b) hand in PRE and POST sessions.

of affected limb), we obtained an evident increase even in variability characterizing the post-timepoints.

D. Reduction of maladaptive CMC patterns according to patients' specific features

In Fig. 2 and 3 we reported instead the PRE vs POST results for two representative patients who received a hBCI-FES training where specific dysfunctional movements were discouraged. In particular, Fig. 2 showed data related to patient P02 who was discouraged in executing mirror movements when attempting to extend the affected hand. By qualitatively comparing PRE and POST CMC patterns in both alpha and beta bands (panel a), we noticed how before starting the hBCI-FES treatment the patient showed CMC patterns strongly influencing the target muscle (ED in right limb) but also the ED in unaffected limb. Such behavior strongly reduces in the POST session. The reduction of mirror movements was confirmed by an evident reduction after the hBCI-FES training of the number of connections involving distal muscles of unaffected limb in both alpha and beta bands (panel b).

Fig. 3 showed the results related to the representative patient P04 who executed a hBCI-FES training which blocked FES activation everytime the patient engaged proximal

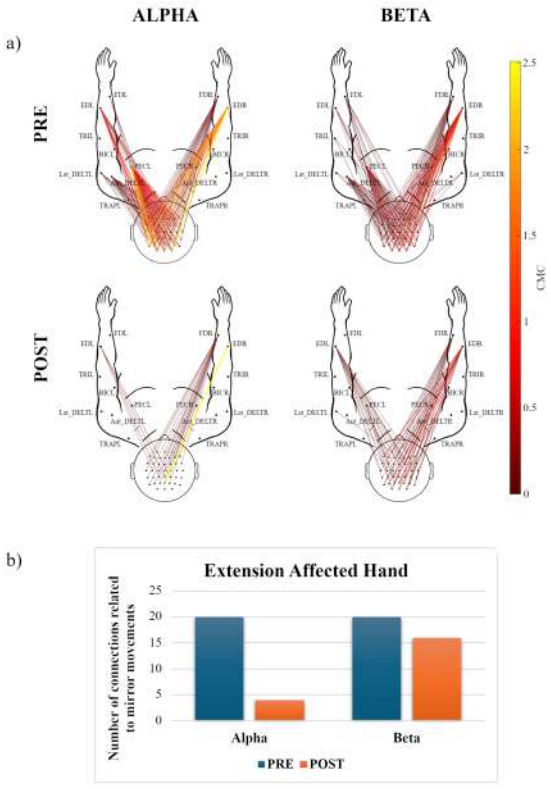

Figure 2. Results obtained for a representative patient (P02) in alpha and beta bands for PRE and POST training sessions in terms of a) CMC patterns during the extension of their affected hand (right) and b) number of connections related to mirror movements computed from CMC patterns.

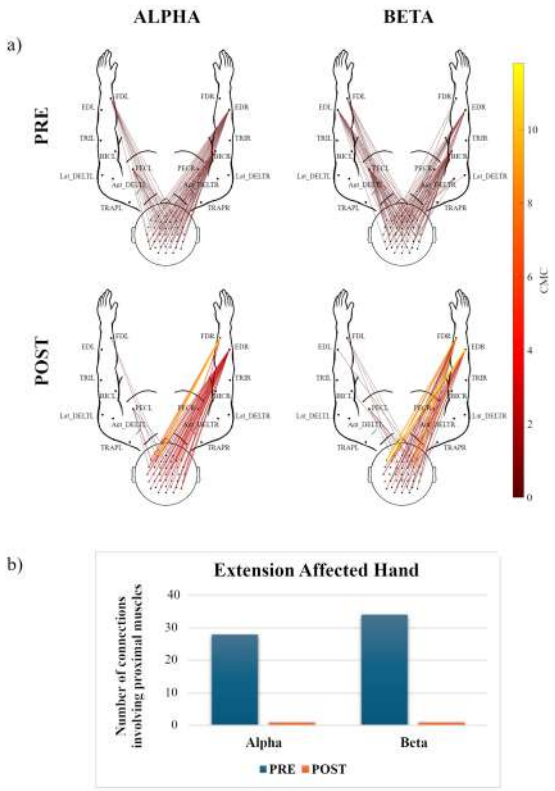

Figure 3. Results obtained for a representative patient (P04) in alpha and beta bands for PRE and POST training sessions in terms of a) CMC patterns during the extension of their affected hand (right) and b) number of connections involving proximal muscles of the affected limb computed from CMC patterns.

muscles of the affected limb when attempting to execute the AH extension. CMC patterns in PRE session showed the involvement of right BIC in both alpha and beta bands that was clearly reduced after the 1-month hBCI-FES training period (panel a). This is confirmed by a PRE vs POST reduction of the number of connections involving the proximal muscles of affected limb in both alpha and beta bands (panel b).

IV. Discussion

Our results confirm that hBCI-based FES training is able to reinforce CMC patterns involving scalp electrodes on the stroke affected hemisphere and target muscles on the paretic upper limb, thus efficiently closing the loop between the damaged brain and the periphery [9], [10]. CMC plays a critical role in motor control by reflecting the functional coupling between cortical and spinal motor networks, which is essential for voluntary movement execution and motor learning [8].

A reduction in CMC is observed after a stroke lesion and the magnitude of such reduction has been correlated with the severity of motor impairment [17], [18], [19]. This decline is thought to result from disrupted corticospinal connectivity and impaired sensorimotor integration, both of which are key targets for neurorehabilitation interventions [20], [21].

The restoration of CMC strength observed at the end of our intervention is particularly relevant, as it is specific to the trained upper limb and thus likely related to the training itself, suggesting that the improvement is directly related to the training itself rather than to generalized neuroplastic changes. Previous studies have shown that rehabilitative interventions that enhance CMC, such as neurofeedback training and brain-computer interface (BCI)-mediated therapies, are associated with improved motor function and neural reorganization in stroke patients [10]. However, while our data support the feasibility and neurophysiological impact of this intervention, its direct influence on clinical and functional upper limb motor outcomes requires further investigation. Larger-scale clinical studies with extended follow-ups are needed to establish whether CMC restoration translates into tangible improvements in motor performance and daily-life functionality.

The most innovative aspect of our hBCI-FES system is the ability to automatically detect and discourage specific CMC features related to maladaptive movement patterns. These patterns are often present in patients with stroke, and despite the efforts of specialized therapists, they remain a significant challenge in post-stroke rehabilitation. Traditional rehabilitation methods, while effective in promoting motor recovery, may not always be able to specifically target these dysfunctional motor synergies. The proposed system, by contrast, offers the advantage of real-time, objective assessment and intervention, allowing for continuous monitoring and immediate correction of unwanted motor patterns. The system automatically selects the most relevant CMC features based on the unique motor characteristics of the patient, ensuring that the intervention is personalized. This tailored approach contrasts with more generalized rehabilitation strategies, which may not always address the specific needs of each patient. While a specialized therapist is invaluable for guiding rehabilitation and providing personalized care, the hBCI-FES system provides a complementary role by offering an objective, automated mechanism that operates continuously. This has the potential to prevent the persistence of maladaptive motor synergies by providing real-time feedback that may be difficult to achieve during traditional therapy sessions, which are limited by time and the subjective nature of human observation.

Our results indicate both an increase of brain-muscles synchrony in the affected hand (targeted by the hBCI-FES intervention) and a reduction of the mirror and compensatory movements, as effect of the hBCI based training we proposed. We investigated it in both alpha and beta frequency bands since they are simultaneously active in motor planning and execution [22]. These results actually demonstrate the clinical significance of our work, specifically how the intervention we proposed well fit the recently born field of restoring physiological brain-muscle connections in post-stroke impaired upper limb [23], [24]. Specifically, alpha band seems to better encode this restoration than beta band in terms of grand average CMC weight increase and single-subject mirror movements reduction. This is probably due to the fact that alpha rhythm is primarily engaged for the local processing of information, whereas beta rhythm coordinates neurophysiological processes on a wider scale in sensorimotor tasks [25]. Moreover, the higher variability shown in post-timepoints could reveal a correlation between each patient's response to the hBCI system and the time since the event, that should be better investigated in future works even enlarging the sample's breadth.

One of the limitations of our work is the fact that patient's ability to perform the task was assessed only in a qualitative way. Future works may provide also kinematic measures. Despite the preliminary nature of this study, the results are promising for an application of CMC not only as a rehabilitation outcome metric but also as an online control feature for a rehabilitative hBCI, which to our knowledge is the first able to monitor and reduce post-stroke motor abnormalities.

ACKNOWLEDGMENT

We thank Giorgio Tartaglia (neurophysiology technician) for the support in data recording.

***Abstract*— Accurate and reliable digital twins of humans and wearable robots can revolutionize rehabilitation robotics. Here, we introduce MyoAssist 0.1, a sub-suite of MyoSuite focused on musculoskeletal simulation environments with assistive devices such as prosthetics and exoskeletons. This open-source platform enables the study and development of human-device interactions, control strategies, and assistive robotics. We present two new simulation environments: myoMPL featuring an arm amputee model with a robotic prosthetic arm, and myoOSL featuring a leg amputee model with a robotic prosthetic leg. The myoMPL environment features a bimanual manipulation task for a shoulder disarticulation amputee using a Modular Prosthetic Limb (MPL), where the task is to pick up an object with the biological hand, pass it to the prosthetic hand, and place it at a target location. The myoOSL environment simulates an above-knee amputee using the Open-Source Leg (OSL) to traverse challenging terrains such as rough surfaces, hills, and stairs. Despite some simplifications in modeling the nuanced constraints of human and prosthetic systems under real-world conditions, these environments provide a foundational simulation framework that supports interdisciplinary research on the interplay between musculoskeletal dynamics and assistive devices. Both myoMPL and myoOSL are featured in MyoChallenge, an annual competition at the NeurIPS conference. All code is accessible through the MyoSuite GitHub repository.**

I. Introduction

Simulation frameworks with accurate and reliable computational models of humans, rehabilitation robots, and their interactions have the potential to transform the field of rehabilitation robotics. These digital twins could enable researchers and clinicians to develop new rehabilitation treatments, refine assistive devices, study patient-specific responses, and optimize therapeutic protocols [1]–[5]. Despite substantial progress, the integration of human-prosthetic interfaces in real-world environments remains a challenge, necessitating the creation of computational models that represent the diverse and dynamic conditions encountered in daily life. Furthermore, learning motor behaviors in simulated musculoskeletal systems with robotic limbs remains an open challenge that requires collaboration across multiple disciplines to achieve successful outcomes [5], [6].

To collectively address these challenges, we are introducing MyoAssist, a sub-suite of MyoSuite focused on musculoskeletal simulation environments that integrate assistive devices such as prosthetics and exoskeletons [7]. MyoSuite is a collection of musculoskeletal environments and tasks in MuJoCo physics simulator [8] in the OpenAI Gym format [9]. Our vision is to create a unified framework where researchers can collaboratively develop and investigate assistive devices, advance sim-to-real transfer, and explore physical human-robot interactions in various settings. MyoAssist aims to foster a shared collection of models and task environments that facilitate the development and refinement of assistive technologies through an accessible and versatile simulation environment. The initial collection will primarily focus on wearable robots, such as exoskeletons and prostheses, with the intention to gradually extend to include other types of assistive devices. The long-term vision is that as MyoSuite advances to include musculoskeletal and control models of people with motor impairments, these models will be seamlessly integrated with MyoAssist.

In this paper, we present MyoAssist 0.1, which introduces two novel models and their respective environments: myoMPL, a model of a shoulder disarticulation amputee using the Modular Prosthetic Limb (MPL) in a manipulation environment, and myoOSL, a model of a transfemoral amputee using the Open-Source Leg (OSL) in a locomotion environment. The two environments are also featured in the most recent series of the MyoChallenge annual competition at the NeurIPS conferences [10], MyoChallenge'24 - Physiological Dexterity and Agility in Bionic Humans. The myoMPL environment focuses on bimanual manipulation in a scenario involving a shoulder amputee wearing an MPL [11], a robotic prosthetic arm starting from a shoulder joint, including the elbow and wrist joints, down to an articulated hand. The MPL is integrated with myoArm, representing a fully articulated intact arm with 63 muscles. The task is to use the intact arm to pick up an object, hand it over to the MPL, and place it at a target location. The myoOSL environment presents a robust locomotion task for an above-knee transfemoral amputee wearing an OSL [12], a robotic knee-ankle prosthetic. The OSL is integrated with myoLeg, a full-body model featuring an articulated leg with 54 muscles (40 in the intact leg and 14 in the hip joint of the amputated leg) to traverse various

terrains.

This paper will first review the current status of MyoSuite and MyoChallenge (Section II). It will then present the details of the myoMPL (Section III) and myoOSL (Section IV) environments, including descriptions of the musculoskeletal and prosthetic models, task setups, reward structures, and baseline controllers. Lastly, we discuss the implications of these environments and outline our future plans to extend MyoAssist with more assistive devices and scenarios (Section V).

II. MyoSuite and MyoChallenge

MyoSuite [13] is an open-source collection of environments and tasks consisting of musculoskeletal models that run in the MuJoCo physics simulator [8], wrapped in a reinforcement learning-friendly interface, OpenAI Gym API [9]. By November 2024, MyoSuite consisted of 7 models and 300 environments/tasks and had been downloaded over 70K times on PyPI alone. All the MyoSuite software including the new environments presented in this paper, myoMPL and myoOSL, are accessible through the MyoSuite GitHub repository [14].

The MyoSuite team has been hosting the MyoChallenge as an official annual competition at the NeurIPS conference, since 2022. The themes include "Learning Physiological Dexterity" (2022) [10], "Towards Human-Level Dexterity and Agility" (2023) [15], and "Physiological Dexterity and Agility in Bionic Humans" (2024) [16]. The myoMPL and myoOSL environments were featured in the MyoChallenge'24, and are released as part of the collection of task environments in Myosuite [7]. The MyoAssist 0.1 initiative was introduced to organize and expand musculoskeletal simulation environments that integrate assistive devices, such as prosthetics and exoskeletons, under a unified framework within MyoSuite.

III. myoMPL Environment

The myoMPL environment simulates a shoulder disarticulation amputee using the Modular Prosthetic Limb (MPL) [11] for a bimanual manipulation task (Fig. 1). The goal is to train a policy to hand an object over from the biological arm to the prosthetic arm and then maneuver the object to a specific target location. The control space includes both muscle activations of the biological arm and motor actuators for the MPL. In the current version, users have the flexibility to either focus on exploring the complexities of controlling a bimanual system with a single policy (without explicitly modeling the limited access to the state and action of human-prosthetic controls in real-world scenarios) or to implement their own policy constraints that better reflect the specific conditions of their system of interest.

A. myoArm and Modular Prosthetic Limb

The right arm of myoArm model is adopted, which comprises 27 degrees of freedom (DOFs) and 63 muscle-tendon units. The model was converted from OpenSim MoBL arm model [17], [18] via MyoConverter [19], [20] and has been used in previous MyoChallenges for manipulation tasks [10], [15]. The entire left arm is replaced with MPL.

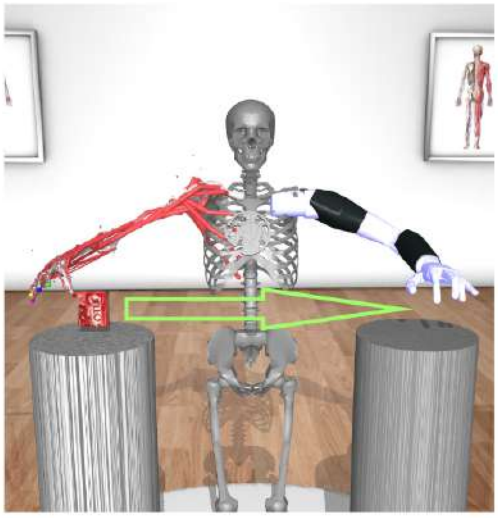

Fig. 1: The myoMPL environment. The task involves moving an object from the pillar on the left side (from the reader's perspective) to the pillar on the right, using both the biological arm and the MPL.

The MPL system has 17 controllable actuators that drive 26 DOFs [11]. Each finger has 3 coupled DOF for flexion. Additional DOFs are provided for abduction in the index, ring, and little fingers, where the latter two are coupled. The thumb has 4 DOFs: three flexions and one abduction. The wrist has 3 DOFs, and the elbow and the humeral rotator each have 1 DOF. The shoulder complex consists of two serial hinge joints for flexion-extension and abduction-adduction, enabling broad upper-arm movements. This model has a near-human level of strength and speed and closely resembles the kinematics of a human arm.

B. Bimanual Manipulation Task

The torso and lower limbs are fixed at the center of a round stage and two pillars are placed at a distance to ensure that both arms can only reach the pillar closer to them. The start and goal positions are defined as the centers of the top surfaces of the left and right pillars. The default object to manipulate is a box weighing 97 g, with dimensions of $72 \times 88 \times 28$ mm, following the YCB benchmark object set [21]. The object's start position and goal position are randomly initialized in each episode (i.e., simulation trial). Additionally, the physical attributes of the object are varied, including its dimensions ($\pm$0–5% for width, $\pm$0–10% for depth, and $\pm$0–5% for height), mass ($\pm$50 grams), and friction (default friction coefficients: 1.0, 0.005, and 0.0001 for sliding, torsional, and rolling friction respectively; variations: $\pm$0.1, $\pm$0.001, and $\pm$0.00002, respectively).

A simulation trial is completed when the object is placed on the goal pillar within 0.1 m along each axis. Each trial lasts up to 10 seconds and terminates early if the object falls below 0.3 m. To ensure bimanual manipulation, each limb must maintain contact with the object for at least 1 second.

C. Action and Observation Spaces

The action space consists of an 80-dimensional continuous vector in the range [-1, 1], comprising 63 muscle actions and 17 MPL position actions. In the simulation, muscle actions are normalized to the range [0, 1] using:

$$s_m = 1/(1 + \exp(-5 * (u_m - 0.5))), \quad (1)$$

where u_m is the muscle action and s_m represents the muscle stimulation, with 0 and 1 indicating no stimulation and full stimulation, respectively. The 17 MPL position actions are mapped to their corresponding joint range of motion for target angle-based control.

A policy/controller has access to a 222-dimensional observation space, extensively describing the body, object, and environment state at each time step (Table I). This observation space includes joint positions and velocities of both myoArm and the MPL, the 6-DOF position and velocity of the object, as well as the muscle stimulations of the arm. Additionally, the contact status of the object is provided, with five labels indicating whether it is touching the biological hand, MPL, start pillar, goal pillar, or any other part of the environment. A full description of the observations is available on the MyoChallenge'24 documentation page [22].

D. Reward and Evaluation

The environment does not provide a predefined reward for completing the task, as we did not want to prescribe a specific approach to solving the task. Instead, users are encouraged to design their own reward structures that are suitable for their chosen methods, whether it be curriculum learning, imitation learning, heuristic control, or any other approach. See an example of the reward for the baseline controller in the following subsection. Another reference for evaluation is the primary criterion in MyoChallenge'24: the success rate of completion across 100 evaluation trials.

E. Baseline Controllers

We provide a baseline solution for the proposed task (Fig. 2). This baseline policy combines a simple position control for the MPL with a deep neural network, trained through reinforcement learning, to manage the grasping behavior of the myoArm. The baseline demonstrates a success rate of approximately 25% in the default simulation setting, which drops to around 3% when full object and environment variations are introduced.

MyoArm Control: The myoArm policy was trained using a heuristically designed curriculum learning setup [23]. The training process was divided into three consecutive curricula: (1) positioning the palm near the object, (2) wrapping the fingers around the object, and (3) bringing the object close to the MPL hand. Across all stages, the policy was trained with the following reward function, which is based on the Euclidean distance between the target and current positions, with the weights σ_{i} varying across the curricula:

$$r_{\mathrm{d}} = \exp(-\sum_i \sigma_{\mathrm{i}} ||q_t^i - q_o^i||^2), \quad (2)$$

where q_o^i and q_t^i are the three-dimensional Cartesian coordinates of the object and body segment i, respectively, and i represents the palm, fingers, and MPL segments. Training begins with the first stage, during which σ_{i} for the palm is set to a high value. As the policy succeeds in stage one and the training progresses through the second and then the third stages, σ_{i} for the fingers and MPL segments are set to be higher, respectively. Once the biological hand reaches within 0.1 m of the MPL arm (indicating completion of stage three), the hand muscles are relaxed, allowing the object to fall freely.

Our algorithm utilizes a symmetric multi-layer perceptron (MLP) architecture for both the policy and value function networks. Each network comprises two hidden layers with 256 units each, employing the ReLU activation function. We trained these networks using Proximal Policy Optimization (PPO) [24], leveraging the stable-baselines3 package [25]. We used an entropy coefficient of 0.001 and a learning rate of 0.0003 for training.

TABLE I: Observation space of myoMPL manipulation task

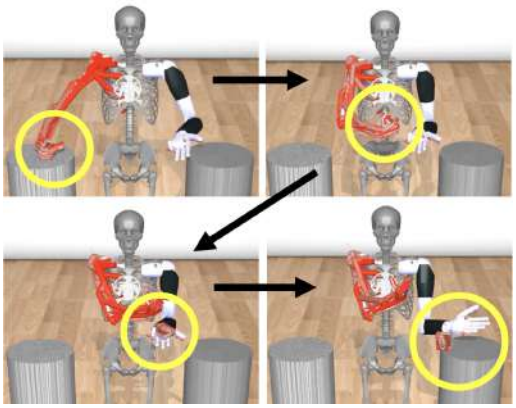

Fig. 2: Snapshots of a baseline solution for the bimanual manipulation task. The biological arm picks up an object from the left pillar, hands it over to the prosthetic arm, and finally, the prosthetic arm places it on the right pillar. The yellow circle highlights the trajectory of the object.

MPL Control: The MPL control was designed to coordinate with the trained myoArm movements. It operates as a position controller that sequentially reaches three target poses, each defined by 17 target joint angles, which switch based on predetermined time intervals. The three target poses are illustrated in Figure 2, with transitions occurring at 2.5 and 3.5 seconds, respectively.

IV. MYOOSL ENVIRONMENT

The myoOSL environment simulates an above-knee amputee using an Open-Source Leg v2 (OSL) system [12], [26] to traverse a straight path over various terrain types (Fig.3). OSL is an open-source platform that provides both hardware designs and a range of control algorithms. The goal is to train a controller for the musculoskeletal model and OSL to effectively traverse challenging terrains, with the OSL behavior modulated by switching between five user-defined control parameter sets. This setup reflects a condition where the user could manually select the control mode using a handheld controller, adjusting to varying terrain conditions.

A. MyoLeg and the Open-Source Leg

The myoLeg model was adapted to represent a person with a right-leg, transfemoral amputation. The original myoLeg contains 28 DOFs and 80 muscle-tendon units. It was converted from the OpenSim full body model [27] via MyoConverter [20] and has been used previously been used in a previous MyoChallenge [16]. The myoLeg was modified to represent a transfemoral amputation at a 50% level. These modifications involved removing muscles that articulate the knee and ankle joints on the amputated side [28], as well as readjusting the femoral inertial properties to reflect the altered geometry and mass distribution of the residual limb.

The myoOSL model integrates the amputated myoLeg with an OSL model. The OSL model is implemented with torque actuators that match its real mass (5.377 kg), peak torques (knee: 142.2 Nm; ankle: 168.2 Nm), and ranges of motion (knee: 0–120 deg; ankle: -30–30 deg) [26], [29]. The myoOSL model features 23 internal DOFs: 19 are actuated by 54 muscles and two OSL actuators, while the remaining 4 DOFs between the residual limb and the OSL represent socket movement and are passively constrained [30].

OSL Control: The OSL model is controlled using a finite-state machine with four states, each implementing impedance control (Fig. 3-(b)). This controller is the default controller provided in the OSL project [31], which we have reimplemented for myoOSL. The four states are early stance, late stance, early swing, and late swing. Each state is defined by eight parameters, where three (stiffness, damping, and target/equilibrium angle) are used for impedance control, and the other five (load, knee angle, knee velocity, ankle angle, and ankle velocity) determine the state transition conditions. Thus, there are 32 parameters (8 parameters per state $\times$ 4 states) for full OSL control. In the myoOSL environment, the user can predefine five sets of these control parameters, which can then be selected by the policy at any moment during a simulation trial. This setup represents a scenario where the prosthesis user, for instance, uses a handheld device to select the appropriate control mode.

B. Robust Locomotion Task

The task is to develop a controller/policy for the amputee musculoskeletal model, as well as to determine OSL control selections, to maximize walking distance across various terrains. The environment includes five types of terrains, each 3 m wide and 100 m long: 1) flat ground, 2) rough terrain, 3) hills, 4) stairs with 3 ascending and 3 descending steps, and 5) a mixture of all terrain types (Fig. 4). The difficulty of the terrain increases progressively with the distance traveled;

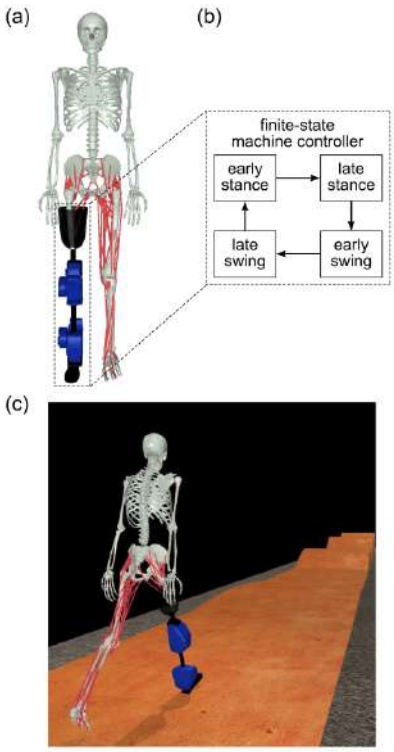

Fig. 3: The myoOSL environment. (a) An amputee model using the OSL v2, which is controlled by (b) the OSL's finite-state machine controller. (c) A myoOSL task environment.

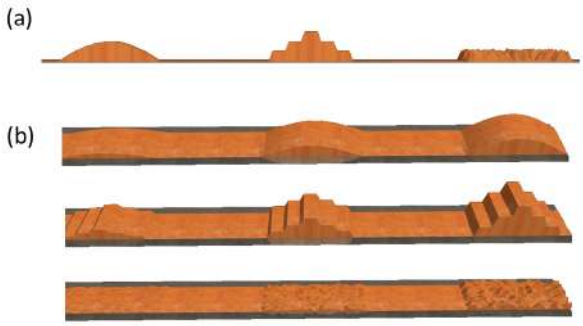

Fig. 4: Terrains in myoOSL. (a) Side view of a mixed terrain sample. (b) Different terrain types with progressively increasing difficulty over the traveled distance.

at 100 m, the roughness reaches 60 cm, the hills become approximately 50 degrees steep and 1.5 m high, and each step on the stairs is 50 cm high.

A simulation trial is considered completed if the amputee model traverses the entire 100 m path without falling. A trial is terminated early if the model falls (head height $<$ 1.5 m) or deviates from the 3 m wide path.

C. Action and Observation Spaces

The action and observation spaces are designed to represent the motor control system of an amputee wearing the OSL. The action space consists of 54 muscle actions (that are converted to muscle stimulations; Eq. 1) and an additional output, [0, 1, 2, 3, 4], that selects between the five control parameter sets that are predefined by the user. A policy/controller has access to proprioception (e.g., joint angles and velocities, and muscle states) and 10 $\times$ 10 height map of the 2 $\times$ 2 m terrain around the amputee, at each time step (Table II). A full description of the actions and observations is available on the MyoChallenge'24 documentation page [20].

D. Reward and Evaluation

The myoOSL environment provides a straightforward reward based on the distance traveled. In MyoChallenge'24, solutions are evaluated over 100 simulation trials on randomly generated terrains.

E. Baseline Controllers

We do not currently provide a baseline controller for the myoOSL environment. However, baseline controllers for the original myoLeg model (featuring two intact biological legs) that produce stable walking are available in MyoSuite [14]. These include the DEP-RL controller [32] and a reflex-based controller [33].

V. Discussion

In this paper, we introduce MyoAssist 0.1, a sub-suite of MyoSuite that includes the myoMPL and myoOSL environments, focusing on musculoskeletal simulations with assistive devices. These environments are part of NeurIPS 2024: MyoChallenge, with respective tracks on manipulation and locomotion. The myoMPL environment simulates a shoulder disarticulation amputee using an MPL to move an object from a pillar on the biological arm's side to a pillar on the MPL arm's side, using both arms. The myoOSL environment presents an above-knee amputee walking across challenging terrains with an OSL v2 prosthesis.

Observation	Dimension
Elapsed time	1
Terrain type	1
Joint positions of myoLeg	17
Joint velocities of myoLeg	17
Ground Reaction forces of myoLeg	2
Socket forces	3
Pelvis angle (in world frame)	4
Muscle activations	54
Muscle lengths	54
Muscle velocities	54
Muscle forces	54
Planar Pelvis position (in world frame)	2
Planar Pelvis velocity (in world frame)	2
Terrain height map	100
Total	365

TABLE II: Observation space of myoOSL locomotion task

The environments have certain limitations in reflecting their real-world scenarios. In MyoMPL, a user can develop a policy that has full access to the observations and actions of both the musculoskeletal and MPL systems, which is not possible in the real world with current techniques. While this approach does not fully replicate the limitations of independent user control of the human arm and prosthetic limb, it aims to investigate the complexities of a bimanual arm paired with a prosthetic arm. Moreover, one can implement realistic policy constraints that better reflect their system of interest.

The myoOSL environment presents a more realistic scenario where the amputee can select between predefined control modes of the prosthetic leg, for instance, using a handheld controller. In myoOSL, the policy mostly represents the neural control of the musculoskeletal system that produces muscle stimulations based on proprioceptive feedback and environmental cues. Additionally, the policy can select from five predefined control parameter sets for the OSL. In the current setting, the OSL control switch can occur at every time step, which is not realistic. Users can easily implement constraints (e.g., a minimum time interval between OSL control switches or limiting control changes to once per footstep) to better reflect realistic scenarios.

Despite some simplifications, these environments serve as a first step toward developing more comprehensive and sophisticated control systems for prosthetics. The myoMPL and myoOSL environments offer a foundation for studying the interplay between musculoskeletal dynamics and assistive devices, as well as understanding physical human-robot interactions. Future iterations will aim to introduce greater realism in modeling physical human-device interactions [34], expand to more complex tasks such as opening jars (manipulation) and avoiding obstacles (locomotion), and improve the robustness of baseline controllers.

Our goal is to advance MyoAssist into an open-source collaborative platform that fosters innovation in assistive technology and neurorehabilitation. In the future MyoAssist 1.0 release, we plan to incorporate a broader range of assistive devices, with a particular focus on various types of hip and ankle exoskeletons [35]. We invite researchers, particularly those specializing in assistive devices that involve physical interactions with humans while needing a means of investigating the devices in simulation, to contribute and collaborate in MyoAssist. By bringing together expertise from biomechanics, robotics, machine learning, and clinical applications, we can push the boundaries of simulation-based assistive technology research, ultimately improving the effectiveness of rehabilitation and the quality of life for individuals with motor impairments.

***Abstract*— Upper-limb activities of daily living like eating and drinking are crucial for self-determination and autonomy and, thus, quality of life. Patients with neurodegenerative diseases such as Parkinson's disease, multiple sclerosis or cerebellar ataxia are often severely impaired in performing these activities of daily living. While these patients are still able to plan motor actions, and their muscle strength is rarely impaired, tremor or overshooting movements disturb the intended movements. This occurs progressively in the course of disease in a way that independent eating and drinking becomes increasingly difficult. The goal of this research project is to develop a non-invasive assistive device suppressing pathological movement components while allowing intended movement. The newly designed hardware will be controlled by a combination of computational methods to detect user intention, detect pathological movement components within intended movements, and predict the required correction forces for several upper-limb activities of daily living. In this manuscript, we will describe concepts of control hard- and software as well as first implementation and experiments with the individual components we plan to integrate in the future.**

I. Introduction

Cutting food or filling a glass from a bottle while dining is crucial for self-determination and autonomy and, thus, quality of life. Patients suffering from neurodegenerative diseases, such as Parkinson's disease, multiple sclerosis or cerebellar ataxia might not be able to perform such activities of daily living (ADL) all the time.

Although these patients are able to plan motor actions, and their muscle strength is rarely impaired, different types of tremor [1] [2] or dysmetric movements (over- and undershooting of goal-directed movements in cerebellar ataxia) [3] [4] [5] disturb the intended movements.

This occurs progressively in the course of disease such that independent eating and drinking becomes increasingly difficult. Assistive devices, which pro-actively suppress pathological movement components and restore the intended movement could dramatically improve patients' motor abilities, as has been shown in approaches to wearable systems for tremor suppression [6].

We here address the field of ADL with the focus on situations like a regular meal where food has to be cut, forked, brought to the mouth and a glass of water has to be filled from a bottle and brought to the mouth. These activities are characterized by a finite number of objects and tasks, a meaningful order of some tasks, but generally open in the location of objects and user and situation-specific in their execution order.

The goal of this research project is to develop a non-invasive assistive device with the capability to suppress pathological movement components while allowing intended movement in patient-relevant ADLs.

A. Methodological Approach

We address the following challenges in the development of such assistive devices:

1) Predicting planned movements during ADL and detecting pathological movement components within executed movements in real-time.
2) Designing a lightweight and mobile assistive device with minimal mechanical complexity and sufficient transparency (to not hinder the movement of the user) and, at the same time, the capacity to apply in real-time the amount of corrective forces sufficient to suppress pathological movement components.

To this end, we combine computational methods to detect (a) the user intention, predict the human arm movement corresponding to the intention, (b) differentiate between desired movement and pathological movement components and (c) develop a neuromechanical model to predict the required correction forces and (d) apply them with an adequately designed assistive device (Figure 1).

The presented concepts differ significantly from concepts for stroke patients, where paralysis of the limbs or spasticity is the main issue (e.g. [7],[8]. Devices for stroke need to exert forces large enough to generate the entire movement and—typically slowly—follow given trajectories, thus, they typically place fewer demands on the real-time constraints in intention detection [9] and movement correction [6].

This paper reports about the overall concept and our first implementations and test of the sub-components. At this

point, these components are not integrated yet leaving the validation of the concept as future work.

II. Methods

A. Multi-modal sensor setup

Multiple sensor modalities were captured synchronously to assess the subject's motion behaviour and infer the intention (Figure 2). To determine gaze direction in real-life scenarios, we used the eye tracking glasses Neon by PupilLabs (Pupil Labs GmbH, Berlin, Germany) [10], which additionally record a video from the egocentric perspective and give information about head movements via an inertial sensor. Multiple IMUs from Xsens Technologies (Movella DOT, Xsens Technologies B.V., Enschede, Netherlands) were placed on both arms and the sternum to track and quantify arm and trunk movements. The stereo depth camera ZED 2i from Stereolabs (Stereolabs Inc., San Francisco, USA) were placed across the table of the subjects and captures the depth and RGB information of the experimental setup. Based on this depth and RGB information, object recognition and skeleton tracking routines were implemented using the camera-related APIs. Fusion of the IMU and depth-camera sensor signals allows for combining the benefits of both sensors: high time-resolution and local accuracy of IMU's and global position accuracy of the depth-image to compensate for drift in the IMU signals. Details of the sensor fusion concept are provided in the next section.

A software architecture based on the ROS2 (Robot Operating System) middleware was implemented to acquire all sensors synchronously with the sensor-specific real-time constraints. ROS2 provides the ability to reliably exchange and store large amounts of data at high frequency and is widely used in medical and industrial applications [11] [12] [13].

B. Development of a Kalman filter-based sensor fusion algorithm for motion tracking

Intention detection, tremor recognition, and prediction of movements require sensor-fusion approaches to combine different sensor modalities. To perform robust motion tracking, we developed and evaluated a Kalman filter-based algorithm for motion tracking and state estimation. The primary aim was to integrate data from multiple sensors to achieve accurate tracking of upper limb motion, particularly the hand and wrist. For this, we combined the complementary strengths of two sensors: the Xsens Movella DOT IMU system, which provides fast precise acceleration and angular velocity data but shows a drift when estimating global positions, and the Stereolabs ZED 2i stereo camera with skeleton fitting, which delivers global 3D position data, but at a lower frequency.

The Kalman filter was selected for its ability to perform real-time state estimation in dynamic systems. Specifically, we employed a discrete-time linear Kalman filter to estimate the states of position, velocity, and acceleration. The filter's structure consists of a prediction step, which uses a kinematic motion model to estimate the next state based on the current state, and an update step, which refines this estimate using sensor measurements. In the filter, weights were assigned to each sensor based on their noise characteristics, ensuring robust performance even under noisy conditions.

The state transition model for the Kalman filter estimates the position $\mathbf{x}$, velocity $\mathbf{v}$, and acceleration $\mathbf{a}$ of the wrist. The discrete state-space model can be expressed as:

$$\mathbf{s}_{k+1} = \mathbf{F}\mathbf{s}_k + \mathbf{w}_k, \quad \mathbf{z}_k = \mathbf{H}\mathbf{s}_k + \mathbf{v}_k$$

where

$$\mathbf{s}_k = \begin{bmatrix} \mathbf{x}_k \\ \mathbf{v}_k \\ \mathbf{a}_k \end{bmatrix}, \quad \mathbf{F} = \begin{bmatrix} \mathbf{I} & \Delta t\mathbf{I} & \frac{\Delta t^2}{2}\mathbf{I} \\ \mathbf{0} & \mathbf{I} & \Delta t\mathbf{I} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} \end{bmatrix}, \quad \mathbf{H} = \begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} \end{bmatrix},$$

where $\mathbf{F}$ is the state transition matrix, $\mathbf{H}$ is the measurement matrix, $\mathbf{w}_k$ and $\mathbf{v}_k$ are the process and measurement noise, respectively, and Δt is the sampling time.

To evaluate the filter's performance, we first designed a testing framework using an ideal trajectory overlaid with experimentally derived noise. Noise profiles for the IMU and stereo camera were characterized through calibration experiments, where the sensors were subjected to static placement evaluation to get their base noise readings. The accelerometer's and stereo camera signal variances were used to estimate the measurement noise covariance matrix.

The primary metric for evaluating performance was the Root Mean Square Error (RMSE) of the reconstructed trajectory compared to the ground truth. Ground truth data was generated using (a) mathematical simulation and (b) a high-accuracy optical motion capture system, which provided precise positional and velocity measurements for the ideal trajectory. By calculating the RMSE, we assessed the algorithm's accuracy in estimating states under various noise levels.

Finally, the sensor fusion approach was validated using real experimental data. This included datasets captured with both the IMU and stereo camera in scenarios simulating upper-limb motion. The fusion algorithm was tested in realistic conditions, accounting for sensor noise, data loss, and calibration challenges.

C. Online detection of pathological movement components

For the detection of pathological movement components, we concentrated on tremors and dysmetric movements (over- and undershooting). In the case of tremors, we have to take into account that the frequency of the tremor may change within the movement in the action and intention tremors. Therefore, we used a Bandlimited Multiple Fourier Linear Combiner improved with a Kalman Filter [14] to estimate thesinusoidal movements with changing frequencies to identify the tremor component of the voluntary motion in real-time. See subsection III-B for preliminary results.

D. Neuromechanical modeling of healthy and impaired movement

Using neuromusculoskeletal arm simulations, we can predict both healthy and impaired movements and estimate the necessary assistive forces for correction [15]. These

predictions helpt to determine the corrective forces required as control inputs to the assistive device, which, in turn, will in the future apply forces to the human arm to correct dysfunctional movements (see Figure 1 c)).

To predict healthy movements, we developed a simulation approach for 3D arm movements that integrates three key factors: optimality principles, task requirements, and stochastic noise. Muscle and multibody dynamics were simulated using the MuJoCo physics engine [16] due to its computational speed and applied reinforcment learning (DEP-MPO) [17] to synthesize the control policy. We build on our previous work with a simplified, two degree-of-freedom arm model with six muscles-tendon units [18]. In this work, we achieved highly realistic arm trajectories (realism index > 0.9), comparable to those of healthy individuals.

Expanding this framework, we tested a more complex model with seven degrees of freedom and 27 muscle-tendon units (see Fig. 4). Our pior work showed that this 3D arm model predicts stiffness characteristics that closely match experimental data recorded from data while still being computationally efficient [19]. This model therefore allows us to predict the effect of corrective forces for our assistive device when attempting to mitigate the effects of motor control impairments.

As a first attempt to simulate pathological movement components, we added a sinusoidal signal to the elbow flexor muscle with frequencies occurring in the targeted diseases and varying amplitudes, generating stereotypic tremor movements (Fig. 4). Albeit its simplicity, this isolated approach is beneficial to determine (joint-)specific correction forces. However, we aim at simulating more naturalistic tremors in the future, by transferring our own and previous experimental data onto the model [20], [15] and by considering neurological origins of dysmetria and tremor [21], [22], [23].

E. Design requirements and hardware development

A lightweight assistive device, schematically represented in Fig. 5, was devised to apply corrective forces. It includes a prismatic joint along the z-axis, enabling force application in the vertical direction (blue), along with two revolute joints arranged in series (both axes parallel to the z-axis) in red and green, which mimic the human shoulder and elbow joints. This coordinated arrangement allows for the application of forces in any direction within the horizontal

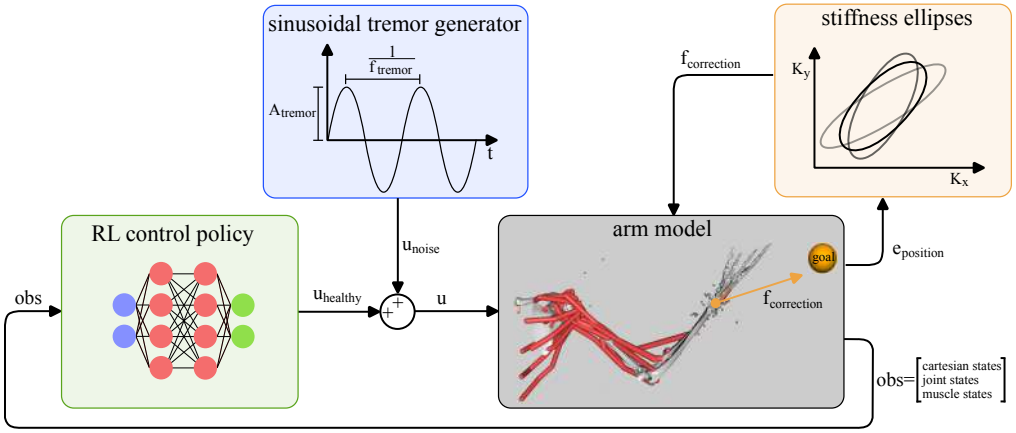

Fig. 4: Simulation of pathological arm movement: RL control policy computes the muscle control command (u_{healthy}) to generate healthy arm movements, while a sinusoidal tremor generator produces a perturbation signal (u_{noise}) with characteristic amplitude ($a_{\mathrm{tremor}} = 0.25$) and frequency ($f_{\mathrm{tremor}} = 4\,Hz$). This perturbation is added to the muscle control command to simulate hand tremors. Finally, corrective forces ($f_{\mathrm{correction}}$) are computed based on stiffness ellipses and position deviation to attenuate hand oscillations.

plane. Although preliminary investigations in simulation suggested that a force of 5 N applied to the hand can already effectively reduce or prevent the aforementioned movement disorders, the device was designed to provide a force of 10 N to account for the more proximal point of application of the corrective forces (forearm) and potential intersubject variability. We chose a bi-articular actuation scheme for the elbow joint actuation, spanning both the shoulder and elbow joints, as simulations indicated that this approach reduces the maximum torque required by the shoulder actuator compared to a mono-articular elbow actuation scheme. Two mechanisms were used to relocate both shoulder and elbow actuators proximally with respect to the vertical prismatic joint: a ball spline mechanism was utilized to transmit the shoulder actuator moment through the linear bearing of the prismatic joint, while a cable transmission was integrated into the scissor mechanism that connects the prismatic joint output to its driving actuator. The integration of the scissor mechanism also facilitated the compact incorporation of a spring mechanism for passive weight balancing of the robotic arm (see Fig. 5(a)(1)). As all three actuators were attached to the base of the device, the moving part of the designed robotic arm is lightweight and exhibits low apparent inertia, which positively contributes to reducing resistance to user movement when no correction is needed.

A mechanical interface (see Fig. 5 (b)) fixed at the tip of the robotic arm facilitates the application of corrective forces to a point approximately located at the midpoint of the user's forearm, thus enabling the generation of corrective moments at both the elbow and shoulder. This interface employs a mechanism similar to a gimbal, ensuring that the applied force is centered relative to the forearm, thereby preventing the generation of parasitic moments. The interface was constructed with two passive revolute joints, with the freedom of rotation along the forearm's longitudinal axis provided by the relative motion of soft tissues with respect to the user's skeleton. The mechanical interface also extends to the wrist, allowing for the application of forces along the longitudinal axis of the forearm with minimal slippage.

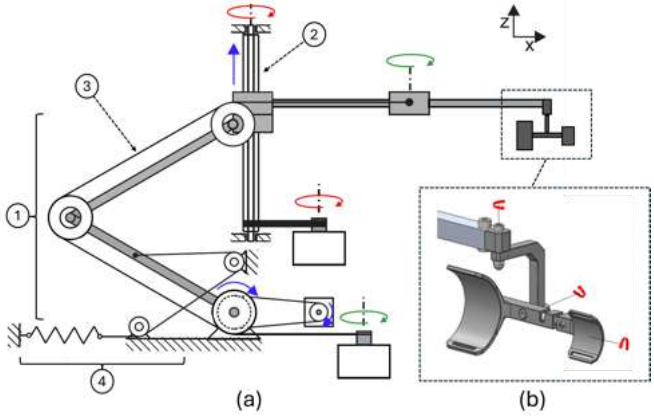

Fig. 5: (a) Schematic of the assistive device with three active DoF. From proximal to distal: a prismatic joint along the z-axis (blue) actuated via a scissor mechanism (1) which motion is constrained by the ball spline mechanism (2), a first rotational joint along the ball spline axis (red) and a second rotational joint bilaterally actuated using cables (3) routed through the scissor mechanism (green). All actuators are fixed to the base of the device, which significantly lowers the mass of the mobile part (arm) of the device. A passive spring mechanism (4) is used to balance the weight of the arm. (b) Close-up of the user interface with 3 passive DoF.

A preliminary evaluation study was performed with the unactuated device. First, we measured the resistive torques or forces experienced when moving each robotic arm DoF with joint velocities typical for the envisioned ADL. Second, we carried out a study with 5 healthy individuals to evaluate the device transparency (Task 1) and range of motion (Task 2). In Task 1, the subjects performed the ADL "Drinking" (fill a glass with the bottle using their right hand and then drink the water from the glass) with the device and were asked to rate from 0 to 10 how much the device was disturbing them (<3: not disturbing; 4-6: little disturbing; >7: very disturbing). In Task 2 the participants were instructed to sequentially place the bottle as close as possible to the four corners of a rectangular workspace drawn on the table in front of them, while avoiding to lean forward.

F. Experimental data acquisition

To achieve the project goal, a novel dataset will be recorded that includes kinematic data, gaze data, and scene

video including depth information (approved by the local ethics committee in Tübingen 474/2023B02). The developed ROS2 software architecture will be used to record a patient group (n = 20) and a group of age-matched healthy controls (n=20).

TABLE I: Planned experimental tasks.

Complex ADLs	Clinical test
Holding an object	Pointing on the table
Peeling, cutting and eating a banana	Moving objects
Drinking from a glass	Drawing the Archimedian spiral
Meal preparation	

The patient group comprises subjects suffering from neurodegenerative diseases such as Parkinson's disease, multiple sclerosis, or cerebellar ataxia exhibiting ataxic dysmetric movements (over- and undershooting of goal-directed movements in cerebellar ataxia) or tremors such as action and intention tremors.

The participants will be recorded performing different tasks that involve the upper extremities, e.g., meal preparation, while sitting at a table. A standardized data acquisition and experimental protocol was developed. The choice of tasks matches the future application scenario of the assistive device, but also fundamental knowledge is gained about the pathological movements (see Table I). This includes tasks with a high level of standardization and tasks with a higher amount of flexibility.

In the eating task, participants will be instructed to peel a banana, to cut the banana with a knife into smaller pieces, and to eat the pieces with a fork. The drinking task includes opening a bottle and pouring water into a glass. In the context of meal preparation, a Tupperware container is to be opened and the noodles inside emptied into a bowl. The Tupperware box should then be closed. In a follow-up task the noodles should be scooped out from the bowl into a cup using a laddle. The "clinical test" includes pointing movements at different locations on the table with the index finger, moving wooden bricks from one place to another predefined location, and drawing the Archimedian spiral in the clockwise and anti-clockwise direction.

The experimental protocol will also include a questionnaire to obtain further information that is relevant for analyzing the recorded data and developing the assistive device. The questionnaire covers socio-demographic and anthropometric data on each subject; pathology and associated symptoms; and expectations, doubts and requirements of such a non-invasive assistive device.

III. Preliminary Results

A. Preliminary Results of Kalman Filter

After preliminary data collection, raw data from the IMU and stereoscopic camera were synchronized and preprocessed before being put into the Kalman filter. Preprocessing included removal of gravity component from raw acceleration data, shifting of coordinate systems of the Xsens IMU and the ZED 2i camera, and upscaling data of the stereo camera to match IMU sampling frequency to enable sensor fusion. The coordinate systems of the stereo camera and the IMU at the wrist were aligned by first translating the origins to the same point and applying a rotation matrix computed using the the Kabsch algorithm [24]. The stereo camera data, although accurate, occasionally suffered from tracking loss, particularly during rapid movements. These limitations were mitigated through the sensor fusion.

In the testing framework using an ideal trajectory as ground truth, the filter achieved low RMSE values of 7.8, 7.8 and 7.4 m^{-4}, in the X, Y, Z directions, respectively. The tests with realistic experimental data demonstrated that the Kalman filter effectively fuses data from the IMU and stereo camera, producing smooth wrist trajectories under varying conditions. The filter successfully estimates motion trajectories while filtering out high-frequency noise.

B. Online detection of pathological movement components

Fig. 6: Snapshot of the recording of the drinking scenario for a tremor patient. Green dots represent the subject's workspace as identified by the stereo camera. Purple dots show the key points of the skeleton tracking. The left part of the image shows the online tracking of the inertial sensors, showing specific accelerations on the wrist sensor for different subphases of movement.

Results on the data collected so far show varying tremor frequencies not only for different patients but also for the same patient in different phases of movement (Fig. 6 + 7). This reflects the clinical impression of action and intention tremors. Such changing frequencies could be tracked with Bandlimited Multiple Fourier Linear Combiner, improved with a Kalman Filter, to estimate the changing frequencies. It allowed to separate the tremor offline (Fig. 7) and in real-time (Fig. 6). Further approaches will aim to incorporate prior knowledge about patient-specific tremor frequencies in order to optimize fast online detection.

C. Simulation of healthy and impaired arm movement

The synthesized control policy can generate both healthy and impaired point-to-point 3D reaching movements (Fig. 8). On the one hand, the direct application of the muscle control command u_{healthy} resulted in arm reaching movements with healthy kinematics characteristics: (i) roughly straight hand trajectories and (ii) bell-shaped velocity profiles (see early

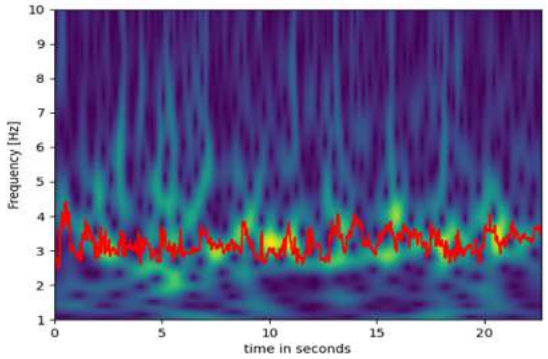

Fig. 7: The bandlimited multiple-fourier linear combiner with Kalman filter adapts to the frequencies of the pathological movement component (red).

reaching phase in Fig. 8, both in healthy and pathological movement). The addition of a sinusoidal signal to the muscle control command of the elbow flexor resulted in periodic positional oscillations around the target position, which is an approximation of tremors.

D. Hardware: Preliminary evaluation of device prototype

The evaluation study (see Fig. 9) revealed that the workspace reachable by the test subjects and available for executing the ADLs was only very marginally (2,2% in average) reduced by the device usage. The test subjects also evaluated positively the mechanical transparency of the device (average rating of 2,2: not disturbing), especially for motions in the horizontal plane but reported a noticeable resistance to vertical motions. This subjective evaluation was confirmed by the quantitative tests: low resistive torques (mean value $<= 0.1$ Nm) were measured for the rotational joints, while a mean resistive force of about 3 N (primarily dry friction) was measured for motions along the z-axis, attributed to internal friction in the ball spline mechanism. In summary, the selected transmission mechanisms, characterized by low internal friction, were shown to enable efficient torque transmission. This design allows using reasonably lightweight motors (approximately 1 kg per actuator) in a quasi-direct drive mode (reduction ratio < 3) to generate the necessary corrective forces. Based on the performance of the direct drive actuation, it is anticipated that interaction forces can be accurately estimated using motor current measurements in the horizontal plane, whereas active force control may be necessary to compensate for friction in the vertical direction. To address this, a single uniaxial force sensor will be integrated in the next iteration between the arm's tip and the mechanical interface with the user.

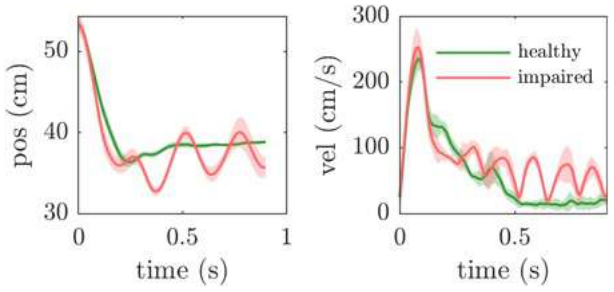

Fig. 8: Neuromechanical simulation of healthy (green) and impaired (red) arm movements. The impaired movement was simulated by adding a sinusoidal signals with frequencies occurring in the related diseases and different amplitudes added to the simulated muscle control signal. Here we show exemplarily 4 Hz and an amplitude of 0.5 (50% maximum muscle stimulation)

IV. Discussion

In this manuscript, we presented the concepts and first implementations of the individual components of our hardware and software architecture for an assistive device for patients with neurodegenerative movement disorders like cerebellar ataxia, multiple sclerosis or Parkinson's disease. These specific movement impairments result in pathological movement components overlaying the intended movements. This leads to specific requirements in the hardware and software concepts [15],[6] which differ significantly from concepts for stroke patients, where paralysis of the limbs or spasticity is the main issue (e.g. [7],[8]. Devices for stroke need to exert forces large enough to generate the entire movement and—typically slowly—follow given trajectories or predefined tasks and, thus, they typically place fewer demands on the real-time constraints in intention detection [9] and movement correction [6]. Thus, the two specific aspects of (a) rapid correction of complex everyday movements with (b) a lightweight and low-cost assistive device are the focus of our developments. With the developments and results so far, we have already been able to take some substantial steps in this direction. However, we still develop the individual components. Next steps will include ML methods for intention detection by combining the gaze estimation

of the eye-tracker with the current state of the movement tracking [25]; more naturalistic modeling of dysfunctional movements [23], [22], [15]; prediction of corrective forces with the neuromechanical model [22], [23], [15]; the real-time integration of all components; first user test.

Development and Evaluation of a Device to Assess Finger Individuation in Neurorehabilitation

Anna Sophie Knill[1,2], Shuyang Shi[1], Chris Awai Easthope[2], Meret Branscheidt[2,3,4], and Olivier Lambercy[1,5]

***Abstract*— Finger individuation, the ability to independently control fingers, is a critical component of hand function that is often impaired in people with neurological conditions. To address the need for sensitive tools to measure finger individuation in clinical and research settings, an assessment device was developed and tested. Equipped with force sensors under each finger, an individuation index (IndX) in both flexion and extension was calculated. Feasibility of the device was assessed by measuring able-bodied participants and neurological patients. The reliability of the finger individuation assessments was evaluated in a test-retest setting, showing high consistency, with Intraclass Correlation Coefficients (ICC) and Spearman correlation classified as moderate to excellent (ICC for flexion of thumb: 0.73, p <0.001; index: 0.68, p <0.001; middle: 0.48, p =0.003; ring: 0.72, p <0.001; little: 0.80, p <0.001). Validity was further examined by comparing the IndX across fingers and between groups, utilizing t-tests and the Area Under the Curve (AUC) from Receiver Operating Characteristic analysis. Although AUC values indicated a mixed discriminative ability, the device successfully captured differences in finger control between able-bodied individuals and patients. These results indicate that the device offers a reliable and effective means of quantifying finger individuation, opening the door to advanced fine hand motor control research and through that, personalized rehabilitation.**

I. INTRODUCTION

The ability to selectively activate fingers in an independent manner, defined as finger individuation, is crucial for fine motor control and hand functionality in everyday life. Finger individuation can be severely affected in patients with neurological impairments, such as stroke or Parkinson's [1], [2], [3], leading to limitations in hand dexterity and overall quality of life. While the clinical significance of impaired finger individuation, which is referred to as higher finger enslaving, is well-recognized [4], the assessment of this specific function is not yet systematically integrated into routine clinical evaluations, primarily due to the scarcity of clinically usable tools to finely measure finger individuation.

Technology-based assessments offer promising solutions for evaluating finger individuation in a sensitive manner. Various devices have been employed in previous studies, including setups that utilize force sensors under the fingertips [5], [6], dual-sensor configurations [7], [8], [9], and robotic devices with cables [10], [11] or rods [12] for force transduction. Others have used instrumented gloves to track individual finger movements and forces [4], [13], [14].

However, existing measurement systems present several limitations. Some do not measure all fingers [5], [10], [15], [8], require two devices for bilateral assessments [6], [16], [17], or are restricted to finger flexion only [18]. The latter is particularly problematic, as it has long been established that enslaving effects also occur during extension movements [19]. Additionally, some devices rely on dynamic tasks [4], [13], which typically require complex and bulky mechanisms to directly move the fingers [4], [9], thereby limiting their clinical applicability. Furthermore, some systems require specific hand positioning, such as pronation on a flat surface [6], restrict the hand to a cylindrical grip [12], or rely on metal ring finger attachments [15], which can compromise comfort and usability.

Thus, there is a need for a measurement device that answers the limitations of existing technologies by providing a more ergonomic, adaptable, and compact system capable of easily assessing both hands, offering accurate and sensitive measurements for each independent finger in both flexion and extension.

In this paper, we present the development and evaluation of a novel device designed to measure finger individuation that builds on the assessments proposed by Xu and colleagues [6]. The key aspects tested is the feasibility of the device and assessment procedures, along with the reliability of its outcome measures (primarily the individuation index, IndX, adapted from Xu and colleagues [6] for both flexion and extension), ensuring accurate and consistent measurements across repeated tests. We hypothesized that i) it would be feasible for neurologically impaired patients to use the device for assessing finger individuation, and that ii) the extracted outcome measures would show high reliability in able-bodied subjects, as well as discriminative ability.

II. METHODS

A. Finger individuation device

The device implemented in this study expands on a previously built prototype designed for assessing finger motor control that was used in prior studies [6]. Its development followed a user-centered design approach, to improve its feasibility for clinical and research applications. The technical requirements were based on literature and clinicians' inputs and an iterative development approach was followed

with end-user testing throughout. This included three design circles (involving five neurological patients) focusing on the software (e.g., comprehensive interface) and hardware (e.g., hand positioning) components. As a result, the novel version of the device consists of six bi-directional load cells (DYLY-109, DAYSEN-SOR, China, -98 to 98N), one for measuring the thumb on each side and four for the remaining fingers, that can be positioned under each fingertip, thanks to linear sliders, to measure the forces exerted by each digit (see Fig. 1A). The force sensors are linked to an amplifier (HX711 analog-to-digital converter) and the signals are then processed by a microcontroller (Arduino Mega 2560, Arduino, Italy), that is connected to a laptop with a custom designed assessment software developed using the MATLAB Designer App (MathWorks, USA) to record, visualize, and analyze the collected force data. The software offers a user-friendly interface, enabling clinicians and researchers to monitor the force applied by each finger individually in real-time during the assessment (Fig. 1B).

The hand is securely positioned on the device with adjustable Velcro straps around each fingertip ensuring proper force transmission in flexion and extension and accommodating for different finger sizes. Additional Velcro straps stabilize the proximal phalanges to prevent unintended bending of the hand. A larger forearm strap secures the arm for proper alignment and a relaxed hand position. This fixation system ensures stability, ergonomic positioning, and accurate force measurements by maintaining a consistent hand position across sizes. Additionally, the device features a rotational axis to switch sides, allowing for measurements of the left and right side in an ergonomical forearm supination with the same apparatus.

B. Finger individuation assessment procedure

Once the hand is secured in the apparatus, the experimenter can choose between the assessment of isometric flexion or extension. The individuation assessment is based on previous studies [6] and starts with a baseline measurement. The subject is asked to relax the hand and fingers and a mean resting force over five seconds is calculated for each finger, which is later subtracted from all force measurements to only measure actively produced forces. Following this, the Maximum Voluntary Force (MVF) is measured. Subjects are asked to flex or extend one finger for five seconds as hard as possible while solely seeing a visual representation of the produced force of the instructed finger on the screen. For each measurement, the maximum is defined as the 95th percentile value of the maximum recorded force data. The MVF is calculated as the mean of three attempts with any measurements falling below 60% of the other values being discarded.

To assess finger individuation subjects are then asked to produce flexion or extension force respectively, with one instructed finger at a time until they reach a desired target range (± 10% of the target force) visualized on the screen (see Fig. 1B). The target force is based on the MVF and is evaluated on four Force Levels (FL): 20, 40, 60, and 80% of the MVF. Each level is repeated four times per block with a trial (i.e., applying the specific force level) being considered successful if the force of the instructed finger remains within the target range for about 0.5 seconds within the 10 seconds trial duration. The force applied by each finger is visualized during the individuation trial, providing feedback on the finger enslaving, and a change in color of the instructed finger indicates that the target range is reached. To ensure true flexion and extension, trials with a MVF smaller (or bigger for extension) than $(FL - 100)/FL$ times the baseline force were discarded.

C. Outcome measure of finger individuation

During the finger individuation assessment, raw force data over time for all fingers is recorded. Based on this, the individuation index (IndX) is calculated to quantify finger individuation which reflects the ability of each finger to produce isolated force as introduced by Xu and colleagues [6]. In our implementation of the IndX, it is calculated by evaluating the force of all uninstructed fingers during all cumulative time points (N) where the instructed finger is within the target range (see blue shaded area in Fig. 2A,B), hence allowing for an analysis of partially completed trials

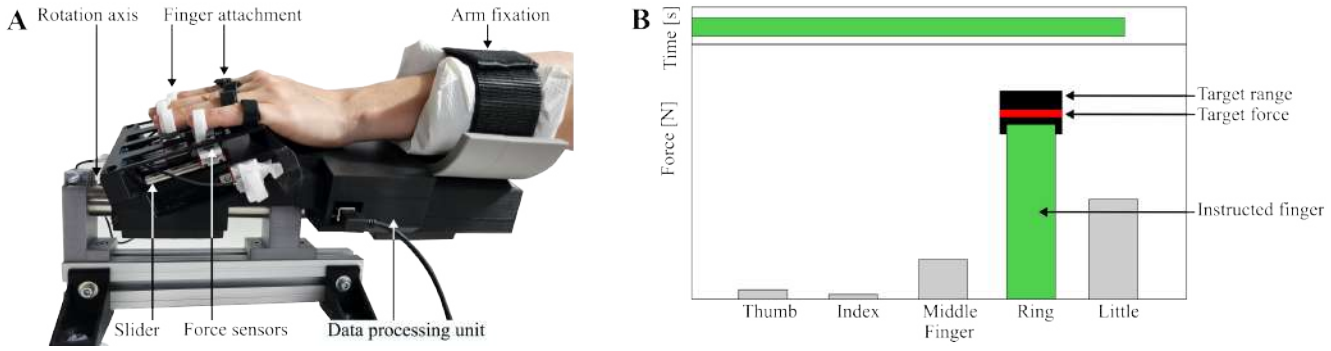

Fig. 1. A: Adjustable finger individuation device with force sensors located under each fingertip to measure isometric flexion and extension forces. B: Visual representation of a finger individuation assessment trial. Participants receive feedback on the force produced by each finger (gray bars) while trying to produce and maintain for 0.5 seconds a target force with the instructed finger (here ring finger). Once within the target range (black box), the bar representing the produced force changes color from blue to green. The target range is defined as 20% of the target force (red) that corresponds to 20, 40, 60, or 80% of the Maximum Voluntary Force (MVF).

as well. With a sampling rate of 80 Hz, the minimum N was set to be 40, reflecting around 0.5 seconds. Afterwards, the Root Mean Square (RMS) of the difference between the baseline force (BF_i) and the force executed by the uninstructed fingers ($F_{n,i}$) for all uninstructed fingers (i) is taken, as can be seen in the equation (1) below:

$$RMS = \frac{1}{N}\sum_{n=0}^{N} \sqrt{\sum_{i=uninstructed} (F_{n,i} - BF_i)^2} \quad (1)$$

Higher deviations from the baseline force in the uninstructed fingers correspond to more enslaving and hence poorer independent control of the fingers. To then calculate the IndX, the mean RMS per block is plotted against the force of the instructed finger for all four force levels, FL (see example in Fig. 2C). Performing a linear regression without intercept gives a slope for every finger, which represents the IndX. A smaller slope (IndX closer to zero), due to less co-activation in the uninstructed fingers, corresponds to better individuation of the instructed finger.

D. Evaluation study

To test the reliability and validity of the individuation device, young able-bodied subjects as well as neurological inpatients from the cereneo, center for neurology and rehabilitation (Vitznau and Hertenstein, Switzerland) were recruited. The study was approved by the local ethics committee (Ethikkommission Nordwest- und Zentralschweiz, 2023-00731). To participate in the study, able-bodied subjects had to be between 18 and 40 years old, show no cognitive impairment, no history of neurological diseases, and no pathologies of the upper extremities. Inclusion criteria for patients were a previously diagnosed neurological disease, subjective impairment of hand dexterity, between 18 and 100 years old, and able to understand task instructions and give consent. Patients with severe visual impairments, pain in the upper extremities, major psychiatric illness, previous experience with the device, or severe hand spasticity or tremor were excluded.

After providing informed consent all participants underwent the baseline and MVF measurement followed by a familiarization trial of the individuation assessment. The testing then included extension and flexion measurements with the force levels and instructed fingers appearing in random order. For the able-bodied participants a second round of testing was performed after a ten minute break, where the hand was removed from the device. This re-test included the measurements of two fingers (thumb and ring) for extension and all fingers for flexion. As a secondary analysis and to validate the strength measurements, the MVF was compared to grip strength (assessed with a Jamar dynamometer) in able-bodied subjects.

E. Statistical analysis

Descriptive statistics, including mean values and standard deviation, were calculated to compare the two groups. Feasibility of the device as an assessment of finger individuation was assessed by observing whether patients could be measured with the device and the corresponding set-up time, while the number of successful trials and the total assessment time was used to determine its clinical applicability. The IndX was computed for each finger to assess finger individuation. Reliability of the MVF and IndX was evaluated in able-bodied subjects using Intraclass Correlation Coefficients (ICC) and Spearman correlation (ρ) to confirm the consistency of measurements across repeated trials. Reliability was classified as follows: ICC values $<$0.5 indicated poor, 0.5–0.75 moderate, 0.75–0.9 good, and $>$0.9 excellent reliability [20]. Spearman correlation coefficients were categorized as $|\rho|$ $<$0.39 for weak, 0.4–0.69 for moderate, 0.7-0.89 strong, 0.9–1 for very strong correlation [21] and statistical significance was always set at a p-value of $\alpha \leq$0.05. For the MVF, concurrent validity was analyzed through a Spearman's rank correlations with respect to clinical assessments of grip strength. Differences in IndX between fingers were tested using t-tests (with a Bonferroni Correction) to compare mean values. Additionally, the Area Under the Curve (AUC) from Receiver Operating Char-

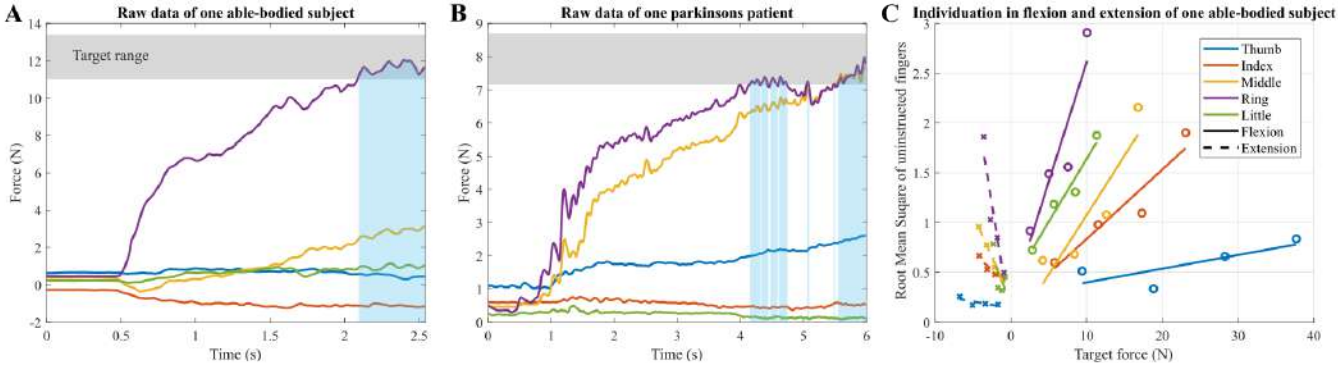

Fig. 2. Raw data of finger individuation assessment of a ring finger flexion trial to reach 80% Maximum Voluntary Force (MVF) for an able-bodied subject (A) and Parkinson's patient (B). Blue shaded areas indicate timepoints where the instructed finger remains within the target range (gray area), which are considered for the calculation of the individuation index (IndX). C: Example of the IndX for flexion (continuous line) and extension (dashed line) in one able-bodied subject. The index is calculated as the slope of the regression line formed by points representing the four levels of MVF versus the Root Mean Square force of the uninstructed fingers. Flatter slopes indicate better individuation.

acteristic (ROC) analysis was calculated to evaluate the discriminative ability of the IndX, determining whether the device could successfully differentiate between patients and able-bodied subjects. AUC values for ROC were classified as 0.90–1.00 for outstanding, 0.80–0.89 for excellent, 0.70–0.79 for acceptable, 0.50–0.69 for poor discrimination, and 0.50 for no discrimination [22].

III. RESULTS

A. Feasibility of the individuation device

Thirty able-bodied subjects and four patients with different neurological conditions and levels of upper limb performance (assessed by Action Research Arm Test, ARAT, with corresponding scores of 53, 44, 56, and 38 points) were assessed to evaluate feasibility (for details see Table 1). This cohort allowed for an analysis of the device's applicability in a real-world clinical setting. Mounting to the device was done in less than five minutes with no report of discomfort at any time and no difficulties understanding the task.

The average total time required to complete a single modality assessment (e.g., flexion) was 19 minutes in able-bodied subjects (with constantly reduced measurement durations in the following sessions) and 23 minutes in patients. Out of the 606 completed trials for the patients 516 were successful (85.15%), demonstrating effectiveness. It has to be noted, that 64 of 90 failed trials can be associated to one subject (patient 4) who suffered from tremor and that solely 5 trials in total could not be analyzed as the total time spent within the target range for those was below 0.5 seconds. For comparison, the 30 able-bodied subjects assessed had a 99.98% success rate (8159 out of 8160 trials).

B. Finger individuation

To quantify finger enslaving, the IndX was derived from the force data collected during the assessment, providing a clear metric for evaluating isolated finger force in flexion and extension (Fig. 2C). Higher levels of enslaving in the uninstructed fingers could be observed with higher force levels, which is represented in the positive IndX (and slopes in Fig. 2C) for flexion and negative IndX for extension respectively (Table 2).

TABLE I

PARTICIPANT DEMOGRAPHICS AND CHARACTERISTICS

Characteristic	**Able-bodied**	**Patients**
Number of participants	30	4
Age (mean ± SD)	24.3 (±2.8)	69.5 (±2.7)
Sex (m, f)	13, 17	3, 1
Handedness (l, r)	5, 25	0, 4
Impaired side (l, r)	NA	1, 3
Condition	NA	Stroke = 1 Parkinson's = 2 Brain tumor = 1
Grip strength (mean ± SD) Dynamometer [N]	(n = 26) 36.68 (±9.35)	(n = 3) 23.43 (±5.50)

C. Reliability

Details of the test-retest reliability analysis in able-bodied subjects is reported in Table 2. For the MVF, ICC indicates good to excellent reliability and strong to very strong correlations between the two measurements for all fingers. Moderate to good reliability (except for the middle finger flexion and thumb extension), as indicated by the ICC, can be seen for the IndX and the results from the Spearman correlation show moderate to strong correlations (except for the thumb in extension) respectively.

D. Validity

For the MVF measurements, all fingers showed significant moderate correlations (thumb: ρ = 0.64, p $<$ 0.001; index: ρ = 0.63, p $<$ 0.001; middle: ρ = 0.63, p $<$ 0.001; ring: ρ = 0.64, p $<$ 0.001; little: ρ = 0.67, p $<$ 0.001) indicating that the strength measurements align well with the established gold standard.

The ability of the IndX to differentiate between able-bodied subjects and patients is visualized in Fig. 3. Extension of the little finger for patient 1 is missing, as the relationship between maximum strength and baseline did not allow for a pure extension assessment. This was also the case for three other 20% MVF blocks in patients, which nevertheless allowed for a calculation of the IndX.

The AUC indicates outstanding discriminant validity for the flexion of the thumb (AUC = 0.99) and excellent for the little finger (AUC = 0.88). Acceptable discrimination was achieved for the flexion of the ring (AUC = 0.71) and poor for the index and middle in flexion (AUC = 0.60 and 0.59)

TABLE II

MVF = Maximum Voluntary Force; IndX = Individuation index; SD = Standard Deviation; ICC = Intraclass Correlation Coefficient; ρ = Spearman correlation; p = significance (* p $\leq$ 0.05)

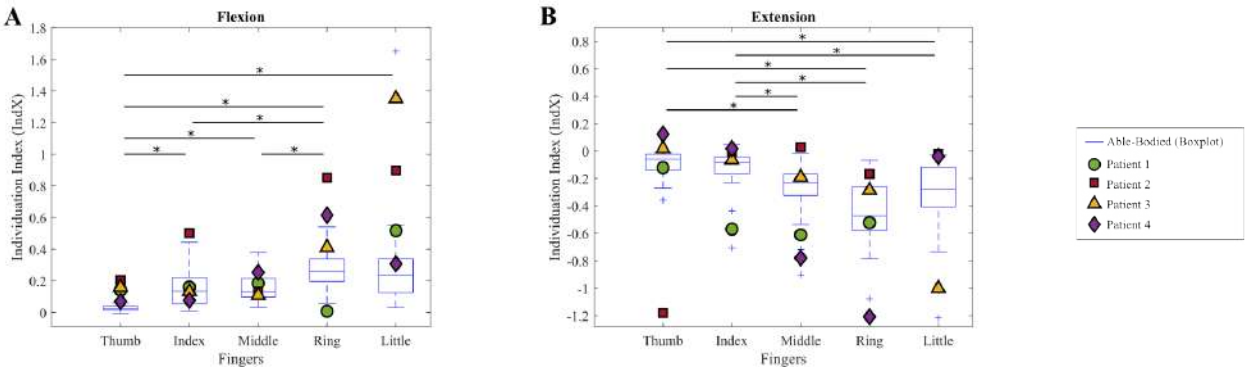

Fig. 3. Individuation index (IndX) for able-bodied participants (blue) and patients (green, red, yellow, purple) in flexion (A) and extension (B) showing medians and interquartile ranges. IndX values closer to zero indicate better individuation. Statistically significant differences between the fingers of the able-bodied subjects are marked with an asterisk.

as well as little, index, and thumb in extension (AUC = 0.67, 0.59, 0.58) while the other fingers indicate no differentiation ability with an AUC of 0.43 and 0.48 and for middle, and ring finger extension respectively.

IV. Discussion

This study presents the development and evaluation of a device for assessing finger individuation, designed to be both user-friendly and reliable. The device allowed for successful measurements of able-bodied subjects and neurological patients, confirming its feasibility and clinical applicability. Across both user groups, adjustable hand and finger fixations via Velcro straps and sliders ensured proper ergonomic positioning and stability for both hands. These findings confirm that the device is well-suited for integration into clinical settings, potentially easing the accessibility of finger individuation measures which could allow for a better identification of the deficit and hence support the development of personalized therapy.

To objectively quantify isometric finger independence, the individuation index (IndX) was developed based on previously established methodologies [6]. Overall, the results obtained align well with findings from similar studies, that demonstrate higher enslaving with higher forces of the instructed finger (Fig. 2C) [5], [15]. In addition, the IndX reveals a distinct pattern of enslaving, with the ring and little finger exhibiting the highest enslaving, followed by the index and middle showing similar levels of enslaving, and the thumb showing the best individuation (Fig. 3 and Table II). This pattern slightly differs from earlier findings [19], [23], where the index was found to show less enslaving than the middle finger. These differences likely stem from differences in calculation of the IndX. Unlike previous studies that could only measure unidirectional forces [6], [5], our approach considers both flexion and extension forces produced by the uninstructed fingers during the individuation task, providing a more comprehensive analysis, but possibly contributed to higher enslaving values. This is partly confirmed by our results better aligning with the individuation pattern found by Xu et al. [24], where all dimensions of the finger (flexion, extension, adduction, and abduction) were measured. Notably, enslaving was generally more pronounced in extension than in flexion, aligning with results from Sanei and Yu [15], [12], with a slight exception for the index finger. Finally, when taking the average IndX of all fingers, it tends to be higher than the slope recorded in previous research (0.087 ±0.046) [6]. This could possibly be explained by the fact that our implementation of the IndX solely considers forces applied while the instructed finger is within the target force, rather than during the entire task duration, as in previous research [6]. While our implementation should better capture enslaving at the defined force levels, it underlines the need for consensus on the calculation of the individuation index to further enhance comparability across studies.

The high test-retest reliability, as reflected in the ICC and Spearman correlation values, indicates the device's consistency in delivering reproducible measurements for MVF and individuation of most fingers. Reliable data collection is essential for both clinical and research applications, as it enables clinicians to track a patient's progress over time and researchers to compare data across studies. Low levels of reliability have only been observed for the thumb during extension. An explanation for this might be the challenge in consistent fixation of that specific finger over different trials, which might be the reason why previous researchers have not considered the thumb in their individuation device [5], [10], [15].

Strong correlations were found between grip strength and MVF assessed with the individuation device, indicating the device's potential to provide an objective strength measurement that corresponds to established clinical evaluations. However, the variable AUC values indicate mixed abilities to distinguish between able-bodied participants and patients in terms of individuation, which might be influenced by the limited number of patients measured and the fact that the patients included in the study did not necessarily exhibit specific impairments in finger individuation. Previous research by Xu et al. [25] summarized that in stroke patients' individuation is decreased, especially in extension. Relatively preserved individuation abilities may be the reason why this pattern is not evident in our study and thereby reducing

the observable differences in enslaving between flexion and extension.

Future studies should investigate the relationship of individuation to other factors influencing dexterity and expand this research to include larger and more varied populations which would provide a clearer picture of the device's applicability across different groups.

V. CONCLUSIONS

This study presents an improved device for the assessment of finger individuation, demonstrating good reliability and moderate validity. The device has potential for clinical applications to more sensitively quantify hand function and provide valuable insights into patient's rehabilitation progress, enabling clinicians to tailor interventions based on individual needs. The practical design of the assessment tool also facilitates its use in research, allowing for standardized measurements in studies investigating hand fine motor control and hence advancing the understanding of finger individuation.

ACKNOWLEDGMENT

The authors would like to thank all the participants that took part in this study. Additional thanks go to Lukas Gerber and Jay Song for their work in the development of the device.

The Impact of Phase Variable Accuracy on Continuous Controller Performance for Knee-ankle Prostheses: A Case Study

David J. Kelly and Patrick M. Wensing

***Abstract*— Robust and effective control algorithms are essential for advancing powered lower-limb prostheses from laboratory settings to broader commercial use. Continuous controllers, which estimate an individual's gait progression to determine desired joint actuator outputs, have recently shown great promise. However, their success relies on accurately estimating the individual's progression through the gait cycle to ensure proper actuator behavior. This study introduces an improved method for computing gait cycle progression using only the global sagittal thigh angle for a knee-ankle prosthesis user, and explores how the accuracy of gait progression estimation impacts controller performance. Two controllers were tested with the original and improved gait cycle estimation algorithm: a joint-level impedance controller and a task-level center of mass controller, extended to the knee-ankle configuration herein. Experiments were conducted with an individual without amputation walking on a knee-ankle prosthesis. Higher linearity in gait estimation (R^2=0.984 vs. R^2=0.980) using the improved method resulted in lower shank velocity (>25%), better symmetry of shank velocity (∼75%), and lower impact into the mechanical hardstop during knee extension in swing for the impedance controller.**

I. Introduction

Over the past decades, there has been an increased effort on the design [1] and control [2] of powered lower-limb prostheses in the research community. This effort has focused on the common goal of improving the performance and capabilities of these powered devices such that they may be made available for commercial use for individuals with lower-limb amputation (LLA).

While there have been recent improvements in design [1] and performance capabilities [3] of powered prostheses, powered knee-ankle prostheses are not yet commercially available. Appropriate control of these devices remains an open research topic to demonstrate clinically significant outcomes to push these devices beyond the laboratory [4]. However, several control methodologies have shown promising outcomes for further progress towards daily use.

A control methodology that has been successfully implemented pairs finite state machines with impedance control [5]. The gait cycle is segmented into discrete phases (e.g., early stance, late stance, early swing, late swing), each with their own set of control parameters for actuator output, and switching conditions handled by sensor data. A downside of finite state machines, however, is the parameter explosion dilemma [6]. For each activity mode, each discrete phase uses its own control parameters and switching conditions, which take time and expertise to tune to the user [5], [7].

This work was funded through the NSF CAREER Grant, award ID CMMI-1943703.

Authors are with the Department of Aerospace and Mechanical Engineering, University of Notre Dame

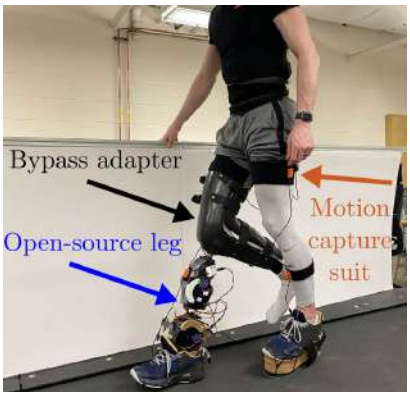

Fig. 1. Visualization of the hardware setup used for the case study. The individual donned a bypass adapter to walk on the Open Source knee-ankle prosthesis, while wearing an Xsens motion capture suit.

Beyond discrete parameter sets and switching conditions, many continuous controllers have also shown promising outcomes. Complementary limb motion estimation combined joint kinematics of the sound limb with a model of inter-leg coordination to continuously determine prosthetic-side actuation [8]. Impedance controllers have defined parameters (joint equilibrium angle, stiffness, and damping) as continuous trajectories [9], which aligns with experimental observations of joints behaving like variable impedance systems [2]. Data-driven approaches to explicitly mimic normative joint kinematics [10], kinetics [9], or both [11], have been used to generate these reference trajectories, either through hand-tuning [10] or optimization methods [11]. A recent task-space control (TSC) framework from the authors demonstrated that reference trajectories for desired center of mass (CoM) kinematics and ground reaction forces (GRFs) could be used to calculate desired joint torques continuously throughout the stance phase for ankle prostheses [12].

The reference trajectories for these controllers are typically defined with respect to the gait cycle, which is estimated using phase variables [2], [13]. The measurable characteristics used for phase variables must result in monotonic progression. For ankle prostheses, the phase portrait of the global sagittal shank angle and shank angular velocity [14] provided robust tracking for level-ground walking [9], [12]. Shank-based methods are less suitable for knee-ankle control however, since the user no longer directly controls the shank.

For knee-ankle control, thigh-based methods have been implemented with varying success [11], [15], [16]. Similar phase portraits have been attempted using the global sagittal thigh angle in combination with either thigh angular velocity [17] or the integral of the thigh angle [18]. However the velocity-based portrait is not monotonic without appropriate

filtering, and the integral-based method drifts without very accurate integration. To remove reliance on temporal factors, phase has been estimated directly from the global sagittal thigh angle using piecewise equations based on different sections of the thigh angle profile [11], [15]. The first implementation of this method (see Sec. II-A.1 for more details) did not account for the fact that the thigh angle retracts prior to heel strike, which led to early saturation of phase estimation [15]. A more recent implementation of this method addressed these issues by introducing a more granular subsectioning of the thigh angle profile, along with a feedforward phase progression when thigh angular velocity was low [11].

This work is inspired by the improvements for thigh-based phase estimation in [11], and looks to investigate extending the methodology used in [15] to avoid incorporating reliance on temporal sensitivities. More specifically, the main contribution of this work is a phase variable for level-ground walking based purely on global sagittal thigh angle progression. The phase variable from [15] is extended to consider maximum thigh flexion near the end of the gait cycle to mitigate early phase saturation without introducing reliance on feedforward or temporal parameters. A secondary contribution is the extension of the TSC framework in [12] for knee-ankle control. The rest of this paper is organized as follows. The phase variable from [15], and the proposed phase variable in this work are defined. The two continuous controllers of interest, an impedance controller and the TSC controller extended to knee-ankle control, are briefly outlined. Results from testing with an individual without amputation (Fig. 1) are presented, followed by discussion.

II. Methods

In this section, two thigh-based phase variables of interest are first defined in Sec. II-A. The two continuous controllers that test the effectiveness of the phase variables are briefly outlined in Sec. II-B. For this work, the global sagittal thigh angle is measured with respect to the vertical, with flexion representing the positive direction.

A. Phase Variable Design

As previously noted, this work draws inspiration from the thigh-based phase variables used in [11] and [15]. To build the piecewise-continuous phase variables, it is important to understand the general thigh angle profile during level ground walking. As illustrated in Fig. 2, the thigh initially starts in a flexed (positive angle) position in front of the individual at heel strike, denoted by θ_{HS}. The individual then vaults over their leg as the thigh progresses towards maximum extension, θ_{ME}. The thigh then moves towards maximum flexion, θ_{MF}, during swing, before retracting back slightly right before the next contact event.

1) Two-piece Phase Variable: The work in [15] assumed that the thigh angle profile was composed of two monotonic sections, separated based on θ_{HS} and θ_{ME}. The phase variable ϕ_{orig} for estimating gait progression was then defined using the following piecewise-continuous equation

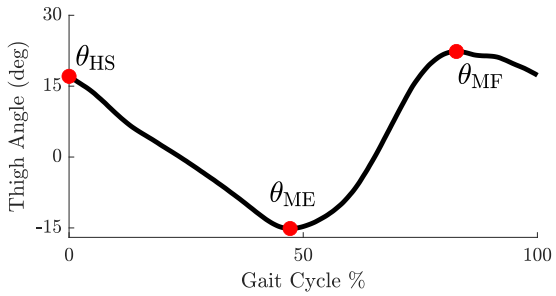

Fig. 2. Global sagittal thigh angle profile over the gait cycle for level-ground walking. Points denoted θ_{HS} (heel strike), θ_{ME} (max extension), and θ_{MF} (max flexion) are key parameters used for phase estimation.

$$\phi_{\mathrm{orig}} = \begin{cases} \frac{\theta_{\mathrm{HS}}-\theta}{\theta_{\mathrm{HS}}-\theta_{\mathrm{ME}}}\phi_{\mathrm{ME}} & \theta_{\mathrm{HS}} \rightarrow \theta_{\mathrm{ME}} \\ 1+(1-\phi_{\mathrm{ME}})\frac{\theta-\theta_{\mathrm{HS}}}{\theta_{\mathrm{HS}}-\theta_{\mathrm{ME}}} & \theta_{\mathrm{ME}} \rightarrow {\theta_{\mathrm{HS}}}^{+} \end{cases}, \quad (1)$$

where θ is the current thigh angle, ϕ_{ME} is the expected progression at θ_{ME} ($\sim$55% [19]), and ${\theta_{\mathrm{HS}}}^{+}$ denotes heel strike of the next gait cycle. Note that a slight change in this work is the use of ϕ_{ME} in the first part of the equation, while [15] used a tunable parameter based on toe-off.

Since initial values for θ_{HS} and θ_{ME} may not align with real-time measurements, these values are updated online at the end of each gait cycle. For each gait cycle, θ_{HS} is determined at ground contact, while θ_{ME} is found when a minimum thigh value is detected. Using the past three gait cycles, the value for θ_{HS} used in (1) is the average value of θ_{HS} for the past three gait cycles, while θ_{ME} is the maximum value (smallest thigh extension) to avoid divergent behaviors that would cause the user to take longer and longer strides.

2) Three-piece Phase Variable: The formulation for calculating ϕ_{orig} above ignores the fact that the thigh flexes beyond θ_{HS}, and retracts back towards θ_{HS} prior to heel strike. The proposed phase variable ϕ_{ours} extends the methodology described above to include considerations of this retraction period by segmenting the thigh angle profile into three monotonic sections. The first section is still defined between θ_{HS} and θ_{ME}. The second section for ϕ_{ours} progresses from θ_{ME} to θ_{MF}, while the third section accounts for θ_{MF} to ${\theta_{\mathrm{HS}}}^{+}$. The phase variable ϕ_{ours} for estimating gait progression was then defined by the piecewise-continuous equation

$$\phi_{\mathrm{ours}} = \begin{cases} \frac{\theta_{\mathrm{HS}}-\theta}{\theta_{\mathrm{HS}}-\theta_{\mathrm{ME}}}\phi_{\mathrm{ME}} & \theta_{\mathrm{HS}} \rightarrow \theta_{\mathrm{ME}} \\ \phi_{\mathrm{ME}}+(\phi_{\mathrm{MF}}-\phi_{\mathrm{ME}})\frac{\theta-\theta_{\mathrm{ME}}}{\theta_{\mathrm{MF}}-\theta_{\mathrm{ME}}} & \theta_{\mathrm{ME}} \rightarrow \theta_{\mathrm{MF}} \\ 1+(1-\phi_{\mathrm{MF}})\frac{\theta_{\mathrm{HS}}-\theta_{\mathrm{MF}}}{\theta-\theta_{\mathrm{HS}}} & \theta_{\mathrm{MF}} \rightarrow {\theta_{\mathrm{HS}}}^{+} \end{cases}, \quad (2)$$

where ϕ_{MF} is the expected progression at maximum flexion ($\sim$80% [19]). In this formulation, the parameters θ_{HS}, θ_{ME}, and θ_{MF} were updated following the same methodology used in [11]. The values for these parameters were recorded from the previous five gait cycles, with θ_{HS} calculated as the average of the median three values, and θ_{ME} and θ_{MF} determined as the average of the maximum and minimum three values, respectively. Offline analysis confirmed that the

different methods for averaging θ_{HS} and θ_{ME} between ϕ_{orig} and ϕ_{ours} did not significantly change phase estimation.

B. Continuous Controllers

To test the efficacy of the two phase variables previously defined, two continuous frameworks were built for control of a knee-ankle prosthesis. The first controller uses an impedance framework to control the prosthesis, while the second controller extends the task-level framework implemented in [12] from ankle-only to knee-ankle control. Note that since the prosthesis used in this work can only be controlled in the sagittal plane, all joint angles are with respect to the sagittal plane. Likewise, all TSC references are defined in the fore/aft and vertical directions.

1) Phase-based Impedance Controller: As previously noted, continuous impedance controllers require reference trajectories to command the appropriate joint torque. For the ankle joint, these reference trajectories are the same as used in [9], [12]. The equilibrium angle, stiffness, and damping trajectories are illustrated in Fig. 3, and manually tuned to replicate a normative ankle torque profile [20]. Note that the equilibrium references do not directly match the normative trajectories in order to properly generate torque.

For the knee joint, the stiffness and damping trajectories are based on [11] for level-ground walking (Fig. 3). Note that the impedance parameters in [11] are only defined for the stance phase since a position controller is used during swing. Therefore, the stiffness and damping trajectories during swing are manually tuned to ensure proper knee flexion for ground clearance, as well as proper knee extension to prepare for weight acceptance at the end of swing. Similarly, the equilibrium angle is designed to ensure weight support during stance and proper knee flexion during swing.

The commanded joint torques $\boldsymbol{\tau}_{\text{I}}$ are then calculated by $\boldsymbol{\tau}_{\text{I}} = \mathbf{K}_{\text{I}}(\boldsymbol{\theta}_{\text{I}} - \boldsymbol{\theta}_{\text{J}}) - \mathbf{B}_{\text{I}}\dot{\boldsymbol{\theta}}_{\text{J}}$, where $\boldsymbol{\theta}_{\text{I}}$, $\mathbf{K}_{\text{I}}$, and $\mathbf{B}_{\text{I}}$ are the joint equilibrium angles, joint stiffnesses, and joint damping matrices, and $\boldsymbol{\theta}_{\text{J}}$ and $\dot{\boldsymbol{\theta}}_{\text{J}}$ are the measured joint kinematics.

2) Task-space Controller: For sake of brevity, a high-level description of TSC is provided here, along with a visual in Fig. 4. The reader is referred to [12] for full details on TSC.

While the impedance controller uses reference joint impedance trajectories to calculate desired joint torques, TSC uses reference system-level trajectories, in this case CoM kinematics and GRF profiles. This methodology aligns with previous research that suggests system-level characteristics may govern observed joint-level responses to balance recovery [21] and natural stride-to-stride variations [22].

These reference trajectories are generated by normalizing able-bodied CoM kinematics [23] by easily measurable parameters (e.g., height and stride duration). For a particular user, these kinematics are then rescaled by that individual's values for those measurable parameters. A custom-built optimization framework then fits the dynamics of human walking template models to the rescaled CoM kinematics, which yields the desired CoM and GRF profiles [24]. This trajectory generation is illustrated at the top of Fig. 4.

The reference trajectories are used in tandem with an Xsens motion capture suit [25] online to determine desired joint torques. The leg on the amputation side is modeled as a three-link system (thigh, shank, foot) with a fixed base at the pelvis, assuming negligible effect from external forces. The reference GRFs $\mathbf{F}$ are converted into feedforward joint torques $\boldsymbol{\tau}_{\text{FF}}$ via the Jacobian $\mathbf{J}$ of the three-link model

$$\boldsymbol{\tau}_{\text{FF}} = \mathbf{S}_{\text{FF}}\mathbf{J}^{\top}\mathbf{F} \tag{3}$$

Note that this formulation calculates torques for the hip, knee, and ankle, though only the knee and ankle components are used via the selector $\mathbf{S}_{\text{FF}} = [0\ \ 1\ \ 0; 0\ \ 0\ \ 1]^{\top}$.

The residual between the reference and real-time CoM kinematics (reference minus real-time), $\boldsymbol{\Delta}_{\text{com}}$, is used for a feedback force correction term. The resulting feedback joint torques on each joint are determined using

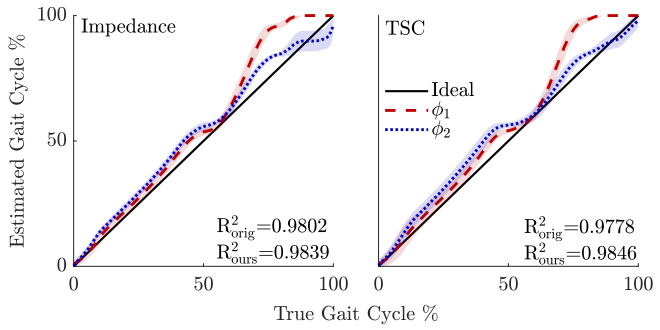

Fig. 5. Average phase estimation throughout the gait cycle for each controller (left: impedance, right: TSC) based on estimation method. An 'ideal' estimation line is included, along with the R^2 linearity values.

$$\begin{aligned} \tau_{\mathrm{FB},i} &= \mathbf{S}_{\mathrm{FB},i}\mathbf{J}^\top(\mathbf{K}_i\boldsymbol{\Delta}_{\mathrm{com}}) - D\dot{\theta}_{\mathrm{J},i} \\ \mathbf{K}_i &= \frac{mg}{H}\boldsymbol{\alpha}_i \end{aligned} \tag{4}$$

where $\mathbf{K}_i$ converts $\boldsymbol{\Delta}_{\mathrm{com}}$ into a force correction term, $D = 8.0\,\mathrm{Nm}\cdot\mathrm{deg/s}$ is a heuristically tuned joint velocity feedback gain, m and H are the mass (kg) and height (m) of the user, g is gravitational acceleration (m/s^2), and $i \in \{\mathrm{knee}, \mathrm{ank}\}$. The matrices $\boldsymbol{\alpha}_{\mathrm{knee}} = \mathrm{diag}([0.1\ \ 13])$ and $\boldsymbol{\alpha}_{\mathrm{ank}} = \mathrm{diag}([0.1\ \ 50])$ each tune the CoM gains for the knee and ankle, respectively. The gains D and $\boldsymbol{\alpha}_i$ do not change across users. The selectors $\mathbf{S}_{\mathrm{FB,knee}} = [0\ 1\ 0]^\top$ and $\mathbf{S}_{\mathrm{FB,ank}} = [0\ 0\ 1]^\top$ choose the appropriate joint torque based off corresponding feedback gains. The feedback joint torques are then $\boldsymbol{\tau}_{\mathrm{FB}} = [\tau_{\mathrm{FB,knee}}\ \ \tau_{\mathrm{FB,ank}}]^\top$.

The feedforward and feedback joint torques are additively combined such that the overall desired joint torques $\boldsymbol{\tau}_{\mathrm{T}} = \boldsymbol{\tau}_{\mathrm{FF}} + \boldsymbol{\tau}_{\mathrm{FB}}$. Since $\boldsymbol{\tau}_{\mathrm{FF}}$ requires GRFs, $\boldsymbol{\tau}_{\mathrm{T}}$ is only active during the stance phase, while $\boldsymbol{\tau}_{\mathrm{I}}$ is active during swing. To ensure continuity between $\boldsymbol{\tau}_{\mathrm{T}}$ and $\boldsymbol{\tau}_{\mathrm{I}}$, a transition torque $\boldsymbol{\tau}^*$ is calculated during the last 7.5% of stance,

$$\begin{aligned} \boldsymbol{\tau}^* &= C_1\boldsymbol{\tau}_{\mathrm{I}} + (1 - C_1)\boldsymbol{\tau}_{\mathrm{T}} \\ C_1 &= \max\left(\min\left(\frac{\phi_i - \phi_{\mathrm{TO}} + 7.5\%}{7.5\%}, 1\right), 0\right) \end{aligned} \tag{5}$$

where C_1 is the weight factor, ϕ_i is the estimated phase variable using either of the methods previously defined, and ϕ_{TO} is the expected phase value at toe-off based on the optimized reference trajectories (typically ∼63%).

C. Hardware

Trials were conducted on the Open Source Leg (OSL) V1 [1] actuated by a Dephy ActPack motor V0.2B [26]. An Xsens MVN Link inertial motion capture suit streamed real-time CoM and lower-limb kinematics at 240Hz using the lower-body plus sternum configuration [25], while two pressure sensors (SEN-08685; SparkFun Electronics) at the heel and toe of the prosthetic foot provided contact estimation. A Raspberry Pi 4 microcomputer handled data reception and code execution. The pressure sensors and motor were wired directly to the Pi, while Xsens data was wirelessly streamed over IP and UDP protocol on a private network using the Xsens Analyze software. Real-time kinematics experimentally ran at ∼210Hz, while data for post-trial analysis was collected at ∼105Hz using the Lightweight Communications and Marshalling library [27]. The individual donned a bypass adapter for the knee-ankle configuration of the OSL, visualized in Fig. 1.

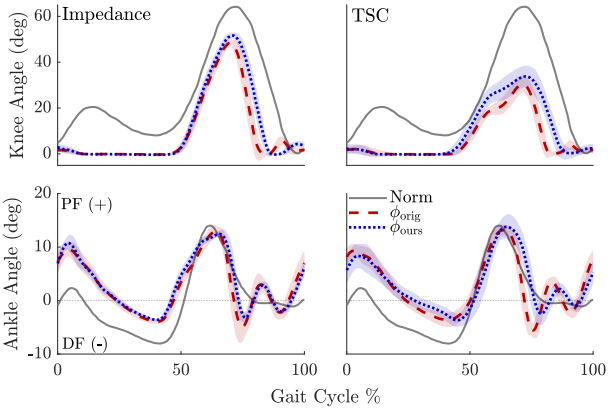

Fig. 6. Average joint progression (top: knee, bottom: ankle) for each controller (left: impedance, right: TSC) based on phase estimation method. Normative kinematics are included for reference [20].

Trials were conducted with an individual without amputation (Male, 28 yrs, 75 kg). Before testing, the Xsens suit IMUs were attached according to the Xsens Link manual, and IMU calibration was conducted as outlined in the Xsens Analyze software protocol [25]. After calibration, the individual acclimated to each continuous controller and phase variable. The individual then walked on the impedance controller with ϕ_{orig} then ϕ_{ours}, then walked using TSC mode with ϕ_{orig} and ϕ_{ours} for a total of four trials. Each trial consisted of walking on a treadmill at 0.7 m/s for 60 seconds, resulting in at least 32 continuous walking strides.

III. Results

A. Phase Estimation

The average phase estimation for each trial is visualized in Fig. 5. For both controllers, ϕ_{orig} saturated to 100% gait cycle early (∼80%) as expected. The first half of the gait cycle was very similar between ϕ_{orig} and ϕ_{ours}, since both methods used the same piecewise function during that time. However, ϕ_{ours} did not saturate early due to the additional piecewise function for thigh retraction. For each gait cycle within a trial (32-35 cycles), the linearity of the phase estimation was calculated. For each controller type, a two-sample t-test was conducted to compare the linearity of the phase estimations. Higher linearity ($p<0.001$) was achieved when using ϕ_{ours} compared to ϕ_{orig} for both controller types.

B. Lower-limb Kinematics

The average sagittal knee and ankle progression for all tested configurations is provided in Fig. 6. The knee kinematics generated using the TSC framework qualitatively match trends for the impedance controller during level-ground walking, however the peak flexion is ∼20° less

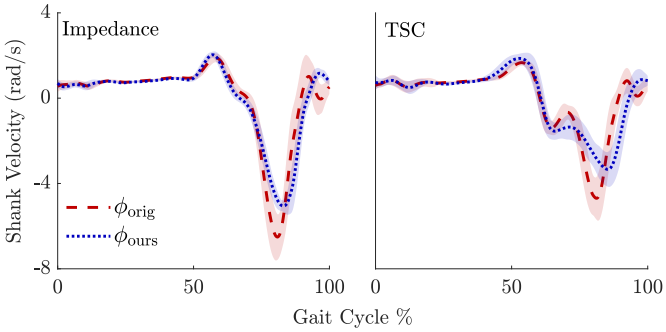

Fig. 7. Average shank angular velocity of the prosthesis for each controller and phase estimation method. Gait cycle starts at heel strike.

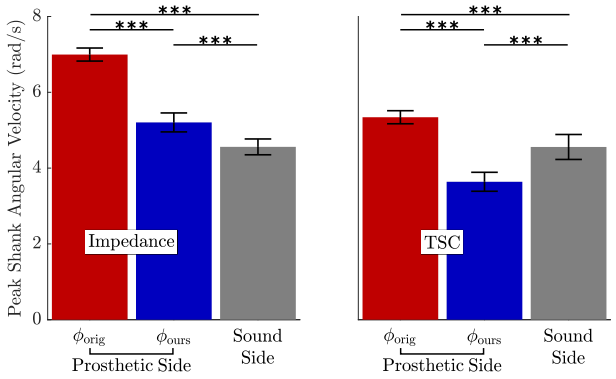

Fig. 8. Average peak shank angular velocity for contralateral shank and each controller (left: impedance, right: TSC) based on phase-estimation method. Asterisks denote statistical significance (***p<0.0005).

than the impedance controller. For each gait cycle, peak knee flexion was recorded for TSC mode using both phase estimation methods. A two-sample t-test showed that using ϕ_{ours} achieved larger flexion compared to ϕ_{orig} (p<0.001).

The angular velocity of the shank was analyzed to investigate why the knee joint hit its mechanical hardstop with higher velocity during the swing phase with ϕ_{orig}, causing some discomfort for the individual. The differences in angular velocity of the shank are shown in Fig. 7, where the peak (minimum) velocity of the shank is on average larger (more negative) when using ϕ_{orig} (7.00 rad/s and 5.34 rad/s for impedance and TSC respectively compared to ϕ_{ours} (5.21 rad/s and 3.64 rad/s for impedance and TSC respectively). For each trial, the peak angular velocity of the shank was recorded for each gait cycle. For each controller type, a two-sample t-test showed statistically significant differences between each phase estimation method (p<0.001).

Fig. 8 compares the average peak shank angular velocity for each trial. While neither estimation method led to strong agreement with the peak shank velocity between prosthetic and contralateral side for either controller (two-sample t-test p<0.0001), the peaks were lower and better aligned for ϕ_{ours} compared to ϕ_{orig}.

IV. Discussion

A. Phase Estimation

Both phase estimation methods used the same calculation through the first $\sim 55\%$ of the gait cycle, which resulted in very similar behavior (Fig. 5). However, accounting for θ_{MF} in ϕ_{ours} eliminated the early saturation seen using ϕ_{orig}, resulting in closer matching to the ideal case of a perfect linear progression using ϕ_{ours}. While ϕ_{ours} saw larger variation during the thigh retraction period, this did not translate to larger variation in joint kinematics during that portion of the gait cycle. This larger variation is because ϕ_{orig} is consistently at 100% during this time.

An interesting consequence of accounting for θ_{MF} in gait estimation is the reliance on thigh retraction prior to ground contact. While θ_{MF} does exist across multiple locomotion modes (e.g., stair ascent/descent, ramp ascent/descent) [19], the timing within the gait cycle does significantly change, such that future work will need to consider updating ϕ_{ME} and ϕ_{MF} based on activity mode or walking speed [19].

B. Lower-limb Kinematics

Extending the TSC framework to knee-ankle control showed promising results. Without any explicit joint characteristics defined in the framework, knee and ankle kinematics were qualitatively similar to those generated by the impedance controller. Compared to normative characteristics [20], early stance lacks knee flexion for both controllers, which may be due to the moment applied to the knee joint locking the joint to its hardstop. The lower knee flexion for TSC may be due to the transition torque between the stance and swing control modes. Increasing flexion is important for future trials to avoid fall risk from foot scuffing.

It is important to note that for each controller, only the phase estimation method changed between trials. The reference trajectories remained the exact same to isolate the impact that phase estimation accuracy has on overall controller performance. Some changes in joint progression did occur when phase estimation diverged. Most notably, for both controllers, the ϕ_{orig} method resulted in earlier knee extension, moreso with TSC than the impedance controller (Fig. 6). However, viewing these joint trajectories without context, there are no discernible characteristics that would suggest one phase method was more favorable than another.

Both visually and in terms of the sound of the prosthesis, the accompanying video highlights the performance impact of the slightly early knee extension in Fig. 6. When using ϕ_{orig} for phase estimation, the early saturation leads to the wrong impedance or task-space parameters being commanded to the motor at the wrong time in the gait cycle, which causes aggressive knee rotation into the mechanical hardstop and oscillations in the prosthetic side limb, which do not occur when using ϕ_{ours}. Removing the saturation with ϕ_{ours} resulted in lower peak shank velocity (Fig. 7 and Fig. 8), leading to improved shank velocity symmetry between the prosthetic side and the contralateral side compared to the controllers using ϕ_{orig}.

C. Limitations

The statistical strength of the results is limited by the lack of subject diversity. Individuals with amputation can experience muscle atrophy and adapt compensatory movements

[28], which impact overall biomechanics such as the presence and magnitude of θ_{MF}. If θ_{MF} is not present, then ϕ_{ours} may not achieve adequate gait progression, which can cause the controller to not achieve appropriate knee extension for the next heel strike. Future work is focused on individuals with amputation across level-ground walking and stair navigation to investigate the efficacy of the ϕ_{ours} and to improve the statistical significance of the outcomes.

The current implementation of the TSC framework uses a motion capture suit to estimate CoM and lower-limb kinematics. Future implementations of this framework may consider simplifying the sensor suite to IMUs attached to the prosthesis, and a single IMU attached to the pelvis.

V. Conclusion

In conclusion, we presented a new proposed phase variable based on the global sagittal thigh angle profile during level-ground walking, which extended a previously existing phase estimation method to account for thigh retraction. It was demonstrated that accounting for thigh retraction improved the linearity of the phase variable and mitigated early saturation. This phase variable was tested on a knee-ankle prosthesis using a continuous impedance controller and a task-space control framework. The improvements in phase estimation significantly impacted controller performance, including less aggressive shank velocity during the knee extension phase of swing. This work also demonstrated that the TSC framework can be extended to knee-ankle control, which will focus future subject trials for level-ground and stair navigation.

Closed-Loop Control of Large Assistive Torques to Unknown External Loads via a Back Support Exoskeleton

Lorenzo Sterzi[1,2], Mohamed Irfan Refai[1,†*], and Massimo Sartori[1*]

***Abstract*— Most control strategies for active back-support exoskeletons (BSEs) do not target users' internal forces while providing assistance, limiting synergy with the user. In our previous study, we proposed a neuromechanical model-based controller (NMBC) that directly targeted lumbosacral (L5/S1) active moments. Despite promising results, the use of a soft exosuit limited the maximum assistance possible, leaving unclear whether increased assistance would have more benefits for the user. Therefore, in this study, we adapted the NMBC to provide assistance via an active rigid BSE and were able to provide higher assistive torques, up to 114.5Nm. We tested three support levels (20%, 50%, 80% of estimated active L5 / S1 moments) provided to three participants lifting two loads (5kg, 15kg) and two lifting techniques (stoop, squat) and compared it with transparent mode (MINIMP) and without exoskeleton (NOEXO). All assisted conditions significantly reduced L5/S1 moments compared to NOEXO, despite the BSE being heavy. A general trend towards reduced effort was observed with higher gains, although, not statistically significant. However, large assistive torques also caused deteriorated torque tracking and instabilities. The system adapted to unknown loads for both techniques. This study demonstrated for the first time the feasibility of using NMBC with larger support gains, highlighting both its potential benefits and challenges.**

***Index Terms*— adaptive support, EMG-driven musculoskeletal model, large assistance, rigid back exoskeletons.**

I. Introduction

Low back pain (LBP) is a prevalent occupational health issue, with an incidence 45% higher in jobs involving manual handling of heavy loads compared to other occupations [1]. The compression forces experienced by the back spine during repetitive lifting cycles can achieve considerable values, increasing injury risk or accelerating degeneration of spinal elements [2]. This process plays a key role in the onset of chronic LBP [3].

In the last few decades, back support exoskeletons (BSEs) have been developed for occupational use to reduce strain on back muscles during manual handling tasks. Passive BSEs utilize elastic components to support the user. Research has demonstrated the significant potential of these devices to reduce back muscle activation during lifting cycles [4], [5]. Furthermore, reductions in mean lumbosacral (L5/S1) joint moments and spinal compression forces have been reported, ranging from 6% to 12% and 5% to 14% respectively[6], [7]. However, their inability to adapt to variations in task dynamics and external loads limit their effectiveness in real-world scenarios.

Active BSEs provide greater control over assistance profiles throughout the lifting cycle and generate larger assistive torques by integrating actuators with advanced controllers. They typically consist of a pelvis module with hip rotational actuators, thigh cuffs, and, in most cases, a thoracic harness [4], [7]. Some designs, however, utilize pneumatic actuators [8]. The median maximal assistance for active BSEs reported in the literature is approximately 72 Nm, compared to 20 Nm for passive ones[4], [5], [7]. Thanks to their higher assistance, active BSEs have a greater impact on user biomechanics than passive ones, achieving greater reductions in muscle activity [4]. Significant reductions in peak compression forces (17.7% on average) and L5/S1 joint moments (11.9% on average) were also reported compared to a no-exoskeleton condition [9]. A key factor in active BSEs effectiveness is selecting a control strategy that ensures synergy with the user's movements. Most control strategies rely on motion-based information, typically using predefined torque profiles [8], [10]. However, these systems often lack adaptability, providing the same assistance regardless of the weight being lifted. To address this limitation, some studies have proposed incorporating electromyographic (EMG) measurements into the control loop to detect movement onset and adapt assistance to different lifting conditions [8]. In these systems, the assistance is directly proportional to the muscle activity. However, since muscle forces depend on the dynamics of muscular contraction, EMG signals or joint angles alone are insufficient to tailor assistance to the user's needs, limiting the synergy with the user [11].

Moya-Esteban et al. (2023) [12] proposed a neuromechanical model-based controller (NMBC) for an active soft exosuit. This controller aimed to exploit model-estimated back muscle moments for support, accounting for the non-linear relationship between EMG signals and biological forces. It used a real-time EMG-driven musculoskeletal model to estimate the active component of L5/S1 joint moments (M_a^{L5S1}). The estimated M_a^{L5S1} was then scaled by a support gain and used to compute the desired assistive force, which was delivered by two linear actuators via force transmission cables. The NMBC significantly reduced mean EMG activity (5kg: 14.4%, 15kg: 25.2%), L5/S1 joint moments (5kg: 18.3%, 15kg: 23.9%), and compressive forces (5kg: 12.1%, 15kg: 16.8%) compared to not wearing the exosuit during stoop lifting. The exosuit design also prevented the use of squat as a lifting technique. The support gain was limited to

(*) equal contribution

20% due to mechanical constraints, restricting the maximum support provided. Higher assistance is expected to induce greater biomechanical reductions, but EMG fluctuations may be amplified causing large, unwanted torque fluctuations.

The main goal of this work was to evaluate whether increasing the support gain could enhance the biomechanical load reduction observed in our previous work [12]. To achieve this, we used a rigid active BSE, as soft exosuits are unable to provide large assistances. The study included both squat and stoop lifting techniques to investigate the NMBC's adaptability to different external loads. This research aims to identify the potential benefits of higher assistive torques on user biomechanics while exploring the associated challenges.

II. Methods

A. Exoskeleton used

A rigid active BSE (weight: 16.5kg) was used in this study. The BSE was developed by the University of Twente (UT) and Delft University of Technology and consisted of a C-shaped rigid frame with 4 series elastic actuators (Bacchus V3, TU Delft), one aligned with the L2-L3 joint and one with the hip on each side. The BSE was attached to the user using an adjustable thorax vest (Laevo FLEX, Laevo, the Netherlands) and two bilateral thigh rigid cuffs. The lumbar actuators were mechanically fixed at an angle of -13° relative to the vertical human axis. The maximum torque of the hip actuators was limited to 60 Nm each for safety. The actuators included torque sensors and encoders to measure joint angles, communicating with a basestation at 1 kHz over EtherCAT, interfacing through TwinCAT 3 (Beckhoff Automation, Verl, Germany). The basestation consisted of a Beckhoff C6025-0000 Industrial PC (Core i5-8365UE 1.6GHz CPU, 8GB of RMA, Windows 10).

B. User instrumentation

EMG signals from back and abdominal muscles were recorded at 1 kHz using 8 Ottobock 13E400 bipolar surface EMG electrodes (Ottobock SE&Co. KGaA, Duderstadt, Germany) following the indications reported in [6]. Raw EMG signals were bandpass filtered (30–300 Hz), rectified and low-pass filtered (3Hz) with 2nd order Butterworth online filters to obtain EMG linear envelopes. Joint angles were recorded at 60Hz using MVN Link inertial motion capture system (Movella, Enschede, The Netherlands). The sensors were placed and calibrated following the manufacturer's guidelines for "Upper Body No Hands" configuration. Both joint angles and EMG linear envelopes were transmitted over Automation Device Specification (ADS) communication protocol to Calibrated EMG-informed neuromusculoskeletal real-time (CEINMS-RT) modeling toolbox [13], where the neuromechanical model was implemented (see section II-C). Within CEINMS-RT, EMG were normalized on maximum voluntary contraction (MVC) values, recorded with isometric contraction tasks for each participant. Before using the system, the model was scaled and calibrated to user-specific biomechanics (see section II-C). To scale the model and compute inverse dynamics (ID) reference moments, the positions of 36 reflective markers on participants' bony landmarks and one on the box's upper edge were recorded. A 12-camera Qualisys motion capture system (Qualisys Medical AB, Sweden) captured the data at 100Hz.

C. Real-time EMG-driven musculoskeletal modeling

A simplified version of the OpenSim lifting full-body model [6] was scaled on each participant geometry using 3D marker data from a static recording (see section II-B) and OpenSim 4.1. The scaled models were then used to build real-time EMG-driven musculoskeletal models, using CEINMS-RT [13] toolbox as described in [12], to estimate user-specific M_a^{L5S1}. Aiming at supporting active muscles' effort, only the active components – i.e., contribution of muscles' contractile element – of the MTU forces were estimated during the model execution. The tendon in the Hill-type MTU model was represented as an infinitely stiff element with a length equal to the slack length. To reduce noise amplification introduced by the derivation of inertial measurement unit (IMU)-recorded joint angles, the force-velocity relationship was neglected. Estimation accuracy was reduced in favor of smoother torque profiles for control purposes. In view of the aforementioned changes, M_a^{L5S1} during model execution was computed as follows:

$$M_a^{L5S1}(t) = \sum_{k=1}^{164} r_k F_k^{mt}(t) \tag{1}$$

where the summation over k spans the 164 MTUs included in the model, r_k is the MTU moment arm over L5/S1 joint, $F_k^{mt}(t)$ the MTU force computed with the following formula:

$$F_k^{mt}(t) = F_{o,k}^m f_a(\bar{l}_k^m(t)) a_k(t) \cos(\phi_k(t)) \tag{2}$$

where $F_{o,k}^m$ is the maximum isometric force, $\bar{l}_k^m$ is the muscle fiber length normalized on the optimal fiber length, a_k is the muscle activation, $f_a(\bar{l}_k^m)$ is the active length-force relationship and ϕ_k is the pennation angle.

For each participant, to obtain a user-specific EMG-driven model F_o^m, tendon slack length coefficient, optimal fiber length and activation dynamic shape factor were calibrated for each MTU. Simulated annealing [14] was used as optimization algorithm, minimizing the summed squared error between reference ID L5/S1 moments and model estimated ones, comprehensive of both active and passive components. The calibration algorithm used EMG signals, L5/S1 joint angles and ID L5/S1 moments of one repetition for each lifting task (see section II-E). ID was performed using OpenSim 4.1 based on IMU-recorded joint angles. The L5/S1 flexion-extension range of motion (ROM) in MVN software differed significantly from OpenSim model. MVN modeled the lumbar spine with 2 segments and 3 joints, while OpenSim accounted for all lumbar vertebrae, making intermediate lumbar joint angles linearly dependent on L5/S1. Therefore, L5/S1 flexion-extension angles were renormalized

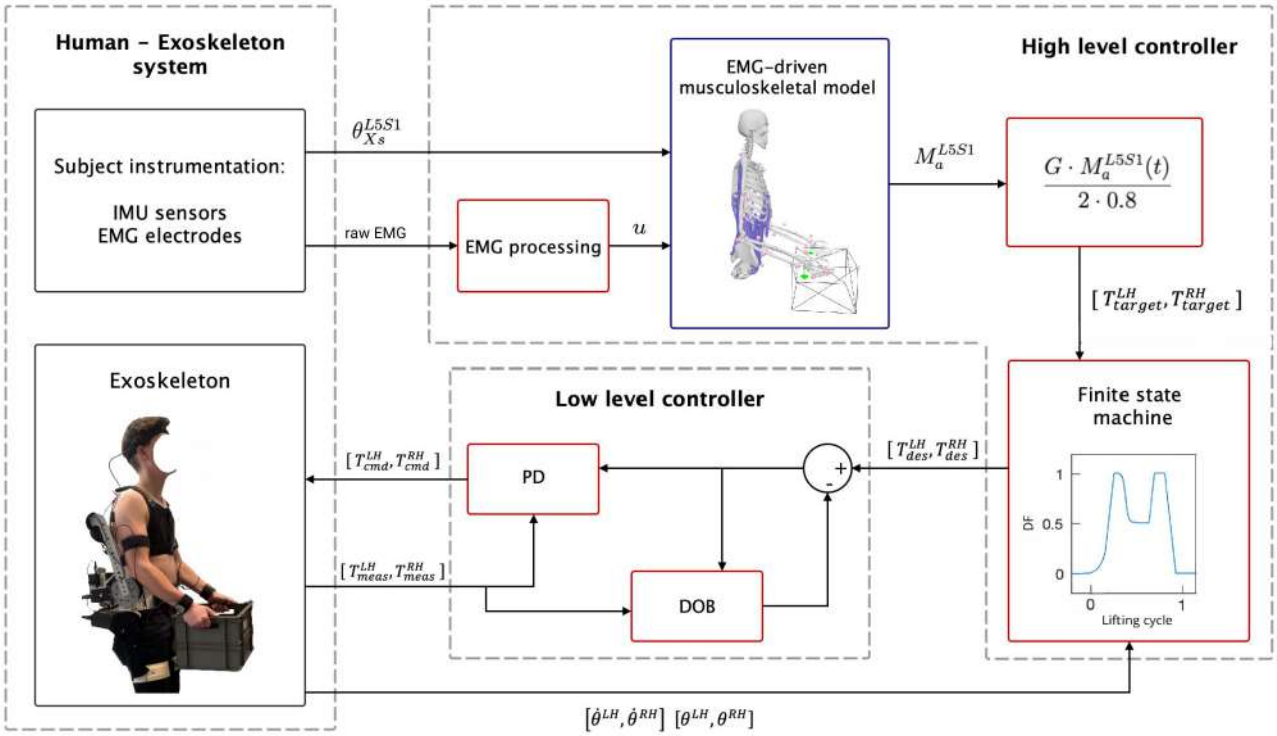

Fig. 1. Schematic diagram of the low-level and high-level controllers used to control the BSE. Blue blocks are executed in CEINMS-RT [13], red blocks are executed in TwinCAT 3. Target torque (T_{target}), desired torque (T_{des}) and command torque (T_{cmd}) are computed for both actuators (left hip (LH), right hip (RH)) in parallel. T_{meas} is the torque measured by the actuators' spring encoders. θ and $\dot{\theta}$ are the actuator's joint angle and velocity respectively.

to match the OpenSim ROM. Gravitational forces acting on participants' hands were added manually to compute ID by calculating the magnitude based on the known load. By tracking the box marker's acceleration, we determined when participants lifted it and the timing of force application. Once optimal internal parameters values were identified, the EMG-driven models were used in open-loop to predict M_a^{L5S1} as a function of measured EMG and IMU data.

D. Neuromechanical model based controller (NMBC)

The control scheme included high-level and low-level controllers (Fig. 1). The low-level controller [15], consisted of an inner loop proportional-derivative (PD) controller and an outer loop disturbance observer (DOB). It regulated torque output at each actuator, tracking a reference torque (T_{des}) set by the high-level controller. Measured torque (T_{meas}) at each actuator was fed back to close the control loop.

The high-level controller, i.e., the NMBC, can be divided into three main stages (Fig. 1). In the first stage, the real-time EMG-driven model estimated M_a^{L5S1}. In the second stage, M_a^{L5S1} was multiplied by a support gain (G), manually set to tune the level of assistance, and divided by a lumbar/hip support ratio fixed to 80%. This value aligned with the physiological ratio of muscle moments at the lumbar and hip levels during lifting tasks [16]. The resulting torque was then equally split between the left and the right hip actuators obtaining a target torque for each one (T_{target}). In the third stage, T_{target} is multiplied by a dynamic factor (DF) tuned by a finite state machine (FSM) to modulate T_{des} at each actuator. The FSM was implemented to minimize interference with the user's movements, particularly during bending, when the assistive torques - always acting against gravity - could otherwise prevent the user from reaching the box to be lifted.

The FSM states were defined as follows:

1) Upright static posture with no weight: DF $= 0$ (no support), ensuring unrestricted movement before lifting;
2) Flexion and static flexed posture without weight: DF exponentially increasing, capped at 1, allowing smooth engagement of assistance;
3) Extension: DF $= 1$ (maximum support), providing full assistance when the user lifts the load;
4) Static weight holding: DF is dynamically modulated, decreasing according to a sigmoid to $0.1/G$, preventing excessive assistance when simply holding the weight;
5) Flexion with weight: DF $= 0.1/G$, ensuring minimal resistance during bending with the load;
6) Static flexed posture while releasing weight: DF exponentially increasing, capped at 1, ensuring a gradual transition back to full support after the weight is released.

The NMBC was implemented in Simulink (MathWorks) and executed in real-time on the basestation in TwinCAT 3 at 1 kHz. CEINMS-RT [13] transmitted the estimated M_a^{L5S1} to TwinCAT 3 via ADS communication protocol.

E. Experimental protocol

The study involved three participants with no history of LBP, aged 23.3 ± 0.6 years, with a body weight of 66.3 ± 8.4 kg, and a height of 1.72 ± 0.05 m. All participants provided their explicit written consent to participate in the study and the experimental protocol was approved by the ethical committee of UT (reference: 240059). The experiment design included 4 lifting tasks of a box (width x depth x height: 40 x 30 x 22 cm) from a 52.2cm high table, given by the combination of two loading conditions (5kg, 15kg) and two lifting techniques (squat and stoop). Each participant was asked to join both a model calibration session and a measurement session. In the former, EMG signals, joint angles and markers' trajectories were measured in one static trial and one dynamic trial for each lifting task to perform model calibration. In the latter, participants performed the four lifting tasks without the exoskeleton (NOEXO), wearing the exoskeleton in transparent mode (MINIMP) and with three increasing support gains – 20% (S20), 50% (S50) and 80% (S80) - for a total of 20 trials, 5 repetitions each. Before the measurement trials, the participants familiarized with the exoskeleton for 15 minutes. All conditions were randomized. To control the speed at which the movement was performed and the timing of each repetition, a metronome at 35 beats-per-minute indicated the start of each stage of the lifting cycle. Participants rested for 2 minutes between trials to minimize fatigue.

F. Data analysis

We assessed NMBC's ability to reduce user effort with large assistive torques by computing mean M_a^{L5S1} normalized to the participant's body weight across the box-lifting stages (mean L5/S1 AM_Ext) for all support conditions, participants and lifting tasks. Each repetition was divided into 12 time-segments (8.33% of the lifting cycle each), with three segments corresponding to a complete movement, from upright to fully flexed posture and back with and without load (similar to [6]). Mean L5/S1 AM_Ext was computed on segments 4 and 5, excluding segment 6, corresponding to near-upright standing. This phase is of high interest as the peak of assistance is expected; the muscles must develop high forces to counteract the effect of gravity [6]. Mean L5/S1 AM_Ext was averaged across the five repetitions of each trial. To evaluate the controller's ability to provide large assistive torques while increasing the support gain and adapt to unknown external loads, maximum sum of the actuators' T_{meas} across the whole lifting cycle (max assistance) was analyzed by plotting its distribution across repetitions of each trial. To assess NMBC's performance in controlling large assistive torques, we computed the root mean square error (RMSE) between T_{des} and T_{meas} across the whole lifting cycle, normalized by T_{des} peak value (TTR RMSE).

G. Statistical analysis

To statistically assess variations in mean L5/S1 AM_Ext and max assistance, a mixed effect model was created with "subject" as random factor, and "lifting task" and "support condition" as fixed factors. Residuals' normality and homoscedasticity were then assessed via Shapiro-Wilk and Breusch-Pagan tests, respectively. Model assumptions were not met for max assistance; therefore, a two-way ANOVA was applied only to mean L5/S1 AM_Ext. Since no significant interaction effect was found, Tukey's multiple comparisons test was used on each fixed factor to identify differences between support conditions and between lifting tasks.

III. Results

A. Torque tracking and controller performance

Considering all lifting tasks and participants, our controller exhibited a TTR RMSE ranging from 14.4 ± 3.3% (subject 2, squat, 15kg) to 39.3 ± 1.5% (subject 2, stoop, 5kg, S80). The average TTR RMSE across all trials associated with the same assisted condition increased with higher support gains (S20: 23.4 ± 6.7%, S50: 26.7 ± 5.7%, S80: 32.1 ± 5.8%). No evident differences were observed in torque tracking between participants that could be attributed to user-specific characteristics or the lifting task. The real-time EMG-driven musculoskeletal model introduced an average time delay of 45.5 ± 38.8 ms across participants, while T_{target} and T_{des} computations added a delay of 76.8 ± 24.7 ms.

B. Maximum assistance provided

Fig. 2 shows the distribution of the maximum assistive torque provided to the user by the exoskeleton actuators throughout the entire lifting cycle (max assistance) for each assisted condition, participant, and lifting task. The mean max assistance across repetitions increased while increasing the support gain for all participants and lifting tasks. The mean percentage variation (MPV) across participants was more pronounced between S20 and S50 (stoop 5kg: 65.5 ± 39.6%, squat 5kg: 67.2 ± 23.1%, stoop 15kg: 65.2 ± 37.4%, squat 15kg: 67.6 ± 40.6%) compared to S50 and S80 conditions (stoop 5kg: 15.1 ± 4.4%, squat 5kg: 19.3 ± 5.3%, stoop 15kg: 14.8 ± 14.7%, squat 15kg: 10.9 ± 3.2%). The max assistance distribution shifted upward for 15 kg tasks compared to 5 kg tasks across all assisted conditions and participants, with an average increase in the distribution mean of 30.1 ± 17.3%. Shapiro-Wilk and Breusch-Pagan tests showed non-normality ($p < 0.01$) and heteroscedasticity ($p < 0.01$) of the mixed model residuals, precluding the use of a two-way ANOVA. The highest max assistance value was recorded in subject 1 during the S80 stoop 15kg trial (114.5Nm).

C. Reduction in L5/S1 moments while wearing the exoskeleton

Fig. 3 reports differences in model-estimated M_a^{L5S1} profiles under the 5 support conditions for a representative participant. Data were averaged across the 5 repetitions of each trial and refer to a squat lifting task with a 5 kg load. During the 4th and 5th time segments (see section II-F), a reduction in M_a^{L5S1} was observed in the assisted conditions (S20, S50, S80) compared to both MINIMP and NOEXO

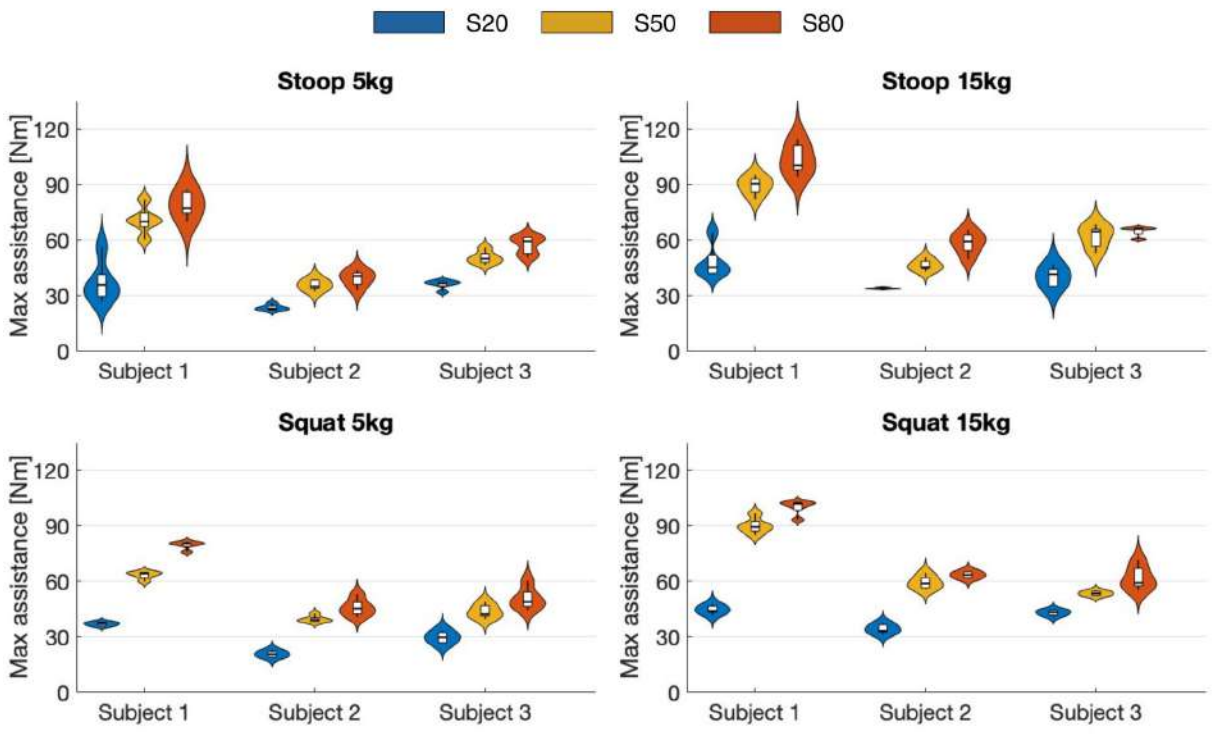

Fig. 2. Violin and box plot distributions across the 5 repetitions of each trial of the measured peak assistive torque (Nm) throughout the lifting cycle (max assistance). Each panel shows data for one lifting task, grouped by subject. The distributions for the 20% support gain condition are shown in blue, those for the 50% condition in yellow, and those for the 80% condition in red.

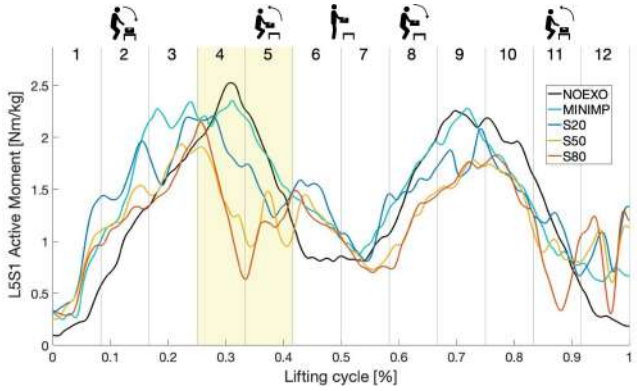

Fig. 3. Real-time model-estimated L5/S1 active moment normalized to participant's body weight (Nm/kg) across the lifting cycle. Data are referred to subject 1 squat 5kg trials: NOEXO (black), MINIMP (light blue), S20 (dark blue), S50 (yellow), S80 (red) conditions. Vertical lines divide the lifting cycle into 12 time segments. Highlighted segments show the instants across which mean L5/S1 AM_Ext was computed (time segments 4 and 5).

conditions based on visual inspection. 2-way ANOVA on mean L5/S1 AM_Ext showed a significant effect for both fixed factors, "support condition" ($F(4,280) = 9.16$, $p < 0.001$) and "lifting task" ($F(3,280) = 32.76$, $p < 0.001$), while their interaction was not significant ($F(12,280) = 1.58$, $p = 0.097$). Tukey's multiple comparisons test on the "support condition" factor revealed a significantly reduced mean L5/S1 AM_Ext in all assisted conditions (S20, S50, S80) compared to NOEXO condition. Similarly, S50 and S80 conditions showed a significantly reduced mean L5/S1 AM_Ext compared to MINIMP condition, while the difference between MINIMP and S20 conditions was not significant. Table I reports the absolute mean difference between the two groups being compared (MeanDiff) and its statistical significance (p-value). The honest significant difference (HSD) was 0.3115. Fig. 4 illustrates the exoskeleton-induced reduction of mean L5/S1 AM_Ext across most lifting tasks, both within participants and as a mean across participants. The MPV across participants for the MINIMP condition compared to the NOEXO condition showed a general decrease in the mean L5/S1 AM_Ext across all lifting tasks: stoop 5 kg (-13.9% ± 21.8%), squat 5 kg (-2.5% ± 21.8%), stoop 15 kg (-3.6% ± 24.7%), and squat 15 kg (-6.5% ± 15.9%). However, the large SD indicated substantial variability among participants. By visually inspecting Fig. 4, no consistent behavior was observed between participants and tasks for the MINIMP and NOEXO conditions. Table II shows Tukey's multiple comparisons test results for the "lifting task" predictor similarly to table I, with an HSD of 0.2318. Mean L5/S1 AM_Ext significantly increased in all lifting tasks with a 15kg load compared to those with a 5kg load. A significant difference between tasks using different techniques but the same load was found only between stoop lifting with 5kg and squat lifting with 5kg.

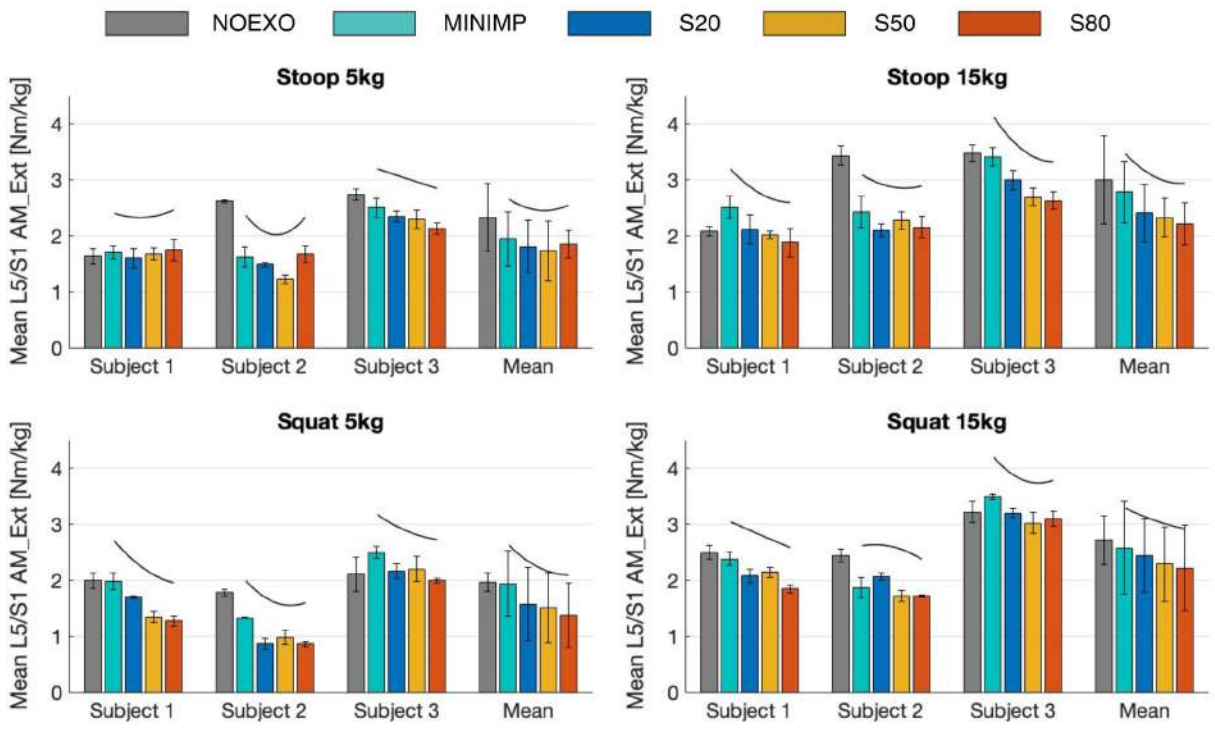

Fig. 4. Mean L5/S1 AM_Ext normalized to participants' body weight (Nm/kg). In each panel, bars are divided into four groups. The first three groups refer to each participant while the bars report the mean of mean L5/S1 AM_Ext across the 5 repetitions of each trial with the relative standard deviation (SD). The last group shows the mean values across participants with the relative error bars (SD). Second-degree polynomial fit of the MINIMP, S20, S50, S80 conditions are reported above each group (curves were shifted along the y-axis for visual purposes).

D. Effect of large support gains on L5/S1 moments

No significant differences across the different assisted conditions were found in mean L5/S1 AM_Ext (Table I). To better illustrate the general trend, a second-degree polynomial was used to fit the mean L5/S1 AM_Ext values across MINIMP and assisted conditions for each participant as well as for the mean across participants (Fig. 4). A decreasing trend in mean L5/S1 AM_Ext as the support gain increased was observed in most participants. MPV in L5/S1 AM_Ext relative to the MINIMP condition was also found to decrease while increasing the support gain in 3 lifting tasks out of 4. For the stoop 5 kg task, the mean variations were as follows: S20: -7.0 ± 1.2%, S50: -11.6 ± 11.5%, S80: -3.1 ± 10.0%. For the stoop 15 kg task, reductions were S20: -13.8 ± 1.6%, S50: -15.6 ± 8.05%, S80: -19.8 ± 7.3%. In the squat 5 kg task, the decreases were more pronounced: S20: -20.8 ± 12.0%, S50: -23.6 ± 10.6%, S80: -30.3 ± 8.9%. Finally, for the squat 15 kg task, the reductions were: S20: -3.6 ± 12.1%, S50: -10.6 ± 2.6%, and S80: -13.9 ± 7.5%. Same trend of the MPV was found in comparison with the NOEXO condition but with much higher variations. It ranged from -10.9 ± 9.1% (squat 15 kg, S20) to -31.0 ± 23.4% (squat 5 kg, S80), with an average value of -20.3 ± 19.7%. In some assisted trials, fluctuations up to 1 Nm/kg were observed during the second half of the trunk extension movement, both with and without

the lifted box, corresponding to time segments 5, 6, 11, and 12 (Fig. 3). This behavior occurred more frequently in trials involving the S50 and S80 conditions and was present across all repetitions of those trials.

IV. Discussion

In this study, we demonstrate the use of an NMBC to apply large assistance proportional to the changes in muscle forces via an active rigid BSE. We successfully increased the support gain up to 80% compared to the previous maximum of only 20% using the same methodology. All assisted conditions reduced muscle effort compared to the NOEXO condition, achieving a net reduction even with an heavy exoskeleton. This reduction was statistically significant, demonstrating for the first time that NMBC can be used with large gains. Furthermore, a decreasing trend in muscle effort with increasing support gain suggests a positive effect of higher assistive torques. However, torque tracking issues and user-exoskeleton interactions likely underestimated results, while the lack of statistical significance prevents drawing definitive conclusions on increasing assistance.

For the first time, we used an NMBC to control an active rigid BSE, adapting a previously proposed controller [12]. To achieve smooth torque profiles, the EMG-driven model was simplified by neglecting the MTU force-velocity relationship and assuming the tendon to be infinitely stiff. To ensure model accuracy, the calibration procedure was refined by using IMUs-based joint angles for computing IK and ID, consistent with the model execution. Additionally, a six-states FSM was integrated in the control loop to prevent the assistive torques from hindering the user's movements when bending. The tracking performance of the system was low, showing an average TTR RMSE of 23.4% even at the lowest support gain. The average TTR RMSE across all trials increased with higher gains, suggesting that the controller's torque tracking ability deteriorates as assistance increases. This likely contributed to the underestimation of the impact of large assistive torques on M_a^{L5S1}. The high-level controller introduced a delay of 122.3 ± 45.98 ms from EMG detection to torque generation, comparable to the physiological electromechanical delay (EMD) (80 ms) [17]. Faster contraction velocities, likely induced by large assistive torques, may have desynchronized assistive and biological moments, compromising user-exoskeleton synergy and causing the fluctuations in Fig. 3.

Despite unfavorable torque tracking performance, we were able to provide large assistive torques, as high as 114.5 Nm. We observed a clear trend of increasing maximum assistive torque as the support gain was raised, confirming the effectiveness of the system in scaling assistance accordingly. Max assistance distributions were distinctly different in most participants and lifting tasks, with no overlap between S20 and S80 in multiple cases, indicating a clear separation (Fig. 2). The larger assistance during 15kg lifting tasks compared to 5kg tasks aligns with the expected outcome. This finding demonstrates the ability of the NMBC to adapt to different external loads with no *apriori* information both for stoop and squat lifting techniques, addressing a gap in prior research [12]. Max assistance differences, observable in Fig. 2, differ across participants since the NMBC is estimated from user specific biological moments. Notably, the maximum torque limit set for the actuators (120 Nm) did not impact the results, as it was never reached during any of the trials.

For three participants, the mean L5/S1 AM_Ext was significantly reduced during the assisted conditions (S20, S50, S80) compared to the NOEXO condition, with an average decrease of 20.3% (Fig. 4). This result highlights the potential of the NMBC applied to an active rigid BSE to reduce biomechanical load during lifting tasks, despite the exoskeleton's considerable weight (16.5 kg). Mean L5/S1 AM_Ext generally decreased in MINIMP compared to NOEXO condition. This effect could be attributed to a shift of load from active to passive tissues, influenced by changes in movement kinematics. However, the difference between MINIMP and NOEXO was not statistically significant. Additionally, no consistent behavior was observed between participants and tasks strengthening the need for a user-specific approach. Lack of significant differences between the S20 and MINIMP conditions suggests that lower support gains may provide insufficient assistance to achieve a substantial reduction in biomechanical load (Table I). Higher support gains (S50, S80) reduced the MPV of mean L5/S1 AM_Ext between assisted and MINIMP conditions, with the exception of stoop 5kg S80 trials. A decreasing trend while increasing assistance, fitted by a 2nd-degree polynomial, was observed for most participants and tasks, as well as in the case of the mean across participants (Fig. 4). However, a two-way mixed-effects ANOVA followed by Tukey's post-hoc test found no significant effects of different support gains on mean L5/S1 AM_Ext, likely due to the high variability in the data. The effect of the "lifting task" predictor was significant, with heavier loads resulting in higher mean L5/S1 AM_Ext, as expected (Table II). The support conditions did not significantly interact with lifting tasks, suggesting that the exoskeleton adaptively modulated support across tasks to match biomechanical demands.

There are a few limitations to the study. The study was conducted on a small number of participants. Moreover, the duration of the experiments and weight of the exoskeleton could have introduced fatigue, which was not quantified. High TTR RMSE values, even at low support gains, suggest that the system struggled to properly track the desired torque, delivering assistive torques lower than intended. This effect may have contributed to an underestimation of the system's beneficial effects on mean L5/S1 AM_Ext. Furthermore, we used a FSM to ensure that the support was provided only during desired instances, which requires inclination information during lifting.

This study must be followed up with experiments from larger and more heterogeneous group of participants. Moreover, the potential impact of the exoskeleton support on other body parts, such as lower limbs and shoulders, should be investigated to fully assess the broader biomechanical impact of assistance. Finally, utilizing garments with embedded

sensors can help reduce the ease of use and applicability of the NMBC in real-world situations [18].

V. Conclusion

This study demonstrates the novel application of an NMBC for providing large assistive torques with an active rigid BSE. Net L5/S1 joint moment reductions were observed for three participants under assisted conditions compared to not wearing the exoskeleton, despite the heavy BSE used. Although not significant, increasing support gains (up to 80%) showed a trend toward reducing muscle effort. Additionally, the results demonstrated the system's adaptability to unknown external loads and user-specific biomechanics. However, challenges in torque tracking and user-exoskeleton interaction must be addressed to improve performance. This study highlights the feasibility of applying large assistive torques with an NMBC, providing evidence of its potential to reduce lumbar effort. These findings support the translation of BSEs into real-life occupational environments, where reducing spinal load is critical for preventing LBP.

Mitigating Compensatory Movements in Prosthesis Users via Adaptive Collaborative Robotics

Marta Lagomarsino[1], Robin Arbaud[1,2], Francesco Tassi[1], and Arash Ajoudani[1]

***Abstract*— Prosthesis users can regain partial limb functionality, however, full natural limb mobility is rarely restored, often resulting in compensatory movements that lead to discomfort, inefficiency, and long-term physical strain. To address this issue, we propose a novel human-robot collaboration framework to mitigate compensatory mechanisms in prosthesis users by exploiting their residual motion capabilities while respecting task requirements. Our approach introduces a personalised mobility model that quantifies joint-specific functional limitations and the cost of compensatory movements. This model is integrated into a constrained optimisation framework that computes optimal user postures for task performance, balancing functionality and comfort. The solution guides a collaborative robot to reconfigure the task environment, promoting effective interaction. We validated the framework using a new body-powered prosthetic device for single-finger amputation, which enhances grasping capabilities through synergistic closure with the hand but imposes wrist constraints. Initial experiments with healthy subjects wearing the prosthesis as a supernumerary finger demonstrated that a robotic assistant embedding the user-specific mobility model outperformed human partners in handover tasks, improving both the efficiency of the prosthesis user's grasp and reducing compensatory movements in functioning joints. These results highlight the potential of collaborative robots as effective workplace and caregiving assistants, promoting inclusion and better integration of prosthetic devices into daily tasks.**

I. Introduction

The loss of a body limb or digit profoundly impacts an individual's physical capabilities and mental well-being. Prosthetic devices aim to mitigate these issues by restoring functionality and enabling users to regain independence in daily living and work-related activities. Prostheses can be classified into three categories: passive, body-powered, and externally powered [1]. Passive devices primarily focus on restoring appearance rather than mechanical functionality [2], however, they can still help to restore opposing grasp capabilities [3]. Body-powered devices, in contrast, utilise the motion of another muscle or limb to control the prosthesis, offering a mechanical and functional simple solution [4], [1]. Externally powered devices rely on actuators, often electric or pneumatic, to restore finer control and dexterity, albeit at the cost of increased complexity, reliance on a power source, and higher expense [5], [6]. By comparison, body-powered devices strike a balance between functionality and usability due to their simplicity and straightforward use.

Despite their benefits, prostheses remain far from replicating the full functionality of natural limbs [7]. They often impose constraints on the user's body mobility, leading to compensatory mechanisms that may involve uncomfortable non-ergonomic postures or inefficient movement patterns [8], [9]. This is especially true for body-powered systems, which by design require some muscles to control the prosthesis in addition to their normal purposes [10], [11]. Over time, these compensations can result in strain, discomfort, and even long-term physical issues. Unfortunately, such challenges are frequently overlooked in the design and assessment of prosthetic devices. To address this gap, studying how human kinematics can effectively adapt to residual impairments and prosthetic limitations provides an opportunity to enhance user comfort, efficiency, and overall experience.

Beyond individual adaptations, the environments where prosthesis users operate (such as workplaces, care facilities, and homes) can be modified to support more ergonomic and functional interactions. In this context, collaborative robots (CoBots) constitute a promising solution [12]. CoBots have demonstrated their ability to improve physical ergonomics by online adapting interaction poses [13] or optimising shared kino-dynamics in co-carrying and co-manipulation tasks [14], [15]. They have also been shown to promote cognitive ergonomics by adapting the proximity and reactivity of the CoBot to balance safety, user stress, and productivity [16]. While some initial attempts aimed at facilitating tasks for users with impairments, these approaches often focused on completely substituting the impaired limb functionality with a robotic system [17], [18] or limiting the movement of the impaired arm in Cartesian space [19]. However, such strategies overlook the nuanced needs of prosthetic users who experience joint-level and task-specific constraints. Additionally, these methods fail to exploit the residual functionality of restricted-mobility users, potentially reinforcing a sense of inability and frustration.

This work takes a novel step toward addressing these challenges by introducing a human-robot collaboration framework that supports prosthesis users in overcoming joint-level limitations and exploiting their residual motion but avoiding harmful compensatory mechanisms. We propose a model of joint-specific functional limitations of prosthesis users and quantify the cost of compensatory mechanisms in functioning joints. This model informs an optimisation problem that computes the optimal user posture for performing

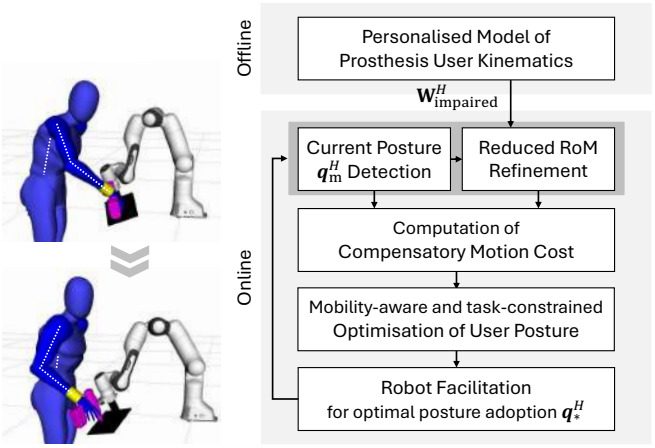

Fig. 1. Overview of the procedure to assess the mobility diversity of prosthesis users and mitigate compensatory movements while adhering to task constraints.

a collaborative task in a functional and comfortable manner, considering task constraints. The solution guides the robot to reconfigure the task environment thus promoting the adoption of the recommended posture. Finally, we present a novel body-powered prosthetic device for single-finger amputees, designed to enhance grasping capabilities through synergistic hand closure but posing constraints in wrist motion. The device serves as a testbed to validate the proposed method.

The remainder of the paper is organised as follows: Section II describes the modelling of impairments and the formulation of the optimisation problem for robot-assisted facilitation to minimise the use of joints with restricted mobility and mitigate the cost associated with compensatory mechanisms. Section III presents the experimental campaign to validate the proposed approach in handover tasks. Section IV discusses the results and outlines potential directions for future work.

II. Methods

The proposed procedure to mitigate compensatory movements in prosthesis users is outlined in Fig. 1. In the offline phase, we first model the user mobility diversity and scale a digital model to automatically match their specific body measurements. During the interaction phase, we continuously monitor the prosthesis user's posture and eventually refine the Range of Motion (RoM) based on modelled residual mobility and prosthetic limitations. Consequently, we calculate the current cost of compensatory motions, defined as the deviation of the functioning joints from a natural, comfortable posture. A constrained optimisation technique is then solved to determine a more comfortable and functional posture that still respects the user's mobility constraints and task requirements. Finally, a robot-assisted motion is planned to facilitate the adoption of such posture.

A. Prosthesis User Kinematics Model

This study models the kinematics of a prosthesis user by assigning a local coordinate frame to each joint, where the x-, y-, and z-axes define the rotation axes for abduction/adduction, flexion/extension, and internal/external rotation, respectively, as outlined in [20]. To account for arm kinematic redundancy, the arm is represented as a seven Degrees-of-Freedom (DoF) system, denoted by $\boldsymbol{q}^H \in \mathbb{R}^7$ and consists of two rigid links: the upper arm ($\boldsymbol{l}_{\text{humerus}}$) and the forearm ($\boldsymbol{l}_{\text{radius}}$) [21].

A coordinate frame is also assigned to the L5 lumbar spine vertebra to represent spine flexion through the first joint angle, q_1^H, and the link, $\boldsymbol{l}_{\text{spine}}$. This inclusion reflects the well-documented role of increased trunk motion as a compensatory mechanism in the literature [11]. The resulting model presents $M = 8$ DoFs, where size-related parameters can be adjusted to fit different arm and trunk sizes.

The shoulder is modelled as a spherical joint, providing abduction/adduction (q_2^H), flexion/extension (q_3^H), and internal/external rotation (q_4^H). The elbow consists of both a hinge and a pivot joint that allows for forearm flexion/extension (q_5^H) and pronation/supination (q_6^H). Finally, the wrist joint is represented as a condyloid joint, enabling flexion/extension (q_7^H) and ulnar/radial deviation (q_8^H) of the hand. Table I provides the Denavit-Hartenberg (DH) parameters used for this kinematic model.

TABLE I
Denavit-Hartenberg parameters of the adopted human kinematic model.

axis, i	$\boldsymbol{\theta}_i$	a_i	α_i	d_i
1	q_1^H	l^z_{spine}	$-\frac{\pi}{2}$	$-l^y_{\text{spine}}$
2	q_2^H	0	$\frac{\pi}{2}$	$-l^x_{\text{spine}}$
3	$q_3^H+\frac{\pi}{2}$	0	$\frac{\pi}{2}$	0
4	$q_4^H-\frac{\pi}{2}$	$-l^x_{\text{humerus}}$	$\frac{\pi}{2}$	$-l^z_{\text{humerus}}$
5	$q_5^H+\pi$	0	$\frac{\pi}{2}$	$-l^y_{\text{humerus}}$
6	$q_6^H+\frac{\pi}{2}$	$-l^y_{\text{radius}}$	$\frac{\pi}{2}$	$-l^z_{\text{radius}}$
7	$q_7^H+\frac{\pi}{2}$	0	$\frac{\pi}{2}$	$-l^x_{\text{radius}}$
hand	q_8^H	0	0	0

Prostheses assist users by restoring some functionality, though they may not fully replicate natural limb mobility, and can impose limitations on surrounding joints. For instance, wearing a partial hand prosthesis may pose limitations in wrist movement, which can lead to compensatory movements in the elbow and/or shoulder. To capture these constraints in the model, we define a diagonal matrix, $\mathbf{W}^H_{\text{impaired}} \in \mathbb{R}^{M\times M}$. This matrix modifies the kinematic model by prioritising movement in healthy or prosthesis-supported joints and reducing or entirely limiting mobility in impaired or blocked joints. This allows for flexibility in modelling partial or complete impairments across joints. For joints with complete functional loss, we set $\mathbf{W}^H_{\text{impaired}}(i,i) = 1$, whereas partially impaired joints are defined proportionally to reflect a preference for minimal use unless essential. In clinical practice, standardised impairment indices are used to assess joint functionality in patients with conditions such as arthritis, injuries, or neurological damage [22]. These indices can be applied to define specific joint limitations within $\mathbf{W}^H_{\text{impaired}}$, helping to personalise the kinematic model to the particular needs and abilities of each prosthesis user.

The cost $\Psi(k) \in \mathbb{R}$, quantifying the impact of compensatory mechanisms at the time instant k, is calculated as:

$$\Psi(k) = \left\| \left(\mathbf{I} - \mathbf{W}^H_{\text{impaired}}\right) \left(\boldsymbol{q}^H(k) - \boldsymbol{q}^H_{\text{n}}\right) \right\|^2, \quad (1)$$

where $\boldsymbol{q}^H_{\text{n}}$ denotes the natural posture, representing a neutral and comfortable arm configuration for the user. This cost measures the deviation of functioning joints from this natural posture. It aligns with established metrics in the literature, such as "instantaneous joints usage" or "ergonomic cost" [23], [13], but is refined here by including weights that account for the desired mobility of each joint, as defined by the matrix $\left(\mathbf{I} - \mathbf{W}^H_{\text{impaired}}\right)$. This modification provides a more precise and personalised assessment of alignment with a comfortable and functional posture, tailored to the user's specific impairments and requirements.

B. Robot Reactive Facilitation for Prosthesis Users

The objective of the robot reactive facilitation is to guide prosthesis users in performing the interactive task in a more effective way, avoiding unnatural postures adopted to compensate for constraints imposed or not fully addressed by the prosthesis. To achieve this, the robot generates movements designed to facilitate human adoption of this recommended configuration. The optimal posture minimises the usage of partially impaired joints, completely restricts motion in blocked joints, and promotes alignment of healthy null-space joints with a comfortable and functional posture throughout the interaction.

The robot reactive behaviour is formulated as an online optimisation problem that considers the user's impaired mobility, kinematic constraints, task requirements, and safety distance thresholds. The optimisation is defined by the following cost function and constraints:

$$\begin{aligned} \min_{\boldsymbol{q}^H} \; & \left\| \mathbf{W}^H_{\text{impaired}} \left(\boldsymbol{q}^H - \boldsymbol{q}^H_{\text{m}}\right) \right\|^2 + \alpha \left\| \left(\mathbf{I} - \mathbf{W}^H_{\text{impaired}}\right) \left(\boldsymbol{q}^H - \boldsymbol{q}^H_{\text{n}}\right) \right\|^2 \\ \text{s.t.} \quad & \boldsymbol{q}^H \in \left[\boldsymbol{q}^H_{\text{min,impaired}}, \boldsymbol{q}^H_{\text{max,impaired}}\right], \\ & \boldsymbol{x}_{\text{obj}}(\boldsymbol{q}^H) \in \boldsymbol{\chi}^R_{\text{task}}, \\ & p_{\text{obj}}(\boldsymbol{q}^H) = p_{\text{task}}, \\ & d^H_{\text{obj}} \geq d_{\text{safe th}}, \\ & d^H_{\text{elbow}} \geq d_{\text{elbow th}}, \end{aligned} \quad (2)$$

where $\boldsymbol{q}^H_{\text{m}}$ is the current measured human posture and $\boldsymbol{q}^H_{\text{n}}$ denotes the natural and comfortable posture for a healthy individual. In the cost function, the first term aims to minimise the deviation of fully or partially impaired joints from their current configuration. This is implemented through the matrix $\mathbf{W}^H_{\text{impaired}}$, which weights the squared distance based on the severity of each joint functional limitation, effectively prioritising the minimisation of displacement for more severely impaired joints. The second term instead minimises the cost Ψ of the compensatory mechanism, namely the squared distance of the functioning joints from the nominal most comfortable arm configuration, weighted by their desired mobility. The parameter $\alpha \in \mathbb{R}$ is a scaling factor that gives less importance to the second term. This reflects the prioritisation of maintaining the current position of impaired joints while subtly promoting the comfortable positioning of the healthy, unconstrained joints.

The optimisation constraints ensure that the joint angles $\boldsymbol{q}^H$ remain in the feasible impaired range, which is derived by reducing the standard RoM to account for user-specific impairments. For prosthesis users, this reduction is modelled by modifying the healthy joint boundaries $\boldsymbol{q}^H_{\text{min}}$ and $\boldsymbol{q}^H_{\text{max}}$ using the matrix $\mathbf{W}^H_{\text{impaired}}$, as follows:

$$\begin{aligned} \boldsymbol{q}^H_{\text{min,impaired}} &= \boldsymbol{q}^H_{\text{min}} + \mathbf{W}^H_{\text{impaired}}\big((\boldsymbol{q}^H_{\text{m}} - \zeta) - \boldsymbol{q}^H_{\text{min}}\big), \\ \boldsymbol{q}^H_{\text{max,impaired}} &= \boldsymbol{q}^H_{\text{max}} - \mathbf{W}^H_{\text{impaired}}\big(\boldsymbol{q}^H_{\text{max}} - (\boldsymbol{q}^H_{\text{m}} + \zeta)\big), \end{aligned} \quad (3)$$

where the parameter $\zeta \in \mathbb{R}$ allows small adjustments in the joint angles, even in severely impaired joints. Task-specific constraints ensure that the position $\boldsymbol{x}_{\text{obj}}$ of the object or tool, which will be in the human's hand during the interaction with the environment ($\boldsymbol{x}_{\text{obj}} = \boldsymbol{x}_{\text{obj}}(\boldsymbol{q}^H)$), is located within the task space of the robot $\boldsymbol{\chi}^R_{\text{task}}$ and satisfies task objectives. In particular, we consider the possibility of imposing an equality constraint on a specific Cartesian coordinate $p_{\text{obj}} = \{x_{\text{obj}}; y_{\text{obj}}; z_{\text{obj}}\} \in \mathbb{R}$ to match the task requirement p_{task}. Finally, the horizontal distance $d^H_{\text{obj}} \in \mathbb{R}$ between the object and the user's body must exceed a safety threshold $d_{\text{safe th}}$ and the horizontal distance d^H_{elbow} between the user's elbow and pelvis is required to exceed $d_{\text{elbow th}}$ to ensure a proper elbow pose.

C. Finger Prosthesis System

In this work, we introduce a novel body-powered finger prosthetic device specifically designed to enhance grasping for individuals with single-finger amputations, featuring a mechanical coupling mechanism that enables synergistic closure with the hand. The prosthesis features an underactuated 3-joint finger, whose motion is controlled by a single tendon. Elastic elements bring the finger back into an open position when the tendon is not actively pulled. As illustrated in Fig. 2, we built a wearable prototype around a wrist brace with a 3D-printed part attached to it. The latter holds a pulley, through which the tendon is rerouted. The other end of the tendon is attached to a ring, which the user has to wear on the finger controlling the prosthetic. Bending that finger will then pull on the tendon and bend the prosthetic. Additionally, a lead screw mechanism can be used to adjust the pretension of the tendon by changing the position of the pulley. For testing purposes, we mounted the designed prosthesis as a supernumerary finger placed near the index. This configuration allows non-impaired individuals to simulate the experience of the prosthesis users.

It is important to note that while the prosthesis enhances grasping functionality, it also imposes constraints on the wrist flexion/extension and ulnar/radial deviation. These limitations can be encoded in the $\mathbf{W}^H_{\text{impaired}}$ by setting the last two diagonal elements to 1, informing the optimisation process of the immobilised wrist.

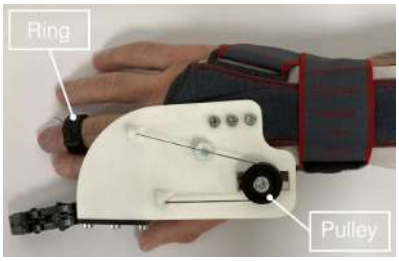

Fig. 2. Picture of the wearable prototype for testing the proposed body-powered prosthesis as a supernumerary finger.

III. Experiments

A. Experimental Setup and Protocol

Experiments were conducted with two healthy human subjects to assess the effectiveness of the proposed method in facilitating functional and comfortable interaction with a prosthetic device[1]. The participants included Subject 1, a 29-year-old male with a height of 1.83 m, and Subject 2, a 28-year-old female with a height of 1.58 m. Diverse physical profiles were deliberately chosen to validate the method ability to adapt to diverse anthropometric characteristics.

The experimental task required subjects to grasp a hotmelt glue pistol positioned at varying lateral distances from their pelvis, i.e. $y_{\text{task}} = \{0.05\text{m}; -0.20\text{m}; -0.45\text{m}\}$. To simulate a quite realistic prosthesis-user scenario, participants performed the task while wearing the proposed prosthetic device configured as a supernumerary finger (see Fig. 2). Before the task, participants underwent a familiarisation phase with the prosthesis. The setup included a table in front of the prosthesis user, marked with three tape lines indicating the potential lateral directions from which the object could be delivered. The healthy RoM was derived from the literature [24] and the nominal prosthesis user posture, $\boldsymbol{q}_{\text{n}}^{H}$, was defined as the most ergonomic posture based on the Rapid Upper Limb Assessment (RULA) Tool [25], with the elbow flexed at $90°$ and all other joint angles set to $0°$. The parameters were set as follows: $\alpha = 0.10$, $\zeta = 5°$, $d_{\text{safe th}} = 0.20\text{m}$ from the human pelvis, and $d_{\text{elbow th}} = 0.25\text{m}$.

The experiment involved two sessions: human passing (*HP*) and robot passing (*RP*). In the *HP* session, a human participant passed the object to the prosthesis user once for each lateral distance y_{task}, simulating traditional handover scenarios involving a human co-worker in industrial settings or a caregiver in assistive contexts. Five healthy participants (four males and a female, 28.2 ± 2.4 years old) were recruited to serve as object passers in this condition. In the *RP* session, the task was executed in collaboration with a Franka Emika Panda manipulator, controlled at 1 kHz, equipped with the Robotiq 2-Finger Gripper 2F-85. The robot optimised the object transfer pose online by solving the constrained optimisation problem defined in Eq. (2), implemented through the Augmented Lagrangian method of the ALGLIB library[2] in a C++ environment. To ensure smooth execution, a B-spline trajectory was generated to achieve the optimised handover pose, which was tracked by the robot Cartesian impedance controller, as in [16]. The robot repeated the object passing at different y_{task} five times to ensure a consistent comparison with the *HP* condition.

We used a wearable MVN Biomech suit (Xsens Tech.BV) equipped with inertial measurement unit sensors to measure body segment lengths and automatically personalise the kinematic model and digital mannequin meshes for the subject. The motion capture system continuously tracked the prosthesis user's movements throughout the experiment. The post-hoc statistical analysis compared the effectiveness of the robot-assisted (*RP*) condition to the baseline human passing (*HP*) condition, with a focus on the impact of embedding a user impairment model in the robot behaviour. Initially, the gathered data were tested for normality using the Anderson-Darling test. If normality was confirmed, repeated measures ANOVA was conducted. In cases where normality was not confirmed, the non-parametric Friedman test was employed to evaluate significant differences. Three performance metrics on the prosthesis user's motion were computed:

- *Task duration* (T_f): the time taken by the prosthesis user to complete the approach and grasping phases, measured from the first movement of the grasping subject, until he/she had full control of the object;
- *Functioning joints usage* ($\bar{\Psi}$): calculated during the duration T_f (with time samples $k = 1, \ldots, K_f$) as:

$$\bar{\Psi} = \frac{1}{K_f} \sum_{k=1}^{K_f} \Psi[k], \tag{4}$$

  where $\Psi[k]$ is the cost associated with compensatory mechanisms performed by the functioning joints, as defined in Eq. (1);
- *Smoothness of joint motion* (J): defined as:

$$J = \Delta t \sum_{k=1}^{K_f} \| \dddot{\boldsymbol{q}}_{\text{m}}^{H}[k] \|^2, \tag{5}$$

  where Δt is the data sampling rate of the Xsens system and $\dddot{\boldsymbol{q}}_{\text{m}}^{H} \in \mathbb{R}^M$ is the joint jerk vector derived numerically from joint velocity measurements.

B. Experimental Results

Figure 3 shows the sequential frames of the middle finger and the supernumerary prosthetic finger in motion to illustrate the progressive flexion movements enabled by the coupling mechanism.

The results of mobility-aware optimisation tailored to specific prosthesis users are reported in Fig. 4, revealing its ability to effectively configure human-robot interaction under varying physical profiles and task constraints. The digital model was automatically scaled to match the anthropometric characteristics of both users based on motion-tracking data. The robot complied with task requirements, namely maintaining different lateral distances from the user's pelvis and adhering to task-specific object positioning areas (indicated by green planes in the figure). More importantly,

[1]The experiments were carried out at the HRII Laboratory of the Istituto Italiano di Tecnologia in accordance with the Helsinki Declaration, and the protocol was approved by the ethics committee Azienda Sanitaria Locale Genovese N.3 (Protocol IIT_HRII_ERGOLEAN 156/2020).

[2]https://www.alglib.net/

Fig. 3. Illustration of the coordinated flexion movement of the user's finger and the prosthetic one.

the robot adapted the position and orientation of the handover object to eliminate wrist movement entirely and mitigate compensatory movements. Each subfigure also reports the cost associated with compensatory mechanisms, Ψ_*, for the ideal case where the human assumed the optimal posture derived from the optimisation.

Figure 5 compares the handover scenarios between human-to-prosthesis user interaction conducted by Participant 3 (*HP*) and the optimised robotic handover (*RP*). Despite the human passer's aim to facilitate the prosthesis user's grasp, the resulting object transfer pose necessitated pronounced compensatory movements from the user due to wrist blockage. Specifically, as shown in the bottom-left plot of Fig. 5, the prosthesis user exhibited greater elbow flexion (purple line), substantial shoulder flexion (orange line), and an elevated elbow posture, which induced larger shoulder external rotation (yellow line) and forearm pronation (green line). Further, the prosthesis user required approximately a second to stabilise the prosthetic grasp in this configuration. Additionally, a hesitation at the beginning of the movement suggested a slightly increased demand on the neural mechanisms for motion planning, as also reported by the prosthesis user. In contrast, the optimised robotic handover, tailored to accommodate the prosthesis user's mobility limitations, enabled a more accessible and efficient grasp. The robot facilitation induces the user to adopt a posture closely aligned with the optimised configuration $\boldsymbol{q}_*^H$ obtained by the mobility-aware optimisation problem (depicted with dashed lines in the bottom-right plot of Fig. 5). While the optimised posture recommended greater reliance on elbow flexion and reduced shoulder flexion, the user adopted a configuration with more balanced flexion between the elbow and shoulder. Despite these minor deviations due to the user's slightly different resolution of the redundancy, the optimised robotic

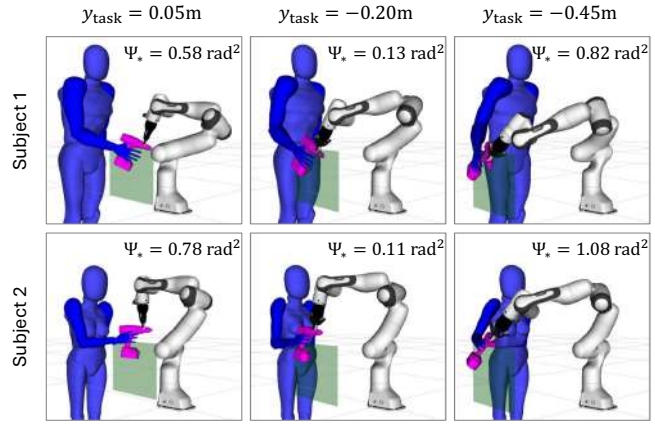

Fig. 4. Optimised robot-to-prosthesis user handover configurations at different lateral distances from the human pelvis on the table, tailored to diverse human body measurements.

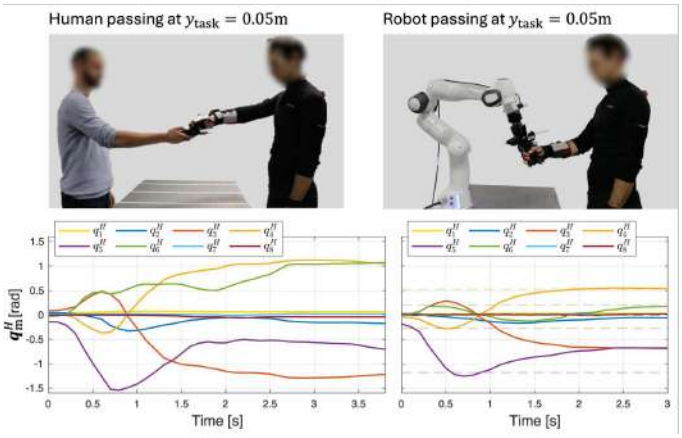

Fig. 5. Comparison between human-to-prosthesis user handover performed by a participant (*HP*) and optimised robotic handover adapted to the prosthesis user's mobility limitations (*RP*).

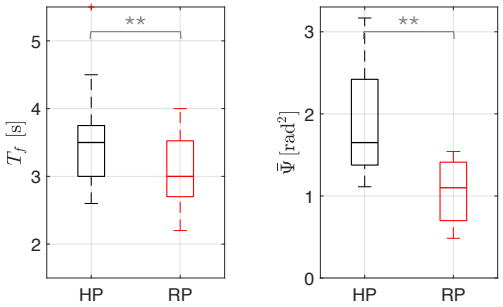

Fig. 6. Statistical comparison between human passing (*HP*) and robotic passing (*RP*) conditions: (left) duration of the approach phase, indicating improved efficiency in robotic handover; (right) mean cost of compensatory movements $\bar{\Psi}$ over the approach phase, highlighting reductions in functioning joints usage. Significance levels are indicated at $^{**}p < 0.01$.

facilitation notably reduced the compensatory movements cost Ψ both at the interaction pose and throughout the approach phase compared to the *HP* condition.

The statistical analysis comparing *HP* and *RP* conditions across all tested y_{task} values demonstrated that the robot handover significantly improved both the efficiency and comfort of the prosthesis user's grasp. Indeed, a significant reduction in the duration of the approach phase was observed, as shown in the left box plot of Fig. 6. Additionally, the measured cost associated with compensatory movements, $\Psi(t_{\text{interaction}})$, at the interaction pose, and the mean cost representing the functioning joints usage, $\bar{\Psi}$, exhibited significant decreases, as depicted in the right box plot of Fig. 6. The norm of joint displacements at the wrist remained consistently close to zero in both handover conditions, as expected. However, in the *HP* condition, wrist displacements occasionally reached up to $6°$, indicating instances where the prosthesis user was forced to violate the wrist constraint to enable the grasp. Regarding joint motion smoothness, the integral of the squared joint jerk during the approach phase (J) was not presented as a box plot due to value variations introduced by the monitoring system and numerical derivation, but comparisons between the two conditions (*HP* and *RP*) provided consistent and meaningful insights. A significant 52.7% reduction in J ($p < 0.01$) in the robotic handover condition revealed smoother

and more seamless grasping approaches.

IV. Discussion and Conclusions

In this work, we presented a novel online method for mitigating compensatory movements in prosthesis users with restricted mobility, an often overlooked issue that can lead to long-term harm. Our approach involves creating a personalised mobility model for the prosthesis user and integrating it into a constrained optimisation framework. This framework computes the optimal user posture for task performance in a functional and comfortable manner, considering task requirements, and informs the robot, which reconfigures the task accordingly to promote the adoption of such a posture. Initial results with healthy subjects using a proposed body-powered finger prosthesis as a supernumerary finger demonstrated that a robotic assistant embedding the user-specific mobility model outperformed human partners. Improvements were observed in both the reduction of compensatory movements in functioning joints and the efficiency of the prosthesis user's grasp during handover tasks. These findings are promising for introducing collaborative robots as workplace and caregiving assistants, promoting inclusion, and facilitating the seamless integration of prosthetic devices into users' daily lives. Despite these encouraging results, we observed some deviations in how users resolved redundancy in joint usage, leading to slight differences in performance. Future works will focus on providing guidance to users on configuring their functioning joints, potentially through visual feedback interfaces developed in our simulations or vibrotactile feedback systems [26]. Additionally, we plan to test the framework with prosthetic devices handling more complex amputations, such as those involving the elbow, and consider partial impairments. Finally, we aim to extend our framework to more complex interactive tasks, further evaluating its potential for enhancing prosthetic device usability in diverse real-world scenarios.

***Abstract*— Increasing integration of robotic devices in rehabilitation necessitates robust usability assessments to ensure effective human-robot interaction. This study presents a meta-analysis of System Usability Scale (SUS) scores reported in robotics-assisted rehabilitation, to evaluate whether the usability of these devices meets the standard SUS benchmark (mean = 68, SD = 12.5) and to identify any factors influencing usability across different users and device types. Following a systematic literature search, we analyzed 67 studies evaluating usability of robotic devices. Devices were categorized into 8 types, including upper- and lower-limb exoskeletons, end effectors and sensor-based systems. From each study, we extracted SUS means, user information (healthy individuals, healthcare practitioners or patients), and scoring origin (developer vs. external investigator). Our results indicate that robotic devices in rehabilitation generally achieve good usability (74 on average), but current studies have a limited sample size (13 on average). Comparisons with the standard SUS benchmark showed a statistically significant deviation in most device categories, thus underscoring the importance of tailored usability standards in robotics-assisted rehabilitation. Future research should focus on larger, more diverse sample sizes and explore usability challenges specific to certain devices and user roles to enhance the development of accessible, user-friendly rehabilitation robots.**

Keywords—Benchmarking, SUS for robotic rehabilitative devices, assistive device usability

I. Introduction

Technological advancement in the field of robotics and Artificial Intelligence (AI) over the last 30 years has led to the development of a wide range of heterogeneous devices, from end effectors to exoskeletons, potentially able to increase efficiency and accessibility to therapy [1]. In 2022, the global rehabilitation robot market was valued at USD 239.1 million, and it is expected to reach USD 1026.2 million by 2030 [2]. As robotics-assisted rehabilitation is spreading, evaluating the usability of such devices in clinical practice can identify potential gaps and drive the development of easy-to-use robots. In fact, the integration of user needs is essential to develop a satisfactory human-robot interaction [3]. According to ISO 9241-11, an important international standard related to usability, usability is defined as "*the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use*" [4]. To measure usability, one of the most popular tools is the System Usability Scale (SUS), a questionnaire of 10 questions to be answered on a 5-point Likert scale (from "Strongly disagree" to "Strongly agree"). Half of the questions refer to "positive statements", asking, for instance, whether the respondent would like to use the device frequently, or if the device is easy to use, while the remaining 5 questions are "negative statements", covering aspects such as the perceived complexity of the device and its inconsistency [5]. A final score from 0 to 100 can be calculated from the 10 questions, with 100 indicating the maximum level of usability. Various studies have investigated whether the SUS scores can be translated into categories to quantify user experience. For example, [6] gathered 1,000 SUS compiled for various types of technologies, such as cell phones and TVs. By adding an additional adjective question to measure the overall usability (from "Worst imaginable" to "Best Imaginable" in a 7-point Likert scale), the authors found that the SUS threshold to consider a device to have sufficient usability is 50.9. Another study analyzed more than 5000 individual SUS responses for various devices, and reported a mean SUS score of 68, with a standard deviation of 12,5 [7]. Following [7], [8], the acceptable SUS threshold for usability is usually considered to be 68. Recently, a review investigated the usability of robots and virtual reality devices in rehabilitation, finding that the SUS was the most utilized scale [9]. However, the study did not examine whether the mean SUS across robotics devices was in line with the aforementioned thresholds for benchmarking [7]. Nonetheless, comparing SUS results obtained from robotics-devices users in rehabilitation with those reported by large-scale studies on heterogeneous, non-robotics devices, such as mobile apps, might be unreliable. Another essential factor in assessing usability in rehabilitation is that there are two primary user groups—therapists and patients—each with distinct characteristics and needs.

Here, our goal is to quantify the reported usability of various types of robotic devices for rehabilitation in terms of SUS scores and to examine whether the benchmark SUS distribution of 68 (SD 12,5) [7] can be reliably used for evaluating the usability in the field of robotics-assisted rehabilitation. In particular, the research questions addressed in this paper are the following:

RQ1: What are the distributions of reported SUS scores across various types of robotics devices?

RQ2: Is there a statistically significant difference between the distribution of SUS scores in robotics-assisted rehabilitation and the benchmark distribution [7]?

RQ3: Are there any differences in usability between patients and therapists?

RQ4: Is there a difference in reported SUS scores when the usability study is conducted directly by robot developers?

To answer the research questions, we have performed an extensive literature search in Scopus, IEEEXplore and Google Scholar to gather studies performing SUS usability assessment on robotics devices in rehabilitation. For each retrieved paper, we extracted the category of device(s) investigated, the reported statistics on the SUS score (mean, standard deviation, median, minimum and maximum, when available), the number and the category of participants (patients, therapists, and healthy volunteers). The device categories, described in the next section, have been previously identified based on the basis of the function (rehabilitative or assistive device); the rehabilitative devices were classified based on their type (robot, advanced technological systems, sensor-based device); the robots were then classified into end-effectors and exoskeletons, and also depending on the body area treated (upper limb, lower limb); the advanced technological systems included devices for the treatment of walking (advanced treadmill) and balance (proprioceptive platform). Sensor-based devices include those using virtual reality, and those for cognitive training.

II. Materials and Methods

A. Literature search and device organization

We first retrieved the literature studies investigating real-world usability in robotics-assisted rehabilitation following the PRISMA guidelines for systematic reviews: we queried the Scopus and IEEEXplore database on October 9th, 2024 using the following query on the Title, Abstract and Keywords: (System Usability Scale) AND Robot AND (Rehabilitation OR Cognitive). We excluded studies that did not report at least the median SUS of the participants. We also queried Google Scholar for specific categories of devices (reported below) to augment the number of retrieved studies.

For each study, we categorized the evaluated technologies into the following eight categories of robotic rehabilitative devices:

(i) assistive and mobile servants, such as eye tracking communicator and market-available robots such as Pepper, developed by SoftBank Robotics

(ii) advanced treadmill, such as the Walker View developed by Technobody

(iii) upper limb (UL) exoskeleton, such as Gloreha Sinfonia

(iv) lower limb (LL) end effector, for example Erigo

(v) LL exoskeleton, such as Lokomat

(vi) assistive UL or UL end effector, for example Amadeo

(vii) Proprioceptive, stabilometric and balanced platform,

(viii) sensor-based, virtual reality and cognitive robots, such as Pablo.

We then extracted the number of participants, the reported mean SUS score, the standard deviation of the median SUS score, the Interquartile range, and the minimum and maximum SUS score (if reported). Additionally, we report whether the study was conducted by robot developers as part of an evaluation of their system or by external investigators (i.e. non-developers), for instance, to evaluate a device before introducing it into clinical practice. The studies were also stratified according to the targeted users, namely the therapists, the patients, or even healthy subjects

B. Statistical analysis

Following [8], we performed a meta-analysis by computing the mean of the retrieved mean SUS scores over the collected papers, but also stratifying for devices categories and target users as described before. The retrieved dataset was analysed with Matlab and Python. To test for normality, we used the Shapiro test. To test the equality distribution of the robotics-related SUS and the benchmark, we used the Kolmogorov-Smirnov and the Mann Whitney test.

III. Results

A. General statistical analysis

A unique number of 67 papers were retrieved (43 from retrieved thanks to the systematic query, the remaining from Google Scholar search). These studies have been conducted in the last 10 years, as the oldest study retrieved was published in 2014 [10]. Among these, one study collected SUS answers from both healthcare practitioners (HPCs) and healthy subjects [11], 7 studies engaged both HPCs and patients[12], [13], [14], [15], [16], [17], [18], and 1 collected results from healthy participants and patients [19]. The majority of the studies focused on usability on patients (86%), involving a total of 816 individuals. Over the 67 papers, the average number of subjects that compiled the SUS among patients was 14, while among HPCs and healthy subjects was 9 and 15,6 respectively. The mean of the reported SUS scores mean across all devices categories is 74,4 with a standard deviation of 11,28. 58% of the studies were conducted by robot developers, showing a mean SUS score of 76, while the mean SUS score for studies conducted by non-developers is 72,5. Figure 1 shows the boxplot of mean SUS scores in studies, stratified by the relevant groups that promoted the study, i.e., robot developers or non-developers. While the distribution of SUS scores seems to be lower in the case of studies promoted by researchers not involved in the development of the robot, we cannot conclude that they come from different populations (Kolmogorov-Smirnov test p-value >0.05).

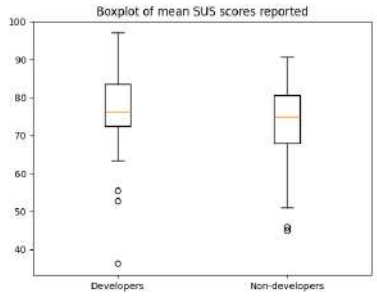

Figure 1: Boxplot of the mean SUS scores, stratified by the relevant groups that promoted the study, i.e. robot developers or non-developers [7]

When analysed according to the respondents types (HCPs, patients, or healthy subjects), we observed that healthy participants usually exhibit higher SUS scores (Figure 2), but their difference is not statistically significant according to the Mann Whitney test.

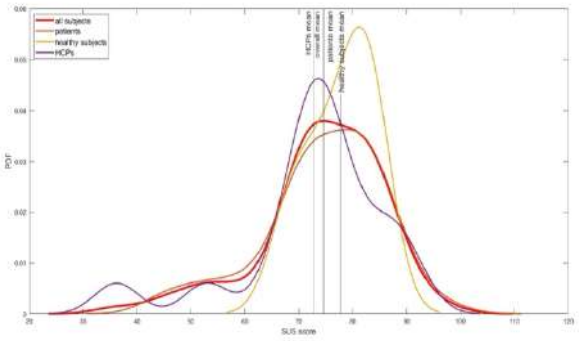

Figure 2: Density plot of mean SUS scores across all studies (red line), or stratified by types of respondents (patients, healthy subjects and healthcare practitioners – HCPs).

We then compared the distribution of SUS scores in robotics-assisted rehabilitation with the benchmark (normal distribution with a mean equal to 68 and a standard deviation of 12,5 [7] (Figure 3). We performed the Kolmogorov-Smirnov test and found a low p-value (<5e-8), indicating a significant difference between the SUS scores reported in rehabilitation and the benchmark, in favor of the former.

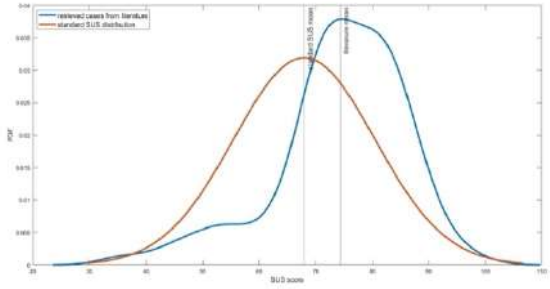

Figure 3: Density plot of the mean SUS scores of robotics devices for rehabilitation (blue) and density plot of the normal benchmark SUS scores distribution [7].

B. Statistical analysis across devices categories

Most studies (15) dealt with assistive (generic) and mobile servants [10], [14], [17], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31]. Thirteen studies evaluated the usability of UL end effector [32], [33], [34], [35], [36], [37], [38], [13], [39], [40], [41], [42], [43]. Twelve studies focused on UL exoskeleton[44], [45], [46], [12], [19], [47], [48], [49], [50], [51], [52], [53]. Eleven studies dealt with Sensor based/Virtual Reality/Cognitive robots [54], [11], [55], [56], [57], [58], [15], [59], [60], [18], [61]. Six studies evaluated usability of LL exoskeleton [62], [63], [64], [65], [66], [67] and LL end effector [68], [69], [70], [16], [71], [72]. Only three studies dealt with Proprioceptive/stabilometric/balance platform [73], [74], [75]. We were able to retrieve only one study evaluating the SUS for advanced treadmill [76]. The boxplot of the reported mean across device categories is reported in Figure 4. Lower limb end effector exhibits the highest median of SUS scores, but also greater variability. For advanced treadmills, the unique study evaluating the SUS on the 6 patients reported a mean SUS score of 68, with a standard deviation of 13 [76], very similar to the current benchmark. When compared to the benchmark, we found a statistically significant difference in the SUS scores for Sensor based/VR/cognitive devices (p-value 0.005), assistive UL or UL end effector (p-value 0.003), UL exoskeleton (p-value 0.002), LL end effector (p-value 0.015).

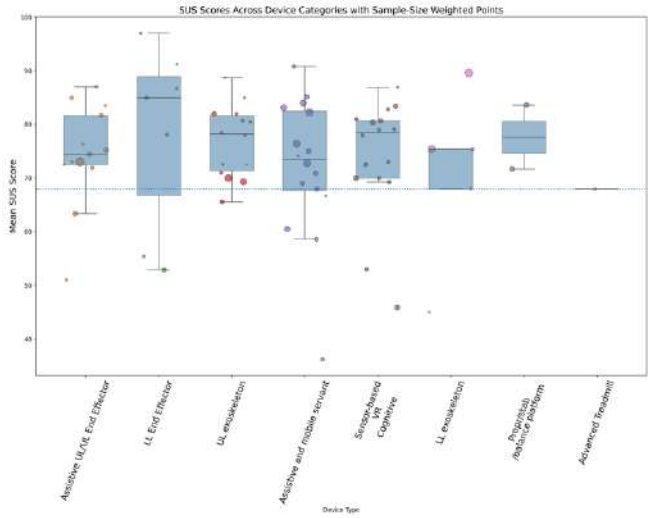

Figure 4: Boxplot of the mean SUS scores across categories. The horizontal blue dotted line represents the commonly used threshold for usability [7]. Each SUS data point is also reported. Each data point has a size proportional to the sample size of the study. The minimum sample size is 4 [15], while the maximum is 47 [33].

Table I reports, across all types of devices and users, the mean and standard deviation of SUS scores. Notably, for the device category "Assistive and mobile servant", patients and healthy participants indicated good usability (above 74), while the SUS mean for HPCs is 62,6, below the 68 thresholds, and with high variability (standard deviation of 17,6). On the contrary, LL end effector exhibits a higher mean SUS on HPCs rather than on patients.

IV. Discussion

In this meta-analysis, we examine the reported usability of robotic devices used in rehabilitation. Given the heterogeneity of these technologies, ranging from exoskeletons to virtual reality systems, meaningful comparisons of SUS scores within the same type of device required a standardized categorization. This classification was established through consensus among researchers and clinicians in the rehabilitation field, resulting in eight distinct categories. However, we recognize that as the field evolves, additional categories may emerge, and certain devices may fit into multiple groups. Nonetheless, for the purpose of this analysis, a single categorization was necessary. The results of our meta-analysis provide important insights into the usability of robotic devices in rehabilitation, as measured by the System Usability Scale (SUS). Below, we discuss these findings in relation to our research questions, highlighting key observations and implications for future development in this field.

Regarding general usability trends and variability across different types of devices (RQ1), Overall, the SUS scores of robotic devices in rehabilitation indicate good usability, with mean scores generally above the widely accepted threshold of 68 (Figure 4). This trend reflects a positive user experience across diverse devices, affirming the progress in designing robots that meet the usability expectations of end-users in clinical settings. However, notable variability exists across device types and user groups. In particular, the mean SUS score for assistive and mobile servant devices, when evaluated by therapists, falls below the 68 benchmark, with a mean of 62 and a high standard deviation (17.6). This lower score may reflect specific usability challenges encountered by therapists, such as operational complexities or inconsistencies in device performance, which could impede effective use in clinical practice. Among the device types, upper-limb (UL) end effectors exhibited the highest SUS scores, highlighting their generally favorable reception by users.

The comparison with the standard SUS benchmark distribution (RQ2) reveals a significant difference in the SUS score distribution for robotics-assisted rehabilitation compared to the standard SUS benchmark (mean = 68, SD = 12.5). This difference was statistically significant across most device categories, reinforcing the notion that robotics devices in rehabilitation generally offer a distinct usability profile compared to other technologies. However, this variance was not significant for certain devices, including lower-limb (LL) exoskeletons, proprioceptive platforms, and assistive and mobile servant devices. For these categories, usability scores aligned more closely with the established benchmark, suggesting that these devices may share usability characteristics with other types of technology or face similar limitations. Based on this finding, we propose establishing a new benchmark specifically for robotic devices. However, given the relatively small sample sizes in previous studies (with a mean of 13 participants), larger-scale studies should be encouraged to ensure more robust and reliable benchmarks. Since the SUS is a general usability assessment tool, the field could benefit from the development of new questionnaires specifically designed for robotic devices in rehabilitation, considering their unique characteristics and requirements. A more tailored approach could not only enhance usability evaluations but also help identify specific needs that should be addressed in the development of future robotic systems. Additionally, future research should explore whether—and to what extent—high usability translates into widespread clinical adoption.

Regarding relevant user group differences (RQ3), we observed no statistically significant differences in SUS scores between therapists and patients, suggesting a generally consistent usability experience across these user groups. This consistency may indicate that the usability design of rehabilitation robots has effectively addressed the requirements of both types of end-users, despite their different roles and interaction needs with the devices.

We also investigated the potential influence of developer involvement on usability score (RQ4). Our analysis indicated that studies conducted by developers tended to report slightly higher SUS scores compared to those conducted by external investigators. However, this difference was not statistically significant, suggesting that while there may be some degree of positive bias when developers assess their own devices, the impact on SUS scores is relatively minor. Additionally, studies involving healthy participants, which were mostly conducted by developers, tended to have a higher recruitment rate (mean of 15.6 participants). This outcome underscores the challenge of recruiting clinical participants, particularly for studies led by external researchers who may not have direct access to patient populations. The results of this meta-analysis underscore the overall positive usability of robotic devices in rehabilitation, yet highlight specific areas for improvement, especially for assistive and mobile servant robots when used by therapists. As the field advances, targeted enhancements in the user interface and operational ease of use for this subgroup could help bridge this usability gap. Furthermore, future usability studies would benefit from expanding beyond developer-led investigations and increasing sample sizes, especially for clinical populations. More diverse and larger samples would help validate findings across broader contexts and contribute to robust usability benchmarks tailored specifically for rehabilitation technologies.

In conclusion, the SUS remains a valuable and adaptable tool for assessing usability in rehabilitation robotics. By continuously benchmarking against a standardized usability distribution and incorporating feedback from varied user groups, developers can refine robotic technologies to better serve the needs of both patients and therapists, ultimately enhancing the integration and impact of these devices in therapeutic settings.

Imitation Learning for Adaptive Control of a Virtual Soft Exoglove

Shirui Lyu[1], Vittorio Caggiano[2], Matteo Leonetti[1], Dario Farina[3], and Letizia Gionfrida[1,4]

***Abstract*— The use of wearable robots has been widely adopted in rehabilitation training for patients with hand motor impairments. However, the uniqueness of patients' muscle loss is often overlooked. Leveraging reinforcement learning and a biologically accurate musculoskeletal model in simulation, we propose a customized wearable robotic controller that is able to address specific muscle deficits and to provide compensation for hand-object manipulation tasks. Video data of a same subject performing human grasping tasks is used to train a manipulation model through learning from demonstration. This manipulation model is subsequently fine-tuned to perform object-specific interaction tasks. The muscle forces in the musculoskeletal manipulation model are then weakened to simulate neurological motor impairments, which are later compensated by the actuation of a virtual wearable robotics glove. Results shows that integrating the virtual wearable robotic glove provides shared assistance to support the hand manipulator with weakened muscle forces. The learned exoglove controller achieved an average of 90.5% of the original manipulation proficiency.**

I. INTRODUCTION

The use of wearable robots has shown promising potential both in neurological rehabilitation protocols [1] and in passive supports to boost neural motor performance [2]. Patients with upper limb neurological dysfunctions or impairments often experience varying degrees of dexterity loss [3]. A personalized rehabilitation strategy is essential to enhance their independence, thereby improving their quality of life [4]. However, designing a tailored rehabilitative intervention that accounts for rapidly changing, patient-specific clinical indicators [5], particularly through wearable robotic devices, remains a significant challenge.

One of the challenges in realizing an intelligent controller for assistive wearable robots is the translation of the unique medical conditions of individual patient into adaptable controllers. For example, patients recovering from ischemic or hemorrhagic strokes, often experience significant limitations in their range of motion, characterized by symptoms such as reduced muscle strength or limitation of range of motion [6]. In clinical settings, such diverse medical conditions are typically managed through ad-hoc manual rehabilitation programs administered under the supervision of trained professionals [4]. However, in the context of wearable robotic rehabilitation, the device controller needs to be timely adjusted to provide clinical support [7], [8]. The development of automated methods for adapting wearable device control to individual patient needs is crucial for enabling personalized and accessible rehabilitation interventions.

Data-driven control approaches for wearable robotics have become widely adopted, enabling more general and accessible solutions for wearable robotic control [9]–[14]. These approaches learn biological features of the user such as kinematics, and muscle dynamics, from sufficient data to control the assistive devices. However, they focus on general rather than specific user behaviours, thus leaving a gap in addressing practical individual-based rehabilitation needs.

The development of personalized control strategies for wearable robots has been employing musculoskeletal models to facilitate adaptable controller training through Reinforcement Learning (RL) [15], [16]. Despite their utility, these approaches often yield non-intuitive behaviours [17] attributable to the absence of reliable human-reference data. To address these limitations, the integration of vision and imitation learning within RL training frameworks offers a promising solution. These methods enhance the fidelity of natural human behaviour modelling by providing enhanced biomechanical insights.

In this work, we propose a framework that uses imitation learning to derive user-specific reference trajectories from a healthy subject's video dataset [18]. These trajectories are used to reconstruct kinematics and muscle dynamics in silico, where hand impairments are simulated. Finally, a tendon-driven exoskeleton glove (exoglove) control strategy that adapts to the simulated impairments is tested using the healthy reference as a basis for optimization reference.

The proposed approach consists of three stages (Fig.1). First, reference trajectories are extracted from video data and learned by imitating the behaviour of a healthy subject through *MyoHand* [19], a biologically accurate musculoskeletal hand model, to replicate the user's natural behaviour. Second, RL-driven manipulation is applied to simulate hand-object manipulation tasks within the musculoskeletal model, and then a simulated impairment is incorporated to reflect reduced functionality in the hand. Finally, a virtual exoglove, modeled after a real device [20], is implemented in simulation, where an adaptive control strategy is developed to compensate for the impaired hand, optimizing hand-object manipulation and improving functionality for the impaired hand.

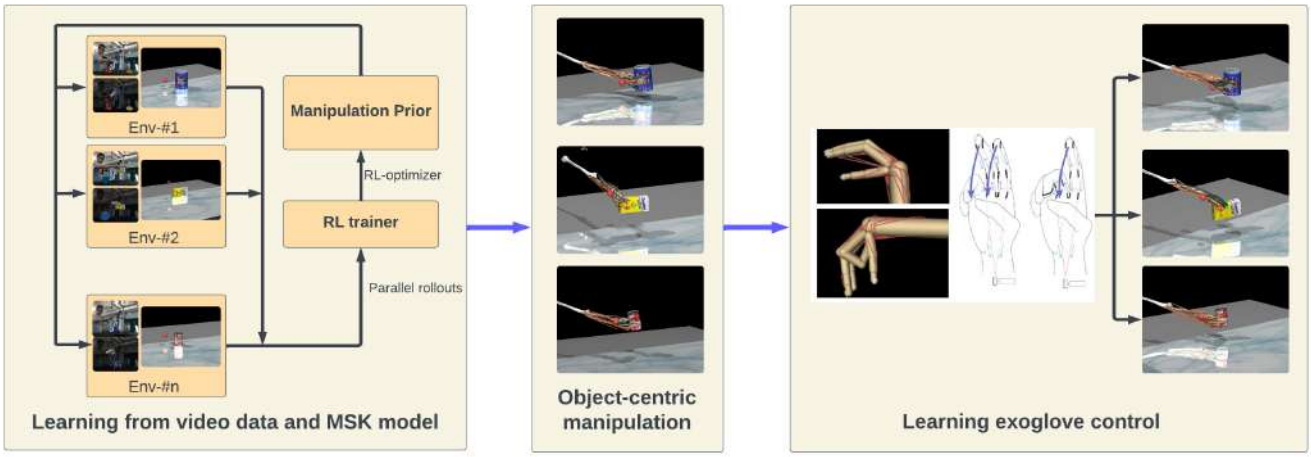

Fig. 1. Pipeline overview illustrating the three main stages: (1) extraction of user behavior via imitation learning from healthy subject video data, (2) training a biologically accurate musculoskeletal hand model for object-centric manipulation and simulating muscle impairments, and (3) development and testing of a tendon-driven exo-glove controller to compensate for impaired hand functionality.

II. Related Work

A. Learning manipulations from human videos and RL

As human video inherently captures the intricate kinematics of hand-object interactions, including the complexity and precision required for dexterous manipulation, extensive research has focused on understanding and modeling these interactions [18], [21]–[23]. Those recorded interactions provide sufficient context for the understanding of dexterous manipulation and facilitate other robotics applications such as handling previously unseen manipulation tasks [24]. Nevertheless, the learned model, referring to computational models trained on human video data to predict or replicate manipulation strategies, depends heavily on human video data and is less robust in handling unseen objects.

RL-based manipulation, on the other hand, is often data-inefficient and explores solutions with computational resources over data. Such an approach gives rise to manipulation understanding that is less relevant to human demonstrations. Object-centric approaches [25], [26], for example, mainly match the object in hand with a reference trajectory, and learn a manipulation strategy even with a high Degree of Freedom (DoF) musculoskeletal hand model.

Recent work [27]–[29] has attempted to combine the advantage from both sides: by using human demonstration video to facilitate RL training, and by using RL to train robust grasping behaviours. In addition, Wan et al. [30] leveraged RL and computer vision to first generate multiple grasping gestures before applying conditioned policy training to achieve generalized grasping behaviour. Chen et al. [17] proposed to use of human demonstration video to guide the RL training while leaving space for RL exploration to handle robot-object interactions. However, most previous works generalize the grasping behaviour and few of the studies were conducted on model-based RL for rehabilitative robotics applications.

B. Model-based wearable robotics control

Recent studies [10], [12], [14], [31], on wearable robotics systems, have focused on integrating high-level task control with low-level hardware control to enhance system performance. This combined approach allows wearable robots to execute tasks more effectively while adapting to the mechanical and dynamic constraints of the hardware. Introducing high-level perceptual information such as egocentric views [32], [33], or user-intent [15], into the control architecture usually improves the system's responsiveness and adaptability. However, deriving accurate and reliable perceptual information requires meticulous modelling of biological states. These models must be biologically accurate to ensure that the system's responses align appropriately with the user's physiological and cognitive conditions, thereby enhancing the overall efficacy and safety of the wearable robot. Hodossy and Farina [15] proposed to use a humanoid model and motion tracking to learn a robust locomotion model to inform the training of an intention-aware prosthesis. Luo et al. [16] leveraged a human musculoskeletal model to train an exoskeleton to provide locomotion support based on the user states. However, few studies have focused on upper-limb wearable robotics aimed at providing shared assistance through musculoskeletal hand models.

III. Methodology

Our approach consists of three main stages. First, we learn the user's behavior context by extracting joint kinematics from a video dataset [18] of a healthy subject. Second, a biologically accurate musculoskeletal hand model is trained for object-centric manipulation tasks, enabling the simulation of hand-object interactions that reflect the user's behaviour. In this stage, the model is also adapted to simulate a designated muscle-weakened hand impairments. Lastly, a tendon-driven soft exoglove is applied to the musculoskeletal hand, with an RL-based glove controller, to support dexterous manipulation

of the impaired hand model. The trained controller is then tested on a muscle-weakened hand model to evaluate its effectiveness in assisting with grasping actions, compensating for the impaired hand's functionality. The pipeline overview is illustrated in Fig.1 .

A. Learning behaviour context from video data

Leveraging video data of a subject grasping daily objects [18], we first learn the subject's behaviour context by distilling them into a musculoskeletal hand model controller via RL-based imitation learning. Three objects of varying size, including a master-chef can, a tomato can and a sugar box from the YCB [34] dataset are used to evaluate the learned hand-object manipulation. The reference grasping type on those objects resembles two commonly used grasp taxonomy types [35], power-grasp and precision-grasp, with variations in object sizes. The hand model observes the reference joint positions and learns a mapping to control the hand's muscle activation signals to follow the reference trajectory. Similar to a previous study [26], a prior model is first trained to capture the essence of the subject's general behaviour context by extracting a joint experience from a number of reference trajectories but from the same subject for training efficiency. The behaviour prior is later fine-tuned to individual hand-object interaction tasks for accuracy. We have observed that learning such behaviour prior can contribute to faster training convergence on previously unseen trajectories and objects. The reward function of such prior model training only comprises the degree of matching of the reference trajectory with the rough gesture shape, similar to the approach by Chen et al. [17]. Nevertheless, we increased the weighting of the thumb tip, to balance it with the other 4 fingertips to follow the reference gesture.

B. Musculoskeletal object manipulator

Imitation learning from video references effectively models user behaviours by capturing hand joint kinematics. However, it does not account for critical hand-object interaction details, such as the contact information for stable grasping and manipulation. To model the contact between hand and object, an RL-based manipulator is employed on the Mujoco [36] physics simulator together with a existing musculoskeletal hand model from Myosuite [19].

In addition, clinical tests such as the Box and Block Test [37] and the Action Research Arm Test [38] are common evaluations of dexterous proficiency of patients with upper-limb motor impairment. Such tests involve moving objects along a required trajectory as in most routine tasks. Thus, we define our exoglove controller training via an object-centric [25] RL approach, namely manipulating an object following a predefined trajectory to align with clinical rehabilitative requirements.

Problem definition

Similar to a previous work [25] on RL-based object-centric manipulation, the problem is defined as a Markov Decision Process (MDP) and solved via reinforcement learning. The Markov decision process is defined as a tuple $M = (S, A, T, R, \rho, \gamma)$, where $S \subseteq \mathbb{R}^n$ and $A \subseteq \mathbb{R}^m$ represent the continuous state space of observations and the action space respectively. The unknown transition dynamics are described by $s' \sim T(\cdot|s, a)$. In addition, $R : S \to [0, R_{\max}]$, denotes the reward function, $\gamma \in [0, 1)$ denotes the discount factor, and ρ the initial state distribution. In RL, a policy is a mapping from states to a probability distribution over actions, i.e. $\pi : S \to P(A)$, which is parameterized by θ. The goal of the agent is to learn a policy $\pi_\theta(a|s) = \arg\max_\theta[J(\pi, M)]$, where $J = \max_\theta \mathbb{E}_{s_0 \sim \rho(s), a \sim \pi_\theta(a_t|s_t)} [\sum_t R(s_t, a_t)]$.

State space

The state space for the musculoskeletal hand model and the exoglove consists of $\{\phi, \psi, \tau, \hat{\theta}\}$. ϕ a 58-dimensional vector of 23 hand and 6 arm joints positions and velocity of the musculoskeletal model. ψ is the object pose (3-dimensional), orientation (3-dimensional) and velocity (3-dimensional). τ is a positional encoding used to represent time steps in the tasks to handle possible repetitions [39]. In addition, the reference motion $\hat{\theta}$ is incorporated as a 63-dimensional vector to indicate the joint position of the wrist, and the four finger joints, including the metacarpophalangeal (MCP), the distal interphalangeal (DIP), proximal interphalangeal (PIP) joints and the fingertip from the human demonstrations.

Action space

The action space for the manipulation baseline is a 45-dimensional vector that consists of continuous activations for 39 muscles of the upper right arm, together with 3D translation and rotation of the shoulder, as in MyoDex [26].

The action space for the exoglove controller is a 3-dimensional vector representing finger contraction and extensions applied on the index and middle finger, with one extra dimension for thumb support.

Reward function

Similar to a previous work by Chen et al. [17], we define two reward functions to support the training. The first function is defined on the object center of mass matching with the one from the reference trajectory, and a second function is defined as matching the musculoskeletal hand joint positions with those from the human demonstration.

For object position $x_t^{(p)}$ and orientation $x_t^{(o)}$ at time step t, the reward function for matching the object position and orientation to the reference trajectory is defined by:

$$\mathbf{R}_{obj} := \lambda_1 exp\{-\alpha_1 ||x_t^{(p)} - \hat{x}_t^{(p)}||_2 - \beta|\angle x_t^{(o)} - \angle \hat{x}_t^{(o)}|\}$$

The reward function for matching the joints' position with those from the human demonstration is:

$$\mathbf{R}_{demo} := -\lambda_2\{\alpha_2 ||x_t^{(p)} - q(t)||_2\}$$

where $(\hat{x}_t^{(p)}, \hat{x}_t^{(o)})$ are the object's reference trajectory's position and orientation at time t, and $q(t)$ denotes the reference joints position from human demonstration data at time t. Here we selected the fingertips of all five fingers and the wrist to accommodate the musculoskeletal hand model. In addition, we increased the weighting of the thumb tip to balance the gesture with reference tracking accuracies. The

constants α, β and λs are part of training hyper-parameters, following the same set-up as in MyoDex [26].

In terms of RL training, both the behaviour prior model that tracks human demonstration and the object-oriented manipulator are equipped with the same state space and action space. Yet the reward function applied to train the two models is slightly different. The prior model is trained by collecting parallel roll-out from a number of manipulation tasks with human demonstrations, each of which contains a different human demonstration, and the reward used is purely $\mathbf{R}_{demo}$ to maximize the following of trajectory. On the other hand, the manipulation model is trained on a reward function defined by $\mathbf{R} = \mathbf{R}_{demo} + \mathbf{R}_{obj}$, to take account of the influence from both the video demonstration and object manipulation for each time step in the training environment and are subject to the specific manipulation tasks.

Object centered interaction

To achieve a realistic interaction modelling with the musculoskeletal model, the hand-object interaction is then trained by fine-tuning the prior model from human demonstrations on individual manipulation tasks. In each of the simulation environments, the controller is required to move the object to follow a predefined reference trajectory, extracted from the human demonstration dataset, and learns a successful manipulation strategy for each object and reference trajectory. To reduce the complexity of the tasks, the controller is trained on top of the human demonstration prior, which was capable of following the human references to facilitate training. In the interaction tasks, the musculoskeletal controller's objective is to find a balance between following the reference and the object manipulation proficiency.

C. Development of the exoglove controller

On top of the manipulation baseline, a tendon-driven exoglove based on a real prototype [20] was implemented in the simulation. Yet the simulated exoglove has an extended degree of freedom (DoF) with a total of 3 controlling dimensions: finger contraction, extension and passive thumb support. To align with the design of the physical prototype, the glove actuation is only applied to the index and middle fingers. The following (Fig. 2) shows the actuation mechanism of the glove in simulation. The thumb support dimension simulates passive support to the palm and only provides internal rotation.

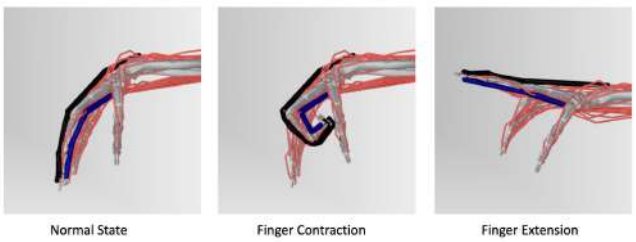

Fig. 2. Visualization of the tendon-driven exoglove actuation in simulation, based on a real prototype [20]. This figure visualizes the exoglove actuation mechanism, from left to right are the hand in normal state, finger contraction, and extension.

Learning compensatory movements

Deriving a suitable, personalized exoglove controlling strategy based on the user behaviour context is challenging. To train such a shared assistive exoglove controller, we adopt the same object-centric approach to support the manipulation behaviour. The objective of such an approach is to match the interacted object coordinates and orientation with a reference trajectory in simulation, which aligns with the needs of motor-impaired users.

Similar to recent work on RL-based prosthesis control [15], the glove controller is equipped with the same set of training hyper-parameters, reward and observation space as for the musculoskeletal hand-on-object manipulation. The aim of such a design is to align the glove controller and musculoskeletal hand model with the same objective of learning how to maximize shared assistance. This design also ensures the information observed by the glove controller is suitable for practical applications, as those features can be extracted via well-researched computer vision algorithms.

IV. Experiments

A. Learning behaviour context from video data

The human behaviour reference data used in this experiment is derived from a video-based dataset DexYCB [18]. The dataset includes a subject manipulating different YCB objects [34], providing the hand joint positions as extracted via computer vision. In our case, the reference trajectories are defined by the extracted joint kinematics, and the data to learn such behaviour all come from the same subject (with ref code: 20200709-subject-01 [18]). Then the training environment for the musculoskeletal model is recreated from the reference dataset using the Myosuite [19] simulator for efficient contact-rich computations.

To extract the behavioral context from the video data, a control agent is initially trained as a motion prior to establish general trajectory tracking capabilities with the musculoskeletal hand model. This agent is then fine-tuned to accurately replicate the specific trajectories of the individual user. A total of 16 environments of extracted reference joint kinematics are incorporated in simulation, including the interaction with 6 objects: chef can, tomato can, tuna can, mustard bottle, pudding box and sugar box. The RL agent learns from the joint experience of the 16 environments by collecting their parallel rollout to control the musculoskeletal hand model. The policy is trained until convergence as a motion prior and is then fine-tuned on individual downstream tasks. Fig. 3 shows the learned prior policy interacting with a chef can and a sugar box. Regarding model robustness, a random Gaussian noise with zero mean and 3% standard deviation is included in the observation space on hand joints and object kinematics in the prior training. We also test the model performance with random initialization (Fig. 4).

The learning of a prior model is a common approach for tasks with high DoF [26]. In this case, we show that this prior model improves the time to convergence for previously unseen reference trajectories from the same subject's data (Fig. 5). The trajectory following error is defined as the

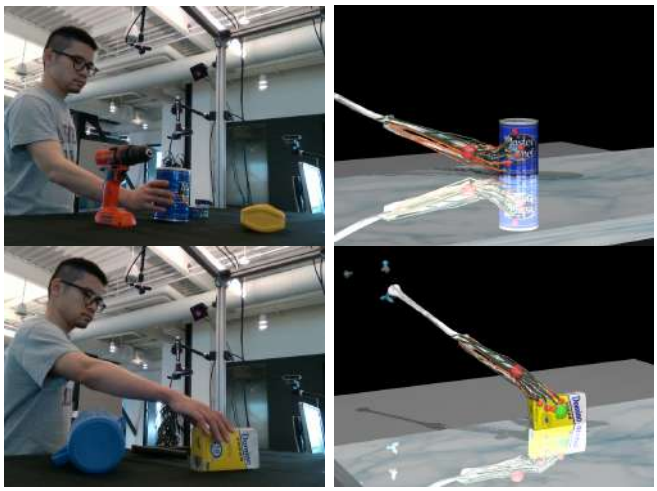

Fig. 3. Visualization of the learned musculoskeletal model policy. The policy is initially trained as a motion prior, capturing general trajectory tracking capabilities, and is subsequently fine-tuned for specific downstream tasks. The figure illustrates the learned prior policy applied to manipulating a chef can (top row) and a sugar box (bottom row).

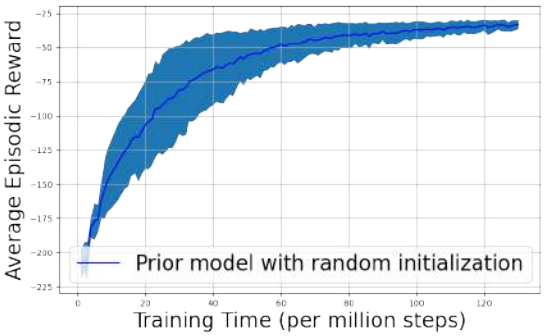

Fig. 4. Prior model training with random initialization

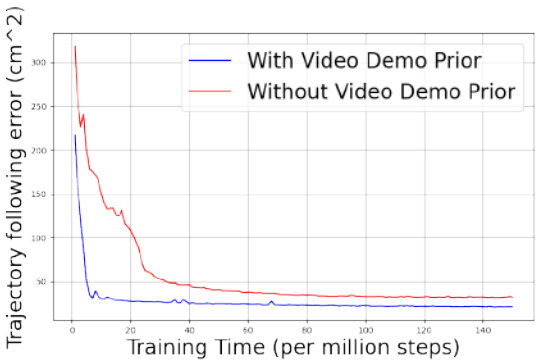

Fig. 5. Comparison of model training **WITH** (blue) and **WITHOUT** (red) the learned behaviour prior on previously unseen object and trajectory pair.

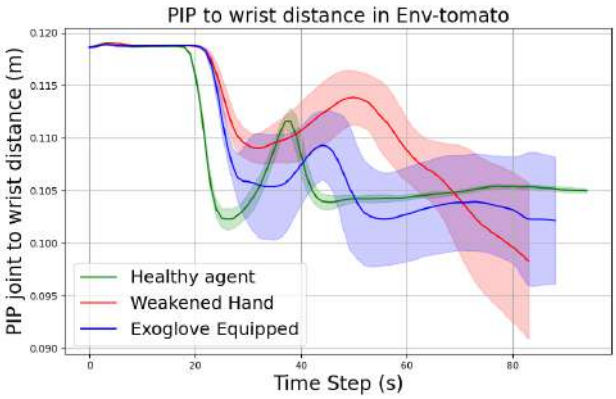

Fig. 6. Comparison of hand actuation behaviours for the tomato can, illustrating the reduction in distance from the proximal interphalangeal (PIP) joint to the wrist during the contraction phase for the healthy baseline (green), weakened hand without assistance (red), and weakened hand with exoglove compensation (blue). The mean and the standardization of the middle finger PIP joint to the wrist are recorded from a total of 30 trials. The figure depicts the exoglove's functionality in compensating for the weakened hand's reduced performance .

absolute value of the average $\mathbf{R}_{demo}$ reward over a training episode. The value serves as an indicator of the spatial difference between the position from human reference and the observed position of the musculoskeletal model. This shows that learning from a collection and diverse range of manipulation video data helps better understand the user's behaviour context.

B. Training of hand-object manipulation tasks

Leverage demonstration prior, a musculoskeletal hand controller is fine-tuned to learn the interaction with specific object and trajectory pairs. For each object-trajectory pair, a single control policy is learned on top of the prior model and the same set of hyper-parameters from MyoDex [26] is given to the RL algorithm. However, the reward function used for object manipulation is the sum of $\mathbf{R}_{demo}$ and $\mathbf{R}_{obj}$. The manipulation model is then trained for 26 million environment steps until fully converge. For each step during evaluation, the object's centre of mass has to be within a 2.5-cm range from the reference position to be considered a success step. The success rate is computed by dividing successful steps over the total steps. Previous literature [25] has noted that human perceives a task as successful if the success rate exceeds 80%. The outcome of the policy training (Fig. 4) and the average success rate over 30 trials on individual objects are recorded in Tab. I.

TABLE I

SUCCESS RATES UNDER 26 MILLION STEPS

Objects	Chef can	Sugar box	Tomato can
Performances	89%	97.6%	93.8%

C. Learning of exoglove control

To simulate neurological muscle weakness, the sarcopenia model from Myosuite [19] is introduced to reduce the maximum muscle strength of the musculoskeletal hand. Then, on top of the weakened hand model, the exoglove controller is trained to compensate for the impaired hand's movements via shared assistance. With the weakened musculoskeletal hand model frozen, the exoglove controller is trained to

learn a compensatory movement based on the hand joint kinematics to provide shared assistance. The exoglove controller is equipped with the same observation space and reward function as the musculoskeletal hand, an approach to ensure alignment in the RL agents' objectives [15]. The exoglove controller is trained until converge, and experiments are conducted to validate the learned exoglove behavior in terms of finger biomechanics and succssess rate, defined in Sec. IV-B.

D. Validation of exoglove biomechanics in simulation

The actuation of the exoskeleton glove exerts a force on the index and middle fingers to support the contraction and extension of the finger during grasping. Given the actuation mechanism, the distance between the PIP joint and the wrist is measured as an indicator of glove support.

Fig. 6 shows the biomechanical assistance provided by the exoskeleton glove. In the healthy case, the distance from the PIP joint to the wrist is first reduced during the closure of the palm, and then increased to hold the grasp gesture. Whereas in the case with simulated muscle weakness, the hand fails to achieve the same contraction due to the lack of muscle strength, causing the hand to drop the object. In contrast, the learned exoglove controller is able to restore an actuation pattern that matches to that of the healthy case, in terms of joint angle changes.

Fig. 7 shows the effect of the exoglove controller to support object-centric manipulations, and measured by an error matrix. The error measures the distance between the object's observed position and the reference position. When the deviation is large, defined by an error of 20 cm away from the reference position, a punishment value is added. The rapid rising of accumulated error, thus, indicates that the simulated motor impairments result in a lack of grasping force, rendering the musculoskeletal hand to drop the object after certain time steps, which aligns to the observed joint angle change as in Fig. 6. Meanwhile, the learned glove controller was able to capture the hand's behaviour and learned a control strategy to provide suitable assistance for enhanced graspin. These results prove that the learned exoglove controller can capture the subject's joint kinematics and provide suitable support.

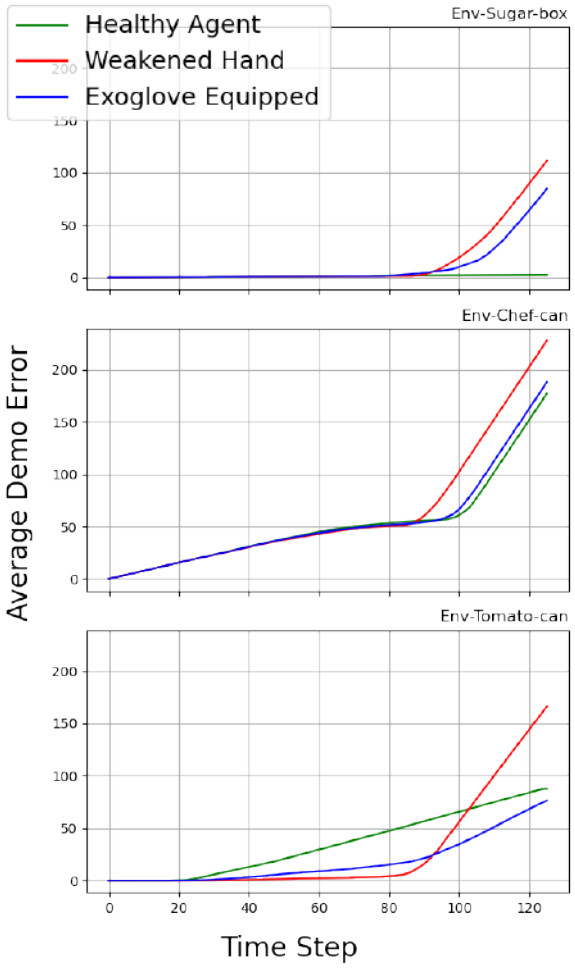

Fig. 7. Accumulated error in object manipulation tasks with the exoglove controller's compensation showing healthy (green) and motor impaired (red) hands, and motor impaired hand with exoglove support (blue). Objects from left to right: chef can, sugar box and tomato can from the YCB objects [34]. The accumulated error illustrates the effectiveness of the exoglove in supporting grasping. The glove controller restores an average of 90.5% of the original success rate.

V. Discussion and Conclusion

In this work, we presented a framework for deriving user-specific reference trajectories using imitation learning, focusing on hand joint kinematics extracted from video data of a healthy subject. These trajectories served as a foundation for reconstructing kinematics and muscle dynamics in silico, where a hand impairment was simulated. We introduced a tendon-driven soft exoglove control strategy designed to compensate for impaired hand functionality. This approach leveraged the healthy reference as a baseline for optimizing the exoglove's control, enabling personalized assistance.

The current approach is not without its limitations. A primary challenge involves translating the simulated outcomes into real-world applications, which remains inherently difficult for most RL-based models. While the state space in simulation can be accurately observed through vision-based extraction algorithms, real-world scenarios introduce complexities such as visual occlusions and partially observable inputs, posing challenges to the exoglove controller's adaptability. Although prior research has explored distilling simulation-trained policies into vision-based policies, the unpredictable nature of real-world environments, particularly in the case of impairments, continues to present a challenge for translating robust and reliable control strategies.

Future work will focus on addressing the deployment of this framework in real-world scenarios, validating the controller with muscle-weakened hands. Additional efforts will also be directed towards bridging the gap between simulation and real-world implementation, increasing generalizability and ensuring the adaptive controller's robustness in dynamic environments across multiple users, objects and tasks.

***Abstract*—Ankle injuries and musculoskeletal disorders often necessitate long-term rehabilitation to restore mobility and balance. The BALANSens robotic platform, designed within the Integrated Balance Rehabilitation (I-BAR) framework, combines ankle, balance, and stepping therapies into a cohesive rehabilitation process. This paper focuses on implementing impedance control on the BALANSens platform, which regulates the dynamic interaction between human limbs and the robotic system, making it suitable for active rehabilitation exercises. Traditional impedance control methods rely on costly six-axis force sensors to measure applied torques. However, this work proposes an affordable alternative using multiple load cells placed under the foot sole. These load cells not only measure ankle joint torques but also capture foot pressure distribution data, a key factor in the later stages of rehabilitation. The paper presents the derivation of joint space impedance control for the platform, with force measurements using load cells, and evaluates the system in a real hardware environment. The results underscore the promise of this approach for active rehabilitation, offering a cost-effective solution that simultaneously enriches the scope of patient assessment data.**

I. Introduction

Ankle injuries and musculoskeletal disorders significantly affect mobility and balance [1], often requiring long-term rehabilitation to restore function. Robotic systems have emerged as valuable tools in rehabilitation, offering precise control over joint movements and allowing for personalized therapy programs. The BALANSens robotic platform [2], [3] was recently developed to implement the Integrated Balance Rehabilitation (I-BAR) framework [4], [5]. This framework provides a continuous rehabilitation process by integrating ankle, balance, and stepping therapies into a structured, sequential program.
There are various control strategies [6]–[8] that can be utilized for rehabilitation robots. Position control is suitable for passive therapeutic movement of the limb along the desired trajectory when no human force is applied [9], [10]. The dynamic control strategy is required for active rehabilitation when both human and robot apply force [11]. Impedance control stands out as one of the effective methods for regulating the dynamic interaction between human limbs and robotic devices [12], [13]. It offers the ability to regulate the dynamic relation between the human applied force and position response of the system, making it particularly suitable for active rehabilitation exercises [14], [15].
Impedance control can be implemented without force sensing [16], [17]. However, for active rehabilitation training, force measurement plays a pivotal role in impedance control, as it enables the robot to adjust its behavior based on the user's applied forces. Traditionally, six-axis force sensors have been employed for this purpose, providing comprehensive data on force and torque in multiple directions. However, these sensors are costly, and usually applied torque measurement is needed only in the direction of ankle movements i.e. dorsiflexion-plantarflexion (DP) or inversion-eversion (IE) directions. Therefore, we propose the use of multiple load cells under the foot sole as an affordable alternative for force measurement [18]. Load cells offer the dual advantage of measuring both ankle joint torque and foot pressure distribution. Knowledge of foot pressure distribution is also important in later phases of I-BAR rehabilitation framework i.e. balance and stepping rehabilitation. By incorporating load cells, we not only reduce system cost but also expand the range of data available for rehabilitation analysis, paving the way for more efficient and cost-effective rehabilitation protocols.
The contribution of this paper includes the derivation of impedance control law and its implementation on the BALANSens robotic platform using the foot pressure distribution as a force measurement for potential active rehabilitation therapy. The outline of the paper is as follows. Firstly, the kinematics and dynamics of the BALANSens robotic platform are discussed briefly and then joint space impedance control

This study was supported by the Scientific and Technological Research Council of Türkiye (TUBITAK) under Grant Number 122E246.

derivation is presented and force measurement using the load cells is discussed. Then impedance control verification is done in the simulation environment and implementation on actual hardware is presented and results are shown. Finally, the conclusion is drawn.

II. Methodology

BALANSens robotic platform has a 3-DOF parallel robot with the revolute-prismatic-spherical (RPS) configuration specifically designed for ankle, balance and stepping rehabilitation considering the I-BAR framework. The lower platform and upper platform are connected with prismatic joints through revolute and spherical joints, respectively. The prismatic joints are actuated whereas spherical and revolute joints are passive joints. The BALANSens robot has been developed and shown in the Fig. 1.

A. Kinematics and Dynamics

Kinematics plays a crucial role in the implementation of impedance control for robotic systems like the 3-RPS parallel robot. To achieve this, an accurate model of the robot's motion in Cartesian space, particularly the position, velocity, and acceleration of the end-effector, is essential. The cartesian position in terms of the joint positions and vice versa can be obtained through forward kinematics and inverse kinematics, respectively, and can be represented as

$$X = f(q) \tag{1}$$

$$q = g(X) \tag{2}$$

where, $X = [x \quad y \quad z \quad \alpha \quad \beta \quad \gamma]^T$ and $q = [l_1 \quad l_2 \quad l_3]^T$. The velocity level kinematics of the 3-RPS parallel robot involves calculating the linear and angular velocities of the moving platform based on the joint velocities of the robot and vice versa and can be represented as

$$\dot{X} = J_{a(6\times3)}\dot{q} \tag{3}$$

$$\dot{q} = J_{k(3\times6)}\dot{X} \tag{4}$$

where, $\dot{X} = [\dot{x} \quad \dot{y} \quad \dot{z} \quad \dot{\alpha} \quad \dot{\beta} \quad \dot{\gamma}]^T$, $\dot{q} = [\dot{l_1} \quad \dot{l_2} \quad \dot{l_3}]^T$ and J_k and J_a, are the kinematic and analytic jacobian matrices of 3-RPS parallel robot respectively. Acceleration of moving platform in terms of the joint variables i.e. link lengths and vice versa can be computed by taking the derivative of the equations (3) and (4).

$$\ddot{X} = \dot{J}_a\dot{q} + J_a\ddot{q} \tag{5}$$

$$\ddot{q} = \dot{J}_k\dot{X} + J_k\ddot{X} \tag{6}$$

The Lagrangian representation of the dynamic model of the 3-RPS parallel can be written as

$$M(X)\ddot{X} + C(X,\dot{X}) + G(X) = F \tag{7}$$

where,

$$\begin{cases} M(X) \in R^{6\times6} & \text{Mass Matrix,} \\ C(X,\dot{X}) \in R^{6\times1} & \text{Coriolis's Vector,} \\ G \in R^{6\times1} & \text{Gravity Vector,} \\ F \in R^{6\times1} & \text{Generalized forces/moments Vector.} \end{cases}$$

Substituting the value of $\ddot{X}$ from equation (5) to equation (7)

$$M(J_a\ddot{q} + \dot{J}_a\dot{q}) + C + G = F$$

Now multiplying J_a^T on both sides and simplifying we get,

$$J_a^T M J_a\ddot{q} + J_a^T M\dot{J}_a\dot{q} + J_a^T C + J_a^T G = J_a^T F \tag{8}$$

The right-hand side of the above equation (8) can be simplified by utilizing the fact that the work done represented in generalized coordinates is equal to the work done represented in joint coordinates, i.e.,

$$\delta q^T.\tau = \delta X^T.F \tag{9}$$

where, $\tau \in R^3$ is the linear actuator force vector and $F \in R^6$ are generalized coordinates forces and moments. Putting $\delta X = J_a\delta q$ from equation (3) to equation (9),

$$\delta q^T.\tau = \delta q^T.J_a^T F$$

$$\tau = J_a^T.F \tag{10}$$

Utilizing the equation (10), we can write the the equation (8) in simplified form as

$$\tilde{M}\ddot{q} + \tilde{C}(q,\dot{q}) + \tilde{G} = \tau \tag{11}$$

where,

$$\begin{cases} \tilde{M} & = J_a^T M J_a \quad \text{is a } 3\times3 \text{ matrix} \\ \tilde{C} & = J_a^T M\dot{J}_a\dot{q} + J_a^T C \quad \text{is a } 3\times1 \text{ matrix} \\ \tilde{G} & = J_a^T G \quad \text{is } 3\times1 \text{ matrix} \\ \tau & = [\tau_1 \quad \tau_2 \quad \tau_3] \quad \text{is linear actuators force vector} \end{cases}$$

B. Impedance Control

Impedance control regulates the interaction between the robot and the external environment by defining a desired dynamic relationship between the forces exerted by the robot and the resulting motion. Impedance control can be implemented in either joint space or cartesian space coordinates. Here, we considered the joint space impedance control.

1) Mathematical derivation: In interaction with its environment, the dynamic model of the robot as presented in equation (9) can be written as

$$\tilde{M}\ddot{q} + \tilde{C}(q,\dot{q}) + \tilde{G} = \tau - \tau_e \tag{12}$$

where, τ_e is the external torque from the environment, τ is the control torque, M, C and G are the Mass, Coriolis and gravity matrices. To generate the desired dynamic interaction behavior of the robot in response to the applied external torque, the impedance model can be defined as

$$M_d(\ddot{q_d} - \ddot{q}) + B_d(\dot{q_d} - \dot{q}) + K_d(q_d - q) = \tau_e \tag{13}$$

where:

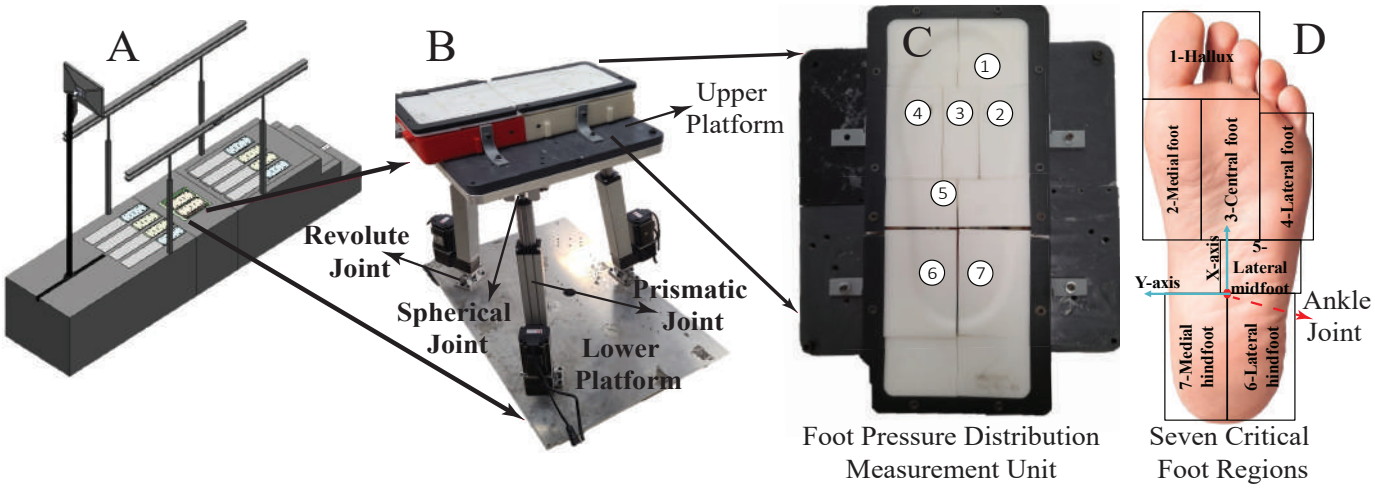

Fig. 1. Representation of the System Details (A) BALANSens platform, (B) 3-RPS parallel robotic manipulator (C) Foot pressure distribution measurement unit (D) Critical foot regions and estimated location of ankle joint

- τ_e is the applied external torque vector.
- M_d, B_d and K_d are the desired mass, damping and stiffness matrices for desired impedance relation.
- q, $\dot{q}$ and $\ddot{q}$ are the actual joints position, velocity and acceleration.
- q_d, $\dot{q}_d$ and $\ddot{q}_d$ are the desired joints position, velocity and acceleration.

we can re-write the equation (13) as

$$\ddot{q} = \ddot{q}_d + M_d^{-1}[B_d(\dot{e}) + K_d(e) - \tau_e] \tag{14}$$

where, $\dot{e} = \dot{q}_d - \dot{q}$ and $e = q_d - q$ are the position and velocity errors. Putting the value of $\ddot{q}$ from equation (14) to equation (13).

$$\tau - \tau_e = \tilde{M}[\ddot{q}_d + M_d^{-1}[B_d(\dot{e}) + K_d(e) - \tau_e]] + \tilde{C}(q, \dot{q})\dot{q} + \tilde{G}$$

by simplification, the following control equation is obtained

$$\tau = \tilde{M}_c M_d^{-1}[M_d\ddot{q}_d + B_d(\dot{e}) + K_d(e) - \tau_e] + \tilde{C}(q, \dot{q}) + \tilde{G} + \tau_e \tag{15}$$

where, τ is the impedance control input torque that ensures the desired impedance behavior between the applied external torque and the robot.

2) Parameters selection: To achieve the desired dynamic response, the matrices M_d, B_d and K_d must be carefully selected. The mass matrix M_d should be selected based on the inertia properties of the robot to avoid oscillations or instability. The damping matrix B_d should be set to provide critical damping or slight over-damping to ensure stability without overshooting. The stiffness matrix K_d should be chosen based on the desired accuracy in positioning, where higher stiffness values correspond to greater resistance to deviations from the reference trajectory. By adjusting these parameters, precise control over the motion while responding appropriately to external forces or disturbances can be achieved. To achieve the desired dynamic response of each linearly actuated joint, the characteristic equation of second order mass, spring and damper system is utilized to select the appropriate M_d, B_d and K_d matrices as follows.

$$s^2 + 2\zeta\omega_n s + \omega_n^2 = 0, \quad s^2 + \frac{B}{M}s + \frac{K}{M} = 0 \tag{16}$$

$$\omega_n = \sqrt{\frac{K_d}{M_d}}, \quad \zeta = \frac{B_d}{2\sqrt{M_d K_d}} \tag{17}$$

whereas, M_d, B_d and K_d are $3X3$ matrices having the mass, damping and stiffness values of three linearly actuated joints.

C. Foot-Ankle torque measurement using load cells

A foot pressure distribution measurement assembly containing the load cells is placed on the upper platform of the BALANSens robot as shown in Fig. 1-B, C. While previous studies (e.g., [19]) have divided the foot into multiple regions, space constraints and physiotherapist consultation led to the selection of seven key regions for load cell placement. The 7 key regions are of hallux, medial foot, central foot, lateral foot, lateral mid-foot, medial hind-foot and lateral hind-foot for the load cells placements as shown in the Fig. 1-D. To ensure accurate measurements, the load cells were calibrated using known weights, and linear fitting was applied to compensate for non-linearity. Additionally, baseline offsets were corrected to eliminate measurement bias. Ankle torque is estimated by leveraging the vertical forces applied by the foot in these regions. A coordinate system is defined with an approximated ankle joint as an origin. The x-axis is defined in the anterior-posterior direction (heel-to-toe), the y-axis is defined in the Medial-lateral direction (side-to-side) and the z-axis is defined in the vertical direction. The ankle joint origin is estimated to be approximately 7-8 cm forward from the back of the heel along the x-axis and 2-3 cm from the medial side (inside) of the foot along the y-axis, based on an average foot size. The subject's foot is positioned so that the actual ankle joint aligns

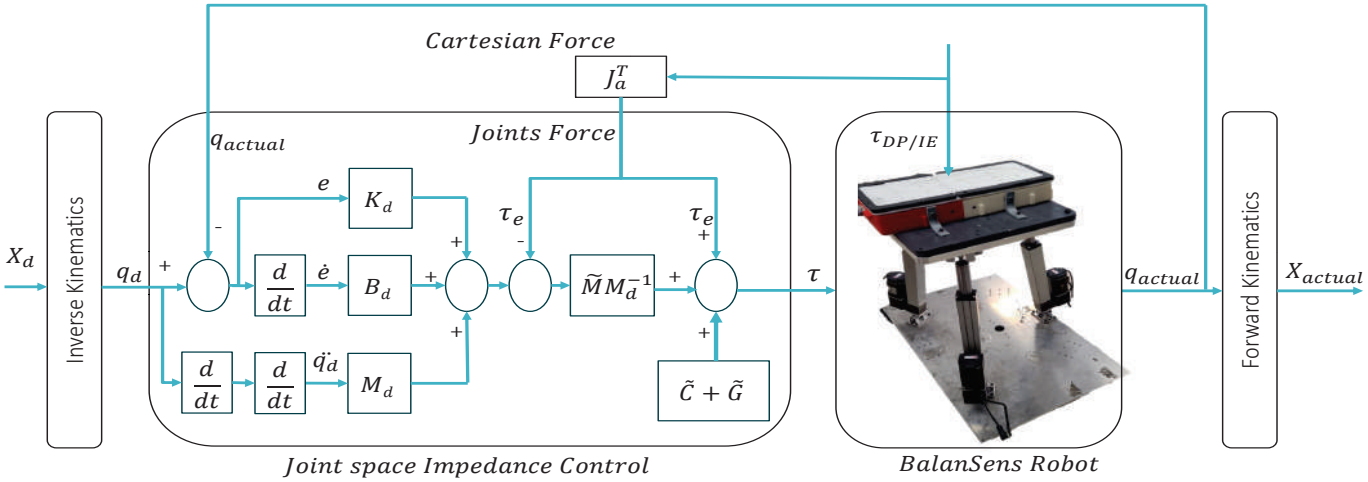

Fig. 2. Block diagram of impedance control implementation on BALANSens Robotic Platform

with this estimated origin. The ankle torque is calculated as the sum of individual torques due to the vertical force of each region about the origin. The torque calculation in DP direction τ_{DP} and IE direction τ_{IE} are represented in equation (18).

$$\tau_{DP} = \sum_{i=1}^{7} x_i F_{zi}, \quad \tau_{IE} = \sum_{i=1}^{7} y_i F_{zi} \tag{18}$$

where x_i, and y_i are the distances between the center of the ith region and the origin along the x and y axis, respectively and F_{zi} is the vertical force measured by the ith load cell. This calculated torque τ_{DP} and τ_{IE} are the applied torque in cartesian coordinates representing the torque in α and β rotations. These are converted to the corresponding torque exerted on the linear actuators by multiplying the cartesian torque with the transpose of jacobian matrix J_a^T using the equation (10) and used in the control loop.

III. Implementation and Results

The mathematical models derived in previous sections were implemented in the MATLAB Simulink environment to validate their accuracy. For real-time application on the actual robotic hardware, these models were programmed in structured text language on an industrial PC. A reference trajectory was generated and fed as an input to the inverse kinematics block, which then computed the necessary link lengths, velocities, and accelerations. These joint space variables, together with external torques acting on the joints, were provided to the impedance control block. This block calculated the torque input required for the servo drives to achieve the desired impedance behaviour. The servo drives used this torque as a reference, with their inner control loops driving the motors to move the robot accordingly. Feedback from encoders measuring the actual link lengths was used in the forward kinematics block to determine the real-time position and orientation of the robot's moving platform. This allowed for a direct comparison between the desired and actual Cartesian space trajectories. A block diagram illustrating the implementation of impedance control on the BALANSens robot is shown in Fig. 2. The parameters K_d, B_d and M_d were selected using equations (16) and (17), ensuring that the system exhibited a second-order dynamic response characterized by a natural frequency of ω_n= 6 and a damping ratio of ζ = 0.5. To test and verify the robot's impedance behavior, an experiment involving a human subject was designed, focusing on three specific test cases for DP and IE movements, as shown by the vertical dashed lines in Figs. 3 and 4. The studies involving human participants are reviewed and approved by the University Research Ethics Council of Istanbul Medipol University under the E-66291034-772.02-4494 number. The participant provided his written informed consent to participate and data sharing in this study. The design testing is performed on one of the authors without a formal recruitment process, i.e., the recruitment period is not used in this paper. In the first test case, the subject applied torque via their ankle while the robot remained in its neutral, zero-reference position. The second test case introduced a sinusoidal reference trajectory without any external torque from the subject, to assess the accuracy of reference tracking during free motion. In the third case, while the robot tracked a sinusoidal reference, the subject applied force with their ankle, allowing observation of the robot's dynamic response to the applied torque.

Figure 3 illustrates the results of the robot's DP motion. In Fig. 3-A, the torque applied by the human subject in the end effector frame (Cartesian space) during the DP motion is shown, while Fig. 3-B displays the corresponding change in the β angle (DP angle of the ankle) of the robotic platform in response to the applied torque. The graphs reveal that the subject applied torque between 4 and 14 seconds, with the β angle showing a standard, slightly over-damped response. Between 22 and 34 seconds, the robot followed a sinusoidal reference trajectory with no torque applied by the subject. After 35 seconds, the subject applied torque multiple times while the robot continued to track the sinusoidal reference. The changes in the β angle in response to the applied torques

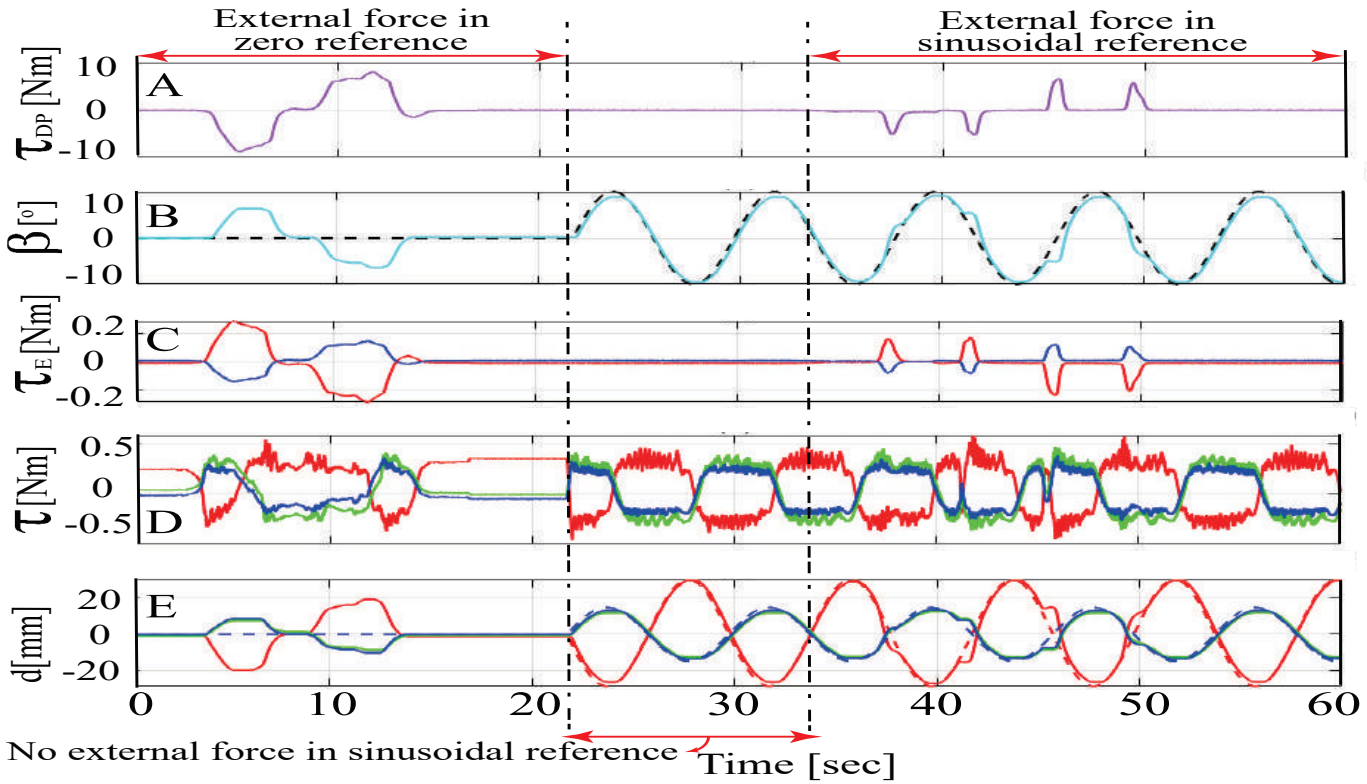

Fig. 3. Dorsiflexion-Plantarflexion (DP) movement: (A) Applied external torque by a human during DP movement (B) DP Angle(β): (Reference:dashed-line, Actual:solid-line) (C) Equivalent external torque on linear joints (Joint1:Red, Joint2:green and Joint3:blue), (green and blue overlapping) (D) Joint Torques: (Joint1:Red, Joint2:green and Joint3:blue), (Reference torque: dashed-line, Actual torque:solid-line) (E) Joint Positions: (Joint1:Red, Joint2:green and Joint3:blue), (Reference position: dashed-line, Actual position:solid-line)

demonstrate the second-order dynamic interaction between the torque and the motion. Figures 3-C and 3-D show the corresponding human torque applied to the linear joints and the reference torque given to the servo drives (calculated from impedance control block) versus actual torques of these joints, respectively, while Fig. 3-E compares the reference and actual positions of the linear joints. The corresponding human applied torque on the second (green-line) and third actuators (blue-line) in Fig. 3-C overlap, while the torque and position tracking of these joints in Fig. 3-D and 3-E show slight deviations due to differences in the dynamic characteristics of each linear actuator. Similarly, Fig. 4 presents the results for the robot's IE motion, considering the same three test cases. These include the response of the robot (Fig. 4-B) when subjected to the torque applied by the subject (Fig. 4-A) while in a zero reference position, the robot's performance during sinusoidal reference tracking without external force, and its response when an external torque is applied while tracking a sinusoidal reference. Figures 4-C, 4-D, and 4-E shows the corresponding human applied torque on the linear joints, torques generated by impedance control and the corresponding change in the linear joint positions, respectively.

The results demonstrate that the BALANSens robotic platform can achieve the desired second-order dynamic relationship between user-applied torque and the angular displacement of the platform using impedance control. Conceptually, the moving platform behaves as if connected to the fixed lower platform by three adjustable leg structures, each modeled with mass, spring, and damper elements. By modifying the values of K_d, B_d and M_d matrices, the system's compliance to the user-applied torque can be adjusted to be more or less responsive. This adaptability makes the approach suitable for customizing compliance levels to match the varying abilities of different users. The limitations of this study include the lack of subject-specific calibration methods to account for variations in foot size and alignment issues, as well as the need for more refined impedance tuning strategies to adapt to individual rehabilitation responses. A video demonstration of the BALANSens platform with impedance control to further illustrate the implementation and functionality is available at https://youtu.be/seuiG2Nziho.

IV. Conclusion

This study successfully demonstrates the implementation of the impedance control method for the BALANSens robotic platform, emphasizing affordability and feasibility for active ankle rehabilitation. By utilizing load cells placed under the foot sole instead of costly six-axis force sensors, the platform effectively measures ankle torques, addressing both cost constraints and data richness. The derived impedance control architecture has been validated experimentally through the

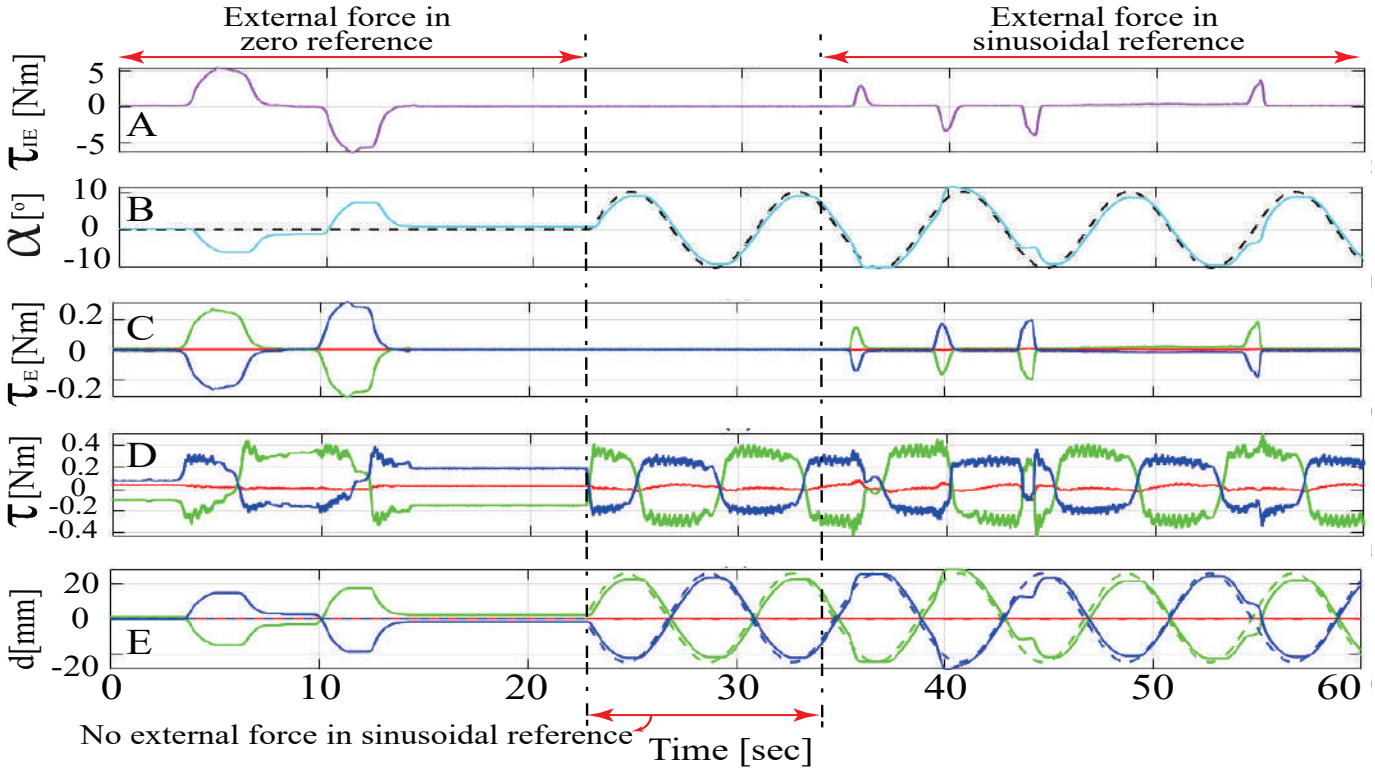

Fig. 4. Inversion-Eversion (IE) movement:(A) Applied external torque by human during IE movement (B) IE Angle(α): (Reference:dashed-line, Actual:solid-line) (C) Equivalent external torque on linear joints (Joint1:Red, Joint2:green and Joint3:blue) (D) Joint Torques: (Joint1:Red, Joint2:green and Joint3:blue), (Reference torque: dashed-line, Actual torque:solid-line) (E) Joint Positions:(Joint1:Red, Joint2:green and Joint3:blue), (Reference position: dashed-line, Actual position: solid-line)

prototype with a human subject, confirming the feasibility of this approach in realistic rehabilitation scenarios. Future work will focus on real-time regulation of compliance levels to accommodate varying ankle strength abilities. Additionally, it includes developing a foot pressure measurement assembly for both feet and extending the platform's application to balance rehabilitation exercises.

***Abstract*— Recent advancements in powered prosthetic leg devices offer enhanced potential for mobility for individuals with lower limb amputations; however, challenges persist, particularly for those with transfemoral amputations and short residual limbs. This study investigates the combination of a bone-anchored prosthetic interface via osseointegration and a powered knee-ankle prosthesis, aiming to assess initial feasibility, functionality, and user experience. A 39-year-old female with a very short residual limb participated, using the Hybrid Knee and Polycentric Ankle powered leg connected to an osseointegrated implant. Training involved level-ground and incline walking, stair climbing, and sit-to-stand weight transfers. Results indicated successful ambulation across all activities, with the participant demonstrating ease in reciprocal stair climbing and improved ease of sit-to-stand movements compared to her prescribed, passive prosthesis. User feedback highlighted the benefits of level-walking knee swing assist and powered ankle plantarflexion, and stair ascent and sit-to-stand knee extension power, though cosmesis and weight remained areas of preference for her prescribed device. This case underscores the potential of combining osseointegration and powered prostheses to enhance functionality and mobility, paving the way for further research on this promising technology.**

Keywords—above-knee amputation, artificial limb, bone-anchored implant, rehabilitation

I. Introduction

Recent advances in prosthetic technology have impacted individuals with lower limb amputations. Despite improvements in prosthetic devices, this population faces substantial challenges in daily mobility, such as high energy expenditure during walking, difficulty with stair climbing, and limitations in other essential activities [1], [2], [3], [4]. Functional mobility often becomes increasingly difficult for individuals with transfemoral amputations when they have a shorter residual limb [5]. Traditional socket-based prostheses, while functional, come with significant drawbacks related to comfort, fit, and mobility for these individuals.

Bone-anchored interfaces offer a promising alternative by allowing direct attachment of the prosthesis to the residual bone, thus eliminating the need for a socket. Osseointegration creates a structural connection between the bone and a biocompatible implant, facilitating natural load transfer and providing a stable attachment point for the prosthesis. Originally developed for dental implants, osseointegration has now been adapted for limb prosthetics and has shown improvements in quality of life when compared to a conventional socket [6], [7]. Various osseointegration systems are actively in use or in clinical trials around the world [8]. To the authors knowledge, use of these lower limb systems with powered prosthetic knees and ankles has not been investigated.

Powered prostheses incorporate motors and sensors that actively assist users in performing activities of daily living. For individuals with a transfemoral amputation, coordinated control of powered knee and ankle joints may allow for improved function and mobility [9]. Studies using powered leg prostheses have reported that users can ambulate on level-ground and inclines, climb stairs with reciprocal gait, and stand up from a seated position with more normative kinematics and kinetics [10], [11], [12], [13], [14].

The increased weight of these powered prosthetic devices can exacerbate socket instability, especially for those with shorter residual limbs who are known to exhibit greater gait deviations [5]. Directly anchoring the prosthesis to the

This work is supported by the Congressionally Directed Medical Research Program (CDMRP) Peer Reviewed Orthopedic Research Program award W81XWH-22-1-0850.

skeletal system via a bone-anchored interface could provide a stable and secure attachment point for powered prostheses. With osseointegration, the load from the powered prosthesis would be transmitted directly to the bone rather than through soft tissue. This secure attachment could make powered prostheses more feasible for everyday use, enhancing the user's ability to perform high-impact or repetitive activities that demand greater strength and stability.

Despite the promising potential of combining osseointegration with powered prostheses, there has been limited research exploring this combination. Recent studies by Frossard et al. [15], [16] have demonstrated that ambulation with a powered knee prosthesis (OSSUR Power Knee™, OSSUR, Reykjavík, Iceland) paired with the Australian Press-Fit bone-anchored system, was safe from a loading perspective. That is, the forces and moments generated by the powered knee prosthesis during walking, as well as ascending and descending ramp and stairs, maintained a safety margin greater than three when compared to published maximum femoral loads observed in able bodied running [15]. To date, there are no published studies discussing the quality of ambulation pairing a bone-anchored interface with a powered knee and powered ankle prosthesis.

This study aims to investigate the feasibility and benefits of combining lower limb osseointegration with powered prosthetics, assessing user control and comfort. In this case study, a 39 year old female was trained to use a powered knee and ankle prosthesis for multiple ambulation modes including reciprocal stair climbing. We include prosthesis sensor data during ambulation as well as the participant's subjective feedback.

II. Methods

A. Participant

A 39 year old female with a right transfemoral amputation (very short residual limb) due to trauma nine years prior participated in this study. She was two years post-completion of osseointegration Stage 2 surgery with the OPRA™ Implant System (Integrum, Mölndal, Sweden). She was 1.75 m tall and weighed 47.6 kg when not wearing her prosthesis. Her clinically prescribed prosthesis, which she used for two years, included an Ottobock C-Leg® knee, Ottobock Trias foot (Ottobock, Duderstadt, Germany), OPRA Axor™ II (Integrum, Mölndal, Sweden), and Ottobock torsion adapter. The prosthesis weighed 3.6 kg. She was an active individual and reported using her prosthesis regularly for recreation and activities including yoga and pilates. She reported no problems using her prosthesis. With her prescribed prosthesis, she ascended stairs using a step-to gait and descended stairs using a reciprocal gait. This study was approved by Northwestern University Institutional Review Board and the individual provided written informed consent to participate.

B. Powered Knee-Ankle Prosthesis

Prior to fitting the powered prosthesis, a 1.5kg weight was added distally to the participant's prescribed prosthesis (i.e., on the distal pylon, just proximal to the prosthetic foot) to simulate the added weight of the powered prosthesis. She was then asked to walk over level ground, ascend and descend a 10 degree ramp, and climb stairs (ascend with a step-to gait, and descend with a reciprocal gait). The participant reported no discomfort or interference with her mobility and thus was fit with the powered device.

Figure 1. Participant with osseointegration using the powered leg prosthesis (Hybrid Knee and Polycentric Ankle).

A certified prosthetist fit the powered knee-ankle prosthesis. The powered prosthesis included the Hybrid Knee [17] and Polycentric Ankle [18], OPRA Axor™ II (Integrum Mölndal, Sweden), and Ottobock torsion adapter (Figure 1). The prosthesis weighed 5.2 kg.. Embedded sensors in each joint measured knee and ankle joint position, velocity and motor currents. Additional sensors included a six degree-of-freedom load cell and an inertial measurement unit (IMU) both mounted in the shank. Shank inclination angle was calculated using the IMU and thigh angle was calculated using the IMU and knee encoder.

The powered knee-ankle prosthesis was controlled in active mode using an impedance-based model according to (1):

$$\tau = -k(\theta - \theta_d) - b\dot{\theta} \quad (1)$$

where τ was the commanded joint torque, θ was the joint angle, and $\dot{\theta}$ was the joint angular velocity. The three impedance parameters were stiffness, k, equilibrium angle, θ_d, and damping coefficient, b.

A finite state machine originally developed by Sup et al. [19] and further developed across various activities with a wide range of individuals [10], [14], [20], [21], [22], [23]. Similar to this previous work, stance and swing phases of each activity and transitions between activities including standing, walking, sit-to-stand and stand-to-sit weight transfers were controlled via mechanical sensor thresholding (e.g., axial load or inclination angle thresholding for state transitions). Transitions between stairs, ramps, and level-ground walking were controlled via a key fob.

Therapist-led functional mobility training was provided according to [24], including starting with educating the participant on the ability of the prosthesis to provide power in knee flexion and extension and the ankle to provide powered plantarflexion and dorsiflexion across multiple activities. Powered prosthesis parameters were only modified if necessary based on user and therapist feedback (i.e., empirical tuning similar to [22]). The participant began in the parallel bars and practiced transitioning between standing and walking. At heel strike, the knee is active and extended to provide a stable knee during weight acceptance. As the user

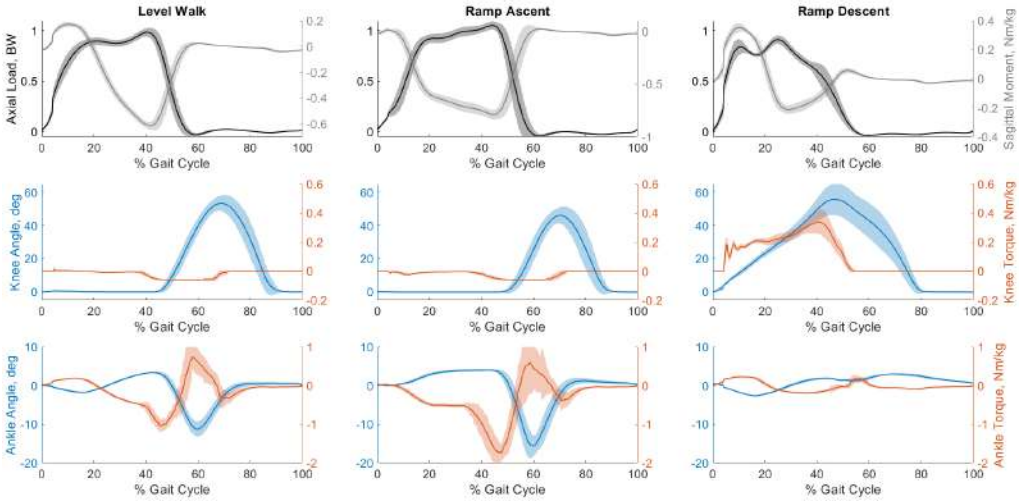

Figure 2. Signals from the powered prosthesis averaged across the gait cycle during level walking (*left*), ramp ascent (*middle*), and ramp descent (*right*) including axial load and sagittal moment both measured in the shank (*top*), knee angle and torque (*middle*), and ankle angle and torque (*bottom*). Positive knee torque indicates knee extension torque and negative values represent knee flexion torque. Positive ankle torque indicates ankle dorsiflexion torque and negative values indicate ankle plantarflexion torque.

progresses over the foot into terminal stance, the prosthesis begins to provide powered ankle plantarflexion and a small amount of powered knee flexion to assist with the transition to swing phase. At the transition of toe-off the knee actively flexes and the ankle actively dorsiflexes for swing clearance and then the leg extends to prepare the prosthesis for heel strike. The participant's training quickly moved from walking within parallel bars to walking around the laboratory.

Training progressed to powered weight transfers. For sit-to-stand, the participant was instructed on proper foot placement, forward trunk lean, and increased hip flexion to aid standing, enabling a smoother transfer of weight through the powered prosthesis. During the stand-up movement, the knee actively extends and the ankle actively moves to a neutral position. For stand-to-sit movements, she was instructed to distribute her weight equally and attempt to sit with forward trunk lean and active hip flexion. During the sit down movement, the knee and ankle provide supportive resistance for sitting. She was instructed to utilize the armrests for balance if needed and trained to sit/stand from various height chairs.

Training for stair climbing began with a shorter curb-like stair step to confirm her residual limb hip flexion strength to raise the prosthesis to the height of the step and confirm her comfort with the knee extension lifting her up. When the prosthetic foot was placed fully onto the step, she was instructed to push down into the prosthesis. This transfer of weight activated knee extension power to assist in stepping up. Training then progressed to a six-step staircase (6" rise) where the user was instructed on reciprocal stair ascent gait. Since the participant was already familiar with reciprocal stair descent with her prescribed prosthesis, minimal training for this activity was necessary, although slight variations in foot placement were explored.

Training was also provided for ascending and descending an 10-degree ramp. For ramp ascent, the prosthesis provided similar stance support, late-stance powered ankle plantarflexion, and active knee flexion and ankle dorsiflexion for swing clearance. For ramp descent, the knee provided stance resistance to "ride" the knee down for controlled descent into knee flexion. The participant was familiar with riding the knee down in a similar way with her prescribed prosthesis.

After comfortable across all trained activities, the research participant completed a custom user feedback questionnaire on her comfort, preference, and ability to perform the activities with the powered prosthesis compared to her prescribed prosthesis.

Sensor data, including joint angles, joint torques, axial load, and sagittal moment, were segmented into strides from heel contact to heel contact based on axial load. The signals were then averaged across multiple strides for each activity and plotted along with their standard deviation.

III. Results

The participant was successful in safely and comfortably ambulating with the powered knee and ankle prosthesis across level-ground, inclines, and staircases. Initial training across all activities took approximately one hour and then additional practice was provided. Though the prosthesis was heavier than her prescribed device, the participant reported that during this training session the additional weight did not cause discomfort at the osseointegrated implant.

Figure 2 shows powered prosthesis signals averaged across the gait cycle for level-ground walking (*left*), ramp ascent (*middle*), and ramp descent (*right*). During level-ground walking and ramp ascent, these graphs show in late stance a burst of ankle torque for propulsion, and in late stance and early swing a small amount of knee torque to aid knee swing flexion. The participant reported increased ease of walking on level ground and inclines with powered plantarflexion and swing assist. During ramp descent, the knee provides extension power to provide stance support as the user rides the knee into stance flexion and (for this session) the ankle provided static ankle support.

The participant was successful in ascending stairs with a reciprocal gait (Figure 3), noting that she could feel the extension assistance of the powered device. Additionally, without a socket to limit hip range of motion, she was able to ascend a staircase with higher-rise steps with ease. For stair

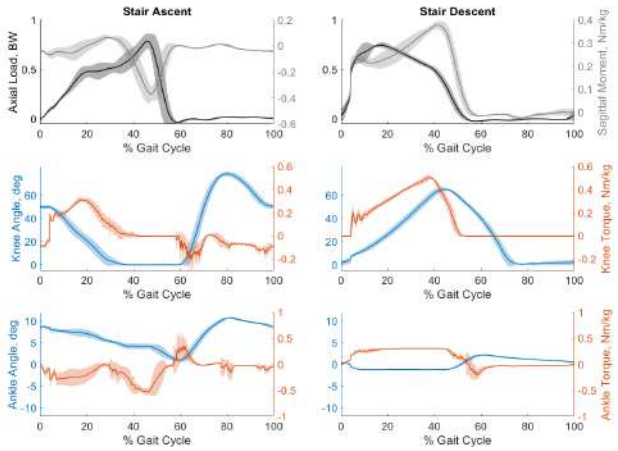

Figure 3. Signals from the powered prosthesis averaged across the gait cycle during stair ascent (*left*) and stair descent (*right*) including axial load and sagittal moment both measured in the shank (*top*), knee angle and torque (*middle*), and ankle angle and torque (*bottom*). Positive knee torque indicates knee extension torque and negative values represent knee flexion torque. Positive ankle torque indicates ankle dorsiflexion torque and negative values indicate ankle plantarflexion torque.

descent, she preferred foot placement similar to her prescribed prosthesis: half off the stair to ride the knee down but not utilize the ankle range of motion.

She was also able to perform sit-to-stand and stand-to-sit movements with ease including successfully transitioning from chairs of various heights. Unfortunately, not all necessary signals were recorded for the sit-to-stand activities to fully reconstruct plots for these weight transfers. Additionally, the participant demonstrated improved ability to reach for low objects and pick items up from the floor, aided by forward trunk bending and hip flexion to lower herself. The subject also utilized the sit-down feature of the prosthesis for squatting tasks.

The participant provided feedback that she preferred the powered knee and ankle prosthesis for level-ground walking, ascending and descending stairs and sit-to-stand and stand-to-sit movements. She preferred her prescribed prosthesis for incline walking and found it more favorable in terms of weight.

IV. Discussion

To the authors knowledge, this study represents the first instance of a participant with a transfemoral amputation and osseointegration walking on a powered knee-ankle prosthesis, highlighting both the potential benefits and unique considerations of combining a bone-anchored interface with advanced prosthetic technology. During training, care was taken to ensure that the powered prosthetic joint torques did not cause discomfort in the participant's residual limb near the implant. While she described some movements as feeling "different" or "odd," she confirmed that they were not painful.

Individuals with transfemoral amputations using traditional socket-based systems face challenges with fit, suspension and stability; those individuals with very short residual limbs inherently have reduced surface area in which to distribute loads [25]. In our decade of experience testing various powered leg prototypes [24], this participant had a shorter residual limb than anyone who used the device with socket suspension. In contrast to these other users, this participant's bone-anchored prosthesis offered quicker fit, improved suspension, and likely enhanced perception of the prosthetic limb compared to a socket. In this case study, these benefits of osseointegration were maintained while using the powered knee and ankle prosthesis. The improved suspension and the potential for osseoperception (e.g., foot placement awareness) suggest that osseointegration could enhance use of powered devices.

Although the participant noted the increased weight of the powered prosthesis, she still preferred it over her prescribed, passive prosthesis for certain activities including level-ground walking, stair climbing and sit-to-stand and stand-to-sit movements. In level-ground walking, she noted being able to feel the powered plantarflexion and swing assist. In stair climbing, she appreciated the knee extension power and enjoyed the ability to climb stairs with a reciprocal gait, noting she had not done this since her injury. She also appreciated the knee extension power during sit-to-stand movements. Although the participant preferred and appreciated the powered assistance, the knee and ankle torques provided were considerably lower than those observed in able-bodied gait and below the device's full capabilities [17], [26]. The session intentionally started with reduced torque levels to ensure comfort at the bone-anchored interface, with plans to gradually increase joint torque to improve movement quality based on her preference, task performance, and therapist feedback. However, during this initial training session, the participant successfully completed each task and found the initial torque levels sufficient. Further testing is needed to determine the optimal joint torques and to assess functionality and comfort over an extended duration.

In this case study, the participant received limited functional mobility training to use the powered prosthesis. This initial training was mostly focused on ensuring comfort through the bone-anchored interface and minor empirical tuning of prosthesis based on user and therapist feedback. Configuration time was similar to other participants who have walked on powered devices with socket suspension. Fortunately, the powered leg control did not need any modifications beyond what was typically configured. Research with more participants with bone-anchored prostheses is necessary to see if similar results extend to a larger population.

There are several limitations of this study including that training and use occurred over a short period of time and were with a highly functional participant. While this study demonstrated effective use of the powered prosthesis, there was no formal biomechanical analysis or comparison with her prescribed, passive prosthesis. Additional studies should include these comparisons including the use of clinical outcomes to quantify differences between devices for individuals with bone-anchored interfaces.

V. Conclusion

This trial demonstrated that an individual with a very short residual limb and a bone-anchored interface could

effectively use a fully powered knee and ankle prosthesis across multiple ambulation modes. Future studies involving a larger sample of participants are needed to explore the broader implications of this approach, including comparing clinical outcomes to passive devices.

Towards the development of dynamic hand orthosis without conventional joints

Leon Schaeffer[1], Felix Rambach[1], Theresa Schmaußer[1], David Herrmann[1], Lukas Lehmann[1] and Valter Boehm[1]

***Abstract*— The human hand is an exceptionally complex anatomical structure with 31 degrees of freedom. In the development of dynamic wrist-hand orthoses, the wrist's multiaxial mobility is of particular interest. To accurately replicate these natural movements, a promising approach is the use of compliant tensegrity structures. Tensegrity structures allow pivot points and axes of rotation to align with anatomical positions, enabling unrestricted mobility in all directions without conventional joints. Additionally, they permit customized movement restrictions based on therapeutic needs. The orthosis's minimalist, lightweight design ensures both effective joint stabilization and free access to key injured regions. Customizing each orthosis to the patient's unique anatomy and functional needs is crucial to prevent unnecessary strain from improper positioning. The positioning of the orthosis is directly linked to the forces applied to the wrist while using. A precise understanding of the behavior of the orthosis and its influence on the wrist forces present is therefore essential. This work explores key aspects of tensegrity-based orthosis development, emphasizing accurate 3D scanning of hand anatomy, initial experimental measurements, and simulated calculations. The proposed methodology provides a solid foundation for the design of initial prototypes of tensegrity-based hand orthoses.**

I. Introduction

The human hand is a complex body region, consisting of 27 bones, 36 joints and 39 active muscles and having three main sections: carpus, metacarpus, and digiti manus. Hand movements are affected by 33 muscles, which are divided into flexors and extensors [1]. Treatment of hand injuries often requires the use of both static and dynamic hand orthoses, with early motion therapy being crucial for effective healing. However, many of the currently available dynamic orthoses are limited by their degree of freedom (DOF), as they typically only allow for uni-axial motion, limiting their functionality during everyday activities. Orthoses with two or more DOF can be bulky or require motors for actuation [2]–[8]. This highlights the need for orthoses that provide multiple DOF, replicating the multiaxial hand movement, without relying on external actuators. Recent research has highlighted the potential of mechanically prestressed compliant structures [9]. In previous studies [15], [16], a possible concept of a dynamic prestressed compliant hand orthosis has been introduced. The orthosis is designed to be based solely on the user's hand movements, providing natural hand movement with adjustable resistance and immobilization for therapeutic purposes. The adjustment of the range of motion (ROM) is possible by carefully selecting parameters such as the stiffness and initial length of the tensioned members, typically made of elastomeric materials [10], [11], to meet specific therapeutic requirements. Current research is primarily focused on the general feasibility of these structures, without restriction to specific diseases or injuries. In comparison to these earlier works, the objective of this study is to present the general development process and additional development steps required for the development of a prestressed compliant dynamic hand orthosis. These steps include, among others, the individual adaptation of the hand geometry to the orthosis. While the functional components of the orthosis rely on standardized parts and regions, the anatomy of each patient is unique, necessitating a method to effectively combine these aspects. Compared to traditional treatment methods such as a plaster cast, it has been shown that customized Orthoses reduce the time of use during treatment and accelerate functionality [12]. The use of customized orthoses compared to conventional, standard-sized orthoses is also evident in an improvement in grasp force and return to activity [13], [14]. As the wrist is a complex joint in which mechanical loads that occur during therapy can influence local muscle activity and joint forces, potentially spreading compensatory forces throughout the body not only 3D adaptation is needed. In order to ensure that dynamic hand orthoses in particular

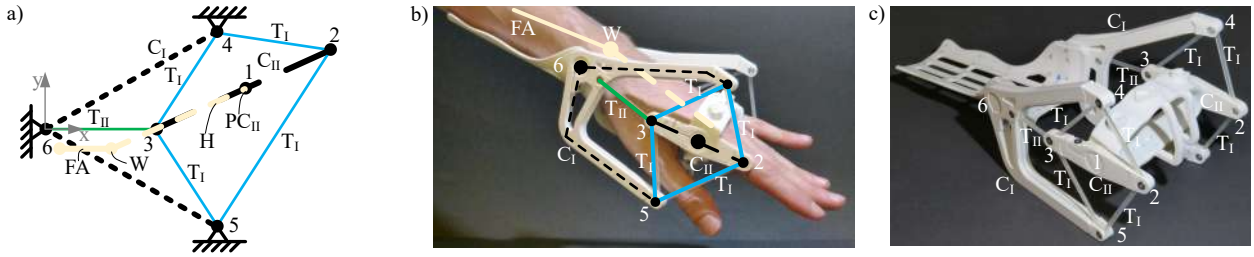

Fig. 2: Hand orthosis, a) 2D tensegrity structure with the applied boundary conditions used for form-finding; PC_{II}: center point of C_{II}, b) Human hand with the first demonstrator of the orthosis based on the described concept and c) Isometric view of the first demonstrator based on the described concept.

can be used effectively as part of therapy, a deeper, more complete understanding of the reaction forces in the hand is essential. For this, this study introduces a first prototype of an experimental test stand for measuring wrist forces. The concept and methodology will be explained, and initial tests will be presented to demonstrate the general functionality of the orthosis as a proof of concept. The test stand is designed to experimentally measure wrist forces as well as basic muscle forces. Furthermore, the maximum deflection and stiffness of the orthosis will be recorded. The work is organized as follows: Section II briefly discusses the anatomy of the human hand, followed by an overview of the hand orthosis in Section III. Section IV explores various methods for studying the body's response to the orthosis. Section V outlines an approach for capturing, digitizing, and processing the human anatomy as these are crucial steps in developing such orthoses with proper placement. Section VI introduces a first prototype test rig for experimental characterization of the hand orthosis.

II. Hand Orthosis

A. Human Hand

The wrist is composed of two joints: the proximal and distal wrist. The proximal wrist is an ellipsoidal joint that allows movement along two axes, while the distal joint acts as a hinge, contributing to stability and enabling grasping and manipulation. The wrist moves along two axes, the transverse axis for flexion and extension and the sagittal axis for radial and ulnar abduction, a third DOF is achieved through forearm rotation, enabling pronation and supination (Fig. 1) [19]. The ROM of the wrist varies depending on the direction and individual flexibility. In the neutral-0-position (0° of deflection in each direction), the hand rests along its axes, stabilized only by a tendon prestress of 8 to 9 N according to [20] independent of resting orientation. From the neutral-0-position, the wrist typically allows an angular deflection range of 50° to 90° for extension and 35° to 95° for flexion. Radial abduction permits an angular deflection of 30° to 60°, while ulnar abduction allows 15° to 35°. Pronation and supination can each achieve a maximum angular deflection of 80° to 90° [21].

B. Compliant Tensegrity Structures

A promising solution which considers the complexity and multi-axis movement of the human hand is the use of orthoses based on prestressed, compliant structures that are inspired by the tensegrity principle. Tensegrity structures consist of a series of compressed members connected by a continuous network of elastic, compliant, tensioned members. In conventional tensegrity structures, only two types of members are used: compressed and tensioned members, which are loaded in uniaxial compression and uniaxial tension. The connection between the members and the properties of the members (such as stiffness and initial length) define the prestress of these structures, their shape and the overall mechanical stiffness. The concept of using mechanically prestressed compliant tensegrity structures to develop dynamic orthoses is interesting for several reasons: With clever design, these structures can accommodate several joint axes with pivot points and axes of rotation outside the structure itself. By choosing the right structural parameters, a single structure can replicate several conventional joints. Appropriate design ensures that the pivot points and axes of rotation of the joints correspond to the anatomical positions, allowing unrestricted mobility in all directions of rotation and permitting individual restrictions of hand movement. By adjusting the prestress through selection of proper mechanical properties, including the initial free length and stiffness of the tensioned members, the overall stiffness can be customized to specific individual requirements. The minimalist composition of the structures through the use of only a few essential members ensures that the affected joint remains freely accessible, while the right design protects it from external loads.

C. Prestressed Compliant Dynamic Hand Orthosis

In previous work [15], [16] such an dynamic orthosis concept based on a compliant tensegrity joint was developed. The joint described has a V-shaped compressed member C_I with a connection to the forearm (FA) and a compressed member C_{II} with a connection point PC_{II} to the hand (H) (Fig. 2a). The compressed members C_I and C_{II} are connected to each other by five compliant tensioned members T_I and T_{II}. Due to the elasticity of the tensioned members, this structure allows movement between the compressed members in the x-y plane (x- and y-axis translation and z-axis rotation) without the use of conventional joints. By extending this tensegrity joint principle into 3D space, dynamic hand orthoses can be realized that allow a wide range of hand movements, including flexion, extension, radial and ulnar abduction. The ROM of the joint depends on the applied

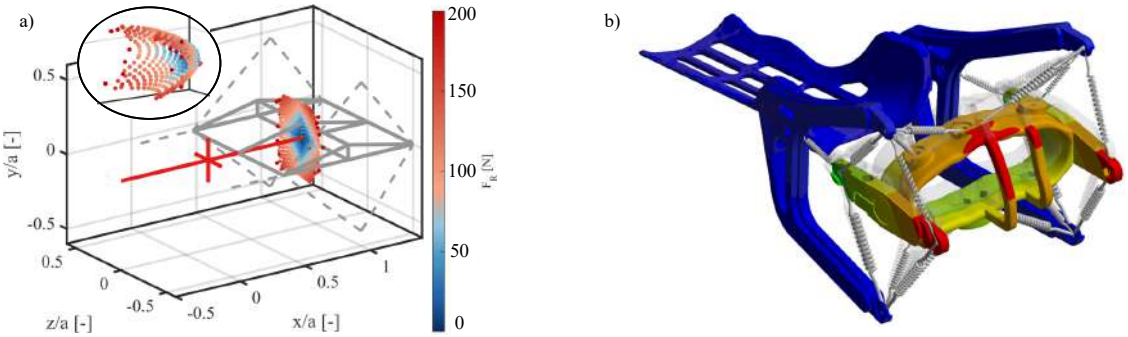

Fig. 3: a) 3D flexibility plots of the orthosis for k = 0.1 N/mm, L = 35 mm ("symmetric orthosis"), standardized muscle force F_S = 100 N, blue (minimum) to red (maximum): resulting joint force F_R; b) equilibrium configuration of the 3D model in the prestressed case with k = 1 N/mm and L_0 = 30 mm for all tensioned members; the two members C_I and the forearm element are fixed (blue; no displacement), the palm element and the two members C_{II} are colored based on the displacement of the equilibrium position (red = maximum displacement) to the initial position (transparent).

forces and is directly related to the stiffness of the structure, ensuring adaptability to different users. Fig. 2b, 2c show a first demonstrator of such an orthosis based on the proposed principle of operation. In the first demonstrator, the individual compressed members of the orthosis are designed to connect form-fittingly to the hand and forearm. The equilibrium arrangement of the structure is determined by the properties of the orthosis members (initial length and stiffness) and the position of the human wrist. By suitably selecting the properties of the tensioned members (initial length and stiffness) and the lengths of the compressed members, the relative position between the two compressed members can be set precisely. The structure is in a prestressed state because the lengths of the tensioned members in equilibrium are greater than in their unloaded initial state.

III. Mechanical Model and Simulations

The design of the dynamic orthosis with regard to their overall stiffness based on the properties of the orthosis members has a significant influence on the resulting body reactions. A profound understanding of the behavior of the orthosis when varying these parameters or when used on different hands is therefore essential in the development process. In the first step in orthosis-characterization the so called form-finding process is applied [22]. In this step the equilibrium position of the orthosis without external forces is determined. This orthosis configuration, which is initially unknown, is given by the parameters of the tensioned members and the shapes of the compressed members. Various methods can be used for form-finding, such as force imbalance [25], consideration of the potential energy of the structure, which is minimal in the stable equilibrium position [15], or with the help of the geometrically nonlinear static FEA [16]. The FEA approach can be realized in MATLAB® using [23], [24] or in commercial tools like Ansys®. Based on the form-finding, the actual characterization of the orthosis itself or in conjunction with the hand can then be carried out. The aim of this analysis is to examine the behavior of the structure under the influence of external forces or the movement of the hand. In this analysis, the overall directional stiffness (force-deflection characteristics) of the orthosis can be determined as a function of the parameters of the tensioned members (stiffness and initial length). In conjunction with the human hand, not only the orthosis' behavior but also the wrist loads can be analyzed. This systematic approach provides a substantiated evaluation of the mechanical behavior of the orthosis and the load on the wrist-joint, and builds the basis for optimization of the orthosis. Fig. 3a illustrates a 3D model of the orthosis, showing the deflection of its center when forces are applied to the cross-shaped segment, referred to as flexibility plots. The tensioned members (dashed lines) have a stiffness of k = 0.1 N/mm and an initial length of L_0 = 35 mm. The results represents one specific case based on the chosen parameters and corresponding orthosis dimensions. The underlying model is generic, while the final orthosis is individually adapted to the patient, directly influencing the final parameter values. Red members represent the human hand, with the red cross marking ideal muscle attachment points, mimicking real hand anatomy. A standardized muscle force (F_S = 100 N) is applied simultaneously to all four endpoints, causing deflection of the orthosis and hand. The force magnitude depends on muscle activity, with 100% activity corresponding to 100 N and 0% activity to 0 N. Varying activity levels at each endpoint produce angular deflections of the hand in one or two directions. The resulting joint force ($F_R = F_x^2 + F_y^2 + F_z^2)^{0.5}$ is shown at the respective deflection positions (blue to red). The shown flexibility plot is symmetric due to the symmetric tensioned members parameters. Fig. 3b shows an example of the equilibrium position determined after form-finding using geometrically non-linear static FEA in Ansys®. The tensioned members, shown here as longitudinal springs, have a stiffness of k = 1 N/mm and an initial length of L_0 = 30 mm. The initial position here is chosen to be in the center of the orthosis, but is chosen random in general.

IV. Digitization of human hand anatomy

Orthoses are typically manufactured in standard sizes, but these may not always meet the individual anatomical needs of patients. This lack of customization can limit therapeutic effectiveness due to poor fit. In the following, a potential methodology for 3D scanning and manufacturing is

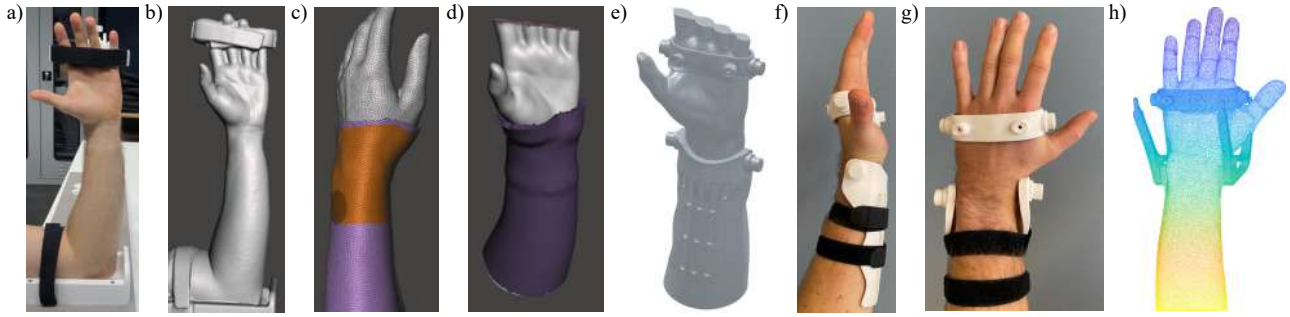

Fig. 4: Process of digitization of the human hand anatomy using 3D scans and the transfer of these scans into patient-specific orthosis using a own custom-developed CAD sequence; a) Human Hand, prepared for 3D scan; b) 3D scan of the human hand, including fixation (Artec® Spider); c-d) shell definition based on the 3D scans using Offset feature (Meshmixer®); e) 3D-adapted, patient-specific orthosis (Solid Edge); f-g) Test subject with 3D-adapted, patient-specific orthosis; h) patient-specific movement model of the hand volume (MATLAB®).

described (Fig. 4), focusing on its application rather than the specific software used, as the methodology itself is software-independent. The cross-software .stl file format can be used throughout the entire methodology. The method is developed using the patient's real arm and hand as demonstrated in Fig. 4a. For obtaining 3D scanned body region data, the Artec® Spider 3D scanner, a portable structured light scanner, was used here to capture the human hand. It has a working distance of 17 to 35 cm and a capture speed of 7.5 FPS. Using Artec Studio software, the individual scans of the hand are merged into a single 3D scan (Fig. 4b). In order to precisely adapt the forearm and palm elements to the patient's individual anatomy the 3D scan must now be included in a CAD design software. However, preparatory steps are necessary beforehand. The first step here is the definition of 3D shells based on the scans, here Meshmixer® was used, which serve as the basis for standardized CAD geometries that are applied to these in order to obtain patient-specific forearm and palm elements (Fig. 4c). Corresponding areas in the 3D mesh of the scan are selected where the orthosis is in contact with the body. An offset is used to create a thickening in these areas, which form the base for the shells (Fig. 4d). The 2D mesh of the scan becomes a 3D solid. The finer the 3D scan and therefore the mesh, the more accurate the fitting of the shells. The shells can be further optimized in terms of local thickness, mesh geometry and smoothness. For example, areas that are subject to higher loads can be reinforced. Optionally, to avoid processing errors and long processing times the shells can be subjected to surface reconstruction. Here NX® CAD software was used. The 3D shells created in this way can now be converted into final forearm and palm elements using a CAD Software (Fig. 4e). Here Solid Edge® was used. The final design is carried out using a custom-developed sequence of operations, which is independent of any specific software and can be applied across different platforms, on the basis of which the 3D bodies can be adapted to the previously developed basic design using your own predefined commands and sketches. This enables standardized and precise placement of component geometries. For this purpose, a temporary wrist point, which is only required for the creation of the CAD models, is defined in the area of the real wrist joint. At a later stage, the joint point will be defined exactly at the previously calculated point using determination methods yet to be developed. However, this current definition is sufficient for the general development of the methodology. The shells are modified in a structured manner, with each functional area of the final hand orthosis being modeled step by step. Once the fitting process is complete, patient-specific orthotic forearm and palm elements are created on the basis of 3D Scans, but with predefined, uniform functional areas (Fig. 4e). In Fig. 4f and Fig. 4g forearm and palm elements manufactured on the basis of this methodology are shown on a test subject. For the development of the orthosis, it is also important to know how far the patient can currently move their hand and to what maximum range it should be deflected as part of the therapy. This helps to further individualize the orthosis for everyday use without the need for a physical model. One method of measuring, recording and visualizing the ROM of the hand, i.e. the volume of hand movement, is described below. The movement of the individual hand segments is measured using "outside-in" motion capturing systems. The software Captury-Live® is used here for this purpose. The motion capture data is imported into MATLAB® with the MoCap toolbox [26] and processed using a custom-developed sequence. The recorded movement data represent coordinates of the individual segments over the recorded time. For the graphical visualization of the captured volume, the previously recorded 3D scans of the respective patients are divided into the same, individual hand segments, which were measured using Captury®. The movement data of the individual segments (forearm, metacarpus, phalanges) are assigned to the corresponding 3D segments. This creates a movable 3D model of the patient's hand, which can be animated using the recorded movement data (Fig. 4e). The resulting ROM or volume can then be used to refine the orthosis design, for example to define areas that must not be overlapped by the orthosis structure.

V. Experimental Setup

A test rig (Fig. 5) was set up to experimentally characterize the mechanical behavior of the orthosis and to determine the joint forces during hand movement. It measures wrist joint forces and primitive muscle forces using an movable artificial hand with a cable-guided actuator system, including tendon pretension, in combination with the dynamic hand orthosis.

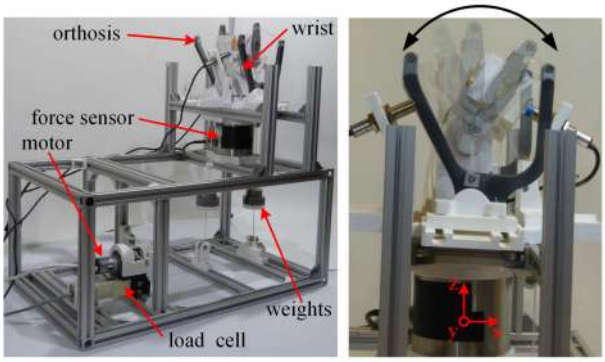

Fig. 5: Test rig for the experimental determination of wrist forces and moments of an artificial hand in combination with a prestressed, compliant dynamic orthosis using cable-based actuation; left: isometric view, right: side view with wrist and orthosis during movement.

The cable pull mechanism mimics the actuation of the hand by muscles. The test rig can be divided into two sections, a lower section with the electronics and the control system and an upper section with the artificial hand, the orthosis and the measuring components. The hand is approximated by a hinge joint with one DOF, which is mounted on a force sensor (ME-Systems, K6D68) that measures the forces in three perpendicular directions in the joint. The outer orthosis members and other test rig components are mounted on a plate that is decoupled from the sensor. This ensures that only joint-related forces are measured and external influences are excluded. By rotating this plate, measurements in different directions (flexion and extension or radial and ulnar abduction) are possible without costly modification of the experimental setup. A motor (33G-312 DC gear motor) with an idle speed of 18 rpm and a peak torque of 0.9 Nm is used for angular deflection of the joint. The movement is controlled quasi-statically by an L298N H-bridge. The cable pull is a closed circuit with one side of the cable pull under tension while the other side is relaxed. The pretension of the cables/muscles, 8 to 9 N according to [20], is simulated by added weights on the cable. A load cell (HBM PW6DC3MR) measures the tensile force exerted by the motor, which can be interpreted as “muscle force”. An inertial measurement unit (IMU; GY-521-MPU6050) is used to measure the position and orientation of the artificial hand. The H-bridge receives, independent of the IMU, a signal from an inductive proximity sensor (LJ12A3-4-Z/BX-5V) when the artificial hand has reached the desired maximum deflection and automatically reverses the rotation direction of the motor. An Arduino Uno R3 is used to control the entire test rig. The start and end of a measurement is indexed by the software Catman® EasyScript in order to activate all sensors and load cells simultaneously. The measurement signals are amplified by an HBM amplifier (1615B) before being processed by Catman®. The position and deflection data determined by the IMU are transmitted via two Bluetooth modules (ESP32C3). The first module (ESP1) is directly connected to the IMU inside the artificial hand and is powered by a 3.7 V battery for cable free operation. The second module (ESP2) receives the data and transmits it serially to the Arduino. The described testing rig can be used to measure the joint forces acting on the wrist for various prestressed, compliant dynamic hand orthoses. In addition, the position, orientation and deflection of the hand as well as the necessary “muscle force” can be determined. To ensure the functionality of the test rig, a first proof of concept measurement was carried out using an orthosis with soft (0.087 N/mm; red) and stiff (0.125 N/mm; blue) tensioned members (Fig. 6). The angular deflection of the artificial hand and the corresponding cable-force (”muscle-force”) and wrist-joint force in x-direction (main direction) in the case flexion and extension were examined. The results show that the movement of the hand and the resulting behavior of the orthosis correspond to the expected behavior. However, there are short plateau phases between the deflection of the neutral 0 positions in the area of the bounce. The maximum deflection of the hand also increases with increasing duration. This effect can only be attributed to a limited extent to the material properties of the tensioned members, as this should only occur with a significant time delay. Overall, however, the proof of concept can be confirmed for the test stand.

VI. Conclusion

In this paper, a prestressed, compliant dynamic hand orthosis enabling hand movements without relying on conventional joints was presented. It can be adapted to the complex multiaxial movements of the hand and thus enables the hand to move over the entire ROM without physical restrictions, although the movement can be limited in certain directions according to the desired therapy. Furthermore, important steps in the development process of the considered orthosis were presented. Selected simulation methods for the theoretical description of the behavior of the orthosis and the wrist loads were discussed. A precise fit between the orthosis elements and the hand, which is crucial for the functionality of the orthosis, is important. For this a possible methodology for digitizing the hand anatomy and designing patient-specific orthoses using 3D scanning was presented. The results show that detailed 3D data of hands can be created with simple 3D scanners and little to no effort. Based on this, the methodology can be used to establish a reproducible, software-independent process for the rapid ($<$ 2 h) production of customized orthoses. In future work regarding the methodology, the current time-precise definition of the reference joint point should be improved. The current self-developed flow chart should also be further developed so that it automatically processes the fabrication. Initial exemplary measurement results confirm the applicability of the measurement principle of the test rig. However, the plateau phases around the neutral-0-positions should be examined to determine their underlying causes. Additionally, the relationship between maximum deflection and the stiffness of the artificial wrist requires further investigation. Future studies with the test rig will focus on comparing the impact of different hand sizes in comparison with the simulation models. A detailed analysis of mate-

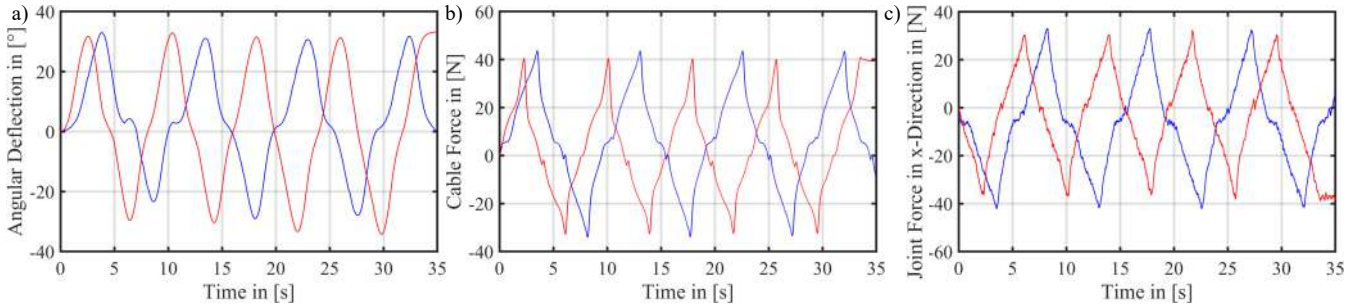

Fig. 6: Evaluation of the test stand for an orthosis with soft (0.087 N/mm; red) and stiff (0.125 N/mm; blue) tensioned members for 4 cycles, 1 cycle corresponds to an angular deflection from neutral-0-position to both maximums in each direction and the return to the neutral-0-position: a) angular deflection, b) cable force and c) joint force in x-direction (main).

rial fatigue in the tensioned members is also of interest. Overall, the results pave the way for future research that could investigate the behavior of the orthosis under external influences such as vibrations, harmonic or transient dynamics or even more realistic simulations of hand movements and muscle activity. Additionally, the developed 3D adjustment methodology allows for consideration of each patient's individual circumstances, proving useful even during the initial practical testing of the orthosis in near future.These findings will improve both the simulated and experimental models, which would further support the practical application of the orthosis in real-life scenarios.

Mechanical Development and Preliminary Control Results of a Cable-Driven Robotic Platform for Whole-Body Rehabilitation*

Juan Fang[1], Michael Haldimann[1] and Niklaus Stocker[2]

Abstract— **To promote whole-body rehabilitation in the early post-injury phase, a system is desirable to provide user transfer, automatic posture change and therapy for various arm-leg movements. This work aimed to present a cable-driven robotic platform that can provide whole-body rehabilitation for the user in a lying position and to demonstrate preliminary results for generation of 3D leg movements. Seventeen compact cable-driven actuators (CDAs) were designed and mounted on a robotic frame. One CDA is the drive for a lift mechanism, while the other 16 CDAs work jointly to change the user's posture and to produce arm-leg movement therapy. The kinematics for production of two representative leg movements were analysed. Using PID and impedance algorithms, a CDA alone provided user-defined resistive training with position guidance (force error: 3.5 N and position error: 21.4 mm). Preliminary control of six CDAs demonstrated the system's ability to produce a 3D leg movement in a back-lying position (mean force error: 12.8 N, mean position error: 52.1 mm) and a walking-like leg movement in a side-lying position (mean force error: 13.7 N, mean position error: 57.0 mm). Through concept description, prototype development, and preliminary control testing, the study showed that the proposed cable-driven robotic platform could potentially offer convenient user transfer, automatic posture change and synchronised 3D arm-leg movement therapy. Future work will present kinetic analysis and control strategies for automatic posture change and arm movement assistance.**

Keywords— cable-driven actuators, whole-body rehabilitation, impedance control, force control, 3D movement control

I. Introduction

Many lower-limb rehabilitation robotic systems focus on producing two-dimensional (2D) movements, despite the fact that 3D body movements are often performed in daily life. The exoskeleton-based robotic systems primarily produce the movement in the sagittal plane. Due to mechanical constraints, the movements in the frontal plane, such as hip abduction/adduction, are not possible [1]. Very few robotic systems modify the structures to allow passive medial-lateral movement [2, 3]. However, hip abductors/adductors should be actively trained to learn walking patterns properly, as they enhance mediolateral balance during walking [4]. During heel strike, the hip adductors contribute to the medial-lateral components of hip loading [5]. To promote walking rehabilitation, patients should practise 3D natural movements.

Cable-driven robotic systems are often employed to provide natural movement guidance. One advantage of these systems over the traditional exoskeleton-based systems is that the cable-driven actuators (CDAs) work analogically to our biological limb in generating dynamic body movements. Our body has muscles which act as actuators for production of daily movement. To achieve accurate movement control, our body relies on a sophisticated sensory system where muscle spindles measure the length and velocity of muscle bundles, while Golgi tendon organs detect the tension [6]. A standard CDA consists of a motor with an encoder, a drum with a wound cable, and a force sensor. The motor provides the power for the required movement, the encoder measures the rotation angle of the drum, from which the length and velocity of the cable can be estimated, and the force sensor measures the tension of the cable. As the configuration of sensors and actuators in CDAs is similar to the sensory-muscular interaction in the human body, cable-driven systems are considered capable of generating natural body movements [7]. Similar to the neuromuscular system where each segment has multiple muscle fascicles for generation of agile movement, cable-driven robotic systems employ multiple CDAs to produce a 3D movement of a segment.

Literature on cable-driven robotic systems shows that four to six CDAs are used to generate a 3D movement of one segment. A minimum of four CDAs are required to produce a 3D movement [7]. In a study on assisted walking on a treadmill [7], four CDAs were used for each leg to produce one degree of freedom (DOF) for rotation and two degrees of freedom for translation. Riener et al. developed the Reactive Rope Robot (r^3) to produce versatile dynamic movement [8]. It consisted of a large-scale cave environment and CDAs. Five CDAs were employed to produce 3D force on one arm for rowing simulation [9]. Due to the versatile structure, r^3 was easily reconfigured to include six CDAs in total for simulation of tennis playing [10]. Similarly, six CDAs were used in the CUBE system [11] to produce a 3D movement for the rehabilitation of a wrist or foot.

Current research on cable-driven rehabilitation robots has led us to envisage a rehabilitation platform for 3D whole-body rehabilitation. Interlimb neural coupling during walking [12] implies that patients should practise synchronised arm-leg training to promote walking rehabilitation. To assist patients in whole-body training during the early rehabilitation phase, especially those confined to a bed or wheelchair, a multifunctional rehabilitation platform has been proposed [13]. The functional requirements include (i) convenient user transfer: to transfer the user between the medical bed/wheelchair and the rehabilitation platform; (ii) automatic

posture change: to transition between sitting and back/side-lying postures; and (iii) 2D/3D arm-leg synchronised movement therapy: to provide ipsilateral/bilateral whole-body training, such as shoulder/hip abduction/adduction and arm-leg synchronised walking-like movement patterns in a lying position.

As the preliminary investigation of the proposed platform, we previously developed two belt-driven robotic systems to produce various leg movements on a bed [13, 14]. However, both systems exhibited swaying problems during the production of walking-like stepping in a side-lying position. The initial system actuated the leg using only one active belt [13]. Leg swaying was expected, because one belt cannot constrain the leg to move solely in the sagittal plane. In the improved system [14], four passive belts meeting at one point were used, but the leg still swayed slightly. Pertinent to these studies, we developed a robotic gait system that demonstrated a well-controlled leg movement using four active CDAs [15]. It was envisaged that a system with active CDAs could provide a solution to the swaying problem.

The aim of this work was to present a cable-driven robotic platform that can provide whole-body rehabilitation for users in a lying position and to demonstrate the preliminary results for generation of 3D leg movements. Future work will include kinetic analysis of various arm-leg movements and generation of automatic posture change and arm movements.

II. Methods

The overall structure of the robotic platform was developed using SolidWorks (Version 2018, Solid Solutions AG, Zurich, Switzerland). The control system comprises an industrial PC and five motion controllers for 17 motors. The movement control algorithms were developed in TwinCAT 3 software (Beckhoff Automation GmbH & Co., Germany).

A. Mechanical Design

The platform included a therapy bed, and a robotic frame made of Bosch profile (Figs 1-2). One CDA (Fig. 3a) is used in a lift mechanism for user transfer, while 16 CDAs (Fig. 3b) are employed for posture change and arm-leg movement production. Each CDA has a compact design, consisting of a motor-controlled drum and a force sensor. The lift system is mounted on the top of the robotic frame. By controlling the length and the tension of the belt, the user is transferred between the wheelchair and the therapy bed (Figs. 1(a-b)). To facilitate posture change and generate various arm-leg movements, 16 CDAs (Fig. 2) are fixed on the top and side of the robotic frame. During training in a back-lying position, the user is in a stable situation without requirement of trunk support from any CDAs. Sixteen CDAs are employed to produce bilateral 3D arm and leg movements (Fig. 2a), with four CDAs jointly actuating one segment (wrist or ankle joint). To enable training in a side-lying position, four CDAs fixed on the top frame are firstly utilised to change the user's posture (Fig. 1c): two CDAs are connected to the harness to stabilise the shoulder, while the other two CDAs, via deflection units, pull the pelvic in the anterior/posterior direction. These four CDAs work in tandem to transition the user between back-lying and side-lying positions. During training in a side-lying position, these four CDAs stabilise the

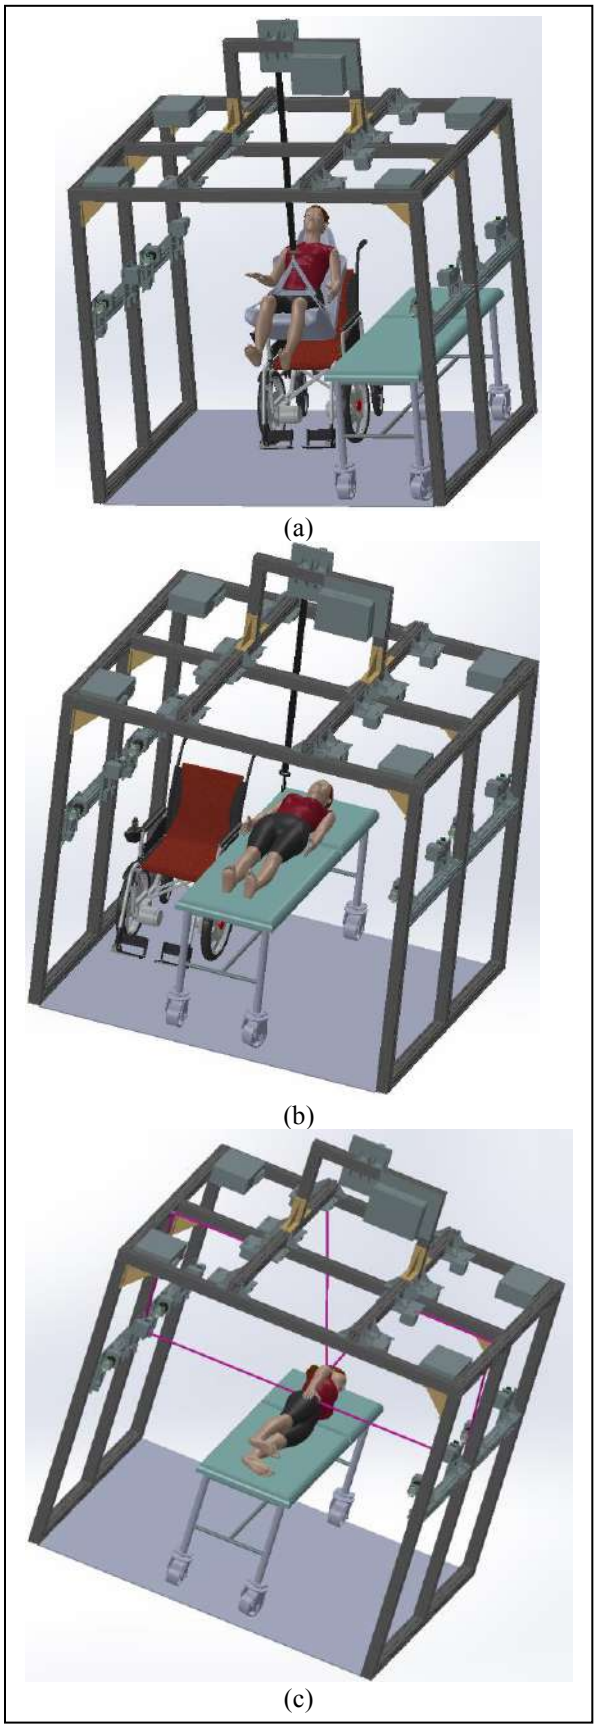

Fig. 1. The concept of the robotic platform: user transfer from sitting on the wheelchair (a) to lying on the therapy bed (b) via one CDA, and posture stabilisation (c) using four CDAs.

trunk of the user. Six CDAs jointly actuate the wrist, while the remaining six CDAs move the ipsilateral ankle joint (Fig. 2b).

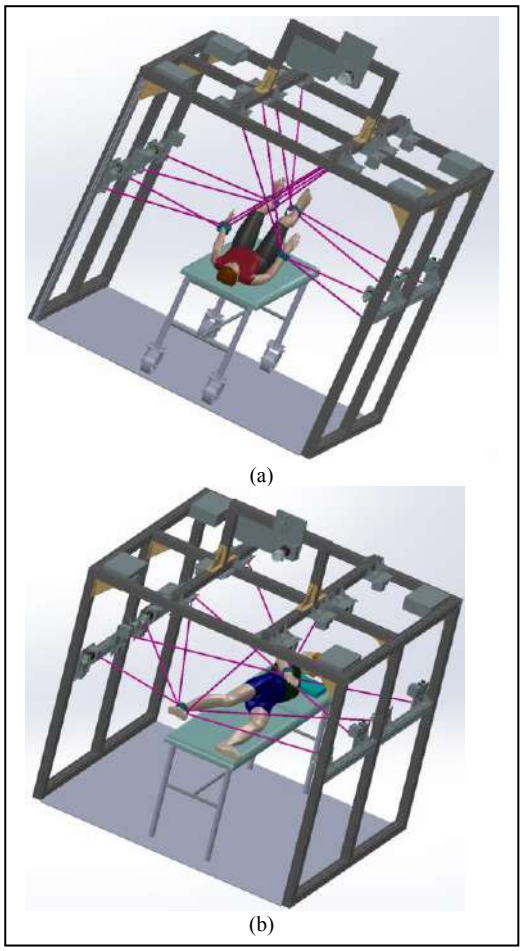

Fig. 2. Cable fixation for production of synchronised arm-leg movement. (a) Bilateral 3D arm-leg movement in a back-lying position; and (b) unilateral arm-leg walking-like pattern in a side-lying position.

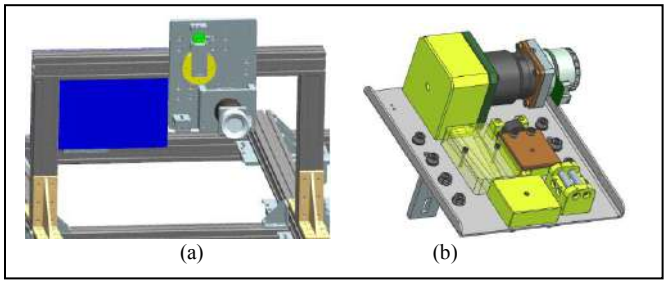

Fig. 3. (a) Lift mechanism with one CDA and its control case; and (b) one of the 16 CDAs for posture change & arm-leg movement generation.

In the prototype (Fig. 4), the commercial aluminium Bosch profile (80 mm × 80 mm) was used to build the robotic frame (size: 2.40 m ×2.16 m ×2.56 m). The lift mechanism (Fig. 5a) on the top of the frame used the CDA assembly (EC motor model EC90, gearhead with a ratio of 100, Encoder MILE 1024 CPT; maxon motor, Switzerland). Sixteen CDA assemblies (EC motor model EC60, gearhead with a ratio of 12, Encoder MILE 1024 CPT; maxon motor, Switzerland), shown in Fig. 5b, are the drives for posture change and arm-leg movement therapy.

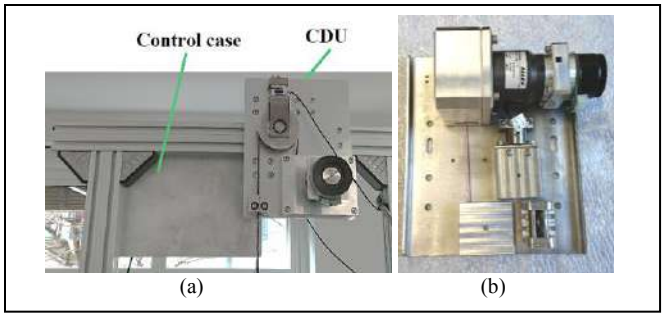

Fig. 5. The prototypes of the lift mechanism (a) and one CDA (b) which is used for posture change & arm-leg movement.

B. Kinematic Analysis

In preparation for movement control (Section II.C), kinematic analysis was conducted to calculate the target cable length of each CDA based on the target segment trajectory. This section focuses on the kinematic analysis of leg movements, although similar algorithms can be applied for production of various arm movements. As shown in Section II.A, the robotic platform can produce various leg movements. However, this section only analyses the kinematics for producing two representative ankle trajectories: a 3D leg movement in a back-lying position (Fig. 6a), and a walking-like ankle trajectory in a side-lying position (Fig. 6b). These movements are produced through simultaneous actuation of the same six CDAs, which are CDA 0, 1, 3, 4, 6 and 7.

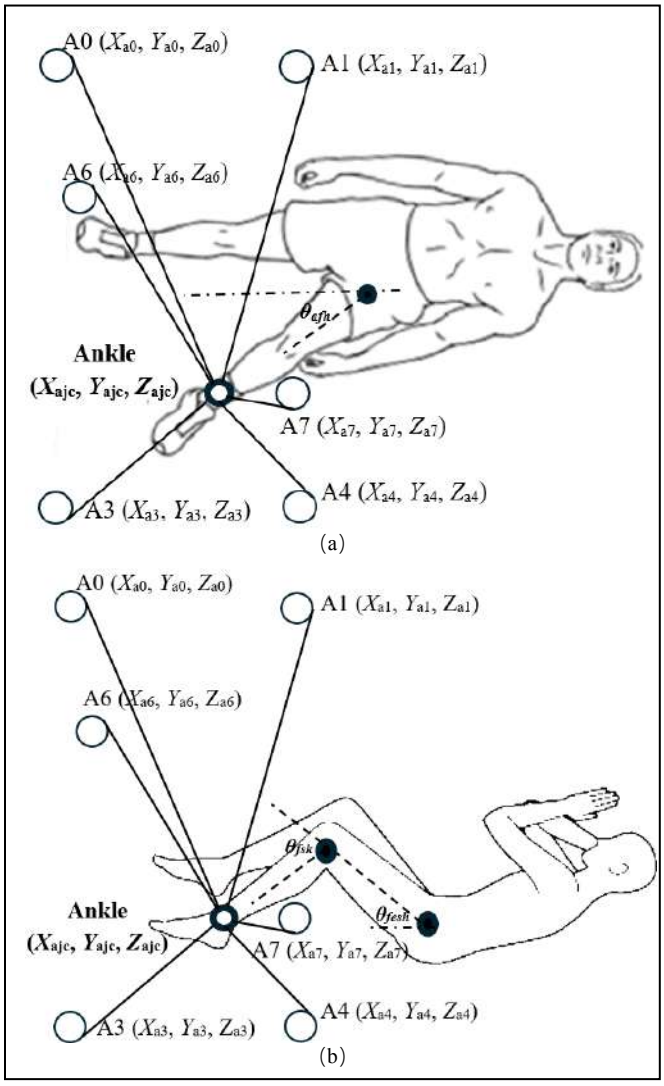

Fig. 6. Top-view of the configuration of six actuators for production of two representative leg movements. (a): 3D leg movement in a back-lying position. (b) Walking-like leg movement in a side-lying position.

Cables 0, 1, 3, and 4, connected to the right-distal-middle (A0), right-proximal-middle (A1), left-distal-middle (A3) and left-proximal-middle (A4) actuators, respectively, were attached to the ankle. To compensate for the weight of the leg, two additional cables, 6 and 7, connected to the right-distal-top (A6) and left-proximal-top (A7) actuators, were also attached to the ankle joint. The centre of the frame is defined as the reference centre (0, 0, 0). The user is positioned in the system by aligning the centre of the two hip joints with the reference centre (0, 0, 0). Using the geometric configuration of the mechanical system, the positions (*X*, *Y* and *Z* coordinates) of the six actuators were determined, and the cable contacting points on the actuators—A0, A1, A3, A4, A6 and A7—were determined (Fig. 6).

The representative 3D leg movement in the back-lying position was defined as a combination of a sinusoidal abduction- adduction in the hip joint angle θ_{afh} in the frontal plane and a sinusoidal flexion of the hip joint angle θ_{fsh} in the sagittal plane. The two angles were defined as:

$$\theta_{afh} = A_{afh} \sin(\frac{2\pi}{T_{afh}} t), \quad (1)$$

$$\theta_{fsh} = A_{fsh} \sin(\frac{2\pi}{T_{fsh}} t + \frac{\pi}{2}), \quad (2)$$

where the amplitudes A_{afh}, A_{fsh} are defined to be π/6, while the cycle time T_{afh}, T_{fsh} are defined to be 4π s. The position of the ankle joint centre in a back-lying position (Fig 6a) was calculated as:

$$X_{ajc} = (L_t + L_s) \sin\theta_{afh} + \frac{1}{2} D_{lrhjc}, \quad (3)$$

$$Y_{ajc} = -(L_t + L_s) \cos\theta_{afh}, \quad (4)$$

$$Z_{ajc} = (L_t + L_s) \sin\theta_{fsh}, \quad (5)$$

where L_t and L_s are the length of the thigh and shank, and D_{lrhjc} is the distance between the left and right hip joint centre.

To produce the walking-like movement, the representative hip and knee joint trajectories in the sagittal plane, θ_{fesh} and θ_{fsk}, recorded in our previous gait analysis experiment [16], were used in this study as the target ankle trajectory:

$$X_{ajc} = L_t \sin\theta_{fesh} - L_s \sin(\theta_{fsk} - \theta_{fesh}), \quad (6)$$

$$Y_{ajc} = -L_t \cos\theta_{fesh} - L_s \cos(\theta_{fsk} - \theta_{fesh}), \quad (7)$$

$$Z_{ajc} = \frac{1}{2} D_{lrhjc}. \quad (8)$$

With the trajectory of the ankle joint centre, the reference length of the cables, L_{ri}, is therefore determined using:

$$L_{ri} = \sqrt{(X_{Ai} - X_{ajc})^2 + (Y_{Ai} - Y_{ajc})^2 + (Z_{Ai} - Z_{ajc})^2}, \quad (9)$$

where *i* means the cable number, which equals respectively 0, 1, 3, 4, 6 and 7. The cable length is used as the reference length L_r for each cable in Section II.C.

C. Movement Control of CDAs

The control system included a power unit, which was fixed on the side of the robotic frame, and five control cases. The programmable motion controllers (MiniMACS6 EtherCAT; maxon motor, Switzerland) were used to regulate the output force from the CDAs. Each motion controller can control 4 EC motors. The 16 CDAs required four motion controllers, which were placed in four control cases at the four corners of the top frame (see the video: https://youtu.be/gLlQfQfEBsY). Each CDA used a force sensor (Bengbu Sensor Company, China; resolution 0.012 N) to measure the actual cable force. The amplifiers of the four force sensors were fixed in one control case. The force measurement was recorded using the analogue input port of the motion controllers. The fifth control case, which was to control the CDA assembly of the lift mechanism, was fixed on the frame of the lift mechanism (Fig. 5a).

As a preliminary production of synchronised movement, this work presents only one control strategy (Fig. 7), which includes a force controller and an impedance controller. Similar control algorithms were implemented in our previous work [17].

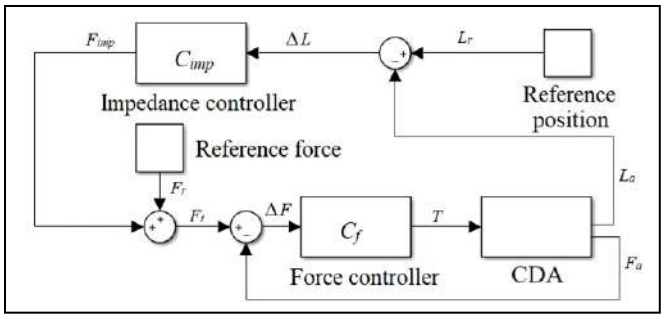

Fig. 7. Impedance control plus force control strategy.

In order to provide force training with a user-defined profile, a PID force controller C_f was implemented in each CDA. The input to and output from C_f are respectively ΔF (the difference between the target and actual force F_t and F_a) and target torque T to CDA. The transfer function of C_f is:

$$\Delta F \rightarrow T\text{: } C_f = K_{pf} + \frac{K_{if}}{s} + \frac{K_{df} s}{\frac{1}{\omega_{lpf}} s + 1}, \tag{10}$$

where K_{pf}, K_{if}, K_{df} and ω_{lpf} are the proportional, integral, derivative gains and the cut-off frequency of the low pass filter, respectively. The reference force F_r for Cables 0, 1, 3 and 4 was set to a constant 10 N. The reference force for Cables 6 and 7 was defined as 20 N, where the joint upward force corresponds to the pull force for a leg of a person of 50 kg, based on the anthropometric data [18].

To provide movement trajectory guidance, a high-level impedance controller was implemented:

$$\Delta L \rightarrow F_{imp}\text{: } C_{imp} = K_{pimp} + \frac{K_{vimp} s}{\frac{1}{\omega_{lpimp}} s + 1}, \tag{11}$$

where ΔL is the difference between the reference and actual cable position L_r and L_a, F_{imp} is the output from the impedance controller. The target force F_t is the sum of the reference force F_r and F_{imp}. The impedance parameters K_{pimp}, K_{vimp} and ω_{lpimp}, which are the stiffness, damping ratio and the cut-off frequency of the low pass filter, respectively.

The force control accuracy was calculated using the root-mean-square error (RMSE) between the target force F_t and the actual force F_a:

$$\mathrm{RMSE}_F = \sqrt{\frac{1}{N}\sum_{t=t_0}^{t_1}(F_a(t) - F_t(t))^2}, \tag{12}$$

where N is the number of data points in the interval t_o and t_1. Replacing the force variables F_t and F_a in Eq. (12) with the cable length variables L_r and L_a, the position control accuracy RMSE_L was calculated.

Test of the controller was performed with informed consent on a healthy person (age of 40 yrs, height of 1.61 m, body mass of 50 kg). An emergency stop was held by the test person (see the attached video). If the system did not move well, then the test person could immediately press the button to stop the system. Since the data are not generalisable, it does not fall under the Swiss Federal Act on Research Involving Human Beings. No ethical approval was needed.

III. Results

This section presents the preliminary test results of movement control using six CDAs. Kinematic analysis yielded the reference lengths of the 6 CDAs (Fig. 8). Cables 0, 1, 3 and 4 have similar ranges of movement, while the movement of Cables 6 and 7 depends on the required movement in Z axis.

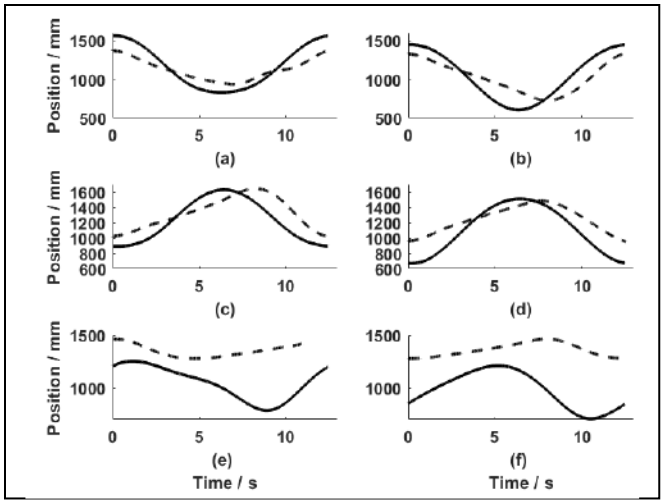

Fig. 8. The reference cable length trajectory of the six CDAs to produce the 3D leg movement in a back-lying (solid lines) and walking-like leg movement in a side-lying position (dashed lines). (a)-(f): CDAs 0, 1, 3, 4, 6 and 7.

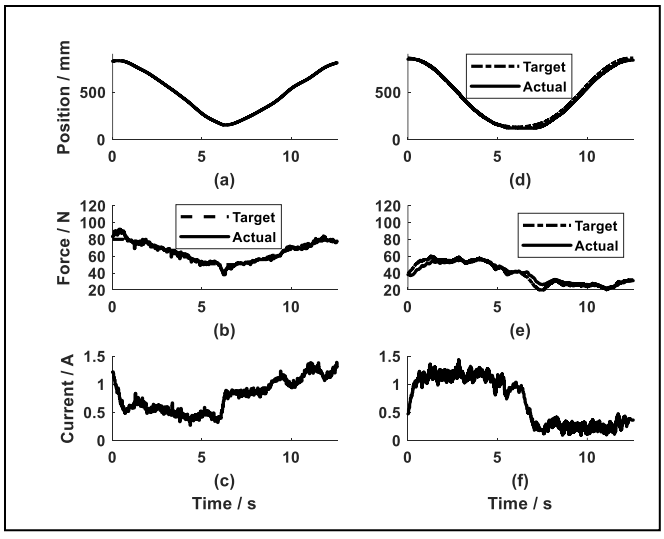

Fig. 9. Control results from one representative CDA 0 alone. (a)-(c): force control alone while (d-f): impedance control plus force control.

During development of the control strategy, an initial test was performed on each CDA alone to tune the parameters of the force and impedance controllers. Using the PID algorithms k_{pf}= 70, k_{if}= 1, k_{df}= 0.01, and a filter with a cut-off frequency of 10 rad/s), each CDA independently produced good dynamic force control (Fig. 9a). For position control with a target profile of a sinusoidal curve, the impedance algorithms

(stiffness of 0.8 N/mm, damping ratio of 0.001 Ns/mm, and a filter with a cut-off frequency of 10 rad/s) worked well. The representative results of CDA 0 were shown in Fig. 9 (d-f). The error in force and position control was 3.5 N and 21.4 mm, respectively.

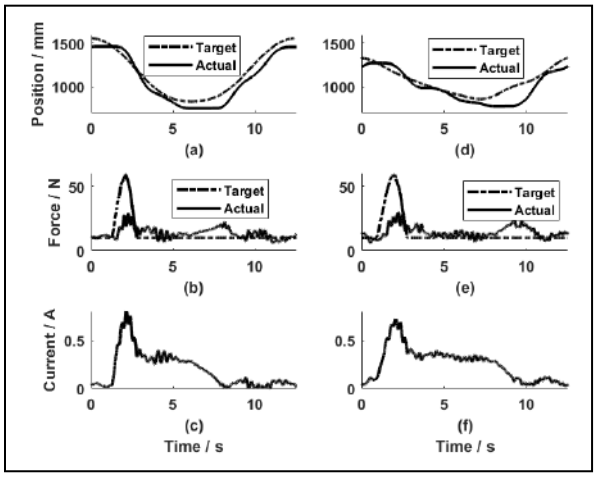

Fig. 10. Movement control results from a representative CDA 0 for production of 3D leg movement in the back-lying position (a-c) and walking-like movement in a side-lying position (d-f).

TABLE I. MOVEMENT CONTROL ACCURACY OF THE SIX CDAS. STD: STANDARD DEVIATION.

CDAs	Back-lying position		Side-lying position	
	RMSE$_F$ (N)	**RMSE$_L$ (mm)**	**RMSE$_F$ (N)**	**RMSE$_L$ (mm)**
Cable 0	9.3	87.0	10.4	97.9
Cable 1	19.7	54.5	21.3	58.8
Cable 3	14.2	45.0	18.3	48.8
Cable 4	18.0	54.6	21.1	67.2
Cable 6	6.7	39.6	6.1	38.5
Cable 7	8.7	32.0	4.8	30.8
Mean±STD	12.8±5.3	52.1±19.2	13.7±7.5	57.0±24.0

The six CDAs (0, 1, 3, 4, 6 and 7) were attached to the ankle joint of the test person so as to produce the two required leg movements. To prevent vibration, the force and position control parameters were reduced to k_{pimp} =10, k_{pimp}=0.3 N/mm for all CDAs. The movement control results of the representative CDA 0 for the back-lying position (Figs. 10 (a-c)) showed a force control error of 9.3 N, and a position control error of 87.0 mm (Table 1). Production of walking-like movement in the side-lying position was also achieved ($RMSE_F$=10.4 N, $RMSE_L$=97.9 mm in Figs. 10 (d-f) and Table 1). The mean force and position errors of the six CDAs were 13.25 N and 54.55 mm, respectively (Table 1).

The prototype of the robotic platform and test results were also presented by a video (https://youtu.be/gLlQfQfEBsY). After the introduction of the main components of the system (Part 1), the video demonstrates the production of the two representative leg movements (Part 2). The control algorithms were first tested on objects, before being implemented on the test person. It was demonstrated that the robotic platform produced 3D leg movement in the back-lying position and walking-like movement in the side-lying position.

IV. DISCUSSION

With the aim of promoting whole-body rehabilitation in the early post-injury phase, we proposed a cable-driven robotic platform to provide convenient user transfer, automatic posture change and various arm-leg movement therapy for users in a lying position. The robotic platform was manufactured with 17 CDAs. The movement control algorithms of PID force controller and impedance controller were implemented in six CDUs. The preliminary results showed that simultaneous actuation of six CDAs produced hip abduction/adduction and hip flexion in the back-lying position, and walking-like movement in the side-lying position. With the potential implementation of a similar strategy to all CDAs, the platform demonstrated the capability to provide automatic patient transfer, enable posture change and produce various 3D arm-leg synchronised movement when the user is in a lying position.

This work presented a multifunctional robotic platform with well-configured CDAs. Our previous research on producing various leg movements [13, 14] revealed the limitations of passive belt actuation. Based on the literature on robotics for 3D movement control [7, 9, 11], we designed the system with a parallel cable-driven robotic structure. A key factor in the design was determination of the suitable number of CDAs. For convenient user transfer, the lift mechanism requires at least one CDA. The generation of bilateral 3D arm-leg movement required 16 CDAs. Using the same configuration of CDAs, the cable fixation for producing unilateral walking with arm swing in a side-lying position was determined: four CDAs would be used to change the patient between back-lying and side-lying positions, while 12 CDAs would be applied for arm-leg movement. Compared to our previous design of CDAs [15], the CDAs developed in the current work had a compact structure, because a drum without threads was used, and the force sensor was fixed next to the drum. Using 16 compact CDAs with a unified structure reduced the manufacturing costs. Similar to [10, 11], the CDAs could easily be reconfigured on the platform, showing potential to generate various 3D arm-leg movements required for general daily activities. An inverse kinematic analysis will be performed in the future to see the overall movement potential of the developed robotic platform.

The control system and movement regulation strategy produced 3D leg movements. Unlike our previous studies [1, 15] which used single-axis servo controllers, we employed multi-axis motion controllers in the current study. The force control algorithms of CDAs were implemented in the motion controllers. The PID algorithms tracked the target cable force (mean force control error of 3.5 N). Based on the movement position trajectory error, the impedance algorithms calculated the new target force, thereby providing position guidance (average position control error of 21.4 mm). The active movement control algorithms were implemented on six CDAs simultaneously to produce 3D leg movements. Compared to our previous systems [13, 14], the current cable-driven robotic platform resolved the leg swaying problem. However, vibration was observed when all six cables were connected to actuate the ankle joint movement. Preliminary investigation

showed that the vibration amplitude was related to the weight of the actuated body and the control parameters. The current study reduced the vibration by lowering down the control parameters. Therefore the control accuracy during production of leg movements was reduced, but still acceptable, which can be seen from Table 1 and the attached video. A detailed investigation into the vibrations will be conducted soon.

The novelties of this study are the concept development and prototype validation of the cable-driven robotic platform for whole-body rehabilitation. Compared to studies [7, 15, 19] which produced walking-like leg movement using CDAs, we introduced additionally two CDAs to produce 3D leg movements. Arm movement has also been produced by cables in studies [20, 21]. Our robotic platform reconfigured multi-CDAs to enable whole-body rehabilitation. Furthermore, production of walking-like movement in a side-lying position was an innovative approach. Compared to studies [22, 23] which produced walking-like movement but in a back-lying position, the platform developed in the current study can prevent high pressure on the pelvic during training. For the safety issue, the test person could press the emergency button in the current study. for the final system which produces the arm-leg movement, then a hand-held emergency button will be implemented, as in our previous study [1]. Furthermore, clinical feasibility, safety and functionality will be investigated in the future.

The current study has several limitations. The 16 CDAs were fixed without performing an inverse kinematic analysis. Force control of the CDAs showed large influence of friction. To improve the control accuracy, new strategies, such as a lead controller [15] or a friction compensator [19], might be required. To ensure an accurate position control, the kinetics of 3D segment movement should be analysed, which will be described in future work. The test of automatic posture change and actuation of 3D arm movement will be performed soon.

V. Conclusion

A robotic platform with 17 CDAs was designed and manufactured. Implementing automatic movement control strategies on six CDAs demonstrated that the system produced a 3D leg movement in a back-lying position and walking-like leg movement in a side-lying position. Using similar control strategies, the innovative cable-driven platform can potentially provide convenient user transfer, automatic posture change and 3D arm-leg synchronised movement required in daily life.

Development of an End-Effector-Based System for Arm Support and Swing during Rehabilitation of Walking*

Juan Fang[1], Michael Haldimann[1,2] and Robert Riener[2,3]

Abstract— **The theory of interlimb neural coupling suggests that arm swing should be integrated into gait training to promote neural control of walking. We previously developed a mobile gait trainer which followed the user during free overground walking. However, it did not provide assistance in the synchronised arm and leg movements. This work aimed to develop a robotic arm module for the mobile gait trainer which offers stiff vertical arm support for balance, provides adaptable arm movement guidance during assisted walking, and allows free arm swing as experienced in daily walking. Based on an analysis of the wrist movement from normal gait, an end-effector-based system was developed, which used a screw drive to produce the vertical wrist movement and a timing belt drive with a force sensor to control the anterior-posterior wrist movement. Position controllers were employed to generate arm swing in passive training. Admittance algorithms were developed for the timing belt drive to generate adaptable horizontal movement. Free movement was produced by simplifying the admittance algorithms to include only a damping term. Preliminary tests showed that the position control algorithms produced arm swing in passive training with an accuracy of 1.78 mm vertically and 3.17 mm horizontally. The admittance controller produced adaptable anterior-posterior movement, where the active force modified the range of swing amplitude. The simplified admittance controller enabled the user to move freely with negligible interference from the robotic arm module. The system managed to offer rigid support for balance, to provide assisted arm swing for gait training with adaptable anterior-posterior movement, and to allow free arm swing. Integration of the arm movement with the mobile gait trainer and mechanism for leg movement will be investigated in future work.**

Keywords—arm swing, adaptable assistance, arm support, admittance control, rehabilitation of walking

I. Introduction

Walking involves not only rhythmic leg movements, but also synchronised arm swing [1]. Coordinated arm and leg movements are demonstrated in newborn infants and are maintained throughout their development [2]. Arm swing stabilises gait stability and optimises energy efficiency [3]. Reflex studies have implied that arm swing during gait is a neural-coordinated motor output [4]. Arm swing modulated the neural activity of the legs during rhythmic locomotion-like tasks [5]. Studies of interlimb neural coupling during walking have suggested a new paradigm for gait rehabilitation: moving the arms to activate the legs [6-8]. Arm swing is an integral component of the afferent input, which is required to facilitate lower limb motor output during walking.

Gait restoration is a process of motor relearning through repetitive training with appropriate guidance. The guidance should be tailored to individual needs. It has been hypothesised that patients should actively learn how to perform tasks through guidance, but should not become dependent on the guidance to perform the tasks [9]. This guidance hypothesis has been validated in many clinical studies [10, 11], where training with assistance-as-needed produced better results compared to the rigid training in passive mode. Physical guidance should be adjusted according to varying needs with the training progress.

In order to accelerate gait restoration process, a platform for overground rehabilitation of walking was envisaged by the coauthors, which inlcudes: (i) arm swing to activate and maximally exploit the neural control of walking for neurological recovery; and (ii) adaptable guidance so that the user can actively relearn walking according to the severity of their impairment. A mobile gait trainer was developed in our previous work [12]. Using computer-vision-based pose estimation, the mobile trainer followed the user during free overground walking. For patients with motor pathologies, assistance in the arm swing and leg movement is desirable. The task of this study was to develop an arm mechanism for the mobile gait trainer, so that patients get their arms actively involved in gait training. The system for assisted leg movement will be investigated soon.

As preparation for robotic development, clinical interviews with physiotherapists and patients were conducted to determine the required functionalities of the arm support mechanism. It was found that the patients after spinal cord injury rely on their upper limbs for balance and stability while standing and walking [13, 14]. Therefore, some SCI patients, such as those who have certain spared arm functions, may prefer to use their arms to maintain balance during training. In this case, stiff vertical support for the arm is required. Hemiplegic stroke patients often have reduced arm swing on the affected side [15, 16]. Assisted arm swing is required to increase gait symmetry [17]. Patients with some arm functions are often instructed to use their arms to propel their legs [18]. Therefore, an adaptable arm swing is desirable. According to research on ballistic walking, arm swing is a natural movement resulting from the energetic optimisation of the

walking pattern. Therefore, patients with relatively good arm function may not need assistance for their upper limbs. Instead, they may prefer to swing naturally without any interference from the robot. In summary, the designed arm mechanism should be able to offer stiff vertical support, produce adaptable guidance of arm swing, and also allow natural, free arm movement as experienced in daily walking.

There are many robotic systems for arm movement, but none of them has produced the functions described above. The systems for rehabilitation of upper limbs range from rigid systems [19, 20] to dedicated cable-driven robots [21]. Detailed information has been summarised in the reviews [22, 23]. Most systems have focused on production of daily arm movement, such as lifting or eating. For generation of arm swing, rigid systems such as a single-link pendular bar [24] or a soft system like a pulley [18] have been developed. However, none of these systems provide stiff support and adaptable arm movement as required in the current study.

As an advancement to walking rehabilitation for individuals with mobility impairments, this work aimed to develop a robotic arm module for the mobile gait trainer which offers stiff vertical arm support for balance, provides adaptable arm movement guidance during assisted walking, and allows free arm swing as experienced in daily walking.

II. Methods

The movement analysis (MATLAB, version 2024, The MathWorks GmbH, Bern, Switzerland) was conducted using a dataset from overground walking. Based on the results of the analysis and conception phase, a robotic arm mechanism with two motors was designed in NX (Version 2019, Siemens AG, Zürich, Switzerland). The system program for movement control was developed in TwinCAT 3 software (Beckhoff Automation GmbH & Co., Lyssach, Switzerland).

A. Target Movement Analysis

The wrist movement during overground walking from our previous study [25] was used as the target trajectory for the wrist. To ensure accurate position control, the target trajectory should be smooth. Therefore, the vertical and horizontal trajectories of the target wrist movement were calculated using functions consisting of lengths of upper and lower arms and angles of shoulder and elbow joints. The Curve Fitting Toolbox in MATLAB was used. The functions were further implemented as trajectory generators in TwinCAT 3 to produce the reference trajectories for motion control (*Section C*). The target wrist position yielded smooth speed and acceleration of the required movement, which are about a maximal speed of 1.5 m/s, acceleration of 11 m/s^2 for the horizontal movement, and about a maximal speed of 0.4 m/s, acceleration of 5 m/s^2 for the vertical movement.

B. Description of the Robotic Arm Mechanism

Based on the required movement analysis, a drive (torque:1.21 Nm, speed: 1500 rpm) with a pulley-belt (diameter: 24.24 mm) was required to produce the horizontal movement. A drive (torque: 0.96 Nm, speed: 3000 rpm) with a trapezoidal thread (pitch: 8 mm, diameter: 10.5 mm) was required to produce the vertical movement. Therefore, two electric motor assemblies (EC90, 400W, with an encoder 6400 CPT, maxon motor AG, Sachseln, Switzerland) were used. The system included a U-shaped frame (Fig. 1a), on which the pulley-belt drive was mounted to produce the horizontal movement of the wrist. The U-shaped frame and the rigid support bar were mounted on the lead screw drive so as to move vertically.

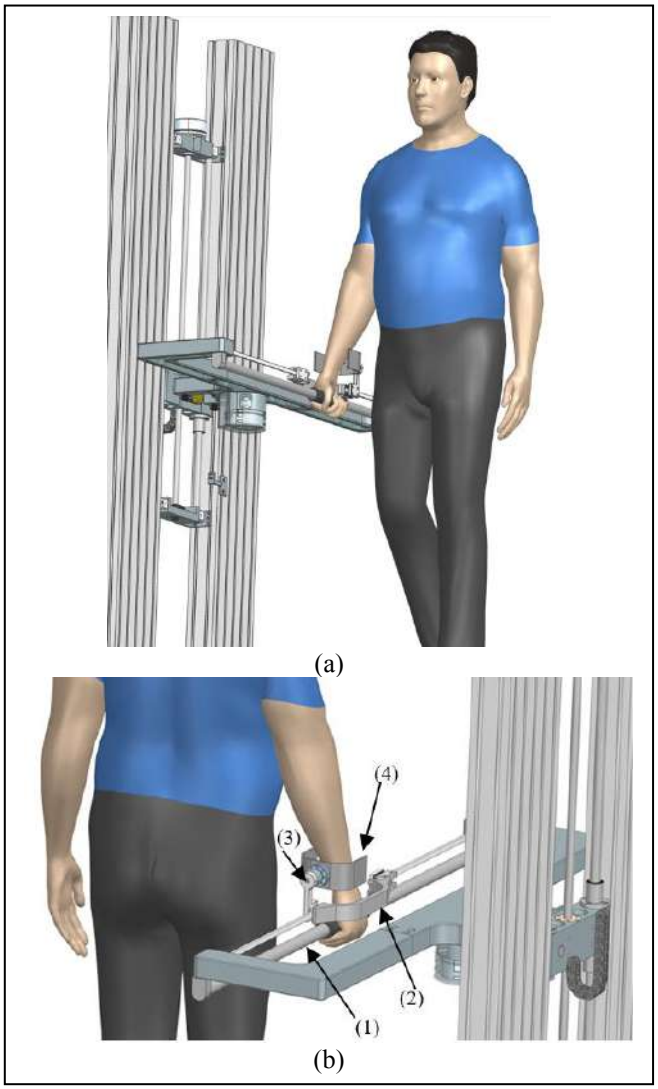

Fig. 1. The CAD concept of the robotic arm mechanism. (a) The U-shaped frame with two drives is mounted on the mobile trainer frame and (b) arm fixation. (1) The rigid bar for stiff arm support, (2) the metal connector for the timing belt, (3) the force sensor and (4) the wrist cuff.

The U-shaped frame was manufactured with aluminum. It was 1.5 m wide to accommodate users with a height between 1.50 m and 2.00 m (Fig. 2). The robotic mechanism was attached to the static frame of the mobile gait trainer. As this work focused on the development of the arm mechanism, the integration of the arm swing and the gait trainer movement was not investigated. Therefore, the trainer was static in this study. A treadmill was used to test the generated arm movement while walking.

As shown in Figs. 1(b) and 2(b), the wrist was fixed in a metal cuff with a soft pad. The two ends of the timing belt were fixed on a metal connector. A force sensor (500 N, Bengbu Sensor Company, China) was fixed on the connector, and a single-channel amplifier (EP3356-0022, EtherCAT

Box, Beckhoff) was fixed on the U-shaped frame. The metal cuff was fixed on the other end of the force sensor. The interaction force between the user and the robotic arm mechanism was measured by the force sensor.

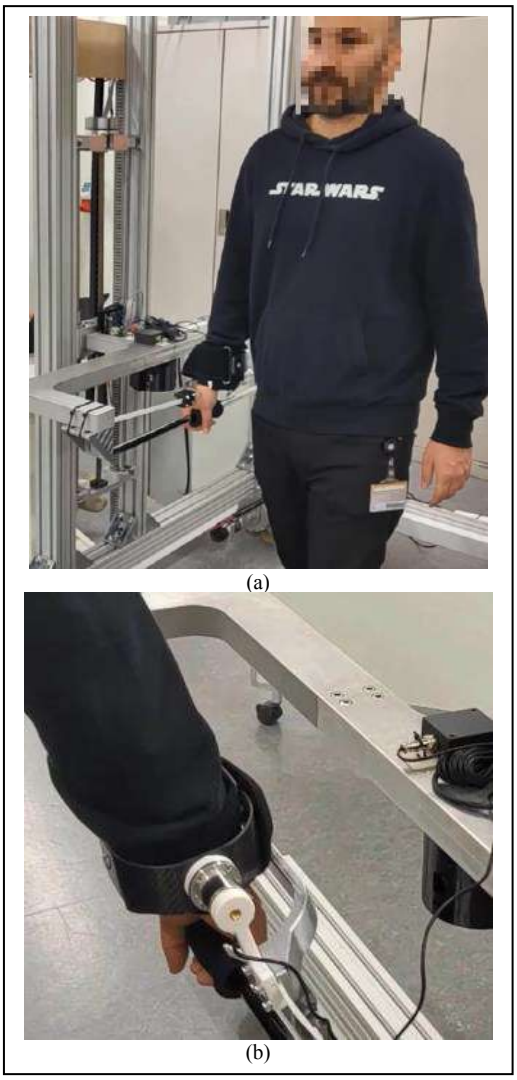

Fig. 2. Prototype of the robotic arm mechanism that is fixed on the mobile trainer. (a) A person walks on the treadmill with the robotic arm mechanism and (b) the fixation of the wrist to the mechanism.

The control system included an industrial PC (IPC, C6032-0070, Beckhoff Automation GmbH & Co., Lyssach, Switzerland) and two positioning controllers (EPOS4 Compact 50/15, maxon motor AG, Sachseln, Switzerland). The positioning controllers were connected in series to the IPC with EtherCAT communication protocol.

C. Movement Control Strategies

The positioning controller has embedded algorithms to get the motor running in torque, velocity and position modes, where the control parameters can be determined using the auto-tuning function in EPOS Studio (maxon motor AG, Sachseln, Switzerland). In this study, the position mode was used. The auto-tuning procedure of the screw drive yielded the PID algorithms (k_p = 21008 mA/rad, k_i = 27392 mA/rads, and k_d = 493 mAs/rad) combined with the feedward velocity (a gain of 45 mAs/rad) and feedward acceleration (a gain of 4.6 mAs^2/rad) to produce the vertical movement. Similarly, the well-tuned PID position algorithms for the belt drive (k_p = 30000 mA/rad, k_i = 480000 mA/(rad.s), and k_d = 580 mA.s/rad) combined with the feedward velocity gain of 55 mA.s/rad and acceleration gain of 4.4 mA.s^2/rad were used to produce the horizontal movement. The passive mode was always implemented in the vertical axis, while three modes were implemented in the horizontal axis: passive, adaptable and free-movement training. During passive training, a rigid position trajectory was provided, where the user followed the movement passively. During adaptable training, the horizontal range of movement was adjusted by the user, while in free-movement training, the user could freely control the anterior-posterior arm movement.

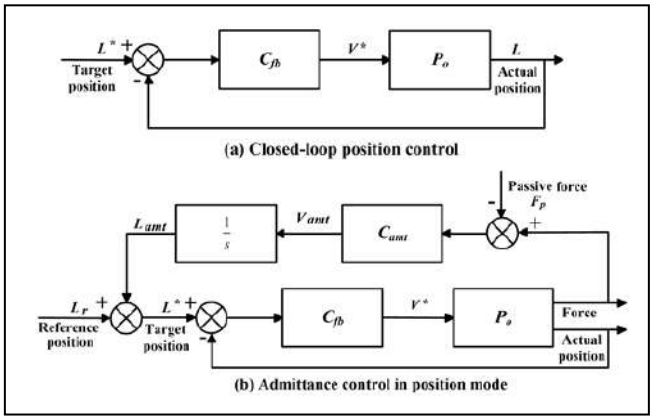

Fig. 3. Movement control strategies.

During passive training, position control algorithms (Fig. 3a) were implemented on the motors for the screw drive and the belt drive. The force sensor on the belt measured the interaction force during passive training F_p.

In order to produce adaptable movement, an admittance controller C_{amt} (Fig. 3b) was implemented on the belt drive. The input to and output from C_{amt} are ΔF (the difference between the actual force and the force during passive training F_p, which is the active force from the user) and the new velocity V_{amt} of the belt drive, respectively. The transfer function of C_{amt} is:

$$\Delta F \rightarrow V_{amt}: C_{amt} = \frac{1}{ms + d + \frac{k}{s}}, \quad (1)$$

where the parameters m, d and k are the mass, damping ratio and stiffness of the system, respectively. An integrator was implemented to get the position L_{amt}. Based on the active force, the target position was adjusted. When the mass and stiffness were set as zero, the system ran in free-movement mode, where the input force was linearly scaled to be the speed of the drive V_{amt}. In this case, no reference position was defined, i.e., L_r=0.

The control algorithms were tested on a healthy person (age of 27 years, height of 1.74 m and body mass of 85 kg). Since the data are not generalisable, it does not fall under the Swiss Federal Act on Research Involving Human Beings. No ethical approval was needed. During the test, he fixed his right wrist on the robotic arm mechanism, held on the palm holder which allows free sliding on the support bar, and then

walked on the treadmill at 2.0 km/h and 120 steps per minute. In passive training, he followed the movement produced by the robotic arm mechanism, while in the adaptable training, he actively swung his arm. In the free-movement training, he tried to swing his arm naturally. Detailed information of the test can be found in the attached video.

The control programme was developed in TwinCAT 3 and downloaded to the IPC. The IPC implemented the programme in real time at a sample rate of 1000 Hz. A Visulisation Manager page was developed to operate the robotic arm mechanism. The position of the U-shaped frame and the offset of the wrist cuff could be adjusted according to the height of the user. The walking speed could be defined. The data were saved using the measurement toolbox in TwinCAT 3.

III. Results

With the aid of MATLAB, the reference wrist position in the vertical and horizontal axes were determined (dashed lines in Figs. 4(a) and 5(a)). The zero position of the horizontal axis is when the wrist is in a neutral, straight alignment with the arm in the upright standing still position. The ground is defined as the zero position of the vertical axis. Implementing the trajectories in TwinCAT 3, the reference trajectories for the screw drive and the timing belt drive were defined.

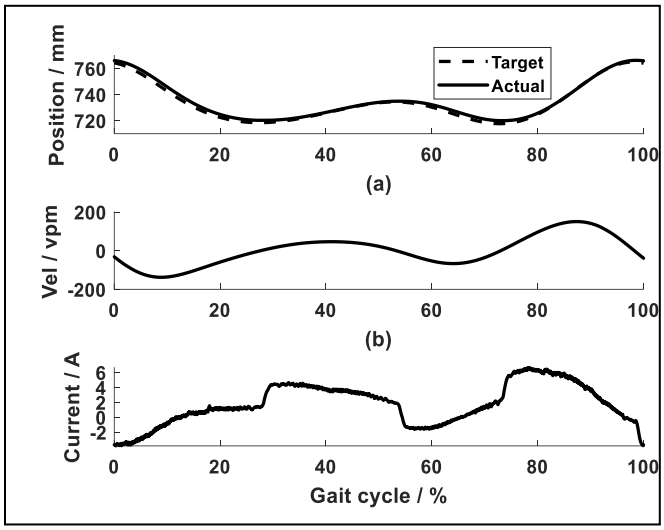

Fig. 4. Vertical movement control in passive training.

The position controller (Fig. 3(a)) produced the actual vertical movement (the solid line in Fig. 4(a)) with a high accuracy. The root-mean-square error (RMSE) between the target position L^* and the actual position L was 1.78 mm. In subsequent tests of the robotic arm mechanism, the same controller was always employed for the vertical movement. By monitoring the motor current of the screw drive (Fig. 4(c)), it was possible to detect whether the user pressed the horizontal bar or not. If yes, the bar could provide stiff support by setting the target vertical velocity of the screw drive to 0.

In order to produce the three types of anterior-posterior movement, admittance controllers in position mode (Fig. 3) were used in the timing belt drive. The position controller (Fig. 3(a)) produced the actual movement (the solid line in Fig. 5(a)) with a high accuracy (RMSE of 3.17 mm). Such a small position difference is barely observable in Fig. 5(a). The average force between the test person and the wrist cuff (Fig. 5(c)) in passive training was 2.17 N forward and 1.15 N backward.

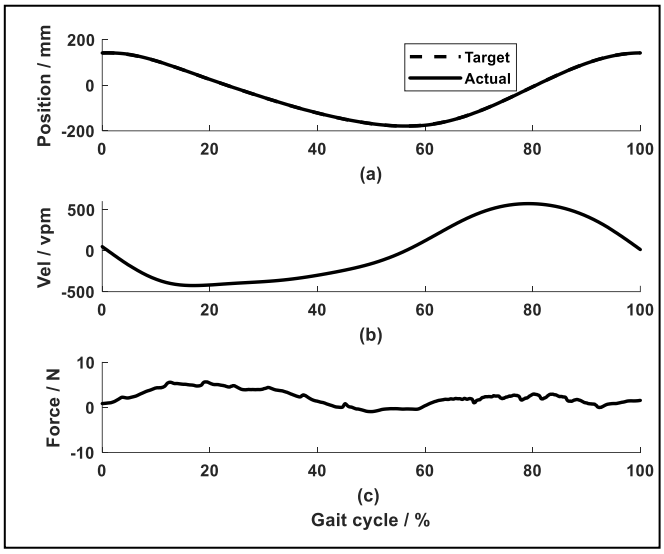

Fig. 5. Anterior-posterior movement control in passive training.

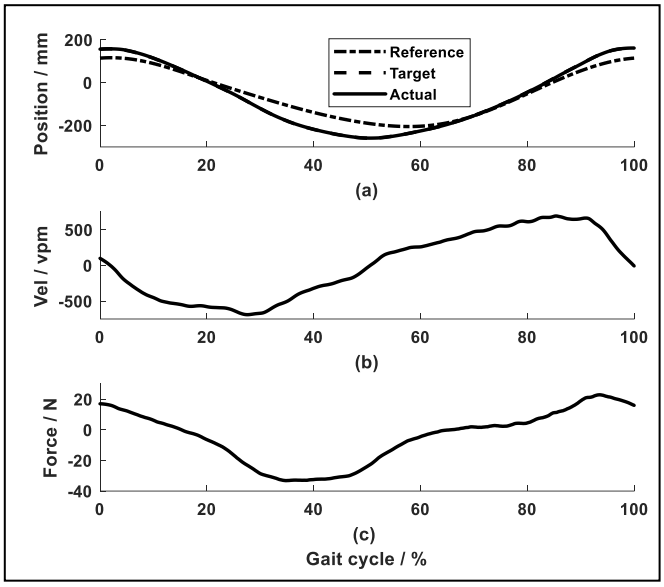

Fig. 6. A representative adaptable movement from the admittance controller.

To test the feasibility of the admittance controller in producing adaptable movements, a controller with parameters (Mass m = 1.0 kg, damping ratio d = 1.0 Ns/m and stiffness k = 1117 N/m) was used. An active forward force of 16.7 N (Fig. 6c) produced an additional forward position of 42 mm (Fig. 6a). The position controller yielded a high accuracy (RMSE = 2.70 mm). The parameters of the admittance controller could be tuned to get movement with different adaptabilities. A lower stiffness or lower damping ratio enabled the user to change the range of movement more easily.

When the admittance controller only included the damping item, the arm mechanism produced free arm movement. A low damping ratio means a larger velocity from the same active force input. To improve system sensibility, a damping ratio d = 0.2 Ns/m was used in the test. The motor moved at a velocity

of about 500 rpm in response to a small active force of 6 N (Fig. 7). Behaving similarly in the transparent mode, the mechanism allowed free natural arm swing.

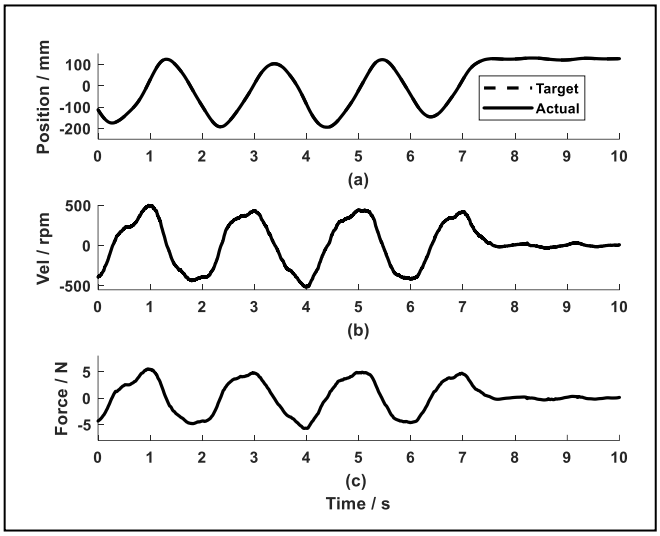

Fig. 7. Free-movement training.

IV. Discussion

This work aimed to develop a robotic arm module for the mobile gait trainer which offers stiff vertical arm support for balance, provides adaptable arm movement guidance during assisted walking, and allows free arm swing as experienced in daily walking. Mounted on the mobile gait trainer, the robotic arm module included a screw drive and a timing belt drive with a force sensor. Implementing admittance control algorithms when the motors ran in position mode, the system produced the required wrist movement. With easy operation, stable communication and adaptable movement algorithms, the developed robotic system was proven to be technically feasible to support arm movement during walking rehabilitation.

The robotic arm module included rigid and soft mechanical components, which made it mechanically possible to provide stiff support, adaptable guidance and free movement. As the clinical test [26] showed that end-effector systems produced significant improvements in the upper limbs compared to exoskeletons, we designed the robotic arm with the end-effector approach. To ensure a stiff vertical support, a trapezoid lead screw drive was used. The user held the rigid bar with a slidable palm holder, so that she/he could keep balance using the arm if necessary. The wrist cuff was driven by a timing belt to produce the anterior-posterior movement during arm swing. The tension of the belt could be adjusted to be softer or stiffer, depending on the user's training requirements. The belt provided anterior-posterior movement without medial-lateral constraints, which allowed natural arm swing in the free-movement training. Compared to the cable-driven devices, which are often over-actuated [27], the timing-belt drive also produces flexible movement but with fewer motors. From a mechanical point of view, the system offered several possibilities, which served as the mechanical base for generation of the required functionality.

In addition to the innovative mechanical structures, the position control strategies were crucial for achieving the required functions. The position strategy embedded in the advanced positioning controller offered convenient parameter-tuning package and provided easy programming environment for movement control. The robotic arm module produced the target wrist movement with high accuracies in passive training. The admittance controller produced adaptable anterior-posterior movement during assisted walking. Compared to our previous study [28] where similar admittance strategies were used, the current study used the robust position control algorithms, which enabled accurate tracking of the target movement. In the free-movement mode, the robotic system produced movement which is similar to that in the transparent mode. The traditional method of generating a transparent mode, as shown in [29], needs to remove the influences from the friction and segment mass. Friction compensation requires repetitive tests to find the friction-speed relationship. By regulating the motor velocity based on the active force input from the user, the current study enabled free movement with relatively good results. Preliminary control tests demonstrated that the system was sensitive to the active force and moved in a manner similar to the natural arm swing. Using the embedded position controller and self-developed admittance algorithms, the arm mechanism not only provided stiff vertical support and adaptable horizontal movement, but also allowed the arm to swing freely.

The functionalities of the robotic arm module were technically evaluated, but more investigation is required prior to clinical application of the system. The robotic arm module belongs in a greater pipeline to a novel neurorehabilitation gait trainer [12]. Representative robotic systems for walking, such as Lokomat and Andago, have rigid bars for balance support. It was found that even a light touch of the fingertip on the bar is useful to reduce postural sway in stroke patients [30]. Clinical study on SCI patients [13] revealed their arm muscles were often involved in the adapted postural control strategies. Therefore, a rigid bar was included in the arm mechanism to contribute to postural stabilisation of the stroke and SCI patients. Furthermore, arm movement has been clinically included to enhance leg activity [18, 31]. It should be noted that the developed arm module can only work in situations where the patients are able to perform assisted arm movement without pain. Formal analysis will be performed to investigate the clinical feasibility of the robotic arm module.

This study has some limitations and requires further work. The timing belt was used to produce flexible horizontal movement. However, belt deformation was observed because the relatively heavy components, such as the metal connector, force sensor and metal wrist cuff, were attached on it. As only a small force was interacted between the user and the cuff, the connector and wrist cuff can be replaced with plastic components. The adaptable movement and free arm swing can be improved by implementing admittance controllers in the vertical axis as well. In order to achieve this, a force sensor can be additionally attached on the palm holder to detect the active vertical press or lift from the user. To enable walking training overground, arm movement should be synchronised with the mobile gait trainer, which will be investigated in future work.

V. Conclusion

An end-effector-based system was developed for arm support and arm swing, as a module to the mobile gait trainer. The innovative mechanical structure with rigid and soft mechanical components enabled the robotic arm module to provide stiff vertical support without medial-lateral constraints of the wrist. Using admittance algorithms, the arm mechanism technically provided adaptable guidance in anterior-posterior movement for arm swing, and allowed free, natural arm movement as experienced in daily walking. The robotic arm mechanism can be integrated into the mobile trainer to assist the required arm movement during rehabilitation of walking. Synchronisation of the arm movement with the mobile gait trainer and the assistance of leg movement will be investigated in future work.

A Task-Agnostic Approach to Unified Multi-Activity Gait Phase Estimation via Bilateral Sensing

Ryan R. Posh and Robert D. Gregg

***Abstract*— Estimating the gait phase is a key aspect for controlling many lower-limb rehabilitation robots, including transfemoral prostheses. Current control approaches often rely on high-level activity classification to then employ a task-specific phase algorithm, which can limit adaptability across tasks and introduce risks associated with misclassification. This study proposes a novel unified phase variable framework with two approaches, one using activity classification and one being entirely task-agnostic. The framework uses predicted gait event information to continuously define a unified phase variable across level walking, ramp ascent/descent, and stair ascent/descent at various inclines and speeds. The classification approach senses the unilateral thigh angle, whereas the task-agnostic approach expands sensing to include the contralateral thigh angle. Simulated evaluations using an able-bodied dataset demonstrate average phase root-mean-square error of 6.8% with classification and 6.3% in the task-agnostic mode. The bilateral task-agnostic approach notably performed the same or better than the unilateral classification-based approach, showing improved consistency across subjects and tasks, particularly during stair ascent. These results highlight the feasibility of task-agnostic gait phase estimation for prosthesis control, demonstrating performance comparable to task-specific models while removing reliance on activity classification.**

I. Introduction

Robotic lower-limb prostheses offer great potential to improve the mobility and quality of life for individuals with lower-limb amputation, but reaching this potential could be largely dependent on the selected control approach. Several prosthetic controllers have been developed for effective level-ground walking [1], [2], demonstrating more normative joint biomechanics [3], less energy expenditure [4], and potentially more endurance [5] when compared to passive prostheses. While these benefits highlight the potential of these devices, it is critically important to develop control algorithms that are also effective across a wide range of activities of daily living (ADLs).

Research focus has shifted to controlling activities beyond level walking, including ramp walking [6]–[8], stair climbing [9], [10], sit/stand activities [11], [12], and even non-standard activities [13]–[15]. The prevailing approach to enabling multi-activity prosthesis control is to employ a high-level task classifier to determine the user's desired activity, and then discretely switch between mid-level controllers with task-specific properties [16], [17]. Several classification approaches in lab settings have achieved accuracy rates greater than 99% [18]–[22], which could enable users to receive the benefits from powered prostheses during several ADLs. However, even infrequent misclassifications leading to the deployment of the wrong mid-level controller could cause negative consequences such as falls. Furthermore, classification approaches require a limited, predefined set of activities, usually leaving many possible tasks (e.g., continuous variations of a predefined task) unaccounted for.

More recently, there has been increasing interest in task-agnostic control approaches that do not require any knowledge of the intended activity. Broadly speaking, there are two primary perspectives for pursuing task-agnostic control: Machine Learning (ML)-based and biomechanical model-based frameworks. ML-based control approaches that account for multiple ADLs without classification often use neural networks (NNs) to map directly from kinematic inputs to joint level outputs such as torque [23]–[26]. These approaches offer high theoretical promise but have demonstrated several associated limitations, including sensitivity to the training data such as bias towards level walking, the potential for unexpected behavior when encountering out-of-distribution inputs, and reduced interpretability, all potentially limiting clinical and commercial acceptance.

The second approach to task-agnostic prosthetic control is to impose some level of structure based on typical human locomotion biomechanics. Incorporating these principals into the model structure could make this framework more robust and interpretable when continuously spanning multiple locomotion tasks. These model-based, multi-activity control methods include heuristic control laws [27] or continuous phase variables that monitor the progression of gait [8], [28]. The ability to continuously monitor gait progression (gait phase) is a key element to many model-based approaches, and has also been used for bipedal robot control [29], exoskeleton control [30], and clinical gait analysis [31].

A phase variable can be defined as a biomechanical parameter that indicates the phase progression from the beginning to end of a locomotion activity, which is typically cyclic in nature. Candidate phase variables have included the center of pressure (for stance progression only) [2], tibia kinematics (typically for prosthetic ankle control) [32], [33], and various hip/thigh kinematics (common for knee-ankle control) [34]. These phase variables support different control architectures including position control [2], [6], [28] and impedance control [7], [8], [33], and they have been used in both model-based and ML-based approaches [35], [36]. In [36], an ML-based, multi-activity phase estimation approach is presented

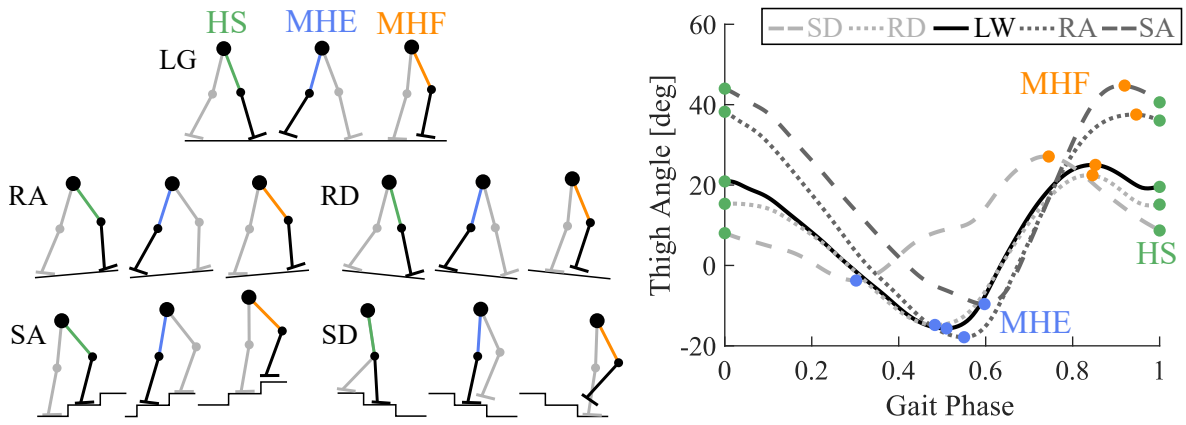

Fig. 1. Left: Gait events of heel strike (HS), maximum hip extension (MHE), and maximum hip flexion (MHF) are each observed in locomotion tasks of level walking (LW), ramp ascent (RA) and descent (RD), and stair ascent (SA) and descent (SD). Right: The corresponding gait phase and thigh angle magnitude of these gait events changes based on locomotion task.

for exoskeletons, but is not shown to generalize to varying speeds, ramp inclines, or stair heights. Model-based phase variables typically have task-specific definitions (e.g., differing definitions for walking and stair climbing tasks [9]) and thus rely on accurate task classification. There is currently no model-based phase variable definition that is unified across the primary ADLs, which limits the development of more robust and interpretable task-agnostic control approaches.

Therefore, in this work, we present a novel piecewise-monotonic phase variable framework that maintains a unified definition across level walking, ramp ascent/descent, and stair ascent/descent at several different inclines and speeds. The contribution herein includes two novel phase model definitions: 1) a unified phase variable based on unilateral thigh sensing that maintains the state-of-the-art task classification structure, and 2) one based on bilateral thigh sensing that is entirely task-agnostic. Both of these definitions represent the first model-based phase variable that is structurally unified across these primary ADLs. By simulating with an able-bodied dataset [37], the effectiveness and potential of these approaches are demonstrated with an overall phase RMSE error of 6.8% with classification and 6.3% when task agnostic. These results suggest that this unified phase variable could be a promising component of seamless prosthesis controllers across locomotion tasks that can be incorporated in a variety of control frameworks.

II. Unified Gait Phase Estimation

A. Piecewise Phase Variable Definition

As in or previous work [8], [9], [38], the phase variable is estimated from the global thigh orientation in the sagittal plane, which can be measured by an inertial measurement unit (IMU) onboard the thigh segment of the prosthesis. The piecewise phase variable, as first proposed in [39], structures the phase estimation with a finite-state machine (FSM), consisting of generally monotonic thigh trajectory regions. A key observation when adjusting for task unification is that the primary tasks of level walking (LW), ramp ascent (RA) and descent (RD), and stair ascent (SA) and descent (SD) all share an initial descending thigh orientation section, followed by an ascending thigh orientation section, and ending again with a descending section (Fig. 1). These three sections define the three states of the FSM (S1, S2, and S3).

Forward progression through this state machine can be defined by key gait events: 1) heel strike (HS), defined as initial foot contact with the ground, triggers the transition to S1; 2) maximum hip extension (MHE), defined as the minimum detected thigh angle for a given stride that occurs after HS, triggers the transition to S2; and 3) maximum hip flexion (MHF), defined as the maximum detected thigh angle for a given stride that occurs after MHE, triggers the transition to S3. These three gait events (HS, MHE, and MHF) are shared events across these primary locomotion tasks, but the corresponding gait phase and thigh angle at which these events occur changes based on the task (Fig. 1). Backwards progression through the state machine can also be considered when implementing in real-time, as in [38], but is not implemented in this work.

To be considered a phase variable that is unified across locomotion tasks, it is critical to ensure that the definition and structure of the phase variable ϕ remain the same for all tasks. Toward this, we define the unified piecewise phase variable to be

$$\phi = \begin{cases} \frac{\theta_{\text{th}}^{\text{HS}}}{\hat{\theta}_{\text{th}}^{\text{MHE}}} \frac{\theta_{\text{th}}}{\hat{\theta}_{\text{th}}^{\text{MHE}}} \hat{\phi}^{\text{MHE}} & \text{if S1,} \\ \phi^{\text{MHE}} + \frac{\theta_{\text{th}}}{\hat{\theta}_{\text{th}}^{\text{MHF}}} \frac{\theta_{\text{th}}^{\text{MHE}}}{\theta_{\text{th}}^{\text{MHE}}} (\hat{\phi}^{\text{MHF}} - \phi^{\text{MHE}}) & \text{if S2,} \\ \phi^{\text{MHF}} + \frac{\theta_{\text{th}}^{\text{MHF}}}{\theta_{\text{th}}^{\text{MHF}}} \frac{\theta_{\text{th}}}{\hat{\theta}_{\text{th}}^{\text{HS}}} (1 - \phi^{\text{MHF}}) & \text{if S3,} \end{cases} \quad (1)$$

where $\theta_{\text{th}}^{\text{HS}}$, $\theta_{\text{th}}^{\text{MHE}}$, and $\theta_{\text{th}}^{\text{MHF}}$ are the measured thigh angle at the detected HS, MHE, and MHF, respectively, and ϕ^{MHE} and ϕ^{MHF} are the most recent estimated gait phase when MHE and MHF are detected (black in (1)). The model parameters $\hat{\theta}_{\text{th}}^{\text{MHE}}$ (blue), $\hat{\theta}_{\text{th}}^{\text{MHF}}$ (orange), and $\hat{\theta}_{\text{th}}^{\text{HS}}$ (green) are the predicted thigh angle for the upcoming MHE, MHF, and HS, respectively, and $\hat{\phi}^{\text{MHE}}$ (blue) and $\hat{\phi}^{\text{MHF}}$ (orange) are the predicted corresponding gait phases for the upcoming MHE and MHF. By definition, the predicted gait phase

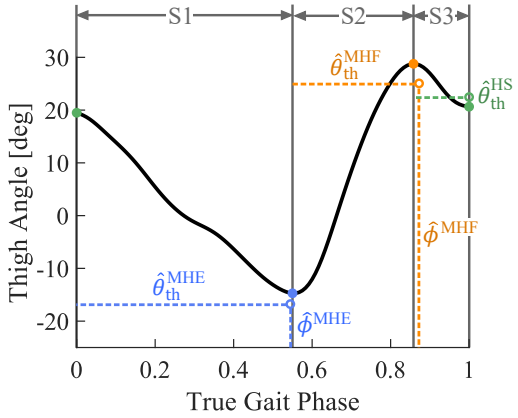

Fig. 2. The phase variable (ϕ) is based on the sagittal plane thigh orientation (θ_{th}). Three key gait events, MHE, MHF, and HS generally subdivide the gait cycle into an initial descending thigh angle state (S1), an ascending thigh angle state (S2), and a final descending state (S3). The unified piecewise phase variable transitions through these finite states by detecting HS, MHE, and MHF and seeks to accurately predict the thigh angle ($\hat{\theta}_{\text{th}}$) and the gait phase ($\hat{\phi}$) of the upcoming gait event (MHE is shown in blue, MHF in orange, and HS in green).

corresponding to the upcoming HS is a value of 1. An additional constraint exists on (1) such that if the phase variable ϕ is estimated to be greater than one or less than zero, it is saturated to stay within these bounds.

These 5 parameters ($\hat{\theta}_{\text{th}}^{\text{MHE}}$, $\hat{\theta}_{\text{th}}^{\text{MHF}}$, $\hat{\theta}_{\text{th}}^{\text{HS}}$, $\hat{\phi}^{\text{MHE}}$, and $\hat{\phi}^{\text{MHF}}$), representing predictions or initial guesses for the thigh angle and gait phase of the upcoming gait events (Fig. 2), collectively define the phase variable. Finding ways to accurately predict these upcoming gait features (referred to as the model parameters hereafter) is critical to ensuring a smooth, accurate, and monotonic phase variable progression. Two approaches for determining these model parameters are described below, first with task classification (Section II-B) and second without any knowledge of the locomotion task, but with contralateral-side sensor measurements (Section II-C).

B. Phase Variable Unification With Classification

If we assume accurate and robust classification among a predefined set of locomotion tasks (an area that has received extensive research focus over the past decade [16], [17]), we may use the classified task to determine the appropriate model parameters to employ. Fig. 3 shows that a relationship exists between the ground inclination (spanning stairs, ramps, and level ground) and the five model parameters. By classifying the locomotion task, these relationships can be used as a lookup table to generate the predictions for the upcoming gait features. In this work, the models for $\hat{\theta}_{\text{th}}^{\text{MHE}}$, $\hat{\theta}_{\text{th}}^{\text{MHF}}$, $\hat{\phi}^{\text{MHE}}$, and $\hat{\phi}^{\text{MHF}}$ are given in Figs. 3a, 3b, 3d, and 3e, respectively and are used directly for the tasks represented in the dataset. Unlike the other parameters, the final predicted parameter $\hat{\theta}_{\text{th}}^{\text{HS}}$ (Fig. 3c) is based on the most recently measured thigh angle at MHF ($\theta_{\text{th}}^{\text{MHF}}$) and the expected change in thigh angle between MHF and HS. This was also explored for other parameters, but only offered benefit when predicting $\hat{\theta}_{\text{th}}^{\text{HS}}$ due to the relatively small change in thigh angle between MHF and HS. Training for these parameter models is described further in Section II-D.

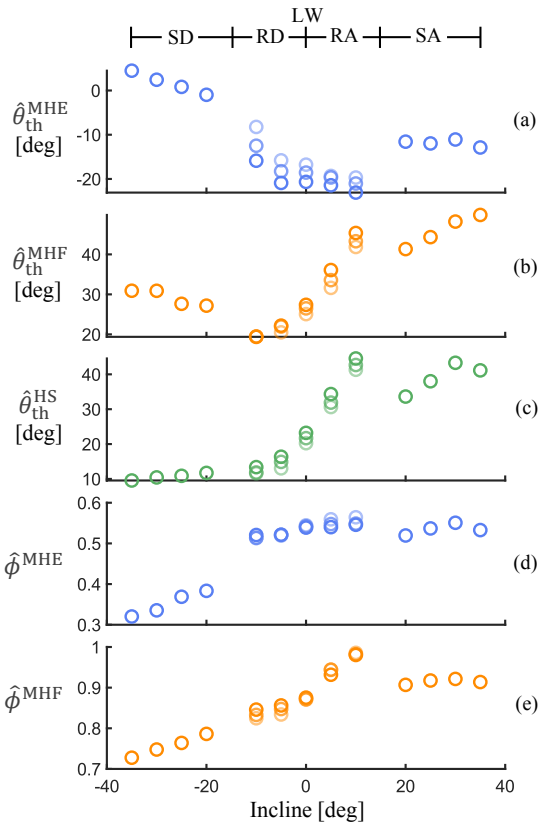

Fig. 3. Using classification, predictions for the expected thigh angle ($\hat{\theta}_{th}$) and gait phase ($\hat{\phi}$) at MHE, MHF, and HS can be generated based on the classified locomotion task. For walking tasks, speeds include 0.8 (more transparent), 1.0 (less transparent), and 1.2 m/s (no color transparency).

While this model is well suited for control frameworks that have high-fidelity task classification, this dependence could potentially be limiting. Using more continuous estimates of speed or ground slope could reduce the classification demands and improve the overall performance [19], but the dependence on classification for this phase variable approach may still be undesirable. Therefore, we also propose a second approach for a unified phase variable definition that is completely task-agnostic in Section II-C.

C. Task-Agnostic Phase Variable Unification

An alternative way to generate predictions for the upcoming gait event parameters is to use bilateral sensing. Figure 3 from the previous model shows that, without classification, the model parameters based only on the prosthesis-side thigh orientation would be redundant across some tasks. For example, there is not enough information contained in the unilateral thigh orientation to distinguish between stair-ascent and −10-degree ramp descent when predicting $\hat{\theta}_{\text{th}}^{\text{MHE}}$ (Fig. 3a) or $\hat{\phi}^{\text{MHE}}$ (Fig. 3d). By measuring the global thigh orientation in the sagittal plane from *both* the prosthesis-side and intact-side legs, sufficient information can be obtained to predict the thigh orientation and timing of the next gait event. In particular, the bilateral thigh orientations of the

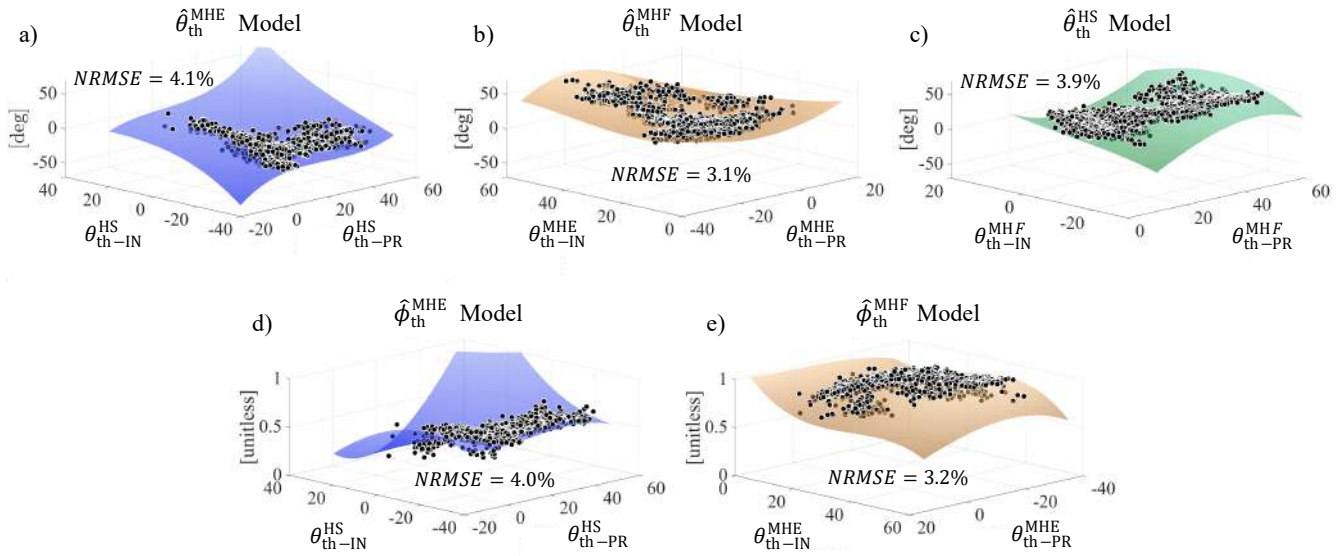

Fig. 4. Without any knowledge of the locomotion task, models spanning several activities can be generated to predict the upcoming gait event information based on bilateral thigh angle information at the time of the previous gait event. The measured thigh angle on the prosthesis-side leg at the moment of prosthesis-side HS ($\theta_{\text{th}}^{\text{HS}}{}_{\text{PR}}$) and the measured thigh angle on the intact-side leg at the moment of prosthesis-side HS ($\theta_{\text{th}}^{\text{HS}}{}_{\text{IN}}$) can be used to predict a) the upcoming prosthesis-side thigh angle at the upcoming MHE ($\hat{\theta}_{\text{th}}^{\text{MHE}}$) and d) the corresponding gait phase ($\hat{\phi}^{\text{MHE}}$). Likewise, measured bilateral thigh angles at the moment of prosthesis-side MHE can be used to predict prosthesis-side MHF thigh angle (b) and gait phase (e). Measured thigh angles at prosthesis-side MHF can predict $\hat{\theta}_{\text{th}}^{\text{HS}}{}_{\text{PR}}$, and the gait phase of the upcoming HS is always 1. All horizontal axes are in units of degrees.

current gait event can be used to define a continuous model for the upcoming gait event, as shown in Fig. 4.

For example, Fig. 4a uses the measured thigh orientation from both legs at the moment of prosthesis-side HS to predict the orientation of the prosthesis-side thigh at MHE. Each parameter is modeled as a cubic surface, taking the form

$$\begin{aligned}\hat{X} = p_{00} + p_{10}x + p_{01}y + p_{20}x^2 + p_{11}xy \\ +p_{02}y^2 + p_{30}x^3 + p_{21}x^2y + p_{12}xy^2 + p_{03}y^3,\end{aligned} \tag{2}$$

where $\hat{X}$ is the model parameter corresponding to the predicted upcoming gait feature, x is the prosthesis-side thigh angle measured at the most recent prosthesis-side gait event, and y is the intact-side thigh angle measured at the same instant. In Fig. 4d, for example, $x = \theta_{\text{th}}^{\text{HS}}{}_{\text{PR}}$ and $y = \theta_{\text{th}}^{\text{HS}}{}_{\text{IN}}$ are used as inputs to predict $\hat{X} = \hat{\phi}^{\text{MHE}}$, the predicted gait phase at the upcoming prosthesis-side MHE. The polynomial coefficients are fit by minimizing the L2-norm of the difference between the predicted and actual signals (e.g., $\hat{\phi}^{\text{MHE}}$ and ϕ^{MHE}) from the training data (details in Section II-D). The normalized root-mean-squared error (NRMSE) performance for each model is given in Fig. 4 as a percentage of the signal range (100 deg for thigh angle parameters and 1 for phase parameters), showing good predictive performance for each model.

D. Data Processing

Both the classification-dependent model (Section II-B) and the task-agnostic model (Section II-C) were assessed using an able-bodied open access dataset consisting of 10 able-bodied individuals completing several tasks [37]. To train both the classification-dependent and task-agnostic models, the data from five of the subjects in [37] were used, and the remaining five subjects were used for validation. Tasks of LW at 0.8, 1.0, and 1.2 m/s speeds, RA and RD at 5 and 10 degrees using the same 3 speeds, and SA and SD at inclines of 20, 25, 30, and 35 degrees at a self-selected pace were used for training and validation. Walking was more represented in the training data than stair climbing, so relative weights were added to the optimization cost to balance the contribution from each task equally. Thigh angles were calculated as the sum of the negative global pelvis angle from vertical and the positive hip angle, both in the sagittal plane, such that a positive/negative thigh orientation corresponds to hip flexion/extension. Heel strike was provided by the dataset and the ground-truth gait phase was defined as the normalized time between consecutive heel strikes. MHE was determined for all strides as the moment between HS events at which thigh angle was minimized, and MHF was determined as the first maximum peak in thigh angle that occurred between MHE and the upcoming HS (a single peak existed in 88.4% of strides in all activities, with 6.8% having no peaks and 4.8% having 2 peaks).

Only steady-state strides were used for all activities. For walking tasks, the right leg was treated as the prosthesis-side, but for stair trials the prosthesis-side was selected as the leading foot to ensure that there were two HS events in steady state on the 4-step staircase [37]. For the task-agnostic model that uses bilateral thigh information, the intact-side thigh information was taken from the continuous streaming dataset, which contained bilateral sensing. Strides exhibiting erroneous discrete jumping behavior in the dataset were removed (6 total out of 4,215), but no outliers were removed otherwise. The classification-dependent gait event prediction models (Fig. 3) were generated by taking the average thigh angle and gait phase for each gait event of HS, MHE, and MHF. For validation, phase prediction error

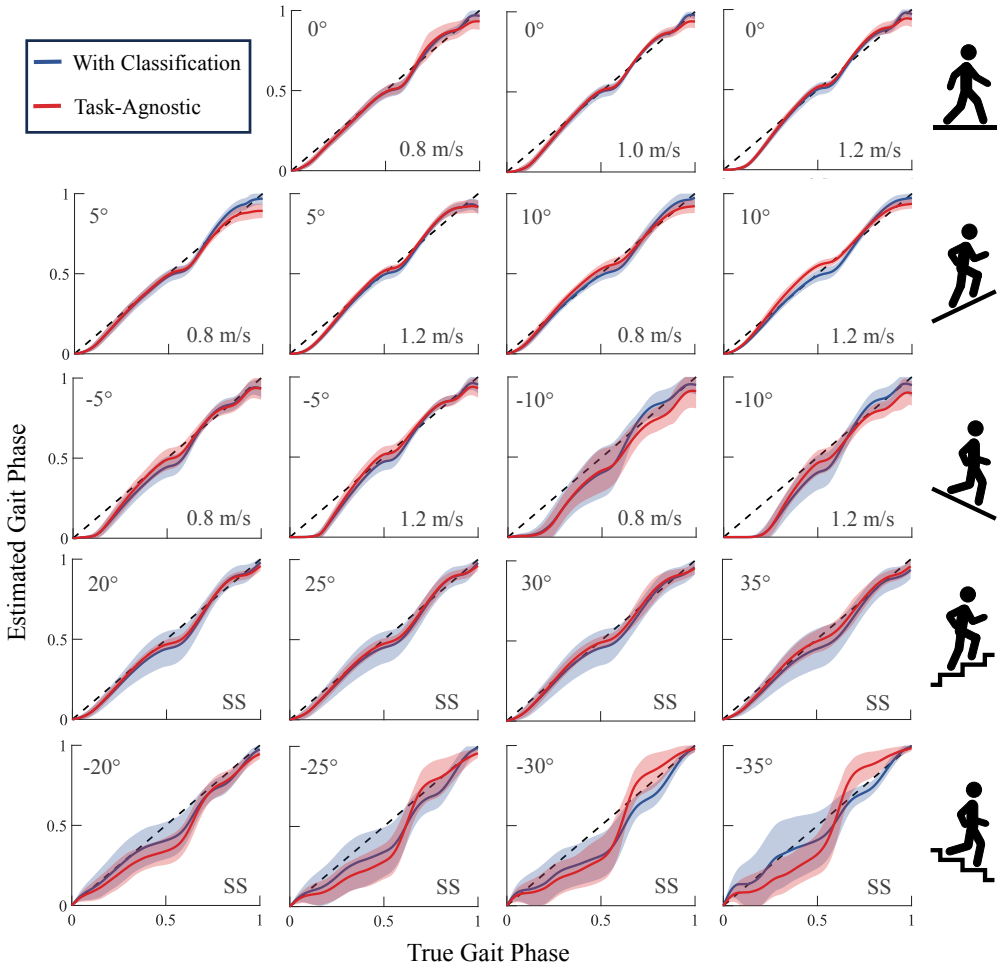

Fig. 5. The average gait phase estimation ± one standard deviation is compared to the true time-normalized gait phase (dashed grey). For each locomotion activity, the task incline is displayed in the top left corner, and the task speed in the bottom right corner (SS indicating self-selected). Averaged across subjects, the unified phase model with classification (blue) and without knowledge of the task (red) exhibit comparable prediction performance across tasks, with the task-agnostic approach having less subject-to-subject variability.

was quantified for each stride by taking the root-mean-squared error (RMSE) between the ground-truth gait phase and the model predicted gait phase. Differences between the classification-dependent and task-agnostic phase models were compared using a two-tailed paired t-test.

III. Results and Discussion

A. Simulation Results

The overall phase estimation performance across multiple ADLs and speeds is shown in Fig. 5 both with classification and without classification (task-agnostic). Across all tasks, subjects, and strides, the overall average RMS phase error for this unified phase approach was 6.8% with classification and 6.3% when task-agnostic. The corresponding average RMS phase error is summarized for individual tasks in Fig. 6. For level walking (LW), the phase estimation is very consistent both with and without the use of classification, with an average phase RMSE between 4-5% for both conditions at all three speeds. This consistency is maintained for ramp ascent tasks, where both models have RMS error less than 5% on average for all speeds and ramp inclinations.

For stair ascent (SA), the task-agnostic approach demonstrated higher accuracy (phase RMSE of 4.9% across stair heights) than the classification-dependent model (phase RMSE of 8.1%) with statistical significance ($p = 4.0 \times 10^{-17}$). The SA phase estimation with classification exhibited higher subject variability, performing better for some subjects (such as AB05: average phase RMSE 5.8% for 35 deg SA) than for others (AB09: 8.6%). SA phase estimation was more consistent across subjects using the task-agnostic model (AB05: 4.4%, AB09: 4.8%, for the same trials). The task-agnostic phase model's better accommodation of subject variability over the approach with classification is also observed in the reduced standard deviation throughout Fig. 5. This is likely due to the incorporation of more recent gait event information in the task-agnostic predictions.

During 5-degree ramp descent, the unified phase approaches maintained repeatability across strides and subjects (low standard deviation in Fig. 5) and an average phase RMSE less than 7.2% with classification and 6.6% with the task-agnostic framework. Phase estimation error increased for the steeper ramp descent of 10 degrees, with an average

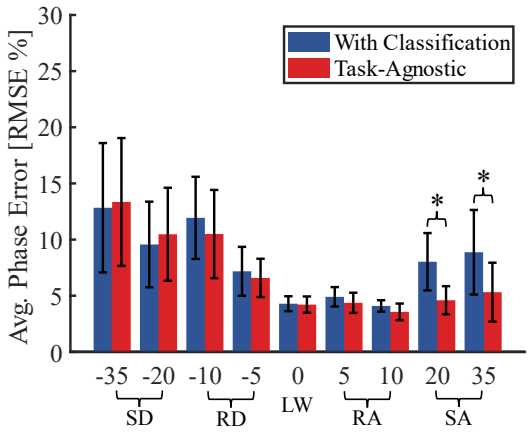

Fig. 6. The average phase root-mean-squared error (RMSE) ± one standard deviation for each locomotion task is measured as a percentage. The task-agnostic approach (red) performed consistently during level walking and all ascent tasks, with increased error for descent tasks. The classification-dependent approach (blue) behaved similarly, but with significantly larger error during stair ascent (SA) across stair heights ($p = 4.0 \times 10^{-17}$).

phase RMSE less than 12% with classification and less than 11% with task agnosticism. Fig. 5 reveals that a significant error exists in the early stance phase (weight acceptance) for ramp descent and generally becomes larger with increased speed and more significant ground inclination. In this region, the phase tends to saturate at zero, meaning that the thigh angle begins to flex after heel strike rather than to approach the predicted MHE value for these tasks. This behavior is consistent with early stance weight acceptance, which is generally increased with higher walking speeds and steeper declines. This early stance error (exhibited in [8] and [9] as well) can also be observed to a lesser degree for LW, with the largest early stance errors presented at 1.2 m/s. Future work could consider an additional optional state to the FSM that could accommodate this early hip flexion for some tasks, although this would introduce increased sensing and modeling demands that could be difficult in practice.

Among all locomotion tasks, stair descent (SD) consistently showed the poorest model performance, with mean phase RMSEs of 12.1% (with classification) and 12.7% (without), particularly at larger stair heights (Fig. 6). The causes of reduced accuracy, however, seemed to differ between the two approaches. In this framework, poor phase estimation generally reflects discrepancies between predicted parameters $\hat{\theta}_{\text{th}}^{\text{MHE}}$, $\hat{\theta}_{\text{th}}^{\text{MHF}}$, $\hat{\theta}_{\text{th}}^{\text{HS}}$, $\hat{\phi}^{\text{MHE}}$, and $\hat{\phi}^{\text{MHF}}$ and their ground-truth values. Figure 7 shows that with classification, SD phase predictions varied across subjects, with better accuracy for some (e.g., AB09) and worse for others (e.g., AB07), occasionally resulting in phase over- or underestimates. The task-agnostic approach, however, consistently underestimated gait phase at MHE and thigh angle at MHF, creating an S-shaped phase curve across subjects. While the task-agnostic model was generally more consistent, its large phase RMS errors for SD reflect optimization trade-offs that prioritize balanced performance across all activities over individual task accuracy.

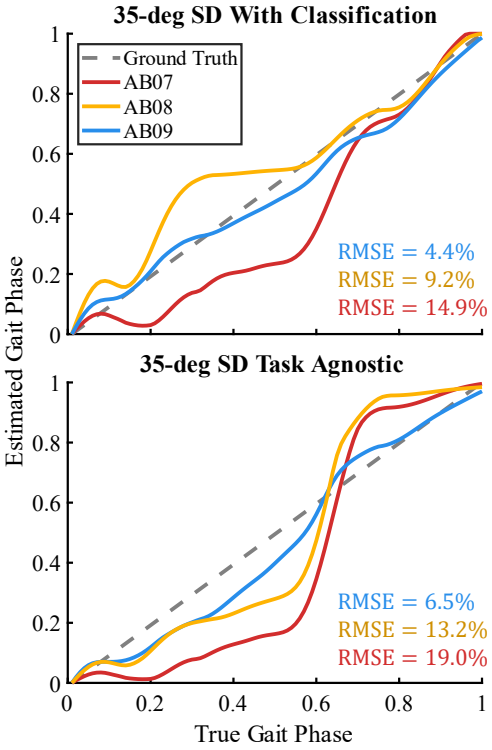

Fig. 7. Both the classification-dependent (top) and task-agnostic (bottom) approaches had the highest phase prediction error during 35-degree stair descent (SD). These models performed better for some subjects (e.g., AB09, blue) and worse for others (e.g., AB07, red).

B. Comparison with Other Multi-Activity Phase Estimators

This work is inspired by the phase definitions in [8], [9], [38] that accommodate variable slope/speed walking, variable-height stair climbing, and obstacle avoidance, respectively; however, the unified phase definition presented herein is the first to unify these definitions into a single framework. Continuous gait phase monitoring across multiple ADLs without classification dependence has also been explored in [18] for prostheses and [30], [36], [40] for exoskeletons. For example, [18] used bilateral sensing to simultaneously predict gait phase and task for a robotic ankle prosthesis, achieving average phase errors under 2% for walking and under 4% for stairs. Similarly, [30] used bilateral sensing and a random forest regression algorithm to estimate gait phase and classify tasks for a soft exosuit, showing effective phase prediction for walking and stairs, with a nearly three-fold error increase during SD compared to LW. Using bilateral sensing and deep neural networks, [36] achieved an overall phase RMSE of 5.04% for exoskeleton control across ten subjects, with errors increasing by 50% during RD compared to LW. RMSE errors reached nearly 10% during SD, similar to the trends observed in this study. With very steep slope walking, [40] also used bilateral sensing to achieve an average phase RMSE of 4.8%, and exhibited large subject dependence in performance.

Each of these approaches used bilateral sensing to obtain a task-agnostic phase estimate, and the present work is the first to do so towards transfemoral prostheses. The related

work and our approaches herein saw a notable decrease in performance during stair descent, which could be due to the relatively small range of motion of the hip that causes sensitivity between the angle of the user's thigh and the gait phase, as proposed in [9]. Unlike [30], [36], this unified phase definition is a model-based approach that does not incorporate ML. The imposed model structure based on common kinematics observed across tasks (Fig. 1) could also be used to enhance ML approaches that could learn the structured model parameters, rather than to learn the full mapping from lower-limb kinematics to gait phase. This could aid in prediction robustness when encountering out-of-training inputs, such as new speeds and inclines. Our approach to unified phase also depends only on bilateral thigh sensing (omitting any trunk, shank, or foot sensors as found in [18], [30], [36], [40]), which holds significant promise for the control of transfemoral prostheses.

C. Challenges for Real-Time Implementation

The analysis presented in this work detected HS, MHE, and MHF offline. In practice, heel strike (or foot strike) information is relatively simple to obtain in real-time, but it can be more difficult to accurately detect MHE and MHF without delay. Fast real-time detection algorithms have been developed to detect peaks in the thigh angle associated with MHE and MHF from a single thigh IMU based on thresholding [38] and multiple moving average algorithms [9]. Appropriate performance of this unified phase definition depends on this real-time detection.

Furthermore, the use of bilateral sensing (as in this work and [18], [30], [36], [40]) increases donning requirements, especially for the use of unilateral prosthetic control, which is undesirable from the perspective of clinical and commercial adoption. If it can be shown, however, that performance or robustness to latent variability could be dramatically increased with the incorporation of additional sensors (such as a single additional IMU on the contralateral limb in this case), the benefits may justify the perceived drawbacks. In this work, we preliminarily suggest that a task-agnostic framework for continuously estimating phase across locomotion tasks may not be feasible with a single thigh IMU, but that it can be done with a pair of bilateral thigh IMUs. While both approaches showed similarly good performance, breaking the dependence on classification is a significant advantage as classification between many activities is challenging and fundamentally unscalable.

D. Limitations and Future Work

While the unified and task-agnostic approach presented has shown promise when simulated offline, future work will seek to validate these results in real-time hardware experimentation. It will be important to ensure the robustness of this approach when transitioning to real environments, accounting for the sensor challenges as discussed, and implementing this with the target population of individuals with unilateral transfemoral amputation.

The primary performance limitation presented for both the classification and task-agnostic approaches is that subject variability was high, leading to good performance for some subjects and worse for others. Personalization of these phase prediction models could lead to significant improvement in performance. While it is undesirable to increase tuning demands, which would require extensive clinician time and training, this approach is an ideal candidate for personalizing to a specific user over time, with techniques such as the Kalman filter (as in [40]). After the gait event information for MHE, MHF, and HS is predicted by the model, the corresponding ground-truth information is then measured for each stride. Comparing the predicted and ground-truth values could be used to improve the model for an individual user over time, which could also reduce the effects of latent variability. Future work will pursue such personalization techniques that do not increase tuning demands.

IV. Conclusion

In this study, we presented a novel unified phase variable framework for robotic lower-limb prostheses, enabling both classification-based and task-agnostic control across a diverse range of locomotion tasks. By unifying phase definitions across level walking, ramp ascent/descent, and stair ascent/descent with several speeds and inclines, this approach addresses limitations of existing methods that are classification-reliant and employ activity-specific phase definitions. Simulation results demonstrated that both classification-based and task-agnostic implementations achieve low phase RMSE, with the task-agnostic approach exhibiting reduced subject-specific variability. The task-agnostic model also outperformed the classification-based model during stair ascent, which highlights its robustness across diverse activities and may justify the use of bilateral sensing. These findings highlight the feasibility of using task-agnostic frameworks in the development of robust and versatile prosthetic control systems that can accommodate a wide range of locomotion tasks.

Abstract— **For individuals with transradial limb loss or difference, myoelectric prostheses providing advanced functionality are often controlled through two control strategies: Amplitude and Threshold Control (ATC) and Pattern Recognition (PR). While ATC, a conventional method which is sometimes called direct control, is commonly used, it can be less intuitive for multi-degree-of-freedom tasks. PR, leveraging machine learning to classify muscle activation patterns, accesses movements using physiologically appropriate contractions. This study evaluates a Reduced-Contact PR (RC-PR) system, against ATC with rate-sensitive switching. Four individuals with transradial limb loss participated in a randomized crossover trial using a two-degree-of-freedom prosthesis. Functional outcomes, manual dexterity, and user perception were assessed using the Box & Blocks Test, Clothespin Relocation Test, AM-ULA, ACMC, and a User-Perceived Control Questionnaire. RC-PR demonstrated superior performance across all metrics and was preferred by participants for its intuitive operation. These findings suggest that RC-PR offers significant advantages in functional outcomes and user satisfaction, presenting a promising alternative to traditional ATC systems.**

I. INTRODUCTION

It is estimated that 541,000 individuals in the United States have upper limb loss, with 41,000 being major loss (wrist disarticulation or higher)[1, 2]. Loss of the hand and wrist can profoundly impact overall function and how an individual is able to complete activities of daily living. Though it is possible to build very complex powered prosthetic devices, one of the greatest challenges is how an individual can control the prosthesis.

The contents of this manuscript were developed under grants from the Department of Defense (DoD) W81XWH2210431, Discretionary laboratory funding, and the National Institute on Disability, Independent Living, and Rehabilitation Research (NIDILRR) 90REGE0003. NIDILRR is a Center within the Administration for Community Living (ACL), Department of Health and Human Services (HHS). The contents of this report do not necessarily represent the policy of NIDILRR, ACL, or HHS, and you should not assume endorsement by the Federal Government.

Historically, individuals with upper limb loss or difference (eg. amputation or congenital absence) would use electromyographic (EMG) signals from agonist/antagonist muscle pairs to control the two directions of movement associated with a degree-of-freedom. This style of control is typically achieved by adjusting the EMG signal amplitude using gains and thresholds [3]. We will refer to this as amplitude and threshold control (ATC) although this is sometimes called direct control. Specifically, a configured gain and threshold allows the processed wrist extensor EMG signal to open the hand, while a similar process using wrist flexor EMG signals enables hand closure. To control a second degree-of-freedom (eg. wrist rotation), a user would use the ATC system with a trigger (ATC-T), such as co-contraction to switch the control of the 2 EMG signals to the second movement [4].

An alternative method to select which degree-of-freedom is operated is to combine ATC with the rate of change (ATC-R) of the EMG signal amplitude to select which motor would be activated. This is achieved by setting a second, higher threshold for each EMG signal in the agonist/antagonist pair [4]. For example, with ATC-R, a quick and strong wrist extension contraction above the second higher threshold within the defined time limit would result in wrist supination and a quick and strong signal of the wrist flexors creates a signal to pronation the wrist. If the user makes a slower contraction, or a contraction that does not surpass the second threshold within the set time, then the respective hand movements would be operated. Using ATC-R allows users to directly access each degree-of-freedom without using a trigger toggle between degree-of-freedom.

For individuals with acquired upper-limb loss, many of the muscles that control hand and wrist functions are maintained in the upper forearm. By recording EMG signals around the forearm from these muscles, pattern recognition (PR) algorithms can be trained to identify these movements allowing for an alternative control that uses more physiologically appropriate contractions and does not rely on unnatural triggers. PR systems are now commercially available [5], with three companies (Coapt, Otto Bock, and Infinite Biomedical Technologies) selling Class II medical devices cleared by the US Food and Drug Administration.

Early research on PR control evaluated various factors of the algorithms to try to identify the optimal values for

clinical applications [6]. One of the factors that was investigated was the number of EMG channels required to identify various patterns of hand and wrist function. From an analysis of offline classification accuracy of 10 movements, it was found that 6-8 optimally placed EMG channels would be required for approximately 93% percent accuracy [7]. Based on plateau in classification accuracy beyond 4-6 channels for six movements, it was estimated that eight channels placed around the EMG of interest would be sufficient and would help to limit the computational requirements of an embedded controller.

More recently, the controllability of two degrees-of-freedom, one at the hand and one at the wrist, in individuals with transradial upper-limb loss or difference using 4, 8 and 16 channels to control a virtual prosthesis and a physical prosthetic device showed 16 channels outperformed conditions with 4 and 8 channels [8]. Additionally, users rated the condition with 16 channels as easier to control when blinded to the condition. This work has shown that additional channels may be useful to control multiple degrees-of-freedom, however it is unclear if these additional channels are necessary for control of simpler system with a wrist rotator and single degree-of-freedom hand. Furthermore, while use of 16 channels of EMG provided improved control, it does provide clinical challenges in placing the electrode contacts within the socket. This can be mitigated by having EMG signals share electrode contacts (Fig. 1), resulting in a reduced electrode contact set. Prior work has shown that sharing electrode contacts provides additional discriminatory information

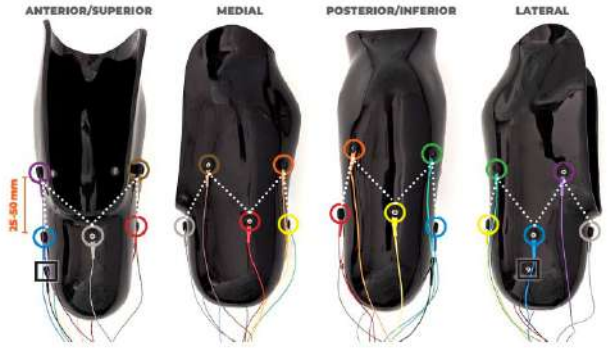

Fig. 1. EMG contact configuration for RC-PR. Image courtesy of Coapt Engineering

that can be useful for classification[9].

PR control systems have proven the ability to control powered upper limb prostheses with three or more degrees-of-freedom more efficiently than ATC systems [10]. While these studies have demonstrated important benefits of myoelectric PR control, there is a lack of evidence comparing PR and ATC when fewer degrees-of-freedom are used. A case study by Resnik et al. attempted to fill this gap by evaluating control with both PR and conventional ATC control for a 2 degree-of-freedom prosthesis [11]. They found similar results in 74% of the metrics examined and improvements in the remaining 26% with ATC-T. However, these findings include those of only one participant who used a ATC device as their home system.

The goal of this project was to evaluate differences in control of a prosthetic system including a powered wrist rotator and a single degree-of-freedom hand. The first control evaluated included a PR system with eight EMG channels configured in a connected zig-zag pattern to reduce the number of EMG contacts from 17 (2 per bipolar channel plus a ground) to 9 (Fig. 1). It was hypothesized that functional outcome performance would be higher with this reduced contact PR control (RC-PR) compared to a two EMG channel ATC-R system.

II. Methods

A. Study Design and Participants

Four participants with unilateral, transradial limb loss secondary to trauma were recruited to participate in a randomized crossover study to compare the two control systems.. Three were male and one was female with ages ranging from 40 to 60 (average age 52). None of the individuals reported having undergone targeted muscle reinnervation (TMR), and all participants had at least minimal prior experience with myoelectric prostheses, whether in their home prosthesis or through participation in research. Of the four, one had experience with only ATC-R (S4), one had experience with only PR (S2), and two were experienced in both ATC-R and PR control (S1, S3). Additional demographic data can be found in Table 1, including age, time since amputation, experience with the various control systems either from previous research experience or past home fittings, and recent home prosthesis useThe study was approved by the Northwestern University IRB and all participants provided written informed consent.

TABLE I. Participant Demographics

ID	*Age*	*Years since injury*	*PR/ATC/ ATC-R experience*	*Recent Home Prostheses*
S1	60	45	Y/Y/N	2-site myo w/ manual wrist rotator
S2	53	1	Y/N/N	Body-powered
S3	40	1	Y/Y/N	2-site myo w/ manual wrist rotator (device 1) & Body-powered (device 2)
S4	55	37	N/Y/Y	2-site myo w/ electric wrist rotator

B. Device

Participants were fit with a prosthetic socket under the supervision of a certified prosthetist. If necessary, a second socket was fabricated if the EMG electrode positions of the two systems did not allow for placement in the same socket. All sockets were designed to be self-suspending and fit over the epicondyles to reduce the amount of intact pronation and supination available and encourage use of the powered wrist rotator. An auxiliary suspension sleeve was utilized when needed.

The prosthetic components included an Ottobock powered wrist rotator and VariPlus Speed Hand (Fig. 2). The two control systems used were the Ottobock Healthcare Myorotronic (ATC-R) and prototype PR system provided by Coapt that came pre-configured such that only 9 electrode contacts created 8 unique EMG channels (RC-

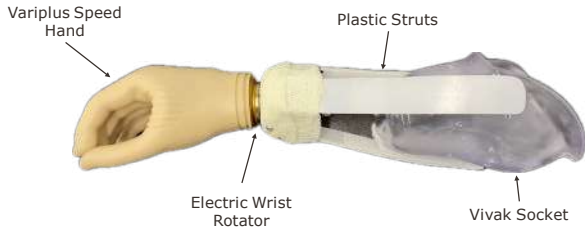

Fig. 2. Prosthetic componentry used for both conditions.

Fig. 3. Myotesting procedure using the Ottobock MyoBoy for configuration of EMG placement for ATC-R

PR). The order of testing with the two conditions was randomized.

For the ATC-R system, myotesting was performed to identify the two best locations for isolated agonist-antagonist control using Ottobock Myobock 13E200 electrodes (Fig. 3). Openings were made for the electrodes in the socket and the participant was trained using the Ottobock PAULA software. The Ottobock Myoselect was used to configure the Myorotronic to "Myobock Program 1" which allows for rate sensitive access of the wrist rotator.

For the RC-PR system, 9 electrode domes were placed around the residual limb over the forearm musculature (proximal third of the residual limb) in a zig-zag pattern, creating 8 EMG channels plus a ground contact following the recommendations provided by Coapt (Fig. 1). EMG signals were digitally filtered between 70-300 Hz, and 3rd order notch filters were used to filter power-line frequencies. Time-domain features [12] and coefficients from a 6-order autoregressive model were used to extract information from 200 ms of data from each signal using a sliding window approach with 50 ms window increments [13]. Features were classified using a linear discriminant analysis classifier. Finally, the speed of each movement was estimated using a previously developed proportional control algorithm [14]. Calibration for the RC-PR system was completed prior to and throughout testing, as necessary.

Participants worked with an occupational therapist in all sessions for each control and practiced with the device for one to two sessions prior to progressing to outcomes testing. Participants began training with basic activities, such as opening and closing the prosthetic hand in various planes without errors (e.g., unintended hand opening). As proficiency improved, they progressed from one-handed to two-handed functional tasks. Training duration and progression to outcomes were tailored to each participant's ability and comfort with functional tasks.

C. Outcomes

For each control condition, after a brief warm-up (10-15 minutes) participants completed the Box and Blocks Test (BBT, number of blocks moved in 1 minute, 3 trials) [15], the Clothespin Relocation Test (CRT, time to move 3 clothespin from a horizontal to a vertical bar, 3 trials) [16], the Activities Measure for Upper Limb amputees (AM-ULA, a scored measure of pre-defined simulated ADL-like activities, 1 trial)[17], and the Assessment of Capacity for Myoelectric Control (ACMC, a Clinician-scored assessment of myoelectric control capacity when performing a bimanual functional task, 1 trial) [18]. Outcomes were typically completed in 1-2 hours, allowing for rest breaks. Outcome testing for each control condition was completed on separate days. After each test session, participants were asked to draw a line on a visual analog scale (horizontal line) to indicate how easy or hard it was to control the prosthesis, overall. A new line was provided for each condition, so marks for the second control configuration were independent from the first. At the conclusion of the study, they were asked which configuration they preferred and why.

Data from all participants who completed the study were used to compare outcomes of the two control schemes. BBT, CRT, AM-ULA, ACMC, and User Perceived Control results were averaged across participants by each of the two conditions and standard error was then calculated.

III. Results

Results of the BBT (Fig. 4) found all four participants performed better with the RC-PR over the ATC-R and a greater than Minimal Detectible Change based on a 90 percent confidence interval (MDC_{90}) improvement (MDC_{90} = 6.49)[19] in performance for RC-PR over ATC-R was noted for two participants. The average blocks moved per minute was 12.83±1.76 (mean ± standard error) with RC-PR as compared to 7.75±1.60 with ATC-R.

RC-PR was also found to outperform ATC-R in the CRT by 31.19 seconds. Group results for the RC-PR and four-channel ATC-R were 17.93±3.10 and 49.12±6.45, respectively (Fig. 4). All four participants had improved performance with the RC-PR configuration, as indicated by the reduced time to complete the task.

Results of the AM-ULA (possible range 0-40, MDC_{90} = 3.70) [17] showed improvement in performance with the RC-PR configuration over ATC-R (Fig. 4). All 4 participants had individual scores higher for RC-PR. Group means were 12.36±0.47 with ATC-R and 16.25±0.83 with RC-PR, with the group difference of 3.89 exceeding the MDC_{90}.

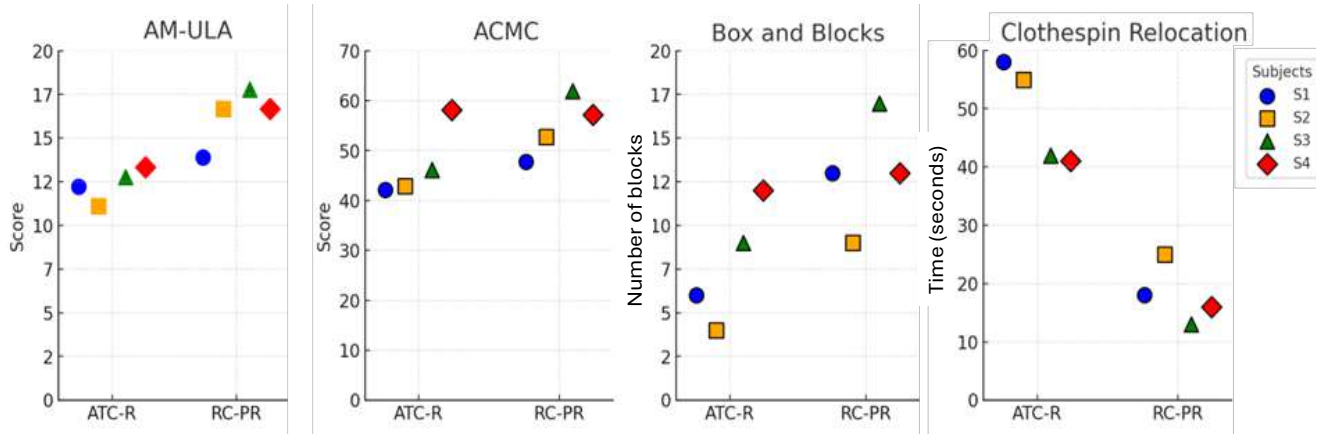

Fig. 4. Outcome results for the four participants. From left to right: AM-ULA (total score), ACMC (total score), Box and Blocks (number of blocks moved in 1 minute), Clothespin Relocation Task (time to move three clothespins). Improved performance is indicated by a higher score for the AM-ULA, ACMC, and Box and Blocks and a lower score for the Clothespin Relocation Task.

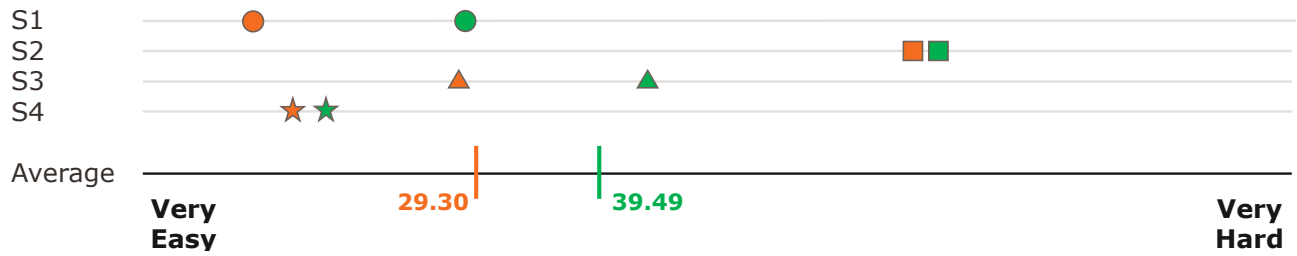

Fig. 5. Overall perceived control. Participants were asked to mark their overall perceived control of the prosthesis on a visual analog scale labeled as "Very Easy" on the left and "Very Hard" on the right. The location of each mark on the line was converted to a percentage of the entire line length. Green symbols correspond to ATC-R ratings and orange symbols to RC-PR.

For the ACMC (possible range 0-100, MDC_{95} = 2.5) [20, 21] the group average score increased from 47.35±3.72 with ATC-R to 54.95±3.03 with RC-PR (Fig. 4). This difference of 7.6 is greater than the MDC_{95} of 2.5 (single rater). Of the four participants who completed the measure, three (S1-S3) achieved higher scores with RC-PR as compared to ATC-R. S4 scored one point higher with the ATC-R configuration.

Following completion of the outcome measures for each control system, participants were asked to mark their overall perceived control of the prosthesis on a visual analog scale labeled as "Very Easy" on the left and "Very Hard" on the right (Fig. 5). The location of each mark on the line was converted to a percentage of the entire line length. Once data collection of both conditions was complete, participants were asked which control scheme they preferred and to provide an explanation as to why. Average overall control difficulty was reported as 39.49±11.36 with ATC-R and 29.30±13.11 with RC-PR. All four participants indicated that the prosthesis was easier to control with the RC-PR configuration and they reported they preferred RC-PR to ATC-R.

IV. Discussion

Amplitude and threshold control and PR are among the most widely used methods for operating myoelectric upper limb prostheses. While there are an increasing number of studies that have found improved prosthetic control and functionality with PR as compared to ATC, there are few studies comparing performance when controlling lower degree-of-freedom devices. This study served to fill this gap by comparing functional outcome measures and user-perceived control of a 2 degree-of-freedom prosthesis using both ATC-R and RC-PR control methods. Though a statistical analysis was not appropriate for only four participants, differences were found in quantitative outcome measures, with RC-PR outperforming ATC-R, as well as in user perceived control difficulty score. Even the participant who utilized ATC-R performed better or similar for the RC-PR condition and was the only participant whose ACMC score was higher (by 1 point) for ATC-R. For the three functional measures with an identified MDC (BBT, AM-ULA and ACMC), 58% of the within participant comparisons (7 of the 12) were higher for pattern recognition. None exceeded the MDC in favor of ATC-R.

These results are different than those reported by Resnik, who found fewer differences between the conditions [11]. A possible explanation is that the prior study used an ATC-T strategy whereas an ATC-R strategy was used in this study. We chose to implement the ATC-R strategy for two reasons. Firstly, with co-contraction switching, a user is much less likely to have inadvertent wrist rotation, unless they accidentally trigger this switching action. However, if this trigger is difficult to perform, this may discourage a user from accessing the wrist movements. With rate control, a user is able to more easily access the wrist movements by changing the magnitude and speed of the signal; but this can result in

more inadvertent movement, specifically when they try to use the hand in a very rapid manner. This may explain the reduction in the number of blocks moved during the BBT compared to the PR condition. The second reason was more practical—the ATC-R was the clinically configured control approach for one of the participants identified for the study and it was decided to keep this condition consistent throughout the trial.

In the current study, RC-PR not only outperformed ATC-R, but participants expressed a strong preference for RC-PR. This is clinically significant as we look to provide transradial prosthesis users with functional devices to optimize their performance in their daily activities. The participants reported RC-PR offered a more intuitive control experience for their prosthesis, as noted by their preferred condition. When selecting the best prosthesis design for users, clinicians must consider ease of control as a crucial factor that can enhance functional potential and reduce the risk of abandonment.

TABLE II. SUBJECT FEEDBACK (PARAPHRASED FROM NOTES)

ID	***Preferred Control***	***Reason***
S1	PR	-ATC-R was too complicated -ATC-R needed more time and practice -PR takes less "brain power"
S2	PR	-PR is easier to maneuver -PR responded more to my intended motions
S3	PR	-PR is easier to control and requires less focus -I have to stop more with ATC-R -With ATC-R, I have to think how hard and fast, where PR it just follows what I do
S4	PR	-PR movements are more natural, but I had to practice to retrain my brain away from ATR-R -PR is easier, especially could see for someone who is a new amputee

Another indicator of ease of control was the estimated training time needed for participants to achieve proficiency. Although training time was not initially recorded, it became apparent during data analysis that this may be a notable factor. Based on visit documentation, the average estimated time to achieve proficiency with the RC-PR and ATC-R systems, excluding socket fitting time, was 1.6 hours and 2.3 hours, respectively. While training time for the study was abbreviated as compared to clinical training, this suggests that RC-PR may require less time to learn, highlighting its more intuitive operation. A reduction in training time is clinically significant, as it helps to promote quicker integration of the prosthesis into users' daily lives.

While the general set-up of the RC-PR system was easier, it required more attention to the overall socket fit. To ensure consistent prosthetic control, full contact of all nine dome locations with the user's limb is necessary. This is crucial when performing tasks in different positions or while carrying a load, as such activities can often lead to loss of contact, particularly anteriorly and posteriorly in the socket. In contrast, a typical ATC system has fewer contact points, with electrodes positioned more medially and laterally, making them less affected by elbow position and load.

Future research is needed to investigate the control of 2 degree-of-freedom transradial prostheses using RC-PR and ATC within a larger population. Additionally, incorporating both rate control and co-contraction switching methods for all participants in the ATC condition would enable a more comprehensive comparison with RC-PR. Examining the degree to which users employ the wrist and any resulting compensatory movements when it is not utilized effectively could reveal the clinical impacts of choosing one system over the other in the daily lives of users. Future studies should also more precisely evaluate differences in set-up and training times for the various control configurations. Including home trials and implementing washout periods would address existing limitations and provide a clearer understanding of how long-term learning influences user control and function.

V. CONCLUSION

This study suggests that RC-PR outperforms ATC-R for a two degree-of-freedom transradial prosthesis across functional outcome measures and user-perceived control difficulty. RC-PR provided improved performance, reduced training times, and stronger user preference, highlighting its potential for more intuitive and effective control. These findings emphasize the importance of developing control systems that enhance ease of use and functionality, thereby reducing the risk of prosthesis abandonment. Future research with larger populations and extended home trials is needed to validate these results and further explore the clinical benefits of RC-PR.

Personalization of Wearable Sensor-Based Joint Kinematics Estimation Using Computer Vision for Hip Exoskeleton Applications

Changseob Song[1]*, Bogdan Ivanyuk-Skulskyi[2]*, Adrian Krieger[1], Kaitao Luo[1], and Inseung Kang[1]

***Abstract*— Accurate lower-limb joint kinematics estimation is critical for patient monitoring, rehabilitation, and exoskeleton control. While previous studies have employed wearable sensor-based deep learning (DL) models for estimating joint kinematics, these methods often require extensive new datasets to adapt to unseen gait patterns. Meanwhile, researchers in computer vision have advanced human pose estimation models, which are easy to deploy and capable of real-time inference. However, such models are infeasible in scenarios where cameras cannot be used. To address these limitations, we propose a computer vision-based DL adaptation framework for real-time joint kinematics estimation. This framework requires only a small dataset (i.e., 1–2 gait cycles) and does not rely on professional motion capture setups. Using transfer learning, we adapted our temporal convolutional network (TCN) to stiff knee gait data, allowing the model to reduce root mean square error by 9.7% and 19.9% compared to a TCN trained on only able-bodied and stiff knee dataset, respectively. Our framework demonstrated a potential for smartphone camera-trained DL model to estimate real-time joint kinematics across novel users in clinical populations with applications in wearable robots.**

***Index Terms*— Joint kinematics estimation, Human pose estimation, Computer vision, Deep learning, Transfer learning**

I. Introduction

Estimating lower-limb joint kinematics has been an important agenda in patient monitoring, rehabilitation, and exoskeleton control [1], [2]. Accurate and rapid estimation of joint kinematics allows biomechanics and exoskeleton researchers to better understand gait patterns and assist users more effectively. This is important for quantifying irregular and pathological gait patterns, which helps identify gait characteristics and find out appropriate treatment or assistance strategies [3], [4]. Hip exoskeletons are particularly important because they support the hip joint, which plays a major role in locomotion energetics. [5], [6]. Precise joint kinematics data is essential for controlling hip exoskeletons: it allows real-time synchronization with the user's natural gait and facilitates personalized assistance [7], [8].

Recent biomechanics and exoskeleton studies have utilized deep learning (DL) models to estimate biomechanical parameters from wearable sensor data without professional motion capture setups [9], [10]. Among wearable sensors, inertial measurement units (IMUs) are particularly popular, as they capture kinematics of limb segments, such as acceleration and angular velocity [9], [10]. Deep learning models leverage this data to accurately predict users' joint kinematics in real time. However, training these models still requires motion capture systems to provide ground-truth labels.

Although many studies have used motion capture systems to extract body kinematics, those systems are expensive, hard to setup, and cannot be easily moved to different places [11]. Particularly, marker-based motion capture is cumbersome, requiring over 10 minutes to attach the markers, and it is accessible only to skilled operators who can accurately locate anatomical key points. Additionally, marker-based methods yield less repeatable results because different experimenters may attach markers in different positions [12].

Marker-less motion capture systems alleviate the burdens of marker-based systems owing to the rapid advances of human pose estimation (HPE) by artificial intelligence (AI) [13], [14]. They detect skeletal joints from raw image frames, estimate the human poses, and reconstruct three-dimensional (3D) skeletal models. However, commercial motion capture systems are proprietary and demand significant computing resources, limiting the accessibility of both marker-based and markerless systems to professional biomechanical facilities. As a result, they are challenging to implement in home settings or remote clinics in smaller hospitals. At the same time, open-source-based HPE algorithms enables the use of a single monocular camera, such as a personal smartphone, to estimate human poses and build kinematic models [13]. Joint kinematics can be easily extracted without incurring additional costs or requiring labor-intensive preparation. These tools can efficiently capture gait information from untrained users, providing valuable biomechanical data.

Recent studies have explored deploying vision models to estimate joint kinematics. For example, OpenCap, a portable biomechanics system, utilizes minimal smartphone cameras to monitor gait patterns [11]. Cotton et al. developed a framework to generate a smooth trajectory of joint positions [15] and fused IMU data with vision-based motion data to enhance knee joint angle estimation [16]. Similarly, Shin et al. established a joint kinematics estimation pipeline using synthetic IMU and video data from extensive datasets [17]. While these studies deployed HPE models to reconstruct 3D joint kinematics, these technologies cannot run in real time for practical uses, especially during outdoor locomotion. Compact vision models capable of real-time operation have been proposed [18], [19], but their accuracy is limited, and they are unsuitable for daily outdoor ambulation due to the requirement for third-person scene capture. liable, real-time joint kinematics estimation mechanism that can adapt effectively across diverse users would significantly enhance applications requiring real-time functionality, such as robotic exoskeleton control [7], [20].

Here, we propose an adaptive joint kinematics estimation framework that leverages computer vision and DL models to accommodate users with irregular gait patterns. We hypothesize that computer vision-based HPE models can serve as a new ground truth for training DL models to estimate irregular gait patterns with minimal settings. This can be achieved by using an open-source HPE pipeline with a monocular video input. By capturing irregular gait patterns and utilizing this information to train the wearable sensor-based DL models, we expect improvements in model performance. This approach will enable biomechanics researchers to have valuable insights to monitor each patient's gait patterns. Additionally, our framework can enhance existing exoskeleton control systems by rapidly personalizing the estimation model to accommodate individuals with irregular gait patterns.

II. Methods

A. Wearable Sensing Suit

We built a wearable sensing suit that can collect IMU data and estimate joint kinematics in real time. The sensing suit consists of 3 IMUs (ICM-20948, TDK InvenSense, Japan) positioned at the pelvis, left thigh, and right thigh, which are fastened by a Velcro strap and a compression band as shown in Fig. 1a. We used a portable computer (Model 4B, Raspberry Pi, UK) to collect IMU data, with a range of ± 1000 deg/s for gyroscope and ± 8g for acceleration, via I2C communication protocol and perform real-time inference in 50 Hz, as illustrated in Fig. 1b. The portable computer was powered by a portable battery inside of a 3D-printed control box. To synchronize ground-truth labels with timestamps logged by a data acquisition box (Lock Lab, Vicon, UK), the potable computer's software architecture was programmed to receive a 50 Hz trigger. Each iteration took less than 20 ms to log the sensor data and perform real-time inference.

B. Computer Vision-Based Kinematics Estimation Pipeline

We used computer vision models to extract the user's body kinematics. We utilized the MMpose [21] library to build

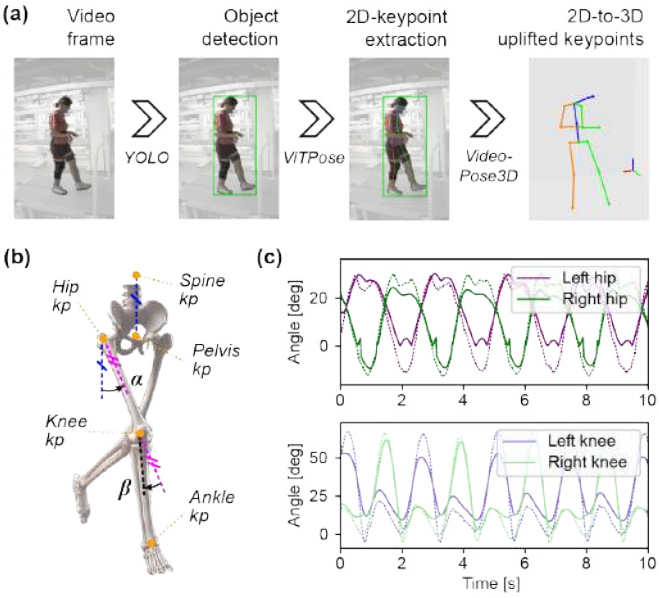

Fig. 2. Pose estimation pipeline using a human vision model. (a) Overall pipeline for extracting 3D joint keypoints from video frames. (b) Visual diagram depicting how joint angles are measured from the 3D keypoints. (c) Plot of estimated joint angles (solid lines) for an able-bodied subject walking at 1.0 m/s, generated using the pose estimation pipeline, compared to the ground-truth joint angles (dotted lines).

the pipeline presented in Fig. 2a that includes: (i) object detection; (ii) two-dimensional (2D) keypoint estimation; (iii) 2D-to-3D keypoint uplifting.

Using 3D keypoints, we calculated the hip joint angle α by measuring the angle between the vector connecting the pelvis and the spine keypoints, and the vector connecting the hip and the knee keypoints. For the knee joint angle, we calculated the angle β between the vector connecting the hip and the knee keypoints, and the vector connecting the knee and the ankle keypoints. We used six RGB cameras (BFS-U3-23S3C-C, Teledyne Vision Solutions, USA; resolution: 1920 × 1200, sampling rate: 100 Hz) to measure ground-truth joint angles with a commercial marker-less motion capture system (Theia3D, Theia Markerless Inc., CA) [12], [22], as depicted in Fig. 3. We selected one of the six cameras as the input of our vision model-based pipeline.

We used the ViTPose [23] human body keypoint estimation model that was pre-trained on the COCO dataset [24], due to its state-of-the-art performance, wide adoption in the field, and robust keypoint predictions. ViTPose utilizes plain, non-hierarchical vision transformers as backbones to extract features from a given person instance, followed by a lightweight decoder for pose estimation. The decoder comprises two deconvolution blocks that upsample the feature maps, followed by a convolution layer that generates localization heatmaps for keypoints. Furthermore, we examined the estimation performance of different ViTPose models across six different camera views depicted in Fig. 3 by averaging root mean square errors (RMSE) between estimated and ground-truth angles for both hip and knee

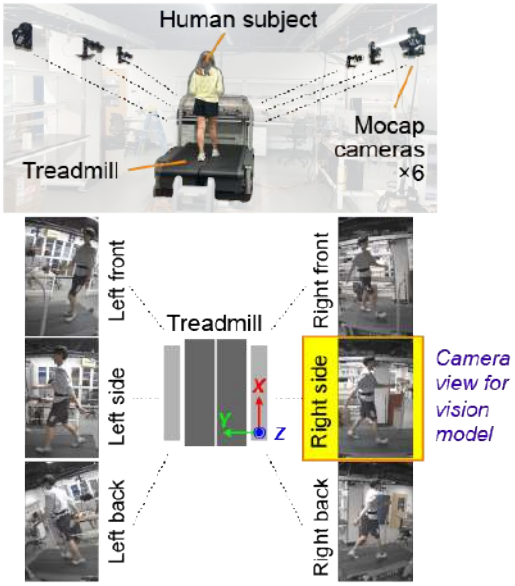

Fig. 3. Motion capture setup for measuring ground-truth joint angles and vision model-calculated joint angles.

joints. As shown in Table I, we obtained the best joint angle detection results from ViTPose-base in the right-side camera view (Fig. 2c) because the side camera views are aligned with the sagittal motion plane, and the right-side view is positioned further away than the left, providing a more direct perspective. After selecting the vision model and camera view, we applied a Savitzky–Golay filter with a window size of 50 and a fourth-order polynomial to reduce jittery noise from the vision pipeline. Overall, for further validation experiments, we used YOLOv8 [25] to detect the human subject, ViTPose-base to detect 2D biological keypoints within the image frames, and Video-Pose3D [26] to reconstruct 3D keypoints from the detected 2D coordinates.

TABLE I

C. Temporal Convolutional Network

For DL models that are used to infer biomechanical information from wearable sensor data, it is essential for DL models to capture temporal features from the input data. While long short-term memory (LSTM) networks [27] have been used for processing sequential data, they are slow to train and have substantial memory requirements. Other popular models like recurrent neural networks (RNNs) face a vanishing gradient problem [28].

Conversely, a temporal convolutional network (TCN) is better suited to handle time-series data because TCNs have dilated convolutional layers, which allows the model to parallelize multiple convolutions and learn long-term dependencies [29]. Therefore, TCNs are faster to train and more memory-efficient than LSTMs or RNNs [30] and have been deployed by many previous studies [29], [31]–[34].

In our TCN implementation (Fig. 4), we built five temporal blocks to extract relevant features from the time-sequential 18-channel data of three IMUs. Each temporal block included two convolutional layers and dilation factor. After passing through the temporal blocks, a fully connected layer mapped four joint angle values. We trained the TCN model using an Adam optimizer with a learning rate of 0.001 and a batch size of 32, for 50 epochs with early stopping. Each convolutional layer had 32 channels with a kernel size of 7, followed by ReLU activation function and a dropout rate of 0.1, which was optimized by a hyperparameter sweep. Once trained, we converted it to an open neural network exchange (ONNX) format to minimize inference latency.

D. Experimental Protocol

We recruited three able-bodied (AB) subjects, one female and two males, mean ± SD: age 25.3 ± 2.1 years, height 174.7 ± 6.5 cm, and weight 67.3 ± 9.0 kg. Within each subject, we collected a training dataset in four constant speed conditions (i.e., 0.4, 0.7, 1.0, 1.3 m/s), 1 minute per trial. Along with collecting IMU data with sensing suit, we obtained the ground-truth kinematic data using the camera setup shown in Fig. 3. Afterwards, to emulate an irregular and asymmetric gait pattern, each AB subject was equipped with a knee brace (Fig. 5a) to constrain their right knee joint motion, which served as a stiff knee (SK) gait pattern as plotted in Fig. 5b. This device not only restricted the right knee motion, but also induced asymmetry between hip joints and lengthened each subject's gait stride. We collected the SK dataset using the same protocol as the AB dataset.

After training the TCN model on the AB dataset (AB model), we adapted the baseline model to an AB+SK model via transfer learning using kinematic data extracted from the HPE pipeline. As shown in Fig. 5c, we analyzed how SK-to-AB dataset ratio affected estimation error on the SK test dataset. To evaluate model performance, we used the RMSE metric, which is particularly advantageous for highlighting outliers by heavily penalizing larger errors. When the SK portion reached 6% (equivalent to approximately 1 to 2 gait cycles for each speed condition) the AB+SK model's test error (on 10% of the total dataset) converged to 4.7 ± 0.4 deg RMSE, while the SK model's error remained at 5.9 ± 0.5 deg RMSE. For real-time validation experiments, we utilized the AB+SK model trained with a 6% SK-to-AB ratio. Similarly, the SK model was trained using the same SK-to-AB ratio, but without leveraging any pre-trained model.

To validate the DL model's estimation performance under various walking speeds and transient conditions with

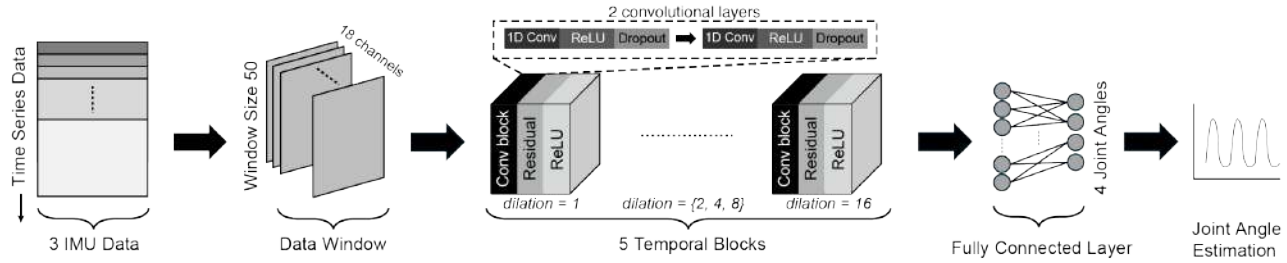

Fig. 4. Structure of the Temporal Convolutional Network (TCN) for training the kinematics estimation model. The dashed line represents a single convolutional block that comprises of two convolutional layers.

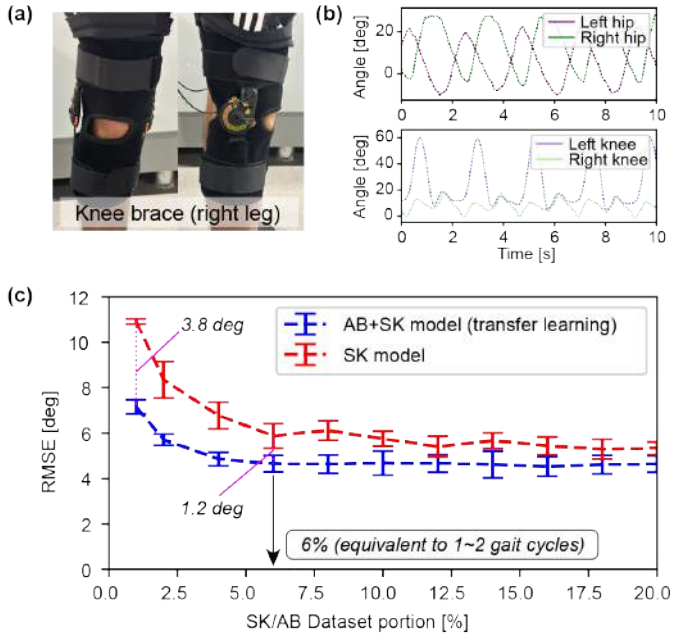

Fig. 5. Experimental setup for evaluating stiff-knee (SK) behavior and the estimation error of a transfer-learned, adapted machine learning model. (a) Knee brace used to replicate the SK gait pattern. (b) Ground-truth joint angle trajectories during SK gait for a single subject walking at 1 m/s. (c) Comparison of estimation errors between the SK model and the adapted AB+SK model across varying SK-to-AB dataset ratios (mean ± SD, three SK subjects).

changing speeds, we conducted experiments using a treadmill (FIT5, Bertec, USA) with the speed profile shown in Fig. 6a. Starting from a stationary position, each subject experienced four speeds (1.1, 0.5, 1.2, and 0.6 m/s, sequentially), which were different from the speeds used during TCN model training. The subject also experienced transient intervals with an acceleration or deceleration of 0.5 m/s². The speed profile lasted 185 seconds in total.

III. Results

To validate real-time estimation performance of the trained TCN model on various subjects, we began by evaluating the AB model's performance on AB subjects as demonstrated in Fig. 6b. For AB model-to-AB subject validation, the hip joint RMSE (3.7 deg) was lower than the knee joint RMSE (7.0 deg). When the AB model was used to estimate the SK subjects' joint kinematics, the hip joint RMSE increased to 5.8 deg, while the knee joint RMSE increased to 10.6 deg. This increase was accompanied by an asymmetry in RMSE values between the right and left legs due to the asymmetric gait patterns, with the right knee joint (stiff knee) exhibiting the highest estimation error among all joints.

For SK model-to-SK subject validation, the average estimation error across all four joints was the highest among all experiments (RMSE of 9.3 deg). Specifically, the hip joint angle estimation RMSE was 6.7 deg, while the knee joint angle estimation RMSE was 11.8 deg. In contrast, using the adapted AB+SK model for SK subjects reduced the hip joint angle RMSE to 4.8 deg and the knee angle estimation RMSE to 10.1 deg, resulting in an average joint angle estimation RMSE of 7.4 deg. This represents an improvement of 9.7% compared to the AB model-to-SK subject case and 19.9% compared to the SK model-to-SK subject case. For estimation performances across different speed conditions, estimation performance during high speed intervals (i.e., 1.1 m/s and 1.2 m/s) was the lowest compared to the low speed and transient speed intervals as shown in Fig. 6c.

IV. Discussion

In this work, we proposed the adaptable joint kinematics estimation framework for irregular gait patterns, particularly using a combination of the computer vision-based HPE algorithm and a TCN model. The vision-trained, adapted AB+SK model exhibited a decreased hip joint angle estimation RMSE of 4.8 deg and the knee joint angle estimation RMSE of 10.1 deg, outperforming the AB model-to-SK subject case by 9.7% and the SK model-to-SK subject case by 19.9%. This result corroborates our hypothesis that computer vision models can facilitate wearable sensor-based DL models to adapt to new gait patterns, which could not be learned by a pre-existing DL model that was trained solely for AB gait patterns. This framework has the potential to function as an effective tool for monitoring joint kinematics in real time, especially in scenarios where only limited datasets are available for model training and professional motion capture systems are inaccessible. Furthermore, we anticipate that our system can be deployed to a hip exoskeleton system where DL models can be generalizable to both AB and SK users.

An unexpected outcome was the higher estimation error of the SK model on SK subjects compared to the estimation

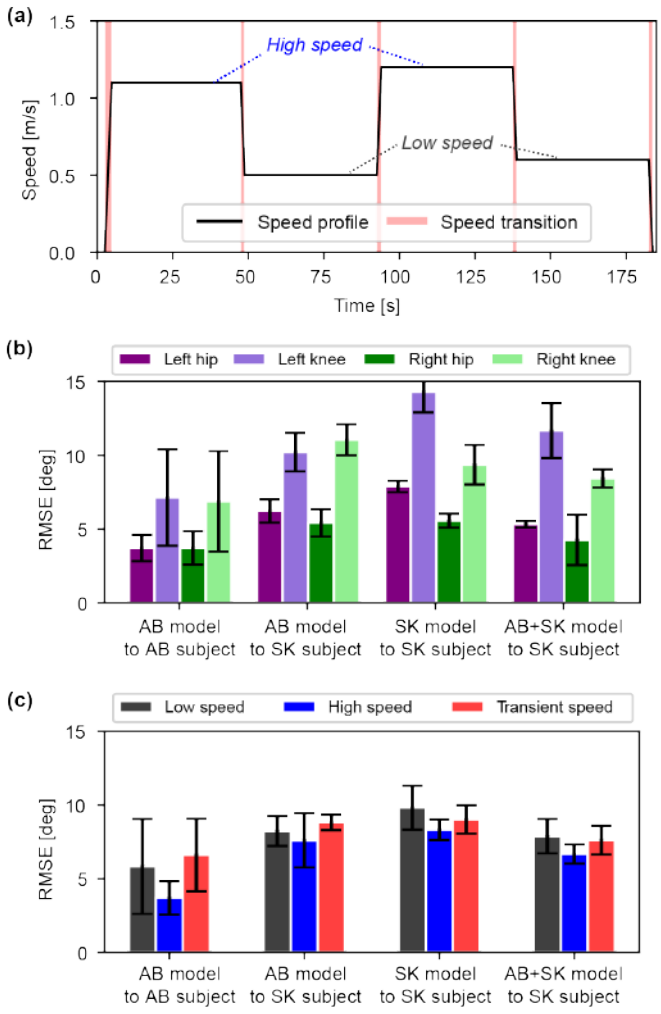

Fig. 6. Results of the Validation Experiments on Real-Time Kinematics Estimation. (a) Speed profile of the treadmill used during the validation experiments. (b) Estimation RMSE for each model across four lower-limb joints (mean ± SD, based on three SK subjects). The trial names indicate the specific TCN models (e.g., AB model, SK model, and AB+SK model) used to estimate data from specific subjects (e.g., AB subjects and SK subjects). (c) Estimation RMSE for each model under varying treadmill speed conditions (mean ± SD, based on three SK subjects).

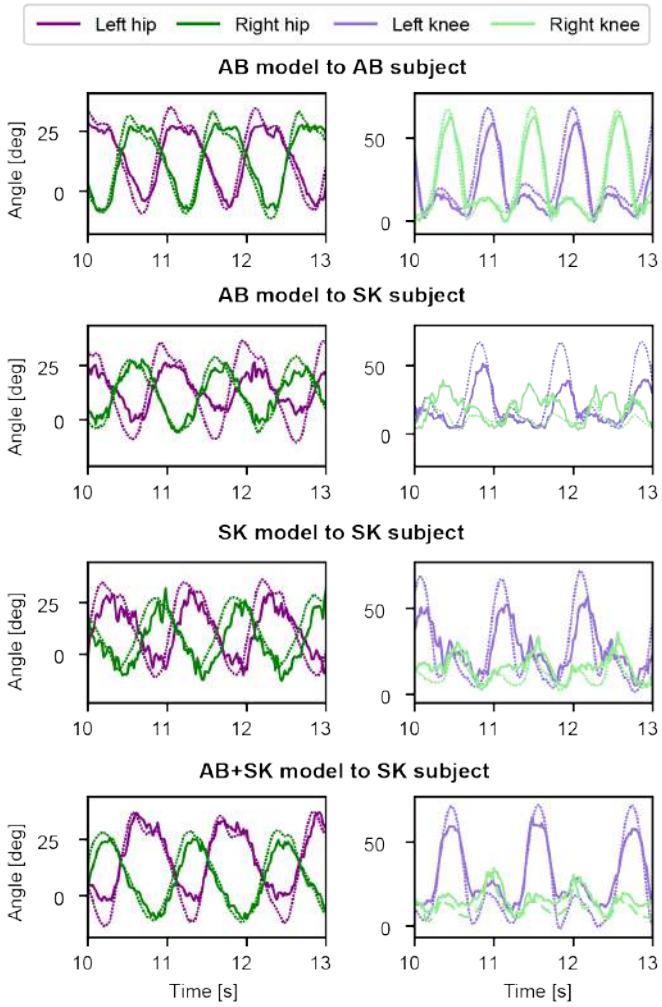

Fig. 7. Exemplary plots of real-time kinematics estimations for each joint across experimental trials. The data corresponds to Subject 1 during a high-speed interval at 1.1 m/s. Solid lines represent the estimated joint angle values, while dotted lines indicate the ground-truth joint angle values.

error of the AB model on the same group, even though the SK gait pattern was different from the AB gait patterns. This could be attributed to our study having a much smaller SK dataset size compared to the AB dataset, which was equivalent to only 1 to 2 gait cycles. Nevertheless, this small dataset portion effectively fine tuned the adapted AB+SK model, resulting in the lowest overall estimation error for SK subjects across all experiments. In addition, knee joint angle estimation errors were consistently higher than the hip joint angle estimation errors. This discrepancy in estimation performance was potentially stemmed from the sensing modality of our suit, which only included pelvis and thigh IMUs. For more precise knee joint estimation (or ankle joints), future work will involve reinforcing our sensing suite with additional IMUs being located at distal lower-limb segments.

The SK model and the AB+SK model also exhibited higher estimation error for the left leg than the right leg in both hip and knee joints. These errors were due to the model failing to track the hip joint angle around its minimum peak as illustrated in Fig. 7. Considering that we selected the right side view camera among six cameras, occlusion effects likely contributed to these left-side errors, as the vision-extracted kinematic data was used for training both SK and AB+SK models. Considering that we utilized only the right side view camera, the observed errors are likely caused by occlusion effects as outlined in [35], hindering accuratadrie detection and introducing noise into the joint kinematics data.

In future work, we aim to replace our monocular camera setup with a multiple camera system to implement a triangulation method, mitigating the occlusion effect from single-side views. We will also examine the estimation accuracy across different vertical camera positions, as well as horizontal camera positions we already tested in (Table I). This analysis will incorporate newly released HPE models, such as Sapiens [36]. Although one of the reasons we used one

of motion capture cameras was to easily synchronize with the ground-truth data, we also plan to build a smartphone camera-based framework for general use. Furthermore, we will expand the size of our AB dataset to enhance the pre-trained model's ability to generalize across diverse gait patterns from different subjects, creating a more robust baseline model that can be further adapted to irregular gait patterns. Since real pathological gaits exhibit additional unique characteristics, we plan to investigate their applicability to real gait impairments. Lastly, we will implement our wearable sensor-based joint kinematics estimation framework for enhancing robotic hip exoskeleton control in real time.

V. Conclusion

We developed a lower-limb joint kinematics estimation framework using a wearable IMU sensor-based TCN model. We adapted this model using computer vision-based HPE. With transfer learning, using a dataset of only 1–2 gait cycles of a new gait pattern, the adapted estimation model achieved improvements of 9.7% and 19.9% in RMSE compared to the models trained solely on the AB dataset and the SK dataset, respectively. This pipeline holds promise as a real-time joint kinematics estimation tool that can be quickly adapted to new gait patterns without requiring a specialized setup.

***Abstract*—There is a need to develop effective physical therapy interventions to enhance walking balance in ambulatory people with chronic stroke (PwCS). Interventions that amplify self-generated movements may accelerate motor learning by enhancing sensorimotor feedback. Here, we applied this concept to walking balance. Specifically, during treadmill walking we used a cable-driven robot to apply lateral forces to the pelvis of 19 PwCS that were proportional in magnitude to real-time lateral center of mass (COM) velocity. The resulting movement amplification (MA) field increased the challenge to control lateral motion of the COM. We found that following 10-min of walking in the MA field, PwCS responded by adopting gait patterns that significantly increased control of COM dynamics (reduced lateral excursion and peak lateral velocity) and resulted in moderate but non-significant improvements in symmetry when compared to walking in a Null (no applied forces) field. These findings motivate further investigation to explore if extended walking practice performed in an MA field can improve walking balance in PwCS.**

***Index Terms*—stroke, biomechanics, walking balance, robotics, force-field**

I. Introduction

Most people with chronic stroke (PwCS) exhibit significant balance deficits that contribute to a multitude of gait impairments [1], [2] and alarmingly low levels of physical activity, including walking [3], [4]. Given the strong association between balance and functional independence [5], there is broad recognition that rehabilitation interventions should directly target walking balance [3], [6]. Thus, there is a compelling need to develop effective interventions to enhance walking balance in ambulatory PwCS.

Current clinical practice guidelines for PwCS recommend practicing walking tasks at moderate to high cardiovascular intensity to improve walking speed and distance [7]. However, interventions engaging in only forward walking have not been found to improve walking balance [8]. Indeed, among twelve gait and balance interventions (e.g., dual-task balance and gait training, treadmill training with external stimulation, etc.) a recent meta-analysis found that simple treadmill training was the least effective modality for improving functional balance in people with stroke [9]. We believe that improvements in walking balance during treadmill training can be substantially enhanced with the addition of external forces applied to the body that directly challenge walking balance, augment balance-related feedback, and encourage practice of movement strategies that control whole body center-of-mass (COM) dynamics. To address this urgent need to design effective strategies for improving walking balance in PwCS, we have developed a simple robotic tool to create and incorporate these balance-challenging training elements into treadmill based gait-training interventions.

Specifically, we use the Agility Trainer, a custom-built, cable-driven robot, to amplify a participant's movement by applying lateral forces to the pelvis proportional in magnitude and in the same direction as the participant's real-time lateral velocity [10]–[12]. The resulting Movement Amplification (MA) field increases the difficulty to maintain lateral balance during a straight walking trajectory. The effect is that when a person moves to the right, the robot simultaneously pulls them to the right, amplifying their motion by the velocity field gain. This setup has several important components for improving walking balance. First, the MA field is designed to challenge medio-lateral motion because the requirements of the nervous system to control lateral balance during walking are considerable in comparison to sagittal plane balance, which benefit from stabilizing body segment mechanics [13]. This is

This study was funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (#1 R21HD112813), and the American Heart Association (#24POST1195671).

highly relevant for PwCS where the challenges of controlling lateral walking balance are well established [14]. Second, because the ability to control COM dynamics (i.e., position and velocity) is critical for maintaining walking balance [15]–[17], the MA field is designed to increase these demands by applying forces that directly amplify lateral COM velocity. Finally, our motivation for creating the MA field is based on research suggesting that interventions that amplify self-generated movements (e.g., error augmentation or movement amplification) will enhance sensorimotor feedback [18]. Thus, amplification may heighten perception and enable PwCS to detect even small movement errors that may otherwise be neglected due to sensory impairments. While movement amplification approaches have shown promise for retraining reaching movements in PwCS [18], [19], this approach has not yet been used to improve walking balance in PwCS.

The purpose of the current experiment was twofold. First, we sought to confirm that in PwCS the MA field would reduce dynamic stability during walking as previously observed in other populations [11], [20]. As the MA field specifically challenges control of lateral COM velocity, we estimated gait stability based on the maximum Lyapunov exponent of lateral COM velocity, a measure that has been suggested to estimate probability of falling [21]. Second, we sought to quantify if and how PwCS change their gait dynamics (COM position and velocity, stepping characteristics, and the relationship between the two) in response to walking in the MA field. If PwCS do not modify their gait when placed in the MA field, the effect would be greater lateral COM peak-to-peak excursions and peak lateral velocity. However, based on our observations in neurologically-intact adults [11], we hypothesized that, with practice in the MA, PwCS would adapt their gait patterns (shorter and wider steps) that in turn would reduce the magnitude of their lateral COM dynamics (excursion and peak lateral speed) when compared to walking in a Null field. If this hypothesis is supported, it would suggest that exposure to a challenging MA field can encourage PwCS to adopt locomotor patterns that, with sufficient practice, could be beneficial for improving the ability to control COM dynamics, a critical component of walking balance.

II. Methods

The Northwestern University Institutional Review Board approved the study protocol. All participants provided informed written consent. Twenty ambulatory individuals (5 females, age: 63 ± 8 years) with stroke related hemiparesis enrolled in the study (9 with right-sided hemiparesis, Stroke chronicity: 9 ± 7 years). Participants had Chedoke-McMaster Stroke Assessment (1-7 scale for the level of stroke-related motor impairment, with 7 indicating performance at the level of a neurologically-intact adult) scores of 4 ± 0.6 and 3 ± 0.9 for the leg and foot, respectively. Inclusion criteria included the ability to walk 10 meters without manual assistance or an assistive device other than a passive ankle-foot orthosis (AFO). Exclusion criteria included cognitive impairment (score $\leq 22/30$ on the Montreal Cognitive Assessment scale) and/or presence of aphasia (score $\leq 71/100$ on the Mississippi Aphasia Screening Test).

A. Experimental Setup

Kinematic data was recorded as participants walked on an oversized treadmill (TuffTread, Willis, TX) in either a Null (no forces applied to the waist) or MA field. A 12-camera motion capture system was used, operating at 100 Hz (Qualisys, Gothenburg Sweden), to record 3D kinematic data from 19 reflective markers placed on the pelvis and feet.

For safety, participants wore a trunk harness attached to a passive overhead support (ZeroG, Aretech, USA). Additionally, a physical therapist and a study team member positioned on either side of the participant provided non-contact guard (or manual assistance in the event of a loss of balance) during treadmill walking.

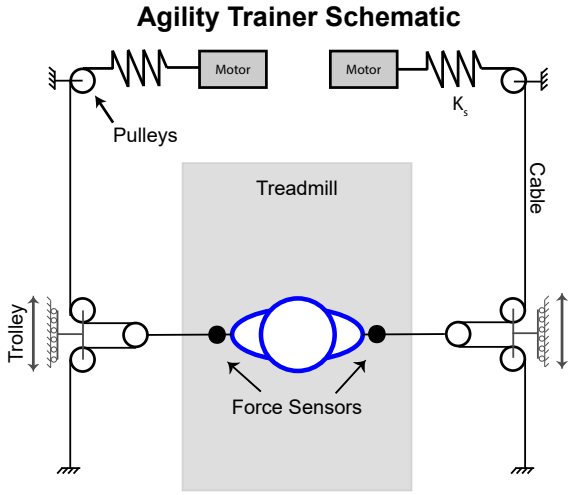

Fig. 1. The Agility Trainer is a cable-driven robotic device used to apply lateral forces to a participant's pelvis [10]. The device consists of two independent series elastic actuators (a linear motor coupled with a spring, $K_s = 0.32N/m$) and a cable transmission system which connects each actuator to either side of a pelvic harness inline with a force sensor to complete the feedback loop. A trolley system allows free fore-aft motion and minimal restriction of normal lateral motion.

The Agility Trainer was used to generate the MA field by applying lateral forces to the pelvis during treadmill walking [10], [11]. The Agility Trainer can generate forces large enough to substantially accelerate the COM of a person (up to 15% bodyweight), minimally restrict normal walking movements, precisely control an unstable field (MA) and operate at bandwidths greater than the frequency of lateral COM movements during walking [10] (Fig. 1). Here, we set the MA field gain to -45 $N\frac{s}{m}$. This field gain was used in a prior study with neurologically-intact adults [11]. A constant field gain was used for all participants to minimize variables. Prior to this study, each participant completed a feasibility session that included a brief exposure (12 min) to the MA field to confirm that they could successfully walk in and tolerate the field gain. The selected field gain was found to be challenging but tolerable for all PwCS enrolled in the current

study. Applied forces from each cable were capped at 100 N for safety.

B. Experimental Protocol

During two walking sessions, spaced a week apart to limit possible carryover effect, participants walked either in the Null or MA field. The order of these conditions (**Null** or **MA**) was randomized across participants. Within each session, participants performed five 2-min bouts of treadmill walking at their preferred speed. The walking bouts were separated by rest breaks and included a mandatory sitting break after the second and fourth bout to reduce potential fatigue. During treadmill walking, participants did not use assistive devices (canes, walkers, handrails) except for any habitually worn passive AFO. Participants were instructed to walk in the manner they felt most comfortable. During MA field sessions, participants were informed that the field would amplify their side-to-side movements and were allowed to interact with the field while standing before the treadmill was started for data collection.

C. Data Analysis

We analyzed the first (**Early**) and last **(Late**) 2-min walking bout of each session. We processed kinematic data in Qualisys Track Manager to label markers, then used Visual3D (HAS-Motion, Kingston, Ontario) to identify gait events, gap-fill and low-pass filter (Butterworth, 6 Hz cut-off frequency) marker data, and generate the COM trajectory from a pelvic model [22]. We found the velocity of the COM (VCOM) by taking the derivative of filtered COM position (same filter as marker data). We used MATLAB (Mathworks, Natick, MA) to compute all metrics.

1) Stability: As an estimate of local, dynamic stability, we calculated the short-term maximum Lyapunov exponent (λ_s) of the lateral VCOM over the last 100 steps of the Early and Late walking bout in the respective field. This measure quantifies the average logarithmic rate of divergence of a system and has shown predictive validity in walking when divergence is considered with respect to the gait cycle [21]. The slope of the mean log of the divergence curves in state space for strides 0-0.5 is reported here as detailed in our prior work [11]. Higher λ_s values correlate with faster divergence from a steady state trajectory and therefore lower local stability.

2) COM Dynamics & Step Characteristics: Parameters occurring every gait cycle including lateral COM excursion the peak-to-peak displacement of COM trajectory per stride (COMexc), step width and length, and the absolute value of VCOM peaks in both directions to yield peak COM speed were calculated. We report the average of peak COM speeds as this is informative of the velocity-field interactions experienced per person, given the set field gain. The mean and standard deviation was found for each parameter during the Early and Late walking bouts.

The spatial, medio-lateral margin of stability (MOS) was evaluated as a metric of coordination between the base of support (BOS), defined as the 5th metatarsal marker on each foot during stance phase, and the COM state (1).

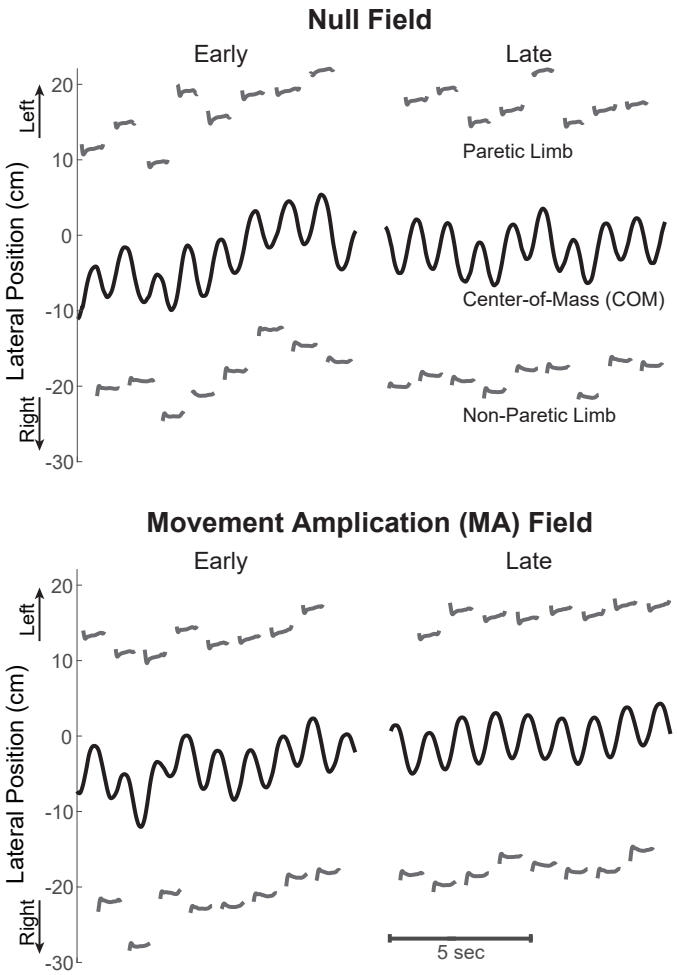

Fig. 2. The COM trajectory and marker data from the 5th metatarsal of each foot (base-of-support (BOS)) during foot contact (heel strike to toe off) for a representative participant with left sided weakness during the first 10-sec of walking in each condition.

$$MOS = BOS - XCOM \tag{1}$$

Where XCOM is the extrapolated COM derived from the COM position and the VCOM divided by the pendulum eigenfrequency [15]. The minimum MOS per step was found to identify the most unstable point within that step. We then found the mean (μ) and the standard deviation (σ) of these values across the Early and Late walking bouts for each condition to evaluate the overall effect of field on instantaneous stability and how consistent this effect was, respectively.

The average MOS across a walking session may have limited value when asymmetric gait is present [23]; therefore, we also investigate the asymmetry of MOS between the paretic and non-paretic limbs. As a measure of balance asymmetry, the MOS per side was evaluated to quantify which side was dominant [24].

$$Asym.MOS = \frac{(MOS_p - MOS_{np})}{(MOS_p + MOS_{np})} \tag{2}$$

Where MOS_p is the $\mu(MOS)$ on the paretic side and MOS_{np} is the $\mu(MOS)$ on the non-paretic side, yielding a value on a scale from -1 to 1 assuming there are no negative $\mu(MOS)$. A positive result indicates greater MOS on the paretic side, negative indicates greater MOS on the non-paretic side, and 0 represents equal MOS on both limbs.

D. Statistics

Paired t-tests were used to check for differences between conditions during the Early walking bout to see if there was an initial effect of field. Then the delta (Δ) of the above mentioned biomechanical measures from Early to Late field was calculated to identify any adaptation from 10-min of walking in the respective field, while accounting for the effect of fatigue. A mixed ANOVA was used with a between-subjects factor of Sequence (order of field exposure), a within-subjects factor of Field (MA or Null), and an Interaction factor between Sequence and Field to compare the effect of each field and test for any bias of exposure order. Significance was set at $p < 0.05$ for all tests and comparisons and python was used to perform them.

III. Results

Nineteen participants completed both sessions without requiring handheld assistance and are reported here. Mean preferred walking speed during the 2-min bouts was $0.45 \pm 0.2(m/s)$. Each participant used the same speed for both sessions. Fig. 2 illustrates the effect of walking in each field for a representative participant.

A significant difference was found during Early walking between field conditions for the λ_s of VCOM, with a higher exponent in the MA field (Table I). No significant differences in Δ λ_s were found between field conditions (Fig. 3).

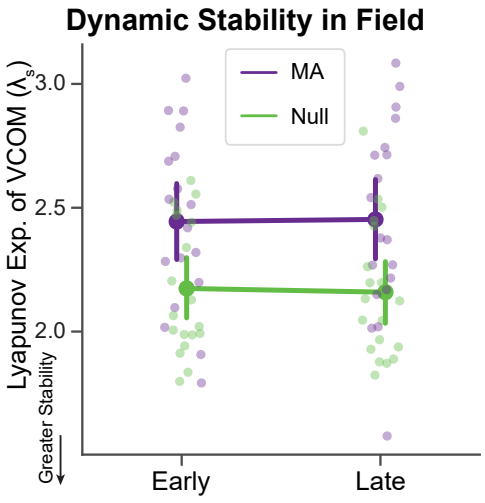

Fig. 3. The rate of divergence of the lateral component of the VCOM as an estimate of local, dynamic stability shows that the MA field was significantly challenging dynamic stability. Note that lower values correspond to a greater metric of stability.

A significant difference was found during Early walking between field conditions for COMexc, with a smaller COMexc in the MA field (Table I). The lateral COMexc increased Early to Late in both fields and no significant differences in Δ COMexc were found between field conditions (Fig. 4).

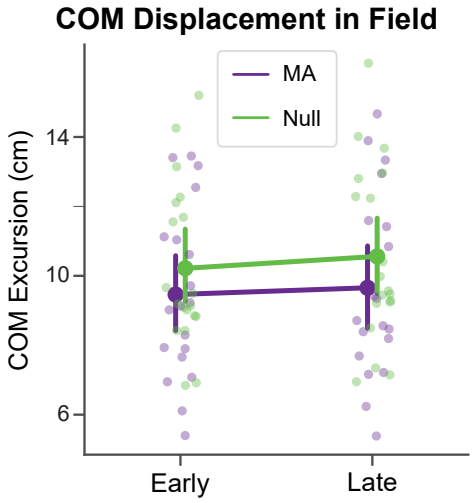

Fig. 4. The lateral displacement of the COM was evaluated per stride and the total excursion averaged across the Early and Late 2-min bouts.

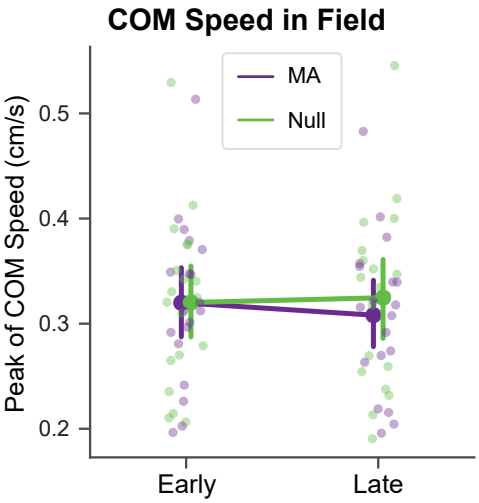

Fig. 5. Peak lateral speed of COM evaluated per stride and averaged across the Early and Late 2-min bout.

No significant differences were found during Early walking between field conditions for the peak of the lateral COM speed (Table I). The peak COM speed decreased after walking in the MA field, and the Δ was significantly different between the field conditions (Fig. 5).

A significant difference was found during Early walking between field conditions for the step length, with shorter steps taken in the MA field. Step width was also slightly wider in the MA field but not significantly (Table I). The Δ step length and step width were not significantly different between field conditions. There was an effect of Sequence for step length but when post-hoc t-tests were performed between the field subgroups by order of exposure, no differences were found.

A significant difference was found during Early walking

TABLE I
SUMMARY AND STATISTICS

Variable	Field	Early Field Mean (Std Dev)	t-test t	t-test p-value	Δ in Field Mean (Std Dev)	Mixed ANOVA for Δ in Field	F(1,17)	p-value

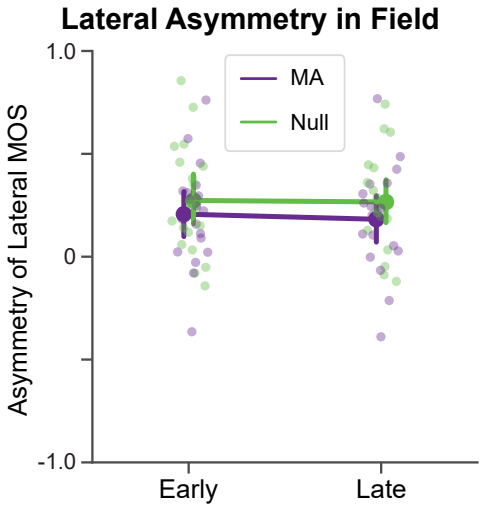

Fig. 6. The lateral margin of stability (MOS) was evaluated per side for symmetry. The Asymmetry of MOS was defined on a scale from 1 to -1 with 0 being equal contributions and a positive value indicating greater magnitude of MOS on the paretic side.

between field conditions for the μ(MOS), with a higher MOS in the MA field (Table I). No significant differences in $\Delta\mu$(MOS) were found between field conditions. No significant differences were found during Early walking between field conditions for the σ(MOS) or the Δ between field conditions (Table I).

No significant differences were found during Early walking between field conditions for the Asymmetry of MOS (Table I). Both groups tended to be more symmetric Late with a greater but not statistically significant improvement in the MA field (Fig. 6). There were no negative $\mu(MOS)$s in the dataset, so the assumptions for the Asym. MOS in (2) held.

IV. DISCUSSION

Our first hypothesis was supported—PwCS did show reduced dynamic stability in the MA field, as evidenced by the greater λ_s of medio-lateral VCOM during walking. This is a positive indication that the MA field can successfully challenge lateral walking balance for PwCS and warrants further exploration of MA as a gait training tool to specifically and continuously challenge lateral balance during walking.

Our secondary goal, to quantify if and how PwCS change their gait dynamics when presented with the challenge of walking in a MA field, also yielded interesting results. A smaller COMexc and greater μ(MOS)observed Early in the MA field indicates that participants immediately responded by adopting walking patterns that could improve stability. The decrease in peak COM speed in the MA field from Early to Late shows that participants further adapted their gait patterns with practice. This is an interesting change since the COMexc actually increased from Early to Late for both fields, and suggests that the VCOM is being modulated directly. This change in VCOM may be due to the sensorimotor feedback experienced in the MA field.

The initial changes in step characteristics—shorter, slightly wider steps—did not last by the end of the 10-min, which implies that in response to the MA field participants initially modulated their stepping characteristics to counteract the effects of the external forces on their COM dynamics. However, by the Late trials, the stepping characteristics in the MA field returned to those similar to the Null condition, while the COM dynamics did not. This suggests that the primary gait adaptation occurred in the COM velocity alone and that participants were capable of decoupling control of the COM velocity and excursion from stepping characteristics when provided with the sensorimotor feedback in the MA

field. This is a positive indication that PwCS can adapt to the specific balance challenges imposed by the MA field and that the MA field may be helpful for facilitating practice of gait patterns that actively control COM velocity in PwCS.

Finally, though not significant, the improvement of symmetry while in the MA field was seen immediately in the first 2-min of walking and was sustained throughout the whole 10-min, even with possible fatigue. Although there was not a significant change in the symmetry over time, it is possible that extended training in the MA field may result in more symmetrical gait patterns. The greater symmetry may have resulted from attempts to control the VCOM or through the increased sensorimotor feedback provided by the MA field.

V. Conclusions

We found that participants, despite being observably challenged to control their walking balance in the MA field, decreased their COMexc immediately and peak COM speed over time in response to the stimulus of the velocity-driven force field. The changes in the COM dynamics were independent of stepping characteristics and led to modest improvements in symmetry as seen in the Asym MOS. This rapid adaptation indicates that PwCS changed their COM dynamics in response to the MA field in a manner that improved control of lateral COM motion. We postulate that the enhanced sensorimotor feedback created by walking in the balance-challenging MA field may help PwCS to identify small movement errors and adopt anticipatory balance control strategies that improve walking balance and symmetry. Potentially exciting is the decoupling of the COM dynamics from stepping characteristics which allowed participants to minimize interactions with the destabilizing effect of the MA field without adopting inefficient general protective strategies (e.g., wider steps).

Our preliminary data finds that in response to walking in a MA field, PwCS adapt their gait in a manner that improved control of their lateral COM motion. While this study was limited to looking at short-term adaptations within the MA field, the observed enhanced control of COM dynamics motivates future research on the efficacy of extended walking practice in the MA field to improve walking balance in PwCS. Training walking balance of PwCS by amplifying self-generated movements is a departure from current practice and could create effective new clinical interventions.

Abstract—Blood flow restriction (BFR) training, which combines low-intensity resistance exercises with restricted blood flow, is effective in promoting muscle hypertrophy and strength. However, its impact on cortical activity remains largely unexplored, presenting an opportunity to investigate neural mechanisms using brain-computer interfaces (BCIs). Deep learning (DL)-based BCIs, with their large capacity for decoding complex brain signals, offer a promising avenue for such exploration.
This study utilized magnetoencephalography (MEG) to analyze cortical responses in six subjects across three conditions—before, during, and after BFR. After preprocessing steps, such as data standardization and Euclidean-space alignment to optimize performance, the BaseNet architecture was utilized to classify the data. The models were tested using within-subject, cross-subject, and cross-time data splits.
The results revealed classification accuracy well above 90% for individual subjects, indicating that cortical responses to BFR are detectable on a personal level. However, cross-subject models achieved only chance-level accuracy (33%), highlighting significant variability between individuals. Cross-time models showed better performance, with accuracy exceeding 50%. These findings suggest that while BFR elicits distinct cortical activity patterns, these responses are highly individualized, presenting challenges for generalization.

Index Terms—blood flow restriction, brain computer interface, neural variability.

I. Introduction

Blood flow restriction (BFR) training, a technique that combines low-intensity resistance exercises with restricted blood flow, has emerged as a promising method for promoting muscle strength and hypertrophy [1]. Its effects on muscle growth are comparable to those of high-intensity resistance training [2], achieved by partial restriction of arterial inflow and full restriction of venous outflow, which create a hypoxic and acidic environment within the targeted muscles [3]. While substantial research has explored the peripheral adaptations induced by BFR [4], investigations into its neuromuscular effects are more recent [5], and its central mechanisms within the brain remain largely unexplored.
Current understanding suggests that BFR alters sensory input by inhibiting type I and II fibers, which are responsible for transmitting sensory feedback from muscle spindles and Golgi tendon organs. This inhibition leads to a reduction in proprioceptive awareness of the cuffed limb. At the same time, BFR leads to increased activation of type III and IV fibers [6]. As a result, BFR alters the overall sensory information relayed to the central nervous system (CNS). In response, the CNS compensates by enhancing the neural drive along efferent pathways [7] and recruiting higher threshold motor units [5], [6]. However, the precise nature of these alterations in afferent and efferent pathways, particularly whether afferent signals are blocked or negatively modulated, remains uncertain.
This study seeks to address these gaps by investigating the changes in central neural drive during BFR. To achieve this, we employ a deep learning (DL)-based brain-computer interface (BCI). Recent advancements in BCIs and DL offer unique opportunities for such explorations [8], as neural networks excel at uncovering patterns in large and complex datasets that traditional analytical methods may overlook [9]. However, the high amount of noise and information present in MEG and electroencophalography (EEG) can lead to overfitting to the time or subject domain of the training data. To mitigate this limitation, BCI models are typically shallow, encouraging them to capture more generalized

features and avoid domain-specific memorization [10]. This can be in part achieved by integrating convolutional layers within the architecture, as they are able to capture spatial as well as temporal patterns in M/EEG data [11]. Using deep learning, we aim to classify and characterize cortical responses related to BFR training, offering new insights into neural processes that may inform novel rehabilitation strategies and enhance the study of sensorimotor degradation.

II. Methods

The dataset used in this study comprised MEG recordings of six subjects while their left index finger was stimulated under BFR conditions. In this chapter, we describe the MEG recordings and stimulation protocols, followed by the preprocessing pipeline. Additionally we introduce the various train-test splits performed in this study to evaluate the model's generalizability across subjects and recording conditions. Finally, we outline the deep learning model and training procedure used to classify MEG trials based on experimental conditions.

A. Data

Before the measurements, the subjects were informed about the contents and procedures of the experiment by the experimenters, and by reading the information sheet and the privacy notice. The procedures of the study complied with the Declaration of Helsinki and were authorized by the local Ethical Committee of Aalto University, Espoo.

The dataset was acquired at the Aalto Neuroimaging (ANI) Infrastructure (Aalto University, Espoo, Finland) in a 3-layer magnetically shielded room (Imedco AG, Switzerland). They were measured using a 306-channel MEG system (TRIUX neo, Megin Oy, Finland), consisting of 102 magnetometers and 204 gradiometers, recorded at 1000 Hz.

The subjects were stimulated in two distinct forms: electrical (ES) and mechanical (MS). To determine the intensity of the ES the mechanical threshold (MT) and sensory threshold (ST) for the stimulation were measured before MEG acquisition. MT marked muscle contraction onset, while ST identified the point of sensory detection of an electrical impulse. Different types of stimulation were then defined for ES and MS: ES amplitudes were set at 120%, 140%, and 160% of the MT and ST. MS involved motor-driven passive flexion and extension of the index finger in 6s cycles (3s per movement). Each stimulation was performed 50 times in succession.

For evaluation of the cortical response to BFR, the data was acquired before (AP01), during (HP01), and after (AP02) BFR. AP01 is designated as the baseline measurement against which HP01 will be evaluated, while AP02 has been differentiated to ascertain whether the neural drive returns to the baseline or is altered on a short term basis.

With a a single measurement comprisng 50 stimulations, each ES block featuring three (120%, 140%, 160% of MT or ST), and MS block involving two types of stimulation (extension and flexion), the resulting number of trials per condition was 250. Repeating this process across three conditions (AP01, HP01, AP02) under the same threshold produced 750 trials per MT or ST block and 1500 trials per subject. Across six subjects, 9000 trials were available.

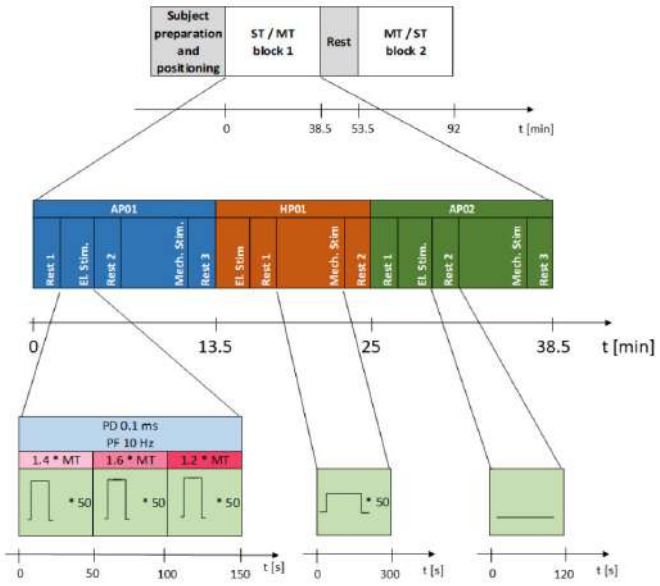

Fig. 1. The experimental protocol, with the lowest level outlining the nature of the different types of stimulation, the middle level detailing how these stimulations are categorized, and the uppermost level presenting the overall protocol framework.. Taken from [12].

1) Preprocessing: In this study, standard MEG preprocessing was employed, starting with a visual inspection for bad channels. During this procedure, peaks in the left hemisphere of the brain were observed, occurring simultaneously with the ES stimulus. Since the right hemisphere innervates the left half of the body, the spatial and temporal attributes of those peaks suggest that they are artifacts of the ES. Therefore those channels were discarded, reducing the number of channels to 288.

This was followed by spatiotemporal signal-space-separation (tSSS). Signal-space separation (SSS) is a method that decomposes the magnetic field measurements into two independent subspaces: one for sources inside the sensor helmet (such as brain signals) and another for external interference. This is accomplished by modeling the magnetic fields with spherical harmonics, allowing the method to mathematically separate the contributions based on their spatial characteristics without relying on previously recorded data. Spatiotemporal SSS (tSSS) extends this approach by identifying and removing temporal components that are common to both the internal

and external subspaces—particularly those arising from sources close to the sensors—thereby preserving the uncorrelated brain signals while further reducing artifacts and interference [13], [14].
Following this step, is the bandpass filtering of 1 to 40Hz. The lower cut-off frequency is used to prevent low-frequency drifts, whereas the higher frequency is chosen as the signals of interest lie within the theta (4 to 8Hz), alpha (8 to 12Hz), and beta (12 to 30Hz) frequency bands, rendering 40Hz cut-off sufficient.
Prior to preparing the data for interpretation by the model, Independent Component Analysis (ICA), in particular the FastICA algorithm, is employed. The goal is to remove artifacts not adressed by previous filtering methods. Once the MEG signal is decomposed, each component is compared against sumultaneaously recorded electrooculography (EOG) and electrocardiography (ECG) signals (eye blinking and heartbeat). Components exhibiting a correlation above a certain threshold are omitted during the reconstruction of the MEG signal [15].
Following the preprocessing steps, the data was scaled. Two distinct approaches were employed for this: standardization, as has been done with similar data for DL-models [16], and Euclidean-space alignment [17].
Standardizing (STA) the data effectively centers the mean at zero with a standard deviation of one, which improves both the convergence and training speed of the training process [18]. This process ensures that all input features are on a similar scale, which prevents features with larger magnitudes (such as gradiometer readings) from dominating the optimization process. In the case of MEG data, this is applied to each channel individually, normalizing the variability across sensors.
The objective of Euclidean-space (EA) alignment is to enhance the similarity between the data distributions of subjects from disparate cohorts, thereby augmenting the model's capacity to generalize to novel subjects. This is achieved through the initial estimation of a reference matrix $\bar{R}$,

$$\bar{R} = \frac{1}{n}\sum_{i=1}^{n} X_i X_i^T, \tag{1}$$

where $X_i \in \mathbb{R}^{C\times T}$ denotes the i^{th} trial of a subject. This is, in effect, an estimation of the covariance matrices for each trial, which are then averaged for each subject. Thereafter, the alignment of all trials of that subject can be performed:

$$\tilde{X}_i = \bar{R}^{\propto 1/2} X_i. \tag{2}$$

The statistics for both methods—namely, the mean, standard deviation, and reference matrix—were calculated separately for each subject. For the within-subject and cross-recording splits, where a subject's data appears in both training and test sets of a model, statistics must be computed exclusively from the training set of the subject to prevent data leakage. These calculated statistics are then applied to all of the subject's data. In the cross-subject split, each subject's data is entirely in either the training or test set, i.e., no information of the test-subject's data is known to the models during training. Consequently, all of a subject's trials can be used for computing their statistics and standardizing or aligning their data.

2) Data Splits: The following section will provide a detailed explanation of the data splits conducted in this study.

a) Within-Subject: In order to assess the models' general ability to learn and classify the conditions for each subject, several models were trained on the data of one subject each. The data was divided into two distinct sets: a training set and a test set. Randomly selected trials from all measurements were allocated to either the training set or the test set, with a distribution of 80% and 20%, respectively. To quantify the effect of temporal autocorrelation, i.e., the similarity of proximal M/EEG trials independent of stimulation type [19], a non-random split was tested as well. This yielded no difference in accuracy.
Overall, six models were trained on within-subject data split, each of which was trained on 1200 trials and tested on the remaining 300 trials of that subject. This process was repeated for both STA and EA data, with each model trained and tested once. In subsequent chapters, these models will be referenced as WS-EA/STA.

b) Cross Subject Models: In evaluating the model's capacity to generalise the learned features for the classification of AP01, HP01, and AP02, and to apply those to an unseen subject, six models were trained. In this instance, each model was trained on five subjects and tested on the remaining one. The data pertaining to the training subjects was divided into three distinct sets: training, validation, and early stopping validation. The validation set was employed to supervise the models' performance on the known subjects using trials not available during training. The training set constituted 75% of the total number of trials in the training data, the validation set constituted 15%, and the early stopping validation set constituted 10%. The early stopping technique was employed to prevent the model from exhibiting overfitting tendencies with respect to the training data. The data were distributed once more randomly across the sets in accordance with the aforementioned method. This resulted in the formation of sets comprising 5625, 1125, and 750 trials, respectively, with the test set containing the 1500 trials of the subject that was excluded from the training process. The models were trained on EA and STA data and henceforth will be referred to as CS-EA/STA. ´

c) Cross Recording Models: In order to assess the model's capacity to generalise across temporal domains, namely the same subject at a subsequent point in time, a training and test split by recording was conducted. This entailed training the models on all subjects' MT data and testing them on all ST data, and vice versa. This process was repeated for both EA and STA data, resulting in the creation of four models in total. The training data was once more divided at random into a training set comprising 80% of the data and a validation set comprising the remaining 20%. This resulted in a total of 3600, 900, and 4500 trials for the training, validation, and test sets, respectively. The cross-recording models will be designated as CR-MT/ST-EA/STA, with the threshold in question representing the training data of the model.

B. Deep Learning Model

For the task at hand, the BaseNet model [10] was employed, a neural network specifically developed for motor imagery (MI) tasks using EEG data. The model features a typical DL-BCI stem block, which includes a temporal and spatial filter implemented through convolutional layers [20]. Additionally, BaseNet incorporates batch normalization within its architecture, ensuring consistent learning and training across different batches and subjects [21]. The model also uses average pooling and 1×1 convolutional layers, which help reduce the number of features and learnable parameters, allowing the network to either perform feature reduction or enable learnable transformations in a more flexible way. Since BaseNet is a shallow neural network, with this input it comprised less than 10 000 learnable parameters.

C. Training

The classification task in this study was to discriminate between the BFR conditions for a MEG trial, defining the labels as AP01, HP01, and AP02. Subsequently, the input of the models was one preprocessed, and either standardized or euclidean-space aligned, MEG trial $X_i \in \mathbb{R}^{C \times T}$. Here C denotes the the number of channels (288) and T the number of samples per trial. Since the data was sampled at 1000Hz and epoched with -0.2 and 0.8s from the point of stimulation t_0, T was equal to 801.

III. Results

The within-subject mean accuracies and their standard deviation is shown in Table I. Whilst STA-trained models achieve a high accuracy, it is surpassed by EA-trained models reaching 99.9% accuracy. The discrepancy between the accuracies of both data types can be attributed to the methodology employed. As discussed earlier, standardization ensures consistent and efficient backpropagation during training. In contrast, EA enhances this process by aligning individual trials to a subject's reference state, further optimizing the learning process. Although such remarkably high accuracy, especially with a limited amount of training data, may suggest potential overfitting [22], this risk is mitigated by the reduced complexity of the shallow deep learning model and the incorporation of regularization techniques, such as dropout [23]. To evaluate whether the models are learning recording-specific features or are capable of generalizing across different sessions for the same subject, further testing is required using data from separate recordings of the same individual.

TABLE I
Mean and Standard Deviation of Singular Subject Models' Accuracies

Model		Test
Within-Subject	EA	99.9 ± 0.1
	STA	85.2 ± 13.1

The validation accuracies of the cross-subject- and cross-recording-models facilitate a similar accuracy as the singular subject models, as can be seen in Table II, exceeding 90%. However, the test accuracy drops significantly when the model is evaluated on domains, time frames or subjects, that were excluded during training. Notably, models tested on unseen subjects do not surpass 40%, staying near the guessing accuracy of 33%. In contrast, the CR accuracy reaches approximately 50%.

TABLE II
Mean and Standard Deviation of Cross Domain Models' Accuracies

Model		Validation	Test
Cross Subject	EA	99.8 ± 0.2	35.9 ± 8.0
	STA	88.6 ± 2.4	39.7 ± 10.6
Cross Recording	EA	99.9 ± 0.0	45.9 ± 20.9
	STA	91.8 ± 1.8	51.3 ± 16.9

The difference in the model's performance between an unseen subject and a different recording of the same subject suggests that the model is learning subject-specific features rather than features relevant to BFR conditions that are consistent across subjects.
This line of reasoning is further supported by recent research highlighting the general flaw in BCI-NNs to learn domain specific patterns [24]. However, visualizing the features learned by the models—exemplified in Fig. 2 for the CS-STA/EA-4 models—provides an additional perspective. These features, extracted as the 96-dimensional output from the second-to-last layer of the BaseNet, were analyzed using t-SNE dimensionality reduction [25], where each dot represents a trial. The visualization reveals clear subject-specific clustering within the broader clusters of BFR conditions. Notably, the extent of subject clustering varies across subjects and conditions, but certain subjects, such as subject 6, consistently occupy specific regions within the clusters.

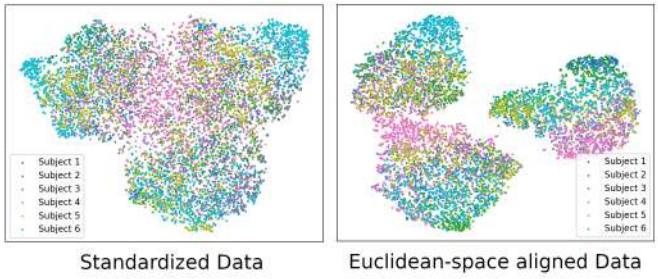

Fig. 2. Feature space of a Cross-Subject model trained on standardized and Euclidean-space aligned data, where subject 4 was left out. The 96 dimensional features were reduced to two dimensions using t-SNE, with every point representing a trial.

While EA-trained models tend to perform worse than STA models on the test data, they demonstrate a clearer distinction between conditions on the known domains. One possible explanation for their poorer performance is the pronounced separation of test trials based on features learned during training. The difference in clustering can be seen in Fig. 3, where all trials are visualized, but the clusters of the conditions are separated more clearly. This pronounced separation of features learned during training likely contributes to the poorer test performance of the EA models, as these features may not generalize well to unseen data. In contrast, STA models show greater overlap in the clustering of label features, which can increase the likelihood of "lucky guesses" by relying on less distinct but more generalized feature representations. While Euclidean-space alignment does not enhance overall performance on unseen domains, its ability to highlight clearer feature separation provides valuable insights into the characteristics the models rely on for classification tasks.

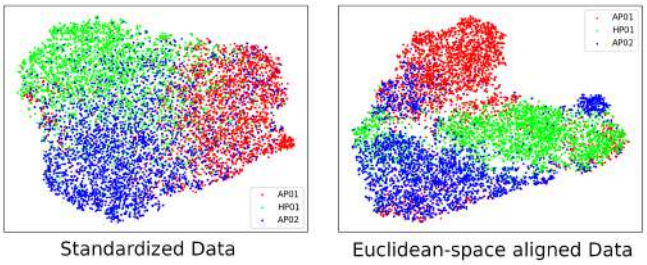

Fig. 3. The feature space of the CR-ST-EA/STA models for all available data, which the models were trained and tested on. The 96 dimensional features were reduced to two dimensions using t-SNE, with every point representing a trial.

Since the CS-models only achieve the guessing accuracy of 33%, a deeper investigation of the confusion for the test data will likely not yield concise insight and will therefore not be discussed further. But the CR models, with their accuracies around 50% may yield information on the nature of the cortical responses. For this purpose, the confusion matrices of the CR-MT/ST-EA models are displayed in Fig. 4. For both, the classification of HP01 seemed to be the most difficult, with a high confusion for AP02. Additionally, for CRT-MT-EA AP01 gets confused with AP02 to a similar extent, same for the AP02 condition with HP01. CR-ST-EA model on the other hand achieves less confusion for both those cases and the wrong classification for AP01 and AP02 are roughly equally distributed between the remaining conditions.

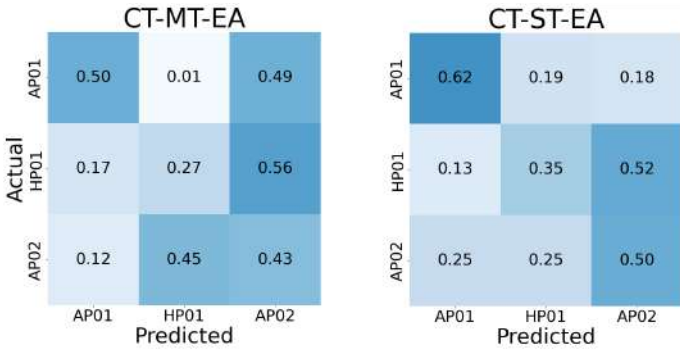

Fig. 4. The confusion matrices of the CS-MT/ST-EA models on their respective test sets. I.e., for the CT-MT-EA model its confusion of the conditions of the ST-data is displayed and vice versa.

IV. Discussion

The models exhibited high classification accuracy when evaluated on within-subject data. Preprocessing with the EA method significantly enhanced model performance, consistently achieving well above 95% accuracy. This preprocessing approach facilitated faster training convergence, effectively highlighted peaks in cortical responses, and improved the model's ability to distinguish between experimental conditions.

However, cross-domain testing, particularly across subjects, revealed significant limitations. Models frequently seemed to prioritize time-specific or subject-specific features rather than cortical responses that differentiated across domains.

The average test accuracy for CS models was below 40%, with substantial variability across subjects in cortical responses. This inconsistency highlights the difficulty of generalizing features across individuals.

The generalization across thresholds yielded more consistent results, with models demonstrating moderate capability to classify conditions across varying stimulation intensities. Nonetheless, performance remained inferior to within-subject classification.

These findings underscore the challenges of extracting generalized cortical features from MEG data, paralleling difficulties observed in similar BCI tasks. Comparable challenges have been reported with EEG data, where achieving high cross-subject generalization accuracy has been notoriously difficult to achieve or replicate [19], [24].

The higher accuracy for the CR-ST-EA model compared to CR-MT-EA can be explained with the increased stimulation intensity of MT, likely yielding more pronounced cortical responses. When training a model on the ST set, i.e., with weaker responses, it likely becomes more sensitive to the data of the MT and is able to better classify the BFR trials.

These findings not only highlight the nuanced effects of stimulation intensity on model performance but also verify the change in cortical responses to stimulations during the BFR conditions. This is further emphasized by the confusion matrices, which reveal a clear separation in cortical responses to BFR. This distinction between conditions supports the supposition of the WS models not overfitting and the possibility of individual models correctly classifying the cortical responses to BFR. The cortical responses do not revert to the baseline of AP01, as the primary confusion is between the conditions HP01 and AP02. This supports the hypothesis [7] of an alteration in the cortical response to BFR within the 40-minute timeframe of the recording. The effect of the alterations of the prior to the subsequent recording block (MT/ST) could not be evaluated in this study, due to the varying stimulation intensities.

The cortical response to BFR shows a high degree of variability across subjects. This variability, both between subjects and within the same subject, has been well-documented in previous research [26], [27]. Therefore the findings discussed above, for BFR to elicit highly individual responses, support this theory. Additionally, the low test accuracies of the cross-domain models can be explained with the "strategic variability", which postulates that the human brain operates in a time-dependent and subject-specific manner [28]. The low test accuracy of the CR models, which perform relatively poorly, although all subjects are known to the model, is a likely result of the time-dependant strategic variability.

The observed limitations in model generalization and the pronounced variability in cortical responses emphasize the need for methodological advancements. A key limitation of this study is the small sample size, which may restrict the model's ability to capture broader neural patterns across subject domains. Expanding datasets to include a larger number of subjects and recordings across multiple sessions could improve model generalizability across domains. Additionally, randomizing stimulation protocols could help reduce temporal autocorrelation [19], encouraging models to prioritize condition-specific features rather than time- or subject-specific patterns.

Overall, this study successfully verified the presence of a cortical response to BFR, along with its highly individualized nature. However, the specific nature of the changes occurring in the afferent pathways could not be clearly identified. Future studies integrating MEG recordings with high-density surface electromyography could offer a more comprehensive understanding of these mechanisms.

V. Conclusion

This study confirms that BFR training elicits measurable cortical responses, which vary significantly between and within subjects. Using MEG data and DL-models, we achieved high accuracy for within-subject classifications but encountered challenges in generalizing across subjects. These findings reflect the individualized nature of neural adaptations to BFR and emphasize the limitations of current deep learning approaches in capturing generalized patterns in brain activity. The achievements made in this study bring us closer to developing tools to better understand the neural processes occuring during BFR training, which may eventually lead to novel rehabilitation strategies and more informed observation of sensorimotor degradation. Future work should focus on expanding datasets, refining preprocessing methods, and diversifying experimental protocols to enhance model generalizability and further explore the neural mechanisms of BFR.

Acknowledgment

Modeling Personalized Difficulty of Rehabilitation Exercises Using Causal Trees

Nathaniel Dennler[1], Zhonghao Shi[1], Uksang Yoo[2], Stefanos Nikolaidis[1], Maja Matarić[1]

***Abstract*—Rehabilitation robots are often used in game-like interactions for rehabilitation to increase a person's motivation to complete rehabilitation exercises. By adjusting exercise difficulty for a specific user throughout the exercise interaction, robots can maximize both the user's rehabilitation outcomes and the their motivation throughout the exercise. Previous approaches have assumed exercises have generic difficulty values that apply to all users equally, however, we identified that stroke survivors have varied and unique perceptions of exercise difficulty. For example, some stroke survivors found reaching vertically more difficult than reaching farther but lower while others found reaching farther more challenging than reaching vertically. In this paper, we formulate a causal tree-based method to calculate exercise difficulty based on the user's performance. We find that this approach accurately models exercise difficulty and provides a readily interpretable model of why that exercise is difficult for both users and caretakers.**

I. Introduction

Stroke is a leading cause of serious long-term disability in the United States [1]. In order to restore mobility, people affected by stroke must engage in long-term neurorehabilitation exercises. Through sustained practice of such exercises, stroke survivors can more easily complete activities of daily living (ADLs), leading to increased quality of life [2]. However, motivation is a major barrier to successfully completing rehabilitation exercises. Rehabilitation robots can increase motivation to perform neurorehabilitation exercises by physically interacting with users and adapting the difficulty of an exercise throughout the exercise session [3]. Adapting exercise difficulty provides an appropriate challenge for the user without making the exercise too difficult to complete.

Previous algorithms that adapted difficulty throughout the exercise have assumed there is only one controllable variable that changes the difficulty of the exercise, such as the distance to reach [4], speed of a virtual competitor [5], or the stiffness of a robot resisting motion [6]. In exercises that reflect daily activities, however, there are many variables that may affect difficulty for a specific user and those variables may vary greatly among people. For example, one stroke survivor may find elbow flexion easier than shoulder flexion, but another may have the opposite experience. To adjust for such differences, clinicians often manually determine exercise difficulty through careful observation of patients [7].

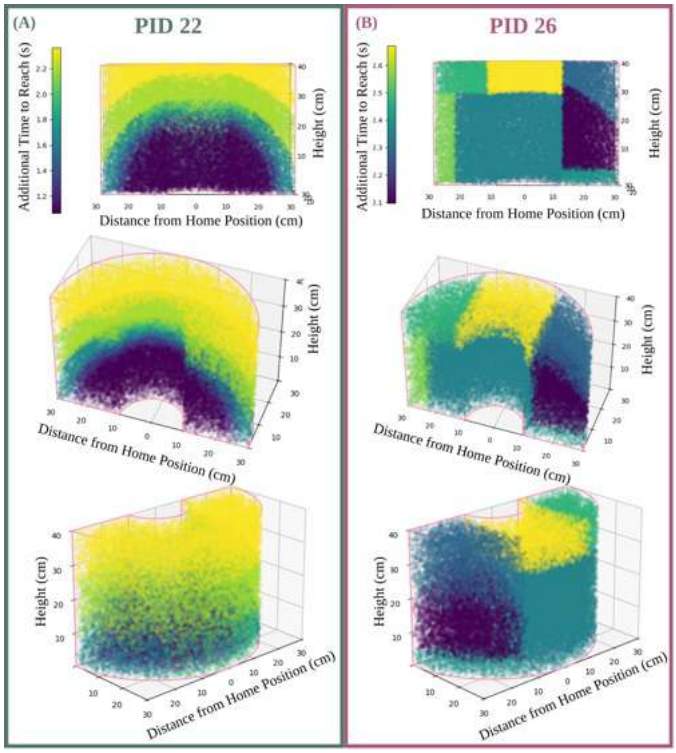

Fig. 1: Multiple views of two users' personalized difficulty scores. Lighter colors indicate regions of higher difficulty, determined by statistically significant increases in individual reach times from baseline values.

Rehabilitation robots have the potential to computationally determine exercise difficulty and subsequently perform these physical exercises. Robots can store these exercise completion data and allow both clinicians and users with limited mobility to track rehabilitation progress. This data collection process provides three key benefits that can aid in rehabilitation. First, robots can provide objective metrics that are difficult for people to accurately measure, and can communicate those objective metrics to support clinicians and stroke survivors in setting personalized goals [8]. Second, robots can encourage exercise by providing instruction and social support while reducing social pressure during the exercise [9]. Finally, robots in homes can provide flexible and consistent access to exercise support for users.

In this work, we present a general algorithm for learning personalized difficulty metrics for rehabilitation exercises from

user data. We designed this algorithm to provide explainable reports for both users and clinicians to understand personal difficulty levels, as shown in Fig. 1. We evaluate the proposed algorithm using data collected from 15 stroke survivors performing a reaching task with a physically assistive robot arm and a socially assistive robot companion.

II. Related Work

Previous work on quantifying exercise difficulty has generally taken one of two approaches. One approach has been to assess the difficulty associated with several specific motor movements in isolation [6], [10], while the other approach has used concepts from control theory to assist people throughout entire tasks as needed [11], [12].

Assessing task difficulty through specific movements in isolation can create a very detailed understanding of personal differences when performing movements such as pinching, elbow flexion, and arm supination [10]. Past work used these assessments to initialize difficulty levels for a variety of rehabilitation games [6]. Assessing individual movements in isolation, however, may not directly transfer to tasks that holistically evaluate combinations of those movements. This is important because activities of daily living involve combinations of many motor functions working together rather than individual motor functions.

In control theory-based approaches, robots adapt in real time to a user to account for the user's level of mobility and other aspects that affect performance, such as fatigue [12]. Often, those approaches rely on exo-skeleton-type assistance to obtain a continuous control signal such as torque exerted by the user [11]. In end-effector rehabilitation robots, however, the control signal is typically more sparse. The decision to increase or decrease difficulty can be made after the task is achieved; for example, after an opponent scores in a game [3] or after the user performs a reaching task [4]. In such approaches, parameters of the exercise are increased by a fixed amount, but that approach does not always correspond to a fixed increase in exercise difficulty.

In this work we aim to augment existing approaches by developing an algorithm that estimates how difficult a task is based on features of that task. Consequently, adaptive rehabilitation exercises can make meaningful difficulty adjustments that correspond to individualized difficulty measurements.

III. Modeling Personalized Difficulty

The Challenge Point Framework (CPF) [13] is a motor learning framework that identifies that there is an optimal level of task difficulty to best acheive task improvement. CPF describes two kinds of task difficulties: *nominal task difficulty* and *functional task difficulty*. *Nominal difficulty* refers to the intrinsic difficulty of a task, regardless of the person performing it. *Functional difficulty* refers to difficulty of a task relative to the skill of the person performing the task.

Quantitatively estimating the difference between nominal difficulty and functional difficulty can be challenging due to the high variance in performance measurements for the same task. To address this measurement variance, we leverage advances from works that estimate heterogeneous treatment effects from patient covariates [14]. Algorithms that estimate treatment effects identify factors that significantly impact outcome measurements, which is highly related to the problem of quantifying task difficulty. At a high level, we learn nominal difficulty by leveraging data collected from neurotypical users completing rehabilitation tasks, and we learn functional difficulty by leveraging the data collected from a specific post-stroke user engaged in the same rehabilitation task.

In order to apply this approach to difficulty estimation, we must make two assumptions. First, we assume that exercises have at least one continuous and measurable outcome, for example the time to complete the exercise, that we will denote as Y. Second, we assume that there are d numerical exercise characteristics that can be modified, e.g., the (x, y, z) location that a user should reach to, that we denote as $X \subset \mathbb{R}^d$. We can use the potential outcomes framework [15] to formalize individual exercise difficulty for task $\vec{x} \in X$ as:

$$\tau(\vec{x}) = \mathbb{E}\left[Y^{(1)} - Y^{(0)} | X = \vec{x}\right] \tag{1}$$

Where $Y^{(1)}$ denotes the outcome measure of a post-stroke user performing the exercise $\vec{x}$ and $Y^{(0)}$ denotes the outcome measure of a neurotypical user performing exercise $\vec{x}$, i.e., the nominal task difficulty. The quantity $\tau(\vec{x})$ denotes the functional difficulty of exercise $\vec{x}$.

Estimating $\tau(\vec{x})$ directly is challenging because Y_i can be noisy due to unmodeled aspects of the task. For example, if the outcome measure is time to completion and a participant is distracted and misses the cue to begin the exercise, they will take longer than usual to reach to the specified (x, y, z) location. Averaging outcome measures of nearby exercises that the user has performed reduces such noise.

Thus, previous works have found that creating a causal decision tree is a robust technique to determine the nearby points in X that should be included when calculating $\tau(\vec{x})$ [14]. Decision trees iteratively partition X by calculating a splitting rule that separates X into two regions, X_{left} and X_{right}. An example splitting rule may be $\vec{x}_z < 0.4m$, where X_{left} consists of all reaching tasks lower than 0.4 meters and X_{right} consists of all reaching tasks higher than 0.4 meters. The specific rule is selected by finding the exercise characteristic that results in the greatest difference in functional difficulty between X_{left} and X_{right}. Formally, the causal tree learns a function $L(\vec{x})$ that assigns each exercise $\vec{x} \in X$ to a unique set L, called a leaf. The estimated functional difficulty for each leaf L is expressed as a difference of averages:

$$\hat{\tau}(\vec{x}) = \frac{1}{|L|} \sum_{\vec{x} \in L} Y^{(1)} - \frac{1}{|L|} \sum_{\vec{x} \in L} Y^{(0)} \tag{2}$$

For more details on the algorithm we used to create the tree, refer to Wagner and Athey [14]. In summary, the causal tree is created using labeled examples from a neurotypical population, $(\vec{x}, Y^{(0)})$ and a single post-stroke participant $(\vec{x}, Y^{(1)})$.

Fig. 2: A post-stroke participant performing a reaching exercise. The Socially Assistive Robot (left) provided instructions and feedback. The robot arm (right) moved the reaching target in front of the user. The user reached to the button 100 times using their more affected side.

The tree can then be used to predict the functional difficulty $Y^{(1)}$ for a given task $\vec{x}$ for the single post-stroke participant.

IV. User Study

To evaluate our technique for estimating individualized user difficulty for a reaching exercise. We collected data from 10 neurotypical participants to use as a baseline value, and we collected data from 15 post-stroke participants to asses how well our approach models individual differences in difficulty. The full user study procedure is detailed by Dennler et al. [9] and only briefly summarized here for context.

A. System Description

Our robotic system that encouraged users to perform reaching exercises, pictured in Fig. 2, consisted of a robot arm and a socially assistive robot (SAR). The robot arm was the Kinova JACO2 assistive arm selected because it is lightweight and has the similar affordances as end-effector robots typically used for other rehabilitative interactions that have been shown to be effective for neurorehabilitation [16]. The SAR was the Lux AI QTRobot that consisted of a screen face running PyLips [17], a 2 degree-of-freedom head, and two 3 degree-of-freedom arms. This SAR platform had previously been validated in motivational rehabilitation games with children with cerebral palsy [18]. The purpose of the SAR was to communicate instructions to the participant, provide positive social reinforcement, and initiate each exercise. This function is similar to previous SAR use in other rehabilitation contexts [18], [19].

We additionally created two low-cost devices to facilitate the reaching exercise. Both were 3D printed and communicated with the robot system via WiFi using an Adafruit Feather M0 development board. One of the devices was a target object that the Kinova arm held in its end-effector for the users to reach for. The target object consisted of a plastic button with an LED light that turned on to indicate the user should press it. The other device was a home position block for the participant to return to after each reaching exercise. The block consisted of two contact sensors that were 2cm in diameter for participants to rest their left and right pointer fingers. The home position block was placed in front of the midline of the participant and the participant's chair was adjusted so that the participant's elbows formed a right angle when resting their hands on the home position block. The chair also used a harness to minimize compensatory trunk movement during the reaching task.

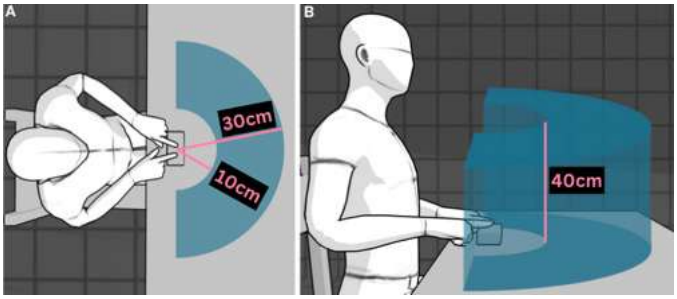

Fig. 3: Participants' workspace. The arm moved the target to different points within the blue-shaded region to estimate difficulty.

B. Procedure

All procedures were approved by the University of Southern California institutional review board under #UP-22-00461. Before beginning the exercise session, the experimenter generated a set of 100 evenly-spaced points in a workspace in front of the home position block, visualized in Fig. 3. This workspace was defined as a region that extends radially from the home position from 10cm to 30cm in a 180 degree arc. The region extended from 0–40cm above the table. The order of these 100 points was then randomized.

Before the participants began the experiment, they signed the consent form. A board-certified physical therapist specializing in neurorehabilitation with more than two years of experience performed the Fugl-Meyer Upper Extremity Motor assessment [20] and the experimenter performed the Mini Mental State Exam [21] to determine eligibility. Participants were eligible to participate if they scored higher than 25 out of 66 on the Fugl-Meyer assessment and scored higher than 25 of 30 on the Mini Mental State Exam.

When the participant began the experiment, the SAR provided instructions about the reaching task to inform the participant what would happen. The robot arm then moved to the first randomized point. The light on the target button turned on, and the SAR cued the person to reach to the button by saying "move", "ok", "reach", or "now". The participant reached to the button with their more affected side. When they pressed the button, the light turned off and the time to reach the button was logged to a file. The SAR periodically provided feedback at random intervals to encourage the participant such as "Awesome job! That was great.", "I'm glad to see that you're working hard.", and "Well done, <Participant's Name>". The participant returned to the home position and

TABLE I: Demographic information of the neurotypical group

	Median	Minimum	Maximum

Ethnicity	4 Asian, 3 Black, 4 Hispanic, 3 White, 1 Mixed-race		

Abbreviations: FM-UE, Fugl-Meyer Upper Extremity;

the robot moved to the next randomized point. This was repeated for all 100 points. The SAR updated the participant on their progress at the 25%, 50%, and 75% completion points by saying statements such as "Three-quarters done! Almost there!".

Each Neurotypical participant completed the procedure once. Each post-stroke participant repeated this procedure up to three times, with at least four days between each consecutive visit. This allowed us to assess the transferability of our approach across sessions.

C. Participants

We first recruited neurotypical participants to model nominal task difficulty and to adjust any system errors before evaluating on our target population of stroke survivors. This practice helps to minimize the chance of any unforeseen risk to marginalized populations, such as post-stroke participants. All neurotypical participants were right-hand dominant; their demographic information is summarized in Table I. The average age of neurotypical participants was 67 $\pm$ 10 years.

We found no major issues with the setup after neurotypical participants completed their exercises. We then recruited post-stroke participants to collect data to model functional task difficulty. All post-stroke participants were premorbidly right-hand dominant. Two participants did not meet the study criteria after screening. Thirteen of the remaining fifteen participants completed all three sessions, and two participants completed two sessions due to scheduling constraints. The average age of post-stroke participants was 57 $\pm$ 11 years; demographic information is summarized in Table II.

V. Results

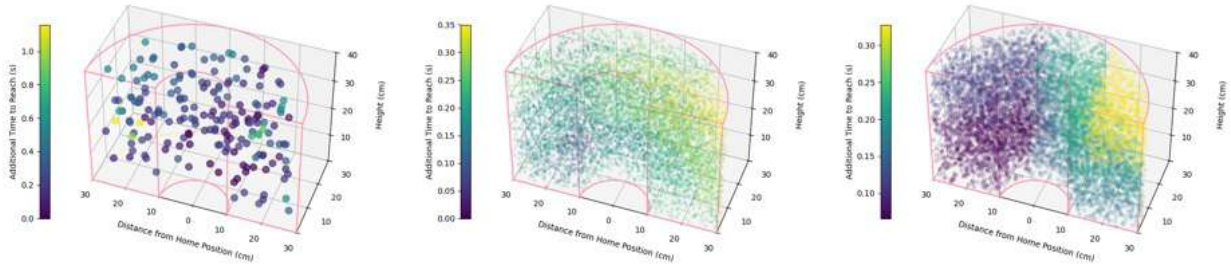
A. Dataset Overview

We collected two datasets: the neurotypical dataset and the post-stroke dataset. Both datasets used time to reach as the outcome measure, Y, and the following numerical exercise characteristics that define each exercise in X: (1) x-position, (2) y-position, (3) z-position, (4) x-position squared—to reflect distance from the participant's midline, (5) distance from home position, and (6) the cue the robot gave to the participant to begin the reaching trial—measured as a categorical variable with four levels.

TABLE III: Hyperparameters used for our experiments.

Model	Hyperparameters
Causal Forest (Ours)	*n_estimators=100, min_samples=5*
XGBoost	n_estimators = 200, learning_rate=0.2, max_depth=7
Random Forest	n_estimators=100, max_depth=100
Neural Network	hidden_sizes=(50, 50), learning_rate=1e-3, max_iter=500
SVM	C=10, gamma=0.0001, kernel='rbf'
k-Nearest Neighbors	n_neighbors=15, weights ='distance', metric='manhattan'
Decision Tree	max_depth=10, min_samples_split=10, min_samples=4

B. Evaluation Procedure



Our Method. We evaluated our method as described in Sec. III. First, we concatenated the training datasets of the participant and the neurotypical population. We created a group-level variable called "condition" and marked entries from the participant as "1" and entries from the neurotypical group as "0". We trained the tree using the econML package [22] with the column "condition" as the treatment variable.

Baselines. The key advantage of using causal trees is that they reduce variance in each leaf by jointly reasoning about the neurotypical and post-stroke exercise variance, i.e., learning both nominal and functional difficulty *simultaneously*. Thus, we evaluate our approach using baselines that attempt to estimate the outcome for each group *separately* and subtract the two estimates, i.e., the baselines were of the form $f_s(\vec{x}) - f_n(\vec{x})$, where f_s is a machine learning model that directly estimates the time to reach for the post-stroke participant ($Y^{(1)}$) and f_n is a machine learning model that estimates the time to reach for all neurotypical participants ($Y^{(0)}$). We evaluated with the following machine learning models as baselines: Decision Tree, Random Forest, Neural Network, Support Vector Machine, k-Nearest Neighbors.

Ground Truth. We are interested in modeling the functional difficulty of the participant, as this difficulty indicates what exercises should be assigned under the Challenge Point Framework. We define the ground truth functional difficulty for a given participant for the exercise $\vec{x}$ in the workspace as the average time of a single post-stroke participant reaches within a ball with a radius of 5cm centered at $\vec{x}$ minus the average time of all neurotypical participant reaches within the same 5cm ball. Because this value includes data from all of the participant reaches, this serves as an accurate measure of the actual time difference between the participant and the neurotypical group.

C. Training Details

We are interested in estimating the personal functional difficulty of a participant. To evaluate this, we aggregated each user's data across visits, so each participant corresponded to a dataset of up to 300 reaches. We split each dataset into 80% training and 20% testing. We used the same neurotypical dataset as the baseline for all participants, reflective of a real-world use case where baseline data are collected prior to system deployment.

(a) PID 33 ground truth. (b) PID 33 XGBoost map of difficulties. (c) PID 33 causal map of difficulties

Fig. 4: Visual comparison of methods. We show the user's ground truth difference from the neurotypical population (a). Independently estimating the stroke survivor and neurotypical data leads to homogenous difficulty estimates over the workspace (b). Using causal trees instead provides distinctive regions of differences in difficulty that are robust to outliers (c).

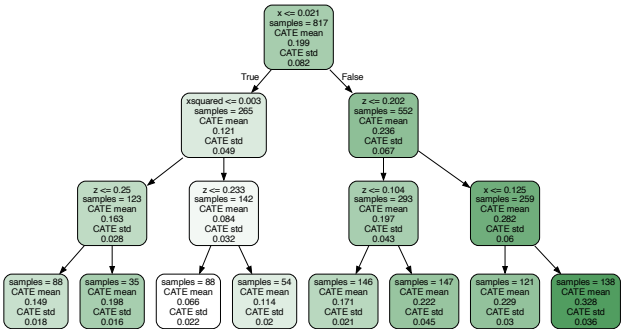


Fig. 5: Tree interpretation of the difficulty map for PID 33.

We randomly selected five participants to tune hyperparameters for all of the algorithms, and used the other participants to evaluate the algorithms. This ensures we do not leak any information from the training set into the testing set. We present the hyperparameters we used for each of the algorithms we tested in Table III. We evaluated across 20 random seeds.

D. Personalized Functional Difficulty Estimation

To evaluate each model, we perform a *within-subject evaluation* and a *aggregated evaluation*. We present our results in Table IV. The *within-subject evaluation* used the mean-squared error (MSE) metric to assess the average difference between predicted and actual functional difficulty, expressed in seconds squared for each participant, we then averaged each participant's MSE to report the final value. We found that causal trees have the lowest MSE of all baseline methods, achieving an MSE of .3 s^2. Our *aggregated evaluation* calculated the r^2 value across all participants' predicted and actual functional difficulty, expressed as a proportion of explained variance to total variance. Causal trees also perform the better than all the baselines we tested, with an r^2 that indicates that 82.6% of the variance in times are explained with this approach. These results indicate that causal trees result in better user models compared to non-causal approaches because they can better reason about uncertainty. We qualitatively compare the causal tree approach and the best performing baseline for PID 33 in Fig. 4, showing that causal trees lead to clearer regions of varied difficulties.

TABLE IV: Personalized functional difficulty results. Arrows indicate the direction of better performance for each metric.

Model	MSE ↓ ($\pm SE$)	agg. r^2 ↑ ($\pm SE$)
Causal Forest (Ours)	**.300 ± .019**	**.826 ± .006**
XGBoost	.324 ± .021	.812 ± .006
Random Forest	.337 ± .021	.805 ± .006
Neural Network	.345 ± .022	.800 ± .006
Support Vector Machine	.488 ± .020	.718 ± .008
k-Nearest Neighbors	.380 ± .024	.780 ± .006
Decision Tree	.745 ± .045	.571 ± .011

E. Visualization of Difficulty

Fig. 4 and Fig. 5 illustrates two techniques to visualize our approach for estimating individual difficulty metrics. In the workspace view (Fig. 4), we show the regions of similar exercise difficulty spatially. These areas are distinctive, which allows clinicians or rehabilitation robots to sample from a particular region in the space to manage difficulty while providing slightly different exercises.

The tree view (Fig. 5) is an explainable diagram that shows how the causal tree splits regions of the workspace based on the user's performance. Each node is colored with the difficulty level; darker colors indicate more difficult exercise regions. Each level of the tree shows different granularities of exercise difficulty. For example, if a rehabilitation specialist only cares about two levels of difficulty, they can examine the second level of the tree, but if they want to reason about eight levels of difficulty, they can examine the fourth level of the tree.

VI. Discussion

This work presented an algorithm that estimates nominal and functional exercise difficulty given a set of exercise parameters and outcome measures. We evaluated this technique on a reaching task performed by both neurotypical participants and post-stroke participants. We found that our method results in more accurate estimations of personalized functional difficulty.

A key benefit of this approach is that it can be applied to other kinds of exercises and outcome measures to estimate difficulty and facilitate adaptation. For example, previous work that adapts tasks based on physiological features [23] or

game performance [3] could leverage this approach to select specific exercises with target difficulty levels. This additionally provides a principled technique for determining difficulty for a variety of tasks, which can encourage the development of new exercises that have various adaptable characteristics, such as in serious games [3].

Limitations. We evaluated our algorithm on a difficulty value based on time to reach. However, there are many metrics that are important for assessing difficulty. For example, movement quality is typically a metric of interest for clinicians and users with limited mobility [2]. Future work may leverage computer vision techniques to predict movement quality as a separate metric and frame personalized functional difficulty modeling as a multi-outcome causal inference problem. Other future work may design metrics that factor both time and quality into a single value to use as an outcome metric.

We additionally only evaluated our difficulty estimation technique on a reaching task. Other tasks may involve other numerical exercise characteristics, such as stiffness for an arm that users push against, which may be more difficult to visualize for users. Future work may evaluate personalized functional difficulty modeling on different tasks, as well as iterate over data visualizations to understand how to effectively communicate these difficulty models to users and clinicians.

Conclusion. We presented a technique for learning individualized models of user difficulty based on causal trees. We found that jointly modeling neurotypical and stroke survivor performance better estimates exercise difficulty compared to separately estimating these quantities, which we evaluated across several stroke survivors. Causal trees provide readily interpretable visualizations that can aid in communication between clinicians and stroke survivors. We hope that this technique opens new directions for adaptable and personalized rehabilitation practices.

***Abstract*—Stroke often causes sensorimotor deficits, impairing hand dexterity and disrupting independence for millions worldwide. While rehabilitation devices leveraging visual and haptic feedback show promise, their effectiveness is limited by a lack of perceptual equity, which is necessary to ensure fair comparisons between sensory modalities. This study refines cross-modal matching protocols to address this gap, enabling unbiased evaluation of multimodal feedback. Using the Hand Articulation and Neurotraining Device (HAND), 12 healthy participants matched visual and haptic stimuli in a structured task. A streamlined protocol, requiring just 2–3 blocks and 3 reference intensities, reduced experimental time fivefold while preserving data integrity. Data were analyzed using linear and exponential models applied to both full and reduced datasets. The results demonstrated consistent participant performance across trials, with higher matching errors at greater stimulus intensities, likely attributable to sensory saturation effects. Furthermore, the study offered practical methodological insights, including the use of reduced data sampling paradigms to enhance experimental efficiency significantly while preserving data integrity. This work advances perceptual equity in multisensory feedback systems, addressing sensory encoding variability to support scalable, personalized therapeutic strategies for stroke recovery.**

I. Introduction

The human hand is fundamental to performing essential activities of daily living, such as grasping, manipulating objects, and executing precise movements. However, hand dexterity is often compromised by neurological conditions like stroke, which impacts over 12.2 million individuals globally each year [1]. The loss of hand functionality not only reduces independence and quality of life but also places significant physical, emotional, and economic burdens on individuals [2].

Efforts to address this challenge have driven the development of innovative strategies to restore hand dexterity post-stroke. Among these approaches, hand rehabilitation devices have shown significant promise by leveraging advancements in robotics, neurorehabilitation, and haptic feedback to promote motor recovery and neural plasticity [3], [4]. Despite these advances, challenges remain in ensuring the accessibility, personalization, and effectiveness of these devices to meet the diverse needs of stroke patients [5].

The Hand Articulation and Neurotraining Device (HAND) was co-developed by Carducci, Xu, and their collaborators [6], [7] to explore individuated finger control and multidimensional co-activation patterns following stroke. Here, we focus on adapting the HAND to study the pinch grasp, a critical fine motor skill required for handling delicate or brittle objects. Pinch grip deficits, often observed in stroke patients, are linked to impairments in sensorimotor processing pathways. These deficits result in diminished tactile and proprioceptive feedback, reducing the ability to accurately modulate grip forces and perform everyday tasks independently [8].

While many existing rehabilitation devices rely heavily on visual feedback for training and recovery [9], evidence suggests that visual feedback alone is insufficient to optimize motor recovery outcomes [10]. Recent studies highlight the potential of integrating multisensory feedback, particularly haptic cues, to promote neural plasticity and enhance functional motor rehabilitation [11]. In this work, we aim to understand how multisensory feedback should best be provided in the HAND by utilizing visual and haptic cues to augment somatosensory pathways. By addressing these gaps, this study contributes to advancing therapeutic strategies and optimizing neurorehabilitation outcomes for stroke patients.

Sensory and motor deficits arising from stroke manifest in diverse and highly individualized ways, resulting in variations in how stimuli are perceived across individuals [10]. To effectively leverage multisensory feedback in rehabilitation, it is crucial for sensorimotor tasks to account for such variability and ensure fairness across modalities. Establishing *perceptual equity* – ensuring that any observed differences in performance between visual and haptic feedback reflect true differences in sensory encoding rather than biases introduced by the experimental setup — is essential for accurately comparing the efficacy of these modalities in healthy participants. This process, known as cross-modal matching, involves calibrating sensory intensities to establish a balance between modalities, enabling fair and unbiased comparisons [12], [13].

Cross-modal matching provides a standardized framework to evaluate the encoding and integration of sensory information across modalities, ensuring perceptual equity by aligning stim-

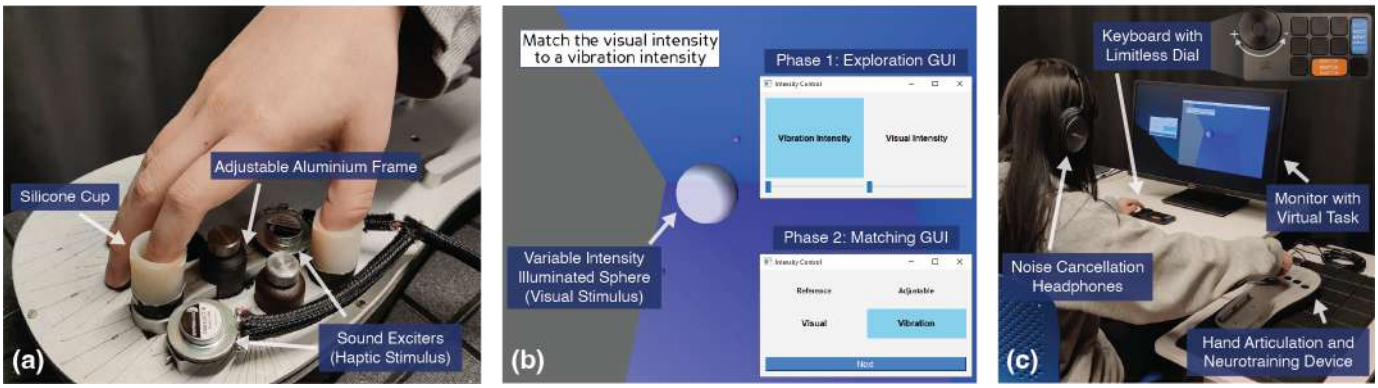

Fig. 1. A modified Hand Articulation and Neurotraining Device (HAND) [6], [7] setup used in this study. (a) Participants interact with the device by placing their fingers in silicone cups mounted on an aluminum frame, with vibrating voice coils providing mechanical haptic stimuli. (b) The virtual task includes a variable-brightness sphere for visual feedback and two user interfaces: the exploration phase, where reference sliders are present, and the matching phase, where no reference sliders are displayed. (c) Wearing noise-canceling headphones, participants use a limitless keyboard dial to adjust the intensity of the presented feedback. Feedback is either haptic – delivered through the HAND or visual – rendered within a virtual task.

ulus intensities. This process is crucial for isolating genuine differences in sensory encoding from biases introduced by experimental setups. However, it can be time-consuming and variable across individuals, which poses a significant challenge, particularly for stroke patients who often experience fatigue during extended tasks [14]. To address these issues, one of the critical aims of this study is to develop pre-experiment cross-modal matching protocols that streamline the process, minimize fatigue, and maintain accuracy. We believe the guidelines derived from this study with healthy individuals will provide a foundational framework for developing efficient, reliable methods in neurorehabilitation research with stroke patients, seamlessly integrating with existing clinical techniques.

II. Methods and Implementation

A. Participants

We evaluated the ability of N=12 individuals with no history of stroke or upper-extremity disabilities (5 males and 7 females; mean age: 25.2±6.1 years; 9 right-handed, 1 left-handed, and 2 ambidextrous) to match the intensity of one feedback modality to an equivalent intensity of another using a custom rehabilitation interface under two distinct feedback conditions. Each participant's handedness was assessed using the Laterality Quotient derived from the administered Edinburgh Handedness Inventory after obtaining their consent [15]. The experiment lasted approximately 60 minutes, and participants were compensated at a rate of $10 per hour. All participants provided informed consent in accordance with a protocol approved by the Johns Hopkins School of Medicine Institutional Review Board (Study #IRB00209185).

B. Experimental Setup

The study utilized a modified Hand Articulation and Neurotraining Device (HAND) built and validated in prior studies [6], [7]. The HAND includes two silicone cups mounted on an aluminum frame, precisely positioned to naturally align with each participant's index finger and thumb, allowing for a customized and comfortable fit as shown in Fig. 1(a). The device is set up for the participants' right hand, and all participants, regardless of handedness, use the same configuration. Each cup is mechanically coupled with a Dayton Audio DAEX13CT-8 Sound Voice Coil, which provides the vibrotactile haptic feedback necessary for the tasks.

The voice coils are driven through a custom amplifier board controlled by a 600 MHz Teensy 4.0 microcontroller. This microcontroller communicates with the primary control software, a Python script running on the computer via a serial interface. The virtual task program transmits 9-bit values to the Teensy, which adjusts the intensity of the voice coil output. Upon receiving these values, the microcontroller employs a MAX521BCPP digital-to-analog converter (Maxim Integrated) and a TPA3122D2 Class-D audio power amplifier (Texas Instruments) to generate 250 Hz sine waves with a variable peak-to-peak voltage range of 0 to 7 V. These signals drive the voice coils, delivering haptic stimuli to participants.

The virtual task consists of a 3D environment featuring a centrally positioned, fixed-size gray sphere illuminated by a distant light source, as shown in Fig. 1(b). The sphere's brightness is adjusted to provide visual stimuli, matching the 9-bit resolution used for the haptic stimuli generated by the voice coils. The virtual environment is created in Python 3.6 and rendered using Panda3D Open Source Framework.

C. Cross-modal Matching Implementation

To ensure fairness and perceptual equity in neurorehabilitation experiments, cross-modal matching is essential for calibrating stimulus intensities across modalities, ensuring that observed differences reflect genuine sensory encoding rather than experimental bias. Building on this principle, we implemented a cross-modal matching task based on the paradigm developed by Pitts et al. [12], [13], constructing participant-specific psychometric curves to align haptic and visual stimulus intensities. The participants were instructed to sit in front of a monitor running the virtual task and rest their

right hand comfortably on the HAND as shown in Fig.1(c). Participants wore noise-canceling headphones that played 60 Hz white noise at a comfortable volume to eliminate potential auditory interference from the voice coils. The experiment was broken into two phases.

1) Intensity Exploration: In the first phase, participants used a graphical user interface (GUI) to explore the full range of vibrotactile and visual stimulus intensities for two minutes. The stimuli were presented continuously, with their intensities adjustable via a limitless dial on an XPPen ACK05 wireless shortcut keyboard (XPPen, China) as shown in Fig. 1(c). Two sliders on the screen indicated stimulus intensity being presented in real time. A clockwise click on the dial increased the intensity, while a counterclockwise click decreased it by 1 unit within a range of 0 to 255. A designated button on the keyboard allowed participants to toggle between the two modalities during the exploration phase, enabling them to choose which modality to adjust. Participants were instructed to familiarize themselves with the full ranges of the haptic and visual stimuli and their correlation, using the sliders as a reference. They were informed that the sliders would not be available in the subsequent phase.

2) Intensity Matching: In the intensity matching phase, participants were tasked with aligning the intensity of one sensory modality (haptic or visual) to a reference intensity provided in the other modality. This involved two distinct conditions: a haptic reference modality, where participants matched the visual stimulus to a given haptic intensity, and a visual reference modality, where they matched the haptic stimulus to a given visual intensity.

Following this setup, participants completed two experimental blocks in each condition. Specifically, participants used the same limitless dial configuration as in the intensity exploration phase to adjust the intensity of one stimulus to match a given reference stimulus. However, in this phase, the sliders were no longer displayed. Participants were allotted 90 seconds to submit their matched intensity for each trial, after which the current value was automatically recorded if the time limit was exceeded. Eight reference intensities, normalized and evenly distributed within the range of 0 to 1 (excluding endpoints), were used. The 8 reference intensities were shown 4 times in a block randomized order for a total of 32 trials. The sequence of reference intensities was maintained across both blocks. The order in which haptic and visual reference stimuli were presented, whether the haptic or visual modality served as the reference first, was counterbalanced across participants.

Upon completing each block, participants completed the NASA Task Load Index (NASA-TLX) questionnaire to evaluate cognitive workload [16]. At the conclusion of the session, participants were asked for a description of their strategies.

D. Data Analysis

We obtained two datasets for each participant: (1) the visual reference experiment and (2) the haptic reference experiment. Before analysis, the matched intensity was normalized such that values ranged from 0 to 1. This enabled a one-to-one relationship between the two modalities. The following analyses of these datasets will aim to (1) compare participants' performance across the two experimental conditions and (2) develop a protocol to help future researchers find participant-specific models that ensure perceptual equity in multimodal motor control experiments.

1) Comparing Dataset and Fit: We compared two different modeling approaches for deriving participant-specific models: a linear model and an exponential model. The linear model was selected because the experimental protocol inherently established a linear relationship between the haptic and visual modalities. Additionally, we included the exponential model because it has been employed in prior research [13], [17]. Thus, for each participant and experiment, the observed data were fit to both linear and exponential models using MATLAB 2024 b's *fitlm* and *fitnlm* functions, respectively.

Prior to model fitting, we applied two distinct data sampling paradigms. In the first paradigm, referred to as "All Data," we used all 32 data points collected across the four blocks, each consisting of eight reference intensities. In the second paradigm, referred to as "Average + Origin," we averaged the data across blocks at the eight reference intensities and added a ninth data point at the origin, as it is assumed that participants can identify when no reference intensity is provided. This second approach aligns with the methodology used in [17].

In summary, for each participant and each experiment, we generated a total of four models, combining two datasets ("All Data" and "Average + Origin") with two fits (linear and exponential). For each model, we report the coefficient of determination, R^2, as a measure of the goodness of fit. To compare each model's ability to sufficiently describe the data, we run a 2×2 (2 datasets × 2 fits) ANOVA on R^2.

2) Finding the Optimal Reduced Fit: To optimize the cross-modal matching procedure for efficiency, we aimed to determine the minimum number of blocks and reference intensities needed to achieve a model fit comparable to that obtained with the full experimental dataset. To this end, we conducted a Monte Carlo simulation for each participant, experiment, and fit. This simulation fit the data under 657 different conditions, derived as follows: we considered three block configurations (2, 3, or 4 blocks, preserving their sequential order to simulate truncated experiments) and all possible subsets of 3 to 8 reference intensities for each stimulus. The subsets of reference intensities were determined using the binomial coefficient $\left]\binom{n}{k}\right)$, where $n = 8$ and k ranged from 3 to 8. Note that a minimum of three reference points was required for fitting a linear model. This resulted in $\sum_{k=3}^{8} \left]\binom{8}{k}\right) = 219$ combinations of reference intensities. Multiplying these 219 combinations by the three block configurations yielded 657 total conditions. By systematically varying these parameters, we aimed to identify an experimental design that balances efficiency and accuracy by minimizing the cost function:

$$cost = \frac{blocks}{4} \cdot \frac{intensities}{8} \cdot 10 \cdot (x_1\ error + x_2\ error) \quad (1)$$

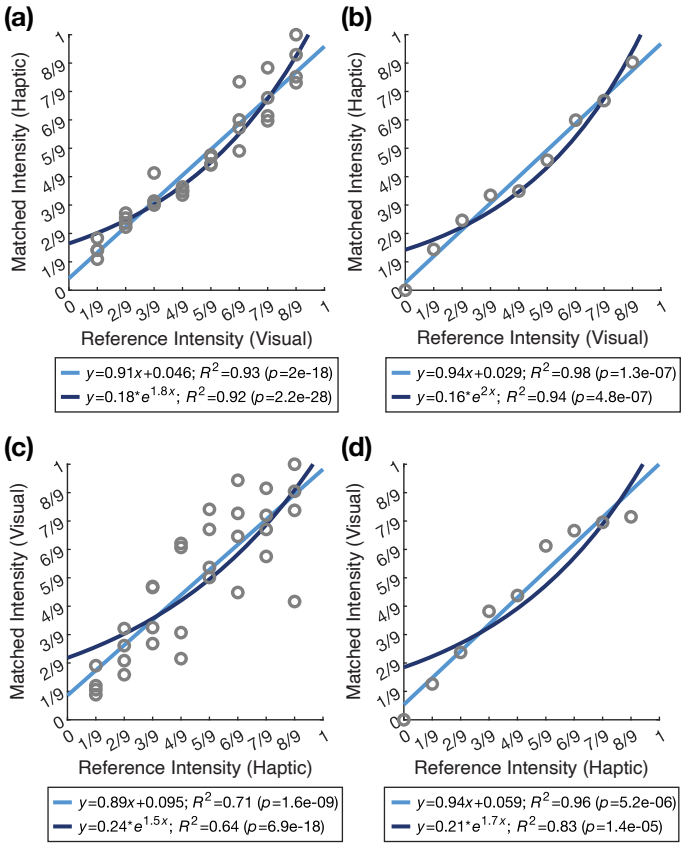

Fig. 2. Linear and exponential fits for a representative participant (Participant 10) in the cross-modal matching experiment. Subplots include: (a) visual modality as the reference (All Data), (b) visual modality as the reference (Average + Origin), (c) haptic modality as the reference (All Data), and (d) haptic modality as the reference (Average + Origin).

where $blocks$ is the number of blocks used, $intensities$ is the number of intensities used. x_1 $error$ and x_2 $error$ represent the deviation between the model's coefficients fitted to the subset of data and the model's coefficients fitted to the full dataset. A weighting factor of 10 was applied to the error term to heavily penalize deviations from the original fit heavily, ensuring the reduced dataset is consistent with the full dataset's fit.

After running the simulation, we identified the best fit for each case as the one that minimized the cost function defined in Eq. 1. This process yielded 24 optimal fits (12 participants $\times$ 2 experiments) for each dataset. To compare the characteristics of these optimally reduced fits, we conducted a paired Student's t-test to evaluate differences in the number of intensities, number of blocks, x_1 error, x_2 error, cost, and R^2 across the datasets.

3) Task Performance: We sought to understand how participants' performance varied between the two experiments. To quantify performance, we calculated error as the absolute difference between the normalized matched intensity and the normalized reference intensity $error = |matched - reference|$. Recall that in Section II-C, the relationship between the two

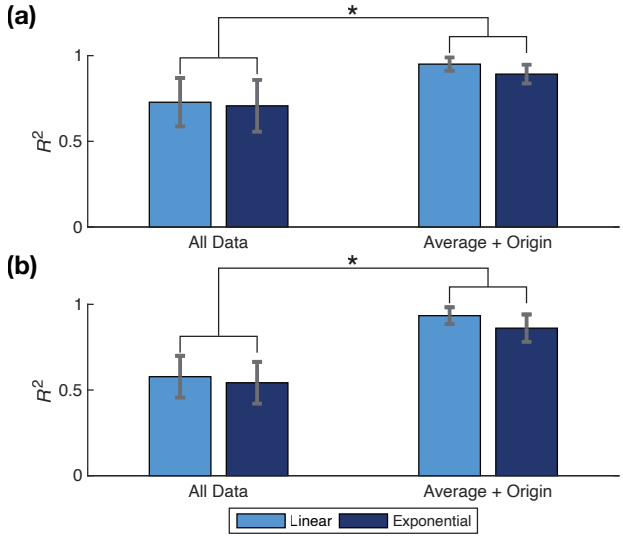

Fig. 3. Average coefficient of determination, $R^2, \pm$ 1 standard deviation for each dataset and fit across participants, with (a) visual modality as the reference and (b) haptic modality as the reference.

modalities was inherently linear; after normalization, it became one-to-one. If participants understood the underlying relationship perfectly, their normalized matched intensity would equal the normalized reference intensity.

To compare performance across experiments, we conducted a paired Student's t-test on the average error for each participant (averaged across all trials within each experiment). Additionally, we tested whether reference intensity or fatigue influenced performance. For reference intensity, we averaged each participant's error across trials at each intensity level and fit a linear model to error as a function of reference intensity. A significant slope would indicate that reference intensity affects performance. For fatigue, we averaged each participant's error across trials within each block and fit a linear model to error as a function of the block. A significant positive slope would indicate a decline in performance over time.

We analyzed NASA-TLX data using a two-way ANOVA to evaluate the effects of reference modality and category (mental demand, physical demand, temporal demand, effort, frustration, and perceived performance) on subjective workload ratings. If a significant effect was found, post-hoc paired Students' t-test was used to identify any significant differences between subcategories.

All data processing and statistical analyses were performed using custom scripts in MATLAB 2024. The significance level for statistical tests was $\alpha = 0.05$.

III. Results

A. Comparing Dataset and Fit

Fig. 2 illustrates the linear and exponential fits for a representative participant, providing a visual comparison of model performance. The models were assessed using the coefficient of determination, R^2, as a measure of goodness of fit.

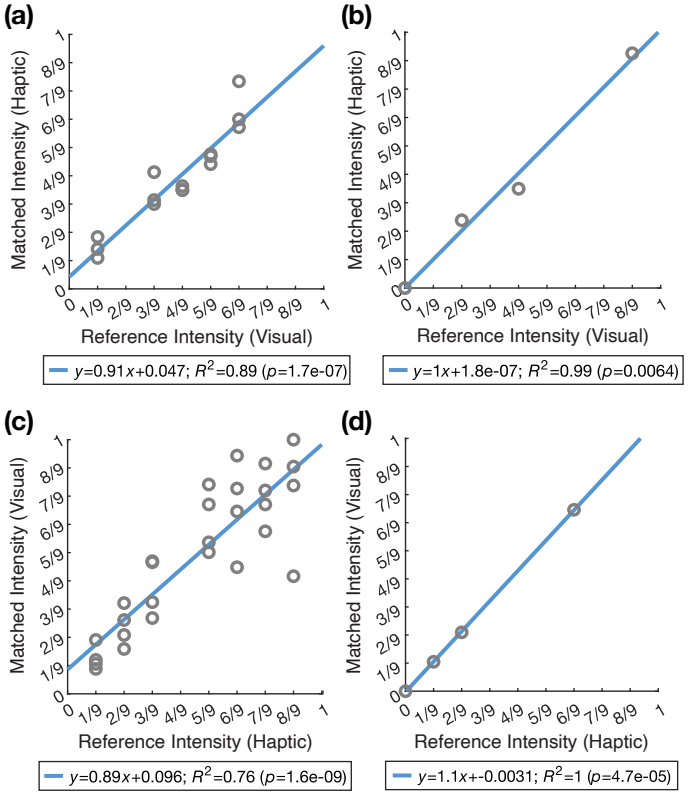

Fig. 4. Optimal reduced fit example for a representative participant (Participant 10), highlighting the reduced blocks and reference intensities. Subplots include: (a) visual modality as the reference (All Data), (b) visual modality as the reference (Average + Origin), (c) haptic modality as the reference (All Data), and (d) haptic modality as the reference (Average + Origin).

Fig. 3 shows the average R^2 across participants separated by experiment, dataset, and fit. Table I shows how each of the 4 models performed, in describing a participant's experimental data. Of note, all models were statistically significant. A 2×2 (2 datasets × 2 fits) ANOVA revealed a significant effect of dataset ($F_{1,95} = 6.458, p = 0.0127$); there was not a significant effect of fit ($p > 0.05$) nor a significant interaction ($p > 0.05$). However, the linear fit generally outperformed the exponential fit.

B. Finding the Optimal Reduced Fit

While the previous analysis included two datasets and two fits, we focused here on the linear fit for succinctness, as it generally performed better than the exponential fit and aligned with the underlying linear relationship in the task. An example for participant 10 is shown in Fig. 4.

Across the 24 optimal reduced fits produced for each of the Linear "All Data" and linear "Average + Origin" data we compared the number of intensities, number of blocks, x_1 error, x_2 error, cost and R^2 across the datasets. A paired Student's t-test revealed a significant effect of dataset on number of blocks ("All": M=3.54, SD=0.88; "Average + Origin": M=2.38, SD=1.06; p<0.001), number of intensities ("All": M=5.42, SD=1.44; "Average + Origin": M=3, SD=0; p<0.001), x_1 error ("All": M=1.4e-03, SD=1.6e-03; "Average + Origin": M=5.2e-03, SD=5.1e-03; p=1.19e-03), x_2 error ("All": M=1.2e-03, SD=1.7e-03; "Average + Origin": M=4.8e-03, SD=7.3e-03; p=2.19e-02), and R^2 ("All": M=0.66, SD=0.17; "Average + Origin": M=0.97, SD=0.022; p<0.001). However, there was not a significant effect on cost ("All": M=0.10, SD=8.9e-02; "Average + Origin": M=0.15, SD=0.11; p=0.10).

TABLE II

PERCENTAGE OF TIMES EACH REFERENCE INTENSITY APPEARED IN THE 24 OPTIMAL REDUCED FITS. 'ALL,' AND 'AVG + O,' DENOTE THE ALL DATA AND AVERAGE + ORIGIN DATASETS.

	Reference Intensity							
	1/9	**2/9**	**3/9**	**4/9**	**5/9**	**6/9**	**7/9**	**8/9**
All	0.71	0.58	0.63	0.58	0.75	0.67	0.75	0.75
Avg + O	0.58	0.29	0.33	0.42	0.42	0.38	0.25	0.33

Table II shows the percentage of times each reference intensity appeared in the 24 optimal reduced fits. In the "All Data" dataset, edge reference intensities (e.g., 1/9 and 8/9) were the most frequently used, but overall, the dataset exhibited some uniformity by often including more than five intensities. In contrast, the "Average + Origin" dataset used an average of approximately 3.54 reference intensities, and mostly included the intensities 1/9, 4/9, 5/9, and 6/9, in that order. This dataset generally excluded higher reference intensities.

C. Performance

Participants' performance was quantified by calculating the error as the absolute difference between the normalized matched intensity and the normalized reference intensity. Then, a paired Student's t-test was conducted to compare average errors across the two experiments for each participant. The test revealed no significant effect of the experiment on performance ($p > 0.05$). However, participants performed better in the visual reference experiment, as seen in Fig. 5.

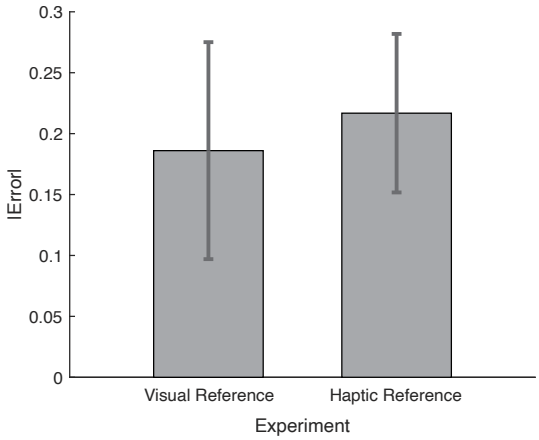

Fig. 5. Absolute error comparison between visual and haptic reference conditions.

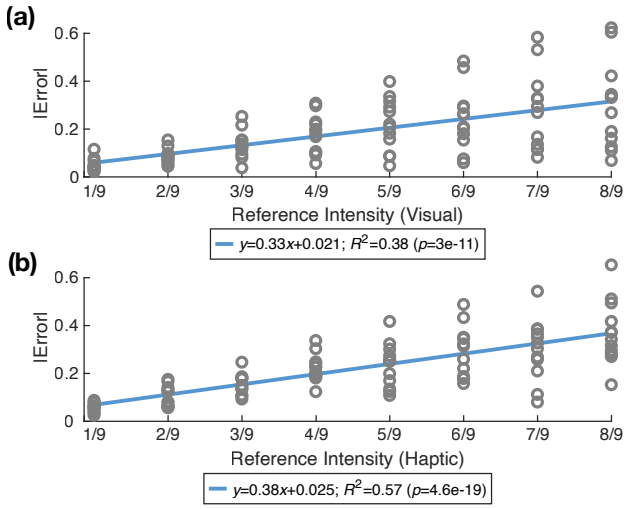

Fig. 6. Participant error as a function of reference intensity, demonstrating increased error at higher intensities. Subplots include: (a) visual modality as the reference and (b) haptic modality as the reference.

To examine the impact of reference intensity on performance, a linear model was fit to the error as a function of reference intensity. In both experiments, the model returned a significant positive slope (visual reference: M=0.33, p<0.001 and haptic reference: M=0.38, p=<0.001) indicating that participants performed worse at higher reference intensities, as shown in Fig. 6.

Similarly, to evaluate the impact of fatigue, a linear model was fit to the error as a function of block. In both experiments, the model did not yield a significant slope (visual reference: M=5.7e-04, p>0.05 and haptic reference: M=1.4e-06, p>0.05), indicating that participants' performance neither decreased nor increased as the experiment progressed, as shown in Fig. 7. This suggests that participants did not suffer from fatigue over the course of the study.

Finally, the two-way ANOVA on workload ratings revealed no statistically significant differences in NASA-TLX scores

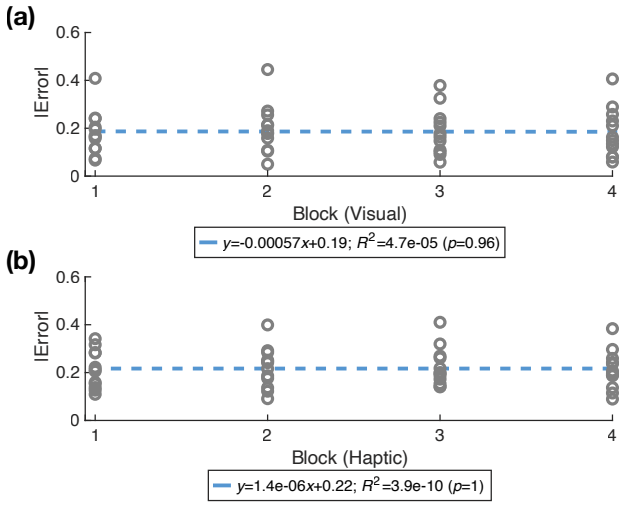

Fig. 7. Participant error as a function of block, showing stable performance throughout the experiment. Subplots include: (a) visual modality as the reference and (b) haptic modality as the reference.

TABLE III
NASA TLX SCORES FOR EACH WORKLOAD DIMENSION ACROSS THE VISUAL AND HAPTIC REFERENCE CONDITIONS. AVG AND SD DENOTE THE AVERAGE AND STANDARD DEVIATIONS ACROSS PARTICIPANTS.

	Visual Reference	Haptic Reference
Mental Demand	-1.25±3.72	0.75±4.77
Physical Demand	-3.33±3.72	-2.58±5.37
Temporal Demand	-5.75±4.18	-6.00±4.35
Effort	0.17±4.06	2.83±3.66

Perceived Performance	11.58±5.16	9.58±2.94

across task categories or reference modalities. Additionally, there was no significant interaction. The survey data is summarized in Table III.

IV. Discussion

This study refined cross-modal matching procedures to enhance perceptual equity in multimodal psychophysics and non-psychophysics experiments by systematically evaluating and optimizing experimental parameters. Twelve participants completed two matching experiments using the HAND [6], [7], aligning visual and haptic stimuli according to a visual or haptic reference (Fig. 1). Data were analyzed using two datasets (All Data" and Average + Origin") and two fits (linear and exponential). The linear fit consistently outperformed the exponential fit, aligning with the task's inherent linear relationship. Simulations identified the minimum number of blocks and reference intensities needed to achieve comparable model fits to the full dataset. The All Data" approach utilized a broader range of intensities, while Average + Origin" favored low-to-mid-range intensities, excluding higher ones. Participants showed greater error at higher intensities but exhibited no signs of fatigue throughout the experiment. These findings provide actionable guidelines for streamlining cross-modal matching protocols while maintaining accuracy and efficiency, contributing to developing effective rehabilitation protocols.

When comparing goodness of fit (R^2), we found that the 'Average + Origin' dataset statistically outperformed the 'All Data' dataset (Table I). This result is supported by mathematical reasoning. The 'Average + Origin' dataset uses fewer data points and averages across blocks, resulting in one matched (output) point for each reference (input) point (Fig 2). This reduction in variance around the fit line increases R^2, producing an artificial advantage. It underscores a trade-off: improved model performance comes at the cost of ignoring trial-level variability. Importantly, the 'Average + Origin' dataset captures the overall trend between modalities, the primary goal of cross-modal matching. By prioritizing the overarching relationship, this approach ensures perceptual equity without being hindered by trial-level noise.

While the 'Average + Origin' method modeled the data well for healthy participants, it assumes no perceptual bias at zero intensity. This assumption may not hold in clinical populations, such as stroke survivors, who often experience sensory deficits or altered perceptual baselines. Testing this paradigm with individuals exhibiting perceptual biases could reveal whether the 'All Data' method provides better fits. Such findings could refine the protocol and offer deeper insights into how sensory encoding variability impacts calibration methods across populations. These considerations will guide future studies to improve the adaptability and robustness of cross-modal matching protocols for motor rehabilitation.

The optimal reduced order fits generated through the Monte Carlo simulation revealed an important observation: while the "Average + Origin" dataset achieved a significantly worse x_1 and x_2 error compared to the "All Data" dataset, the overall cost was not significantly different between the two datasets (refer to Section III-B. Upon closer inspection, the errors in both datasets were quite small (x_1 error: $\sim 1.4 \times 10^{\infty 3}$ and $\sim 5.2 \times 10^{\infty 3}$ for "All Data" and "Average + Origin," respectively; x_2 error: $\sim 1.2 \times 10^{\infty 3}$ and $\sim 4.8 \times 10^{\infty 3}$, respectively). This indicates that the 'Average + Origin' dataset, while slightly sacrificing fit accuracy compared to the non-reduced dataset, achieved this with fewer blocks and reference intensities. The reduced order fit suggested 2-3 blocks and 3 reference intensities. While participants were allotted 1 minute per trial, they completed each trial in an average of 12 seconds. Based on this performance, a full experiment following the reduced order fit, including both reference modalities, would take less than 5 minutes. Even if participants used the full allotted time, the reduced protocol would take only 12 to 18 minutes, significantly shorter than the original maximum length of 64 minutes (4 blocks × 8 reference intensities × 2 experiments). The result is a more efficient protocol that still captures the cross-modal relationship between modalities. This trade-off highlights the utility of the 'Average + Origin' approach for balancing efficiency with maintaining critical insights into sensory integration.

The performance of participants, measured by absolute error, did not differ significantly between the two tasks (Fig. 5). This result is further confirmed by the NASA-TLX results, which showed no significant differences in workload across the tasks. This consistency across tasks highlights the robustness of this cross-modal matching experiment and its potential applicability beyond the visual and haptic modalities explored here. Such an approach could be useful for studying other sensorimotor modalities where perceptual equity is critical, such as auditory-haptic or proprioceptive-visual interactions. Future work should build on this foundation by conducting similar experiments to explore these modalities, further broadening the scope and impact of cross-modal matching techniques in sensorimotor research.

Participant performance, measured by absolute error, was unaffected by the number of blocks in the experiment (Fig. 7). Performance remained consistent across blocks, indicating no significant changes due to fatigue or learning effects as the experiment progressed. This stability suggests that reducing the number of blocks, as proposed by the reduced order fit, would not negatively impact results. By maintaining consistent performance throughout the task, the reduced order approach ensures overall trends are captured accurately without compromising data integrity or missing potential learning effects. This finding further supports the feasibility of streamlining cross-modal matching experiments for improved efficiency.

In contrast, there was a clear effect of reference intensity on participants' error; participants exhibited greater errors at higher intensities, possibly due to sensory saturation (Fig. 6). This trend explains why the optimal reduced fits in the 'Average + Origin' dataset tended to exclude data points at higher intensities. This observation is a critical consideration for future experimenters. It suggests that certain ranges within a modality, in this case, higher intensities, may lead to diminished performance and weaker correlations between modalities. To address this, experiments should avoid operating within these problematic ranges and exclude them from cross-modal matching tasks to ensure robust results. Our formulation of reduced order fits offers a distinct advantage here: it programmatically identified these problematic intensity ranges and excluded them. Moreover, in stroke survivors, altered sensory processing may exacerbate sensory saturation, impacting clinical applicability. Future work should explore adaptive scaling corrections to optimize feedback precision.

A. Limitations

In this study, we initially compared linear and exponential fits to the data and found no statistical difference between the two fits. Based on this result and the predetermined understanding that the relationship between visual and haptic modalities in this task is inherently linear, we focused our analysis on linear fits. This approach was justified for this specific task, as the experimental design deliberately established a one-to-one relationship between modalities after normalization. However, other experiments may not have such a predetermined understanding of the underlying relationship between modalities. In these cases, it may be necessary to explore a wider range of models, including nonlinear fits, to accurately capture the relationship in the data. However, that is beyond the scope of this study.

Another limitation of this study is that it was conducted exclusively with healthy participants, which may limit generalizability to clinical populations, such as stroke survivors. However, our results showed that performance remained stable across blocks in healthy participants, with no evidence of fatigue affecting performance. This finding justifies the use of a reduced protocol, as reducing the number of blocks does not compromise data quality. Such a streamlined protocol is particularly valuable for patient populations, where fatigue and task duration are critical concerns. Additionally, stroke survivors' perceptual deficits may introduce non-linearity in matching tasks; here, we included exponential fits to account for such variations. Nonetheless, future research should validate these reduced protocols with clinical populations to ensure they retain effectiveness while accommodating the unique challenges posed by sensory and motor impairments.

B. Impact

This work advances cross-modal matching experiments by identifying reduced experimental designs that maintain accuracy while minimizing participant fatigue and time requirements. Here, we reduced the duration of the study by a factor of 5. These streamlined protocols are particularly beneficial in neurorehabilitation, where patients often face physical and cognitive limitations. By reducing the number of trials and reference intensities, this approach simplifies the experimental process while preserving data quality, paving the way for broader adoption in clinical and research settings.

The study also emphasizes the importance of perceptual equity in multimodal experiments by providing a framework for fair comparisons across sensory modalities. By aligning stimuli to achieve comparable intensities, it addresses a key challenge in sensory integration research [5]. These principles extend beyond visual and haptic modalities, offering a methodological foundation for investigating other sensory interactions and their roles in motor control and neurorehabilitation. For example, strategies such as limiting the upper stimulus range or implementing real-time adaptive algorithms could help mitigate errors in individuals with sensory deficits [18] and enhance clinical utility.

The methodological framework introduced in this study extends beyond just visual and haptic matching. This approach could complement protocols like those of Xu et al. [7] and Seim et al. [19], enabling perceptual equity calibration during individuated finger training. Integrating cross-modal matching into functional grasping or co-activation tasks could better tune sensory feedback across modalities, optimizing patient outcomes. By programmatically optimizing experimental parameters, this method scales to other sensorimotor modalities, such as auditory-haptic or proprioceptive-visual interactions. This scalability broadens its relevance to fields like prosthetics, virtual reality, and human-computer interaction, where multimodal integration is critical. Efficiently determining perceptual equity across modalities provides researchers with a versatile tool for advancing both experimental research and practical applications. Establishing perceptual equity through cross-modal matching is not just a refinement – it is a necessary evolution for multimodal research, rehabilitation, and beyond.

***Abstract*— Robotic and biofeedback-assisted interventions are promising alternatives to surgical intervention and supplements for traditional physical therapy for children with gait impairments. This work utilizes a human-in-the-loop optimization strategy to adaptively modulate parameters for a lightweight robotic knee exoskeleton and biofeedback video game to maximize learning potential following the challenge point framework. We tested our approach on three able-bodied participants and one pediatric patient with genu recurvatum, a common walking pattern in children with neurological injuries. We implement a Covariance Matrix Adaptation-Evolutionary Strategy (CMA-ES) optimizer to enforce a target success rate of 70% by continuously adjusting visual biofeedback and exoskeleton assistance parameters. Our experimental results demonstrate the system's ability to maintain the target challenge level for the pediatric participant. Stance hyperextension decreased significantly from pre- to post-training trials on day 2 (9.2°) and 3 (3.2°) of the case study. Swing flexion approached the clinical target of 65° by the end of the third day. The promising optimizer performance and changes in gait kinematics validate the feasibility of autonomous parameter tuning to maximize learning potential in pediatric gait rehabilitation.**

I. INTRODUCTION

Children with neurological injuries often have walking movement disorders that impact the knee joint, with a common presentation being genu recurvatum. Genu recurvatum is characterized by knee hyperextension during the stance phase of gait and limited knee range of motion during swing phase. Typically patients with genu recurvatum hyperextend between 0° and -15° [1]. Genu recurvatum limits functional mobility and can lead to long-term joint and ligament pain [2]. Treatments include strength training of the calf and quadriceps muscles and motor control exercises [2]. In many cases, invasive treatments like surgical alterations of the bony and soft tissue elements is required [3]. Physical rehabilitation is another effective tool for treatment of genu recurvatum and similar walking impairments, but it is time-intensive, requires clinician expertise, and is physically demanding for the therapist.

This work was supported by Shriners Hospitals for Children and NIH Grant No. 1DP2HD111709-01.

Recent research on autonomous robotic exoskeletons has shown potential for assisting gait rehabilitation by offloading the clinician's physical effort to a robotic system [4]. The addition of biofeedback has further been demonstrated to help improve outcomes and engage the participant more actively in therapy [5]. Conner & Lerner [6] showed that children using visual biofeedback with a robotic exoskeleton had higher levels of plantar flexor muscle activity compared to using the exoskeleton alone. Importantly, effective rehabilitation can only occur when the patient is learning from the interaction. Research suggests that to encourage volitional learning, the training environment should engage the participant and provide sufficient challenge to promote learning without discouraging participation [7], [8].

The challenge point framework [8] suggests that the optimal challenge level for learning a given task varies as the individual's skill increases. The nominal difficulty of the task should increase alongside skill so as to track the optimal success rate to facilitate the fastest transition from "novice" to "expert". Prior work explored this approach for stroke rehabilitation, with a video game as the task, where users self-selected a challenge level [9]. The authors found that participants settled at a 74% success rate. In a similar study, players with an approximate 70% success rate showed the most learning in a "Pong" style video game. This evidence suggests that physical rehabilitation may be encouraged and more effective if an ideal success rate is enforced (where the task is not too hard or too easy) [10]. However, the modulation of challenge may be patient-specific, task-specific, etc., and manual tuning of multi-parameter systems is infeasible [11]. Thus, automated approaches for personalizing rehabilitation systems to specified challenge levels are necessary to deploy these devices in practice.

Human-in-the-loop optimization (HILO) has been used to individually customize exoskeleton parameters, resulting in superior performance over using generic device settings [12]. Exoskeleton control policies, even with few parameters, can result in different behaviors across individuals and finding ideal parameter combinations is non-trivial. In HILO, a formal numerical optimizer looks for the control policy that best fits a particular individual by testing and evaluating different parameter combinations. Covariance Matrix Adaptation-Evolutionary Strategy (CMA-ES) [13] is a common HILO optimization framework, particularly suitable when an individual's response to the same set of parameters is expected to vary with time, such as due to motor adaptation or learning [12]. Few studies have extended HILO

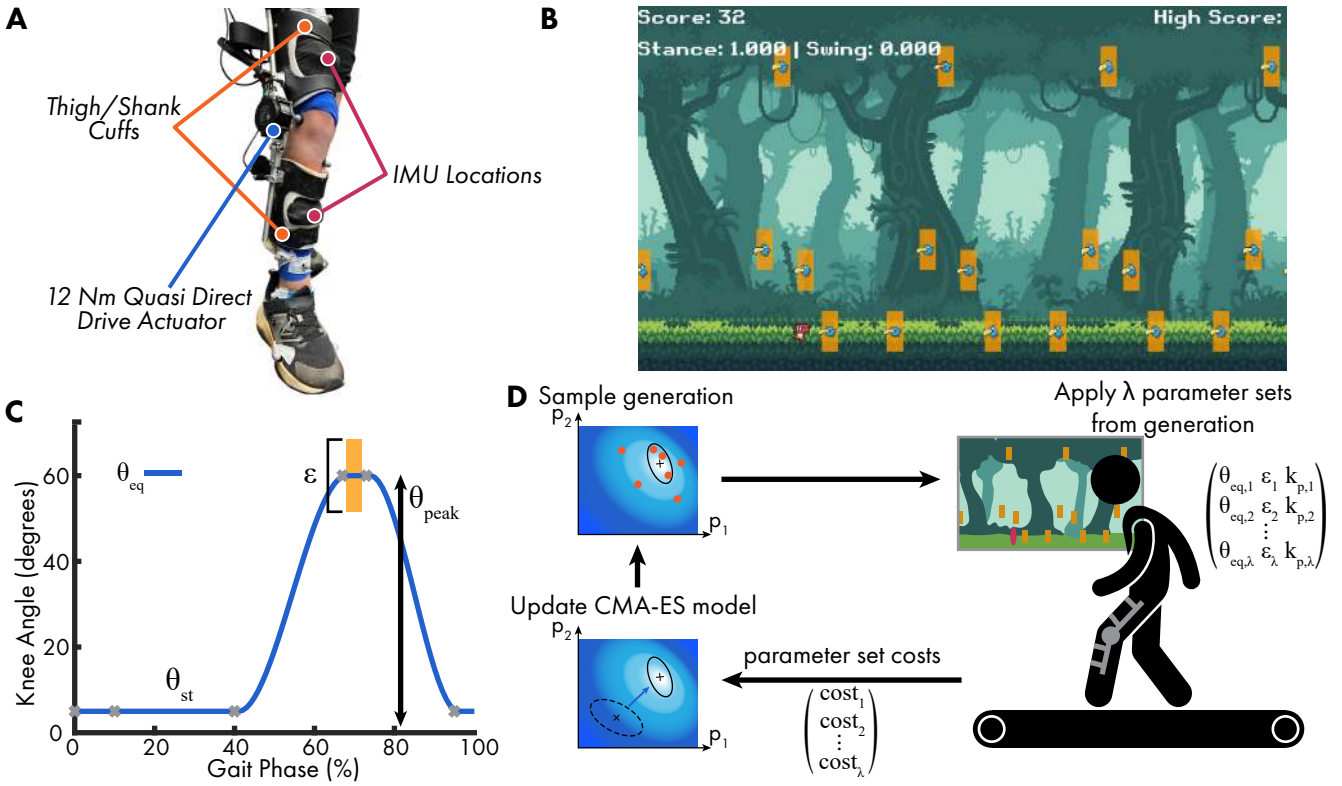

Fig. 1. (A) Knee exoskeleton designed to provide unilateral torque assistance. (B) The biofeedback video game. The red dinosaur avatar displays the user's knee angle, and the yellow boxes/birds represent the target kinematic profile for θ_{eq}, an example of which is shown in (C). The yellow box shows the tolerance factor ϵ. While the current knee angle is inside the tolerance, the assistance is set to $0\,\mathrm{Nm}$. (D) The algorithm loop to personalize gait parameters. Each CMA-ES generation applies λ parameter sets, the cost for each set is computed and used to update its estimate of the optimal region.

to rehabilitation or to motor adaptation and learning contexts. Li et al. [14] implemented HILO to encourage active voluntary participation in an upper limb movement task in stroke patients. Wang et al. [15] targeted engagement in a virtual cycling task by optimizing parameters to maximize neural engagement. This prior research and the relatively small number of studies exploring HILO for motor learning applications form the motivation for adaptively modulating challenge level, or task difficulty, to maximize the learning potential during gait training with an exoskeleton augmented by gamified biofeedback.

In this work, we formulated a knee exoskeleton and visual biofeedback system as a HILO problem to maximize learning in a walking task. We collected experimental data from three able-bodied (AB) participants challenged to walk in a crouch gait pattern, and one pediatric clinical participant with genu recurvatum (GR) prescribed to walk with a normative knee angle profile. The visual biofeedback system showed the user a goal kinematic profile in the form of a video game, while the exoskeleton applied assistive torque as needed to correct deviations from that profile. Independent stance and swing CMA-ES optimizers modified various system parameters to maintain the targeted 70% challenge level.

II. METHODS

A. Knee Exoskeleton Hardware

A lightweight ($\sim$1 kg) powered knee exoskeleton was developed to provide torque assistance to the wearer (Fig. 1A). The device assisted unilaterally, actuated by a quasi-direct drive motor (CyberGear Micromotor, Xiaomi Corp., CN), capable of $12\,\mathrm{Nm}$ of peak torque and a continuous torque of $4\,\mathrm{Nm}$. The device is an adapted version of the system in [16]. The knee joint featured a frontal plane passive degree of freedom, allowing the device to fit on individuals with deviation in frontal plane knee angles (i.e. valgus/varus). The device was secured to the participant with thermoplastic cuffs at the thigh and shank, both of which could be rotated to accommodate varying tibiofemoral transverse alignment. The device was powered by a $20\,\mathrm{V}$ off-the-shelf lithium polymer power tool battery (Dewalt, MD). A waist belt held the battery and mircrocontroller and acted to suspend the device to prevent movement during long walking sessions.

B. Knee Exoskeleton Control

The device was controlled with a Nvidia Jetson Orin Nano (Nvidia, CA) and programmed in Python 3.11. Assistance was applied using an impedance control law (Eq. 1), where the torque was defined by a stiffness parameter k_p, the measured knee angle θ_k, and an error from an equilibrium angle θ_{eq}, and an additional velocity damping term k_d, set to a constant value of $0.002\,\frac{\mathrm{Nm}}{\mathrm{deg{\cdot}s}}$. A tolerance, ϵ, was defined to set zero assistance if the error was less than ϵ, which created an assist-as-needed effect.

$$\tau = \begin{cases} 0 & |\theta_k - \theta_{eq}| \leq \epsilon \\ k_p(\theta_k - \theta_{eq}) - k_d\dot{\theta}_k & \text{else} \end{cases} \quad (1)$$

TABLE I
PARTICIPANT DEMOGRAPHIC DATA

Participant	Age	Weight (kg)	Height (cm)	Gender	Gait Pathology
AB1	28 yr	64.9	170	Male	N/A
AB2	22 yr	63.6	175	Female	N/A
AB3	24 yr	78.0	180	Male	N/A
GR1	12 yr	37.0	155	Male	*genu recurvatum*

Stance and swing optimizers use independent variables.

Knee angle was computed using two 9-axis inertial measurement units (IMU) (Microstrain by HBK, VT), placed on the thigh and shank. The difference in the roll orientation between the two sensors defined the knee angle, zeroed to a static measurement taken during quiet standing. The orientations were computed using the built-in sensor fusion algorithm. Gait phase was estimated in real-time using ground reaction forces from the treadmill, with a foot-contact threshold of $40\,\mathrm{N}$, and communicated to the controller over UDP. The estimated gait time averaged the previous two gait cycles. The controller was transitioned from stance phase into swing phase at toe-off and back to stance phase at heel contact. All control and sensing was executed at $200\,\mathrm{Hz}$.

C. Visual Biofeedback Game

The biofeedback game displayed an avatar representing the IMU measured knee angle of the participant, with targets placed along a goal kinematic trajectory (Fig. 1B). The trajectory was defined by a Piecewise Cubic Hermite Interpolating Polynomial (`pchip`), with prescriptions for stance knee angle (θ_{st}) and peak knee flexion (θ_{peak}), and all other points being interpolated. The θ_{eq} profile definition (Fig. 1C) used control points at 0, 10, 40, 67, 73, and 95% gait cycle. The game targets were displayed at 10, 40, 60, 70, and 85% gait cycle, and the target movement across the screen was aligned with the real-time estimated gait phase. The user controlled the avatar vertically on the screen, by flexing or extending their knee joint. The player received points for each target they hit and were instructed to score as many points as possible. The game was written in the Godot Game Engine (Godot Foundation) using free online assets [17], [18], [19]. The game communicated with the controller over UDP to receive real-time knee angle estimates.

D. Difficulty Adaptation Optimizer

The system was optimized using CMA-ES, a method designed to optimize black box systems by sampling and producing generations of parameter sets, ranking them by cost, and adapting its estimate of the search space. A "generation" consists of parameter sets sampled from the same search space. We selected CMA-ES based on its previous use in rehabilitation context and its suitability to time-varying spaces, but to our knowledge, this algorithm has yet to be applied in gait rehabilitation with the explicit goal of maximizing learning potential. Stance and swing phases were simultaneously optimized by independent optimizers, with the stance parameters being θ_{st}, ϵ_{st}, and $k_{p,st}$, and swing being θ_{peak}, ϵ_{sw}, and $k_{p,sw}$. Each parameter set's cost was the absolute difference between the target, 70%, and actual success rate, defined as the ratio of points scored to the total possible points over the last 10 strides of a parameter set.

$$\text{cost} = |\text{success rate} - 0.7| \tag{2}$$

For the AB participants, the bounds on θ_{st} and θ_{peak} were set to $[25, 45]^\circ$ and $[60, 85]^\circ$ respectively to challenge them to walk in a crouched posture. The bounds for the GR participant were set to $[0, 15]^\circ$ and $[45, 65]^\circ$ to encourage a normative gait profile [20], [21]. Both stance and swing bounds on ϵ were set at $\pm[1, 10]^\circ$. For the stiffness parameters, we set the maximum allowable torque to 20% of the expected peak knee moment, when the error between the current knee angle and equilibrium angle was 20°. Expected peak knee moment was taken from average kinetic profiles from literature [20], to be $0.5\,\frac{\mathrm{Nm}}{\mathrm{kg}}$ and $0.25\,\frac{\mathrm{Nm}}{\mathrm{kg}}$ for stance and swing respectively. Thus, bounds for $k_{p,st}$ and $k_{p,sw}$ were set at $[0, 0.005]\,\frac{\mathrm{Nm}}{\mathrm{deg}\cdot\mathrm{kg}}$ and $[0, 0.0025]\,\frac{\mathrm{Nm}}{\mathrm{deg}\cdot\mathrm{kg}}$. The optimizer was implemented using the `cmaes` package in Python 3.11 [22]. For the AB participants, the optimizer was configured with default recommended parameters and parameters were normalized to the recommended scaling [23]. For the GR participant, population size (λ, number of parameter sets per generation) was set to 5 instead of the default of 7. This change was made to increase the adaptation rate of the optimizer, slightly sacrificing global search performance for faster convergence, so the participant would spend more of the experiment close to the target learning rate. The effect of this change was tested using an offline bootstrapped simulation with a population size of 5. An analysis of experimental results from AB participants showed that using $\lambda = 5$ causes a shift in the next generation's estimate of each parameter by less than 10% compared to $\lambda = 7$. Given the high time cost of collecting experimental data with a pediatric subject, the smaller λ was used for this case study.

E. Experimental Protocol

We recruited N=3 able-bodied (AB) pilot subjects and N=1 pediatric genu recurvatum (GR) participant. Each visit consisted of a one-minute pre-training baseline walking trial, followed by the training session, and a one-minute post-training baseline. The primary outcome for the AB participants was optimizer performance and so they were only evaluated over one visit. The GR participant completed three visits on subsequent days to additionally evaluate knee kinematic changes. During training, the participant wore the exoskeleton and played the biofeedback game simultaneously. Every 30 seconds, a new parameter set was sampled from the CMA-ES optimizer. Once all parameter sets from a generation were trialed, the optimizer was updated (Fig. 1B). AB1 and AB3 completed 8 generations, while AB2 only completed 7 due to time restrictions. For the GR participant, 10 generations were collected each day, and the optimizer retained its state from the previous day. Kinematic data were collected using motion capture (Vicon, UK), and inverse kinematics was performed to compute joint angles (OpenSim, CA). Participants walked on a force-plate instrumented treadmill (Bertec, OH) at 80%

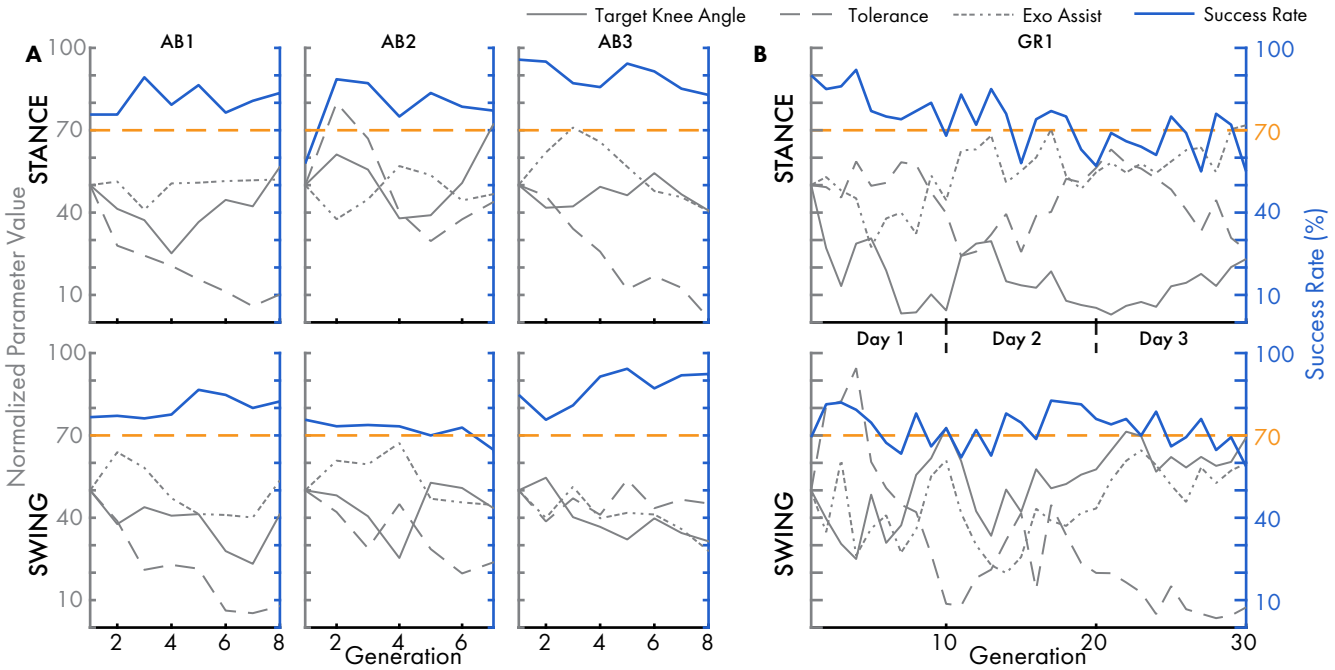

Fig. 2. Success rate and optimizer estimates over each generation for (A) AB subjects and (B) GR subjects. Blue lines denote the average success rate of each generation and grey lines denote each parameters normalized mean. Yellow dashed line marks 70% target success rate.

self-selected speed, determined through the 10-meter walk test across an instrumented gait mat (Protokinetics, PA). The AB participants took breaks as needed and breaks were enforced every 3 generations for the GR participant to minimize fatigue. The experimental protocols H19167 and H19006 were approved by the Georgia Institute of Technology Institutional Review Board.

F. Data Analysis Approach

The CMA-ES optimizer's performance was evaluated by its ability to maintain the participant's success rate at 70%. We estimated the relevance of each parameter to the optimizer by computing the variance of the optimal estimate for AB participants. High variance indicates the high relevance to maintaining the success rate. To better quantify the GR participant's responses to changes in parameters, we fit a linear model (`fitlm`, MATLAB, Mathworks, MA) comparing the inter-iteration change in parameter values (Δparam) to the change in success rate (Δsuccess rate) for each parameter. The 149 parameter set differences across three days allowed for significant correlations to be determined for this single participant. Next, we computed a personalized challenge level for each phase using a 2-norm of the set of parameters at a single iteration, where each parameter was weighted by its coefficient in the linear model, and normalized to the maximum possible challenge. Knee kinematic results were evaluated within the GR participant using one-way ANOVA with a Tukey post-hoc test to determine significant changes between conditions (`multcompare`).

III. RESULTS

A. Optimizer Performance

1) Able-Bodied Subjects: AB1 and AB3 showed a relatively high performance in the task both during stance and swing, with the optimizer being unable to pull either subject to 70% success rate by the end of the session. The optimizer was more successful with AB2, with stance phase ending within 10% of the target success rate, and achieving the target success rate during swing within 5 generations (Fig. 2A). During stance phase, for all AB participants, the target tolerance parameter selected by the optimizer consistently varied the most. For swing phase, we saw similar results for AB1 and AB2, with tolerance being the most varied parameter. In AB3, the peak knee flexion angle and exoskeleton assistance were varied more by the optimizer.

2) Pediatric Genu Recurvatum Subject: The CMA-ES optimizer was able to maintain the targeted score rate for the GR participant (Fig. 2B). During stance we saw a decreasing trend towards the 70% target, coming to within 10% of the target by the end of day 1. This target was maintained on subsequent days with mean success rates of 72% and 66.2% on days 2 & 3 respectively. The swing phase score rate started and remained close to the target across all days, with mean success rates of 73.4%, 74%, and 70.27% on days 1, 2, and 3 respectively. The stance optimizer varied all three parameters to a similar extent across the three days, whereas the swing optimizer primarily varied the tolerance parameter.

B. Score Rate Changes and Challenge for GR Participant

The swing phase score rate model identified tolerance as the only significant parameter ($p \ll 0.001$) and the others are excluded from the challenge level estimation. The knee angle and tolerance parameters were significant factors ($p \ll 0.001$) affecting stance phase score rate (Table II). The challenge level estimated from these parameters (Fig. 3) shows a strong increasing trend in swing and a soft increasing trend in stance ($p \ll 0.001$).

TABLE II

PARAMETER IMPORTANCE: (*:$p < 0.05$)

Δsuccess rate $= \beta_0 + \beta_1 \Delta\theta_{st/peak} + \beta_2 \Delta\epsilon_{st/sw} + \beta_3 \Delta k_{p,st/sw}$		
	Δstance success rate	Δswing success rate
β_0	0.0384	0.1119
β_1	3.3265*	-1.6403
β_2	4.8127*	5.0875*
β_3	1.6784	0.1668
stance challenge$_i$ $= \left\| \begin{bmatrix} \beta_1 \theta_{st,i} \\ \beta_2 \epsilon_{st,i} \end{bmatrix} \right\|_2$		swing challenge$_i$ $= \epsilon_{st,i}$

C. Kinematic Outcomes for GR Participant

Knee kinematic results were compared during the pre-training and post-training baseline conditions, as well as the last generation (5 parameter sets) on each visit for the GR participant (Fig. 4A, Section II-F). For knee hyperextension (stance phase), significant improvements between pre-training and the last generation of training were seen on all visits (4.3°, 7.3°, 7.5° on days 1, 2, and 3 respectively, $p < 0.05$). Significant improvement between the pre- and post-training was seen on days 2 (9.2°) & 3 (3.2°) (Fig. 4B). During swing flexion, we set 65° as a reference, because that was the maximum target the system could show the participant. The day 1 pre-training baseline had the lowest peak knee flexion and in each subsequent condition, peak knee flexion exceeded the 65° reference. We saw significant changes in peak knee flexion (Fig. 4C) and, at the end of the last day, the participant was closest to the 65° reference.

IV. DISCUSSION

In this work, we demonstrate a HILO approach to customize exoskeleton and biofeedback parameters to maintain a specified level of success during a task. Through an experimental study, we 1) establish the efficacy of an adaptive algorithm for challenge modulation, 2) quantify parameter importance identified from the algorithm's estimations, and 3) evaluate the effects of the exoskeleton-biofeedback framework on joint kinematics. Our results from a pilot experiment with three AB participants and a clinical case study with a pediatric participant with GR provide promising evidence for simultaneous exoskeleton and biofeedback modulation to target kinematic adaptation for gait rehabilitation.

The CMA-ES algorithm showed limited ability to match the desired score rate in AB participants, despite increasing task difficulty. They could easily achieve the crouch gait with a high success rate, rendering parameters needed for a 70% success rate outside the set parameter bounds. The algorithm was more successful for the pediatric participant, as walking with a normative gait was more challenging due to their GR. The parameters required to keep the GR participant at the 70% success rate changed over time suggesting the participant was improving. An optimization strategy that cannot account for a dynamic environment (such as human adaptation) like Bayesian Optimization or Gradient Descent would not track changes in optimal parameters. Our results indicate a need for a time-varying algorithm like CMA-ES. A potential limitation of CMA-ES is the time of convergence. Some approaches to address this limitation include shrinking search spaces and faster adaptation rates.

The parameter importance computed from the sampled parameter sets suggests that target tolerance was the most important parameter for both stance and swing optimizers. A decrease in tolerance requires more precise knee motion to hit the kinematic targets, thus requiring increased volitional control over the knee joint. For the GR participant, a higher knee flexion target was associated with lower success rates in swing phase, but an increase in stance flexion target lowered the challenge of the task. This likely stems from compensatory crouch gait behavior that individuals with GR often use to avoid hyper-extension. A target stance angle close to 0° could not be met using crouch gait resulting in lower score rate due to lack of precise volitional control. Thus, the stance knee angle target had a similar effect as tolerance, forcing the participant toward precise knee joint control to prevent hyperextension. In stance, the exoskeleton assistance parameter was near-significance ($p = 0.0519$) and further experimental analysis is necessary to verify whether this parameter is important in participants with more severe impairment or different impairments, such as crouch gait.

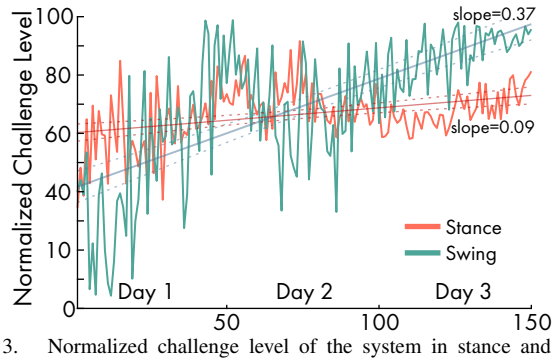

Fig. 3. Normalized challenge level of the system in stance and swing phase over each iteration for the GR subject. Both conditions trend towards higher challenge levels by the end of the experiment.

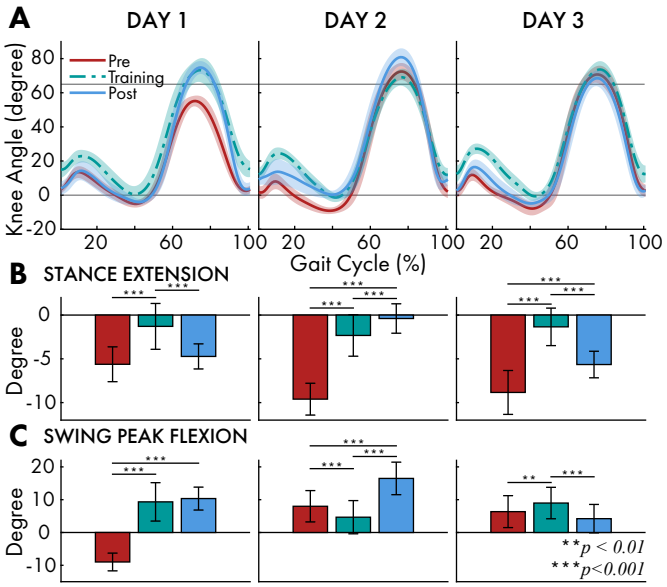

Fig. 4. (A) Knee profiles for the GR subject from (red) pre-, (teal) last generation, and (blue) post-training. (B) Minimum stance extension. (C) Peak swing flexion difference from 65°. Error bars and shaded areas: ±1 standard deviation.

In swing, the changes in exoskeleton assistance did not significantly change the success rate. However, there was a significant positive correlation ($R^2 = 0.44$) between the optimal peak knee flexion angle and exoskeleton assistance that the optimizer estimated (Fig. 2B). This correlation suggests that for the optimizer to maintain the intended success rate, increases in the peak knee flexion parameter must be accompanied by increases in exoskeleton assistance. In other words, the participant may have relied on the device to achieve more challenging knee flexion targets consistently. Future versions of the optimizer could be tuned to limit over-utilization of the device over the course of rehabilitation to ensure users receive maximal carryover benefit.

The exoskeleton and biofeedback system affected immediate changes in gait kinematics toward the target behaviors, with some evidence for retention across days. Although the pediatric participant exhibited exaggerated peak swing flexion (i.e. steppage gait) on the first and second days going beyond the target of 65°, on day 3, this exaggeration was less severe. This trend suggests the participant adapted to the desired behaviors over time despite initial overcompensation. In stance phase, hyperextension improved during training on all visits, with carryover from pre- to post-training on days 2 and 3. Both these kinematic outcomes could be negatively affected by a limitation of the visual biofeedback game which only rewards meeting the knee angle targets. As the game does not explicitly penalize hyperextension during stance or exaggerated flexion during swing it may inadvertently reinforce compensatory behaviors. Future versions of the game will incorporate such penalties alongside positive rewards.

The long-term goal of this research is to encourage gait rehabilitation in pediatric patients with gait impairments such as genu recurvatum and crouch gait. The able-bodied pilot and pediatric clinical case study presented in this paper are a first step toward this goal. Future work in this direction should aim to further evaluate different adaptation algorithms, their effect on a larger population and more diverse set of impairments, and the efficacy of adaptive training for long-term rehabilitation. The current study and ongoing improvements in the design and control of exoskeletons and serious games highlight the promising potential of adaptive training protocols for gait retraining through autonomous modulation of task difficulty to encourage learning.

ACKNOWLEDGMENT

We thank our participants for their time. We also thank Emily Rice, Dennis Green, Arina Kucinskaja, and Antonio Garcia Jimenez for their help during data collections.

***Abstract*—Upper limb tremors from Parkinson's Disease (PD) and Essential Tremor (ET) disease affect an estimated 6% of the global population. Patients face difficulties performing activities of daily living, leading to a reduced quality of life. Though treatments such as medication and deep brain stimulation exist, their limited applicability and potential risk leaves a large patient subset untreated. In contrast, non-invasive peripheral electrical stimulation (ES) therapies can be tailored to the user to optimally mitigate the symptoms of tremor. Fatigue-inducing functional electrical stimulation (FES) protocols have the highest efficacy of ES methods, with suppression ratios in the 50%s. In this work, we aimed to suppress tremors at the same level using sensory electrical stimulation (SES), which currently has efficacy levels in the 30-45 percent range. In addition to specially targeting the forearm pronator and supinator for stimulation, we introduce the use of deep interferential current (DIC) as a method to suppress postural wrist tremors in PD and ET populations. 1 ET and 1 PD subject completed a cup lift-and-hold task to elicit tremor as we applied and evaluated SES and DIC techniques. We found significant variability in performance between our PD and ET subjects, with the highest suppression (>60%) observed during SES for the PD subject. However, suppression was observed in all subjects for both SES and DIC, demonstrating the viability of our DIC approach while indicating the need for significant protocol optimization and individualization.**

***Index Terms*—tremor suppression, interferential current, sensory electrical stimulation**

I. Introduction

Approximately 7 million people in the United States and as much as 6% of the world population experiences upper-limb tremors that lead to difficulties in performing activities of daily living (ADL) such as buttoning a shirt, holding a cup, etc. Parkinson's Disease (PD) is a prevalent condition that leads to tremors in about a third of the affected population. Essential tremor disease (ET), which affects an even larger population, is an idiopathic condition from which patients experience mostly upper-limb tremors. There are no known biomarkers and the neural pathways or localized biomechanisms by which the tremors propagate are unclear, making personalized symptom-mitigation the focus of treatments rather than addressing the root cause. [1]- [3]

Current treatments for tremors include pharmacological supplements, surgical intervention, and assistive devices. Pharmacological solutions have limited efficacy while expensive surgical interventions are only prescribed for unmanageable symptoms and carry high associated risk [4]. Recently, non-invasive electrical stimulation (ES) techniques, which apply low-level current to motor or sensory neurons, have shown efficacy in suppressing tremors with no side effects. ES approaches address the limitations of other orthotic devices by being lightweight and highly wearable, as adhesive transcutaneous electrodes are easy to apply and remove [2]. Peripheral nerves are targeted at stimulation (current) amplitudes above or below the motor threshold (around 4-8 mA) depending on the protocol. Functional electrical stimulation (FES) methods stimulate above motor threshold and are effective in tremor suppression with about a 50% reduction in intensity [2]. However, the associated muscle fatigue due to unnatural muscle recruitment patterns limits the duration it can be used [5]. In contrast, sensory electrical stimulation (SES) methods stimulate sensory neurons below the motor threshold, which does not result in any muscle fatigue. When used to mitigate tremors, SES methods are currently less effective than FES methods, with suppression ratios in the 30%s and 40%s [13].

Both SES and FES are traditionally implemented using

This work was partially supported by NIH grant #1R21EB032059.

two stimulation sites in a given pair of agonist/antagonist muscles, with the most popular being the flexor carpi radialis (FCR) and the extensor carpi radialis (ECR). This type of method mainly addresses one axis of tremor: the flexion and extension component. However, most tremors manifest in multiple degrees of freedom (DOF). In particular, the rotational component of tremor has not been significantly explored, and with evidence suggesting that wrist pronation-supination is a significant contributor to PD tremor [10], the need for more rotation-targeted tremor suppression becomes apparent.

To address suppression in multiple DOF, FES or SES must be capable of stimulating multiple muscle groups, some of which are deeply located and are inaccessible through non-invasive means.

In this work, we introduce the pronator and supinator muscles as stimulation targets as well as the use of deep interferential current (DIC) to suppress wrist tremors. DIC is conventionally used in pain reduction [7] [8], but the potential to stimulate the deeper forearm pronator [6] and supinator muscles encourages its use in tremor suppression. DIC stimulation amplitudes remain below motor threshold so electrical stimulation-induced fatigue is minimal or nonexistent, making it more comfortable for the user [8].

The primary benefit of DIC over other stimulation methods is the administration of current via high frequency carrier waveforms that maintain an outer frequency equivalent to conventional SES methods. An example of DIC and SES 10 Hz outer frequency waveforms are shown in Fig. 1. This carrier frequency allows the current to better penetrate through tissue and reach the target muscle. The mechanism by which it works is fully described in [9].

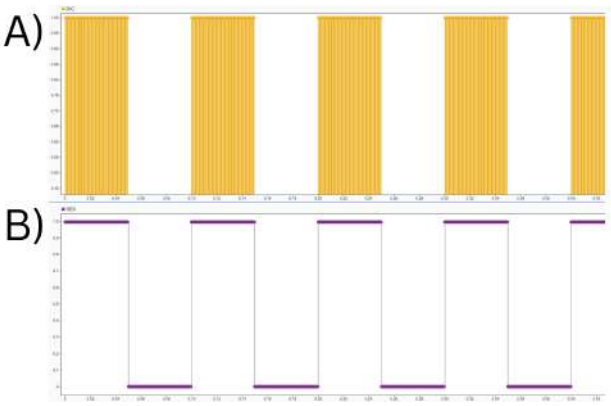

Fig. 1. DIC (A) vs SES (B) Stimulation Waveform Visual Example

II. Methods

1 PD and 1 ET subject were recruited for this study. Informed consent was collected prior to any experimentation, with methods approved by the Institutional Review Board of North Carolina State University.

We compared the tremor suppression efficacy of our DIC approach against an SES-based technique during active tremoring. For both techniques, we stimulated the four major forearm muscle groups: FCR, ECR, pronator, and supinator. Our subjects were asked to perform a cup lift-and-hold task for a period of one minute. This task is typically used by clinicians to elicit and observe tremor. As shown in Fig. 2 (muscle diagrams reproduced and edited from [11] with same-colored icons corresponding to antagonist-pair stimulation targets), electrodes were placed on each subject's FCR, ECR, pronator, and supinator, and an inertial measurement unit (IMU, Yost Labs) was securely attached to the back of their hand to collect data on tremor kinematics. Electrode and IMU positioning remained constant throughout all trials. The cup lift-and-hold task has the subject, when prompted, grabbing the handle of a standard mug (<450 g) and lifting it off a table in front of them for the trial's duration. The goal of the lift is to ensure there is no support to the subject's elbow, and they are holding their arm in free space. No stimulation was applied for the first fifteen seconds to allow for tremor to occur and to measure the trial's tremor amplitude baseline. Stimulation was turned on at fifteen seconds and applied continuously for the remainder of the trial (45 s). During a given trial, only one of a SES (II-A) or DIC (II-B) approach was used. A no-stimulation trial was also collected separately for further baseline use. Five DIC and three SES trials were conducted, with at least a minute of rest given between trials to remove any residual effects of stimulation. For consistency, SES trials were performed first, and a ten-minute break given before starting DIC trials.

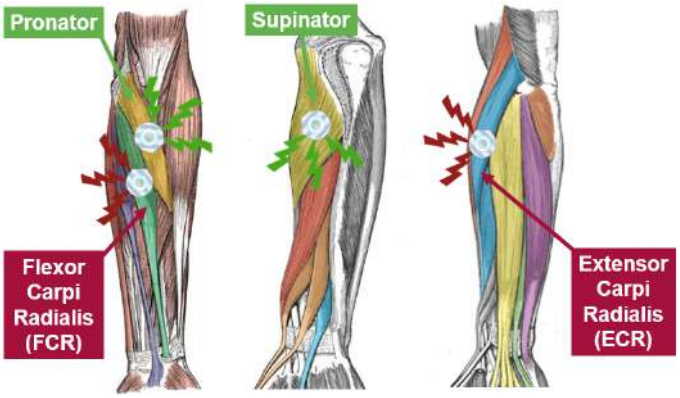

Fig. 2. Forearm Electrode Placements

A. SES Protocol

For the SES-based tremor suppression protocols, we stimulated all four electrode pairs using a Rehastim device (Rehastim, HASOMED GmbH, Magdeburg, Germany). This differentiation allowed us to determine the impact of introducing the pronator and supinator as stimulation sites. Before experimentation, the optimal stimulation inner wave frequency for each subject was determined using a process described by us in [12]. The same frequency was used throughout all SES trials. Each subject's SES parameters are listed in Table I. As we stimulated at 10 Hz, the outer frequency, or pulse-width, was 0.1 seconds.

TABLE I
SES STIMULATION PARAMETERS

Subject ID	Inner Pulse Frequency (Hz)	Amplitude (mA)
S1	150	4
S2	200	4

B. DIC Protocol

In the DIC protocol, we connected the electrodes on each subject's pronator and supinator to a Digitimer device (Digitimer DS8R, Digitimer Ltd., United Kingdom), which allowed us to apply DIC to only these muscles while SES was applied to the FCR and ECR. The rationale is that since the FCR and ECR are relatively superficial, SES is sufficient for activation and DIC is reserved for the deeper muscles.

For consistency, we applied the same DIC stimulation parameters across all subjects. The carrier frequency was 2 kHz and the burst (outer) frequency was 10 Hz (outer pulse width 0.1 seconds). The carrier frequency was chosen by the capabilities of the stimulating device, and the burst frequency selected from a range of 2-12 Hz, which are considered the lower and upper limits of tremor muscle activation frequency. For comparison with SES, 10 Hz was selected for both stimulation methods.

C. Data Analysis

Tremor suppression ratios, expressed as a percentage, were calculated for each DOF (see Fig. 3) within each trial to ensure comparability between trials. The formula is given in (1).

$$R_{suppression} = (1 - \frac{T_{stim}}{T_{base}}) \times 100 \quad (1)$$

where T_{base} is average tremor amplitude during the baseline period of no stimulation and T_{stim} is average tremor amplitude during stimulation. The amplitudes are derived from the angular velocity data given by the IMU. The tremor suppression rate for each trial is calculated separately to isolate the effects of stimulation on the tremor that occurred during a given trial.

III. RESULTS

The average suppression ratios for each subject are shown in Fig. 4. Positive suppression ratios indicate that stimulation has mitigated tremor for a given DOF. On average, we observed tremor suppression in all DOF for both SES and DIC protocols. However, the scale of suppression was different between subjects. Our PD subject (S1) experienced notable suppression (>60%) in all DOF with SES, whereas the largest suppression ratio for DIC trials was 47.9% in the z-axis. In contrast, our ET subject (S2) had suppression ratios ranging from 14.1-37.6% for SES trials and 9.5-29.5% for DIC trials. Notably, S2's highest suppression was from SES in the z-axis.

IV. DISCUSSION

Our results indicate that there are benefits to our targeted stimulation approach as an extension of current 2-stimulation-site SES methods. With the complexity with which tremors

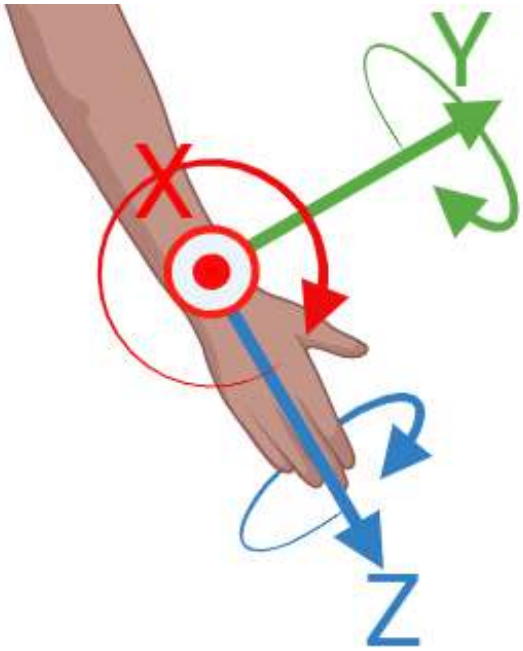

Fig. 3. DOF Axes for Tremor Suppression Calculations

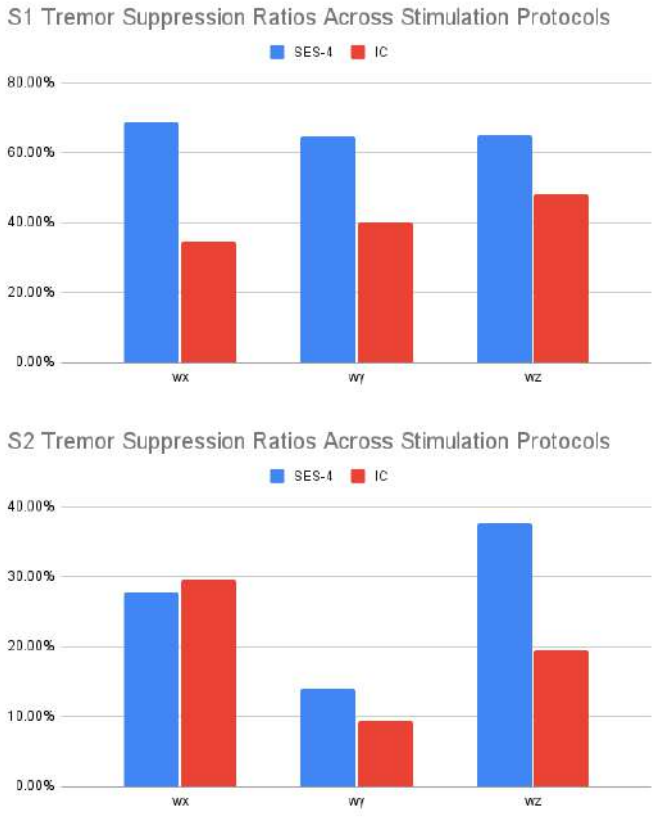

Fig. 4. Avg. Tremor Suppression Ratios in each DOF for SES and DIC Protocols

manifest in each individual, it stands that expanding the stimulation targets from two to four muscle groups may improve tremor suppression in individuals that experience tremor in all 3 DOF. However, the variability in our results underline the importance of tailoring stimulation protocols to the individual.

For our PD subject to experience average tremor suppression ratios in the 60's from SES demonstrates that for this individual, SES has approximately the same level of efficacy as FES protocols tend to have for the PD population. In order to strengthen our findings, we will compare tremor suppression with our 4-stimulation-site SES and DIC methods against the traditional 2-stimulation-site SES and FES methods.

We used the same DIC protocols for both subjects, but personalizing these protocols may improve tremor suppression. Even with basic stimulation of only the ECR and FCR, simply altering the inner stimulation frequency results in visible differences in how tremors are mitigated [12]. These optimal values can vary greatly per person, and depend on when stimulation is applied (e.x. right when the tremor begins/is detected, after a brief delay, or in pulses at a given outer frequency with or without a starting delay). Similar parameters can be adjusted for DIC, including the carrier frequency (going anywhere from 2-12 kHz) and burst frequency (2-12 Hz). This work is meant to demonstrate the feasibility of using DIC in tremor suppression, so even though we observed higher suppression ratios with SES compared to DIC, we find promise in the significant room for optimization of stimulation protocols. We plan to expand on our results in this work by trying a variety of carrier and burst combinations and introducing a variable time delay at the start of stimulation to determine each subject's optimal DIC protocols. Particularly, higher carrier frequencies are known to better penetrate into muscles, so we will focus on the higher end of the spectrum (10-12 kHz). In theory, this should improve activation of the appropriate neural pathways that lead to tremor suppression and lead to functional benefits in individuals that experience tremors.

We also collected qualitative data on user experience for each protocol. All subjects reported feeling no discomfort during any of the protocols. There was also no noticeable difference in feeling between the DIC and SES protocols, which is to be expected with the low current amplitude - differences would be difficult to observe so close to the sensory threshold. Our PD subject noted prior to experimentation that they felt their tremor had a significant rotational component (corresponding to the z-axis), and they felt and saw it almost disappear during the DIC trials. Since this is not supported by the observed findings - DIC resulted in smaller suppression ratios than SES - we are very interested in exploring subject perception in relation to stimulation approaches. The same subject also self-reported a potential carry-over effect of DIC stimulation, with their tremor appearing to be slightly mitigated in the period directly following experimentation. We are interested in quantifying these findings in the future using clinical scales.

V. Conclusion

Previous studies have shown that SES is a viable method of wrist tremor suppression for people who have PD or ET. However, the limited stimulation sites and activation from SES limited its efficacy, especially compared to fatigue-inducing FES protocols. In this work, we introduced the use of deep interferential current as a method to activate the forearm pronator and supinator during wrist tremors, thereby providing suppression with the absence of FES-induced muscle fatigue that SES methods have. Our DIC approach has significant room to improve by individualizing stimulation protocols and experimenting with different application timings, with the results of this work supporting continued research in this area.

Towards Safer Rehabilitation: Improving Gait Trajectory Tracking for Lower Limb Exoskeletons Using Offline Reinforcement Learning

Matthew Wong Sang[1], Jyotindra Narayan[3], Bukeikhan Omarali[2], A. Aldo Faisal[1,2,3]

***Abstract*— The application of online reinforcement learning (RL) in lower limb exoskeleton control has the potential to improve gait rehabilitation for individuals with impaired mobility. However, online RL approaches require real-time exploration and pose safety risks during training as suboptimal policies can lead to unstable or unsafe actions being executed by the exoskeleton. This study explores the application of offline RL methods, including Implicit Q-Learning (IQL), Twin Delayed Deep Deterministic Policy Gradient with Behavior Cloning (TD3+BC), and Revisited Behavior Regularized Actor-Critic (ReBRAC), for trajectory control of lower limb exoskeletons using a pre-collected dataset. The transition involved generating a diverse and representative dataset using online RL methods like Proximal Policy Optimization (PPO), which was then utilized to optimize offline RL models with advanced hyperparameter tuning via Optuna. Our results demonstrate improved gait trajectory tracking over a PPO baseline, with our TD3+BC model achieving the best performance. These findings highlight the potential of offline RL to enhance exoskeleton trajectory control while minimizing safety risks inherent in online approaches.**

I. Introduction

Gait impairment, commonly caused by neurological disorders such as spinal cord injury and stroke [1], affects millions worldwide, severely impacting their mobility and quality of life [2]. Conventional gait rehabilitation methods, while effective, often require intensive manual therapy, limiting scalability and accessibility [3]. Lower limb exoskeletons have emerged as a promising solution for providing repetitive, task-oriented training, which is essential for motor recovery [4]. However, controlling these devices effectively is complex due to the variability in human-exoskeleton interactions [5]. This complexity has driven interest in advanced control strategies such as reinforcement learning (RL), which can adaptively address these challenges.

RL allows controllers to learn directly from interaction data while bypassing the need for predefined dynamics models. Initial RL applications used algorithms like State-Action-Reward-State-Action (SARSA) [11] and Q-learning [12] to tune control parameters dynamically. More recent approaches leverage Deep Reinforcement Learning (DRL) to handle the high-dimensional nature of multi-joint human-exoskeleton systems. For instance, DRL-based controllers, using algorithms like Proximal Policy Optimization (PPO) [13], have been developed to adapt assistive torque profiles in real-time [14], while others use DRL methods completely end-to-end to directly map sensor data to control actions [15]. Additionally, DRL has shown promise in rehabilitation settings beyond exoskeletons, such as functional electrical stimulation cycling, where DRL controllers outperform traditional methods in providing adaptive neurostimulation for cycling movements in paralysed patients [16], [17], [18]. While these online RL approaches have demonstrated success in adaptive control, such methods require extensive interaction data and policy exploration, which can be potentially unsafe in real-world clinical environments [19]. This is because real-time training with online RL can result in suboptimal policies being deployed during learning, potentially leading

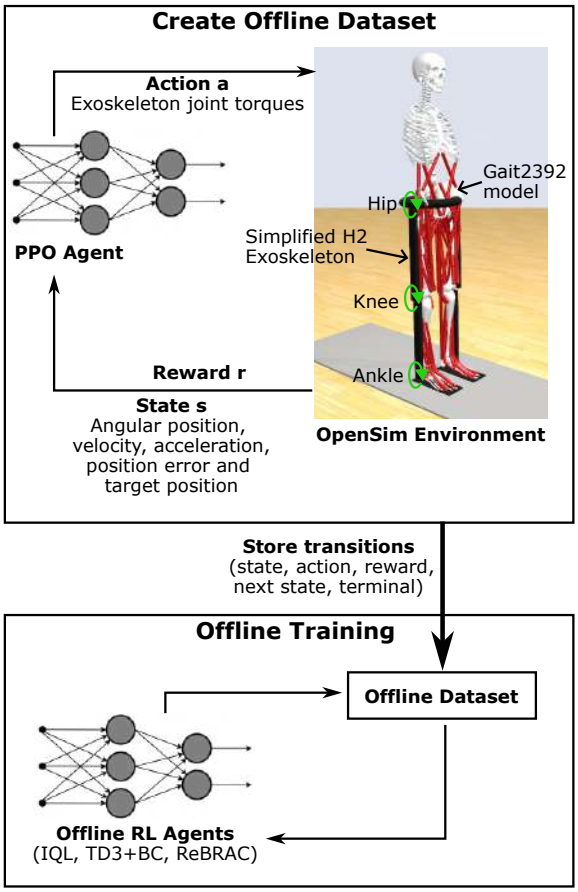

Fig. 1. Overview of proposed methodology. Online training is conducted using the Stable Baselines 3 library [6], in a custom RL environment based on OpenAI's Gymnasium library [7], which leverages biomechanical simulations in OpenSim [8]. These online interactions are stored in an offline dataset which is used for offline training using the d3rlpy [9] library. Models are optimized using Optuna [10] and their performance is evaluated and compared.

[1]Brain and Behaviour Lab, Department of Bioengineering, Imperial College London, UK. [2]Brain and Behaviour Lab, Department of Computing, Imperial College London, UK. [3]Chair in Digital Health, Universität Bayreuth, Germany
{aldo.faisal}@imperial.ac.uk

to unstable or unsafe actions by the exoskeleton, which risks causing discomfort or harm to the user.

Offline RL addresses these challenges by enabling models to learn from pre-collected, fixed datasets, eliminating the need for real-time exploration and reducing risks associated with direct patient interactions [20]. Designed to handle distributional shifts and prevent unsafe actions [19], offline RL is particularly well-suited for clinical settings where safety is critical. However, unlike online RL, offline RL lacks the ability to adapt dynamically to new patient-specific variations, as it does not continuously interact with the environment. This trade-off prioritizes safety but limits immediate adaptability. Additionally, offline RL's reliance on a fixed dataset may exclude certain types of gait impairment if unrepresented, potentially limiting its effectiveness. Nevertheless, the dataset can be incrementally expanded with new observations, improving generalization to evolving patient conditions over time. In rehabilitation robotics, offline RL has been primarily applied to robotic knee prostheses, where a policy iteration-based approach was used to optimize impedance parameters from pre-collected data [21].

In this work, we focus on applying offline RL to lower-limb exoskeleton control. We first trained an online model using PPO to generate an offline dataset instead of using an existing one to ensure consistency between the simulation environment and the collected data. This approach allowed us to construct a dataset with well-defined state transitions, control inputs, and reward functions tailored to the specific exoskeleton control task. This was then leveraged to train and evaluate our offline models based on IQL[22], TD3+BC[23], and ReBRAC[24]. Our goal is to enhance gait rehabilitation outcomes by developing control systems that can safely improve trajectory tracking and accommodate individual variability over time. This paper explores the potential of offline RL in overcoming the limitations of online methods, contributing to the advancement of data-driven exoskeleton-based rehabilitation.

II. Methods

Our proposed methodology (see Fig.1) begins with the description of the simulated human-exoskeleton system, including the creation of a custom *gym* environment. Next, the generation of the offline dataset using the PPO algorithm is described. This dataset is used to train offline RL models using the IQL, TD3+BC, and ReBRAC algorithms. Finally, the evaluation metrics used to assess the performance of our models are detailed.

A. Human-Exoskeleton System

OpenSim was chosen as the multi-body dynamics simulator due to its open-source availability and widespread use in biomechanical research [8]. The Gait2392 musculoskeletal model [25], commonly used in gait simulation and analysis research, was employed to develop the human-exoskeleton system. This model was scaled to represent a subject with a height of 1.8 meters and a mass of 82 kg, ensuring consistency with the selected subject from a publicly available dataset containing gait patterns from 138 able-bodied individuals and 50 post-stroke individuals [26].

TABLE I

Adapted H2 Exoskeleton Model Parameters [27], [28]

Body	**Thigh**	**Shank**	**Foot**	**Hip Support**
Mass[kg]	1.5	1.5	0.5	5
Length[m]	0.47	0.42	0.26	-
I_{xx} [kg m^2] *	0.015	0.059	0.337	0.003
I_{yy} [kg m^2] *	0.005	0.003	0.009	0.051
I_{zz} [kg m^2] *	0.014	0.057	0.338	0.063
Joint limits **	**Hip**	**Knee**	**Ankle**	**Pelvis**
Minimum (°)	-20	-3	-20	N/A
Maximum (°)	100	100	20	N/A

* The I_{xx}, I_{yy}, and I_{zz} are the moments of inertia.
** Negative joint angles indicate extension/plantarflexion while positive ones indicate flexion/dorsiflexion

To define the desired gait trajectory, a pair of individuals—one post-stroke patient and one able-bodied individual—were selected based on their similar physical characteristics, including sex, height, and weight. This approach ensures that the desired gait pattern assigned to the hypothetical gait-impaired patient is realistically achievable. The desired trajectory used in the simulation corresponds to the gait pattern of the able-bodied individual walking on level ground.

The Gait2392 model components were modified to include an adaptation of the H2 ambulatory lower limb exoskeleton [27], consisting of thigh, shank, and foot bodies, along with a hip support (see Fig. 1). To achieve the desired simulation, torque actuators were added at the hip, knee, and ankle joints to represent the assistance provided by the exoskeleton controller. The exoskeleton operates in *passive-assist mode*, meaning that the simulated subject is assumed to be lower-limb paralyzed, and the exoskeleton provides the necessary torque to track the desired gait trajectory. The exoskeleton actuators, originally rated at 220 Nm on the H2, were increased to 400 Nm. This adjustment allows our approach to be applicable to heavier individuals and exoskeletons with higher torque capacities. All exoskeleton parameters discussed in this section are summarized in Table I.

B. The Reinforcement Learning Environment

To develop and evaluate our models, a custom RL gym environment was created. This environment, was built using OpenAI's Gymnasium library [7] and integrated with OpenSim. The primary objective of the RL agent in this environment is to learn the assistive torques required to minimize the deviation of the observed joint angles of the simulated human from the desired gait trajectory while adhering to joint limits - ensuring patient safety.

1) Action Space: The environment's action space is defined as a continuous three-dimensional space, with each dimension corresponding to the control input for the exoskeleton actuators at the hip, knee, and ankle joints. The control signals are in [-1, 1] range, representing the proportion of the maximum actuator torque applied at each joint.

2) Observation Space: The observation space provides a comprehensive state representation of the human-exoskeleton system. Specifically, the observation vector includes 15 features: the current joint angle, angular velocity, angular acceleration and position error, and the target angle, for each joint. The observation space is bounded to reflect the physical limits of the exoskeleton's joints, ensuring that the RL agent operates within a realistic and safe range.

3) Reward Function Design: A critical component of the environment is the reward function, which is designed to encourage the agent to achieve the desired gait pattern while adhering to joint limits. The reward, r is composed of three main components and is bounded in [-1, 1] range:

$$r = w_{tr} r_{tr} + w_{acc} r_{acc} + w_{lim} r_{lim} \quad , \quad r \in [-1, 1] \quad (1)$$

Here, r_{tr} is the trajectory tracking reward with weight w_{tr}, r_{acc} provides an additional reward for maintaining errors within an acceptable margin with weight w_{acc}, and r_{lim} is the joint limit reward with weight w_{lim}. These weights were assigned values of 1. Importantly, the agent starts in a state where r_{acc} and r_{lim} are received by default, effectively incentivizing the agent to take safe steps in the environment from the outset. These rewards are then reduced based on the agent's deviation from the desired trajectory, as measured by r_{tr}.

This reward structure is designed to balance exploration and safety, ensuring that the agent learns to prioritize both trajectory tracking accuracy and adherence to joint constraints. By providing a baseline reward for acceptable behavior and penalizing deviations from the desired trajectory, this approach helps to stabilize the training process and aligns with the safety-critical nature of exoskeleton control for gait rehabilitation.

a) Trajectory tracking reward: This component encourages the agent to minimize the absolute error between the observed angles q and desired angles q_{des} at each joint. The reward is structured to provide no penalty when the trajectory error is zero, and a linearly increasing penalty as the error grows:

$$r_{tr} = w_h A_h(q) + w_k A_k(q) + w_a A_a(q) \quad (2)$$

where w_h, w_k and w_a are weights for the hip, knee and ankle respectively. We opted for values of one third for these weights.

$$A_i(q) = -\frac{|q - q_{des}|}{q_{\max} - q_{\min}} \quad (3)$$

where i represents the hip h, knee k and ankle a. The error is normalized by dividing by the maximum deviation possible at each joint, i.e. the difference between the upper $q_{\max}$ and lower $q_{\min}$ exoskeleton joint limits.

b) Acceptable Margin Reward: A scalar reward is given to the agent if the absolute hip, knee and ankle joint errors are less than a specified threshold m. We chose m=2° to balance tracking precision with minor gait variations.

$$r_{acc} = B_h(q) + B_k(q) + B_a(q) \quad (4)$$

TABLE II
PPO HYPERPARAMETERS USED TO CREATE THE OFFLINE DATASET.

PPO Hyperparameter	Value
Learning Rate (α)	1e-4 - 7e-4
Number of Steps	1024
Number of Epochs	10
Batch Size	64
Discount Factor (γ)	0.99
GAE Lambda (λ)	0.95
Clip Range (ϵ)	0.2

Value Function Coefficient	0.5
Maximum Value for Gradient Clipping	0.5

$$B_i(q) = \begin{cases} 0.3 & \text{if } |q - q_{des}| \leq m \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

c) Joint Limit Reward: To encourage safe and realistic joint angles, a reward is given if all joint angles stay within their expected ranges $[q_{\min}, q_{\max}]$ across the gait cycle.

$$r_{lim}(q_i) = \begin{cases} 0.1 & \text{if } q_{i,\min} \leq q_i \leq q_{i,\max} \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

The weights and scalars were chosen to maintain a bounded reward function and ensure smooth gradients, facilitating stable and effective learning.

4) Episode Description: Each episode begins by resetting the OpenSim model to its initial state—the first state of the desired gait pattern. The RL agent must control the exoskeleton throughout the simulated gait cycle, applying appropriate torques to guide the limb along the desired trajectory. An episode is terminated when any joint angle goes beyond its limits defined in Table I, or when the end of the trajectory is reached. In our simulation environment, unintended randomness, likely stemming from numerical solvers and simulation time-stepping, introduced variations across episodes. Rather than removing this randomness, we retained it to inject noise into the system and evaluate the robustness of our models.

C. Dataset Generation Using Proximal Policy Optimization

To enable the use of Offline RL, we required a pre-collected dataset of transitions $\mathcal{D}$ generated by a behavior policy π_β. We trained an online agent for this purpose using the Proximal Policy Optimization (PPO) algorithm [13]. In our study, we utilized the open-source implementation of PPO provided by Stable-Baselines3 (SB3) [6]. This implementation integrated seamlessly with our OpenSim simulation environment, facilitating the training process. The key hyperparameters used in training are presented in Table II. Parameters not mentioned were held at their SB3 defaults to aid rapid development and progression to the offline training phase.

The dataset $\mathcal{D}$ was generated by storing transitions in the form of (s, a, r, s', d) tuples during the later stages of training, where s denotes the current state, a the action taken, r the reward received, s' the next state, and d a boolean value indicating episode termination. The dataset

consists of 207 episodes and approximately 200,000 transitions. The maximum undiscounted return observed in the dataset, representing the highest performance achieved by the PPO behavior policy π_β, was 813.2 (see Fig. 2 for the corresponding trajectory tracking sample). This policy serves as the baseline for evaluating our Offline RL models.

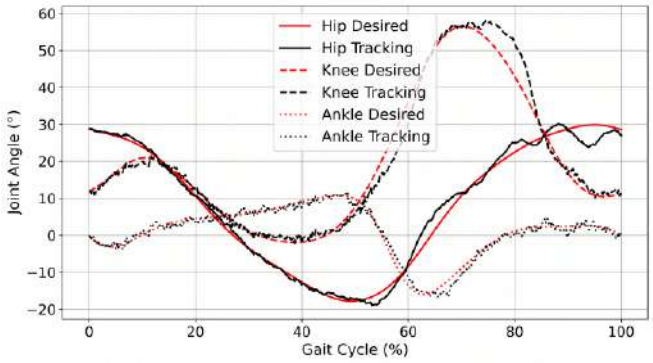

Fig. 2. Best trajectory tracking performance from the PPO dataset based on the undiscounted return

D. Offline Training

With the dataset created, we applied a set of offline RL algorithms: IQL, TD3+BC and ReBRAC. These algorithms were chosen due to their established effectiveness on continuous control tasks within the Datasets for Deep Data-Driven RL (D4RL) benchmark, with each offering distinct advantages for tackling challenges typically encountered in offline RL scenarios.

1) Implicit Q-Learning: The core of IQL involves alternating between fitting a value function through expectile regression and performing Bellman updates on the Q-function [22]. After the Q-function has successfully converged, the corresponding policy is derived using advantage-weighted behavioral cloning. By leveraging this technique, the method avoids explicitly querying out-of-distribution actions, which could lead to suboptimal or unstable learning behavior. Instead, it focuses on dataset-supported generalization, ensuring that the extracted policy remains well-grounded within the training data distribution and effectively captures high-value decision-making strategies [22].

2) Twin-Delayed Deep Deterministic Policy Gradient + Behavior Cloning: The TD3 algorithm, when combined with Behavior Cloning (BC), provides a balanced approach to policy improvement in offline RL [23]. By modifying the policy update to include a behavior cloning term, TD3+BC encourages the learned policy to stay close to the behavior policy present in the dataset, while still permitting generalization and exploration.

3) Revisited Behavior Regularized Actor-Critic: ReBRAC[24] builds upon TD3+BC, incorporating several key modifications aimed at enhancing performance in offline RL settings. By leveraging these enhancements, ReBRAC demonstrates state-of-the-art performance among competing offline RL methods [24], providing robust solutions to diverse continuous control tasks.

TABLE III
TUNED HYPERPARAMETERS FOR IQL, TD3+BC, AND REBRAC

Tuned Hyperparameter	IQL	TD3+BC	ReBRAC
Actor Learning Rate (α_{actor})	8.5e-04	4.1e-04	3.0e-04
Critic Learning Rate (α_{critic})	2.3e-03	7.4e-03	3.0e-03
Batch Size	128	512	512
Discount Factor (γ)	0.990	0.993	0.999
Soft Update Rate (τ)	0.004	0.007	0.005
Expectile (τ_{exp})	0.785	N/A	N/A
Alpha (α)	N/A	0.136	N/A

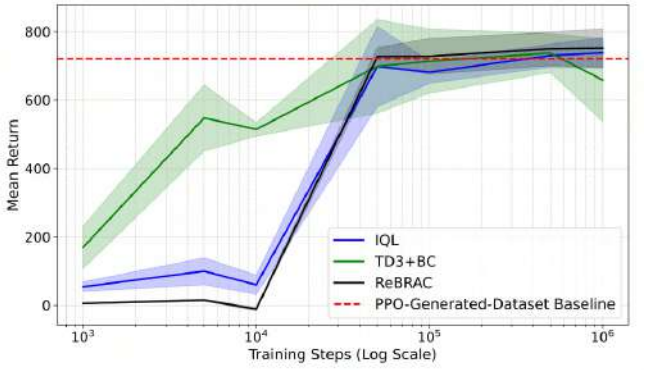

Fig. 3. Learning curves for IQL, TD3+BC and ReBRAC. Models checkpoints during training were saved and evaluated for 10 episodes. The mean is indicated by the solid line and the shaded regions represent the standard deviation. The mean return of the PPO dataset is illustrated by the red line. Note that the standard deviation for ReBRAC was very small and is barely visible until after 10^5 steps.

4) Implementation and Training: These offline RL algorithms were implemented using d3rlpy [9], an open-source offline RL library. In addition, Optuna [10] was used to perform automatic hyperparameter tuning. The best parameters from each optimization session are shown in Table III, while parameters not explicitly mentioned were maintained at their default values. Using these optimized parameters, we retrained our models for 1 million training steps to ensure convergence. We saved the models at various intervals and evaluated them over 10 episodes, to monitor mean returns during the training, see Fig. 3. All models demonstrated convergence after the 50k training step checkpoint.

E. Model Evaluation

The evaluation of our offline RL models against π_β was carried out using the Mean Absolute Error (MAE), Root Mean Squared Error (RMSE) and undiscounted return. The MAE indicates how closely the exoskeleton follows the desired trajectory, the RMSE offers additional insight by penalizing larger errors more heavily and identifying significant deviations from the desired trajectory, and the undiscounted return reflects the cumulative success of the policy in achieving the desired behavior during the gait cycle. We conducted our evaluation over 100 episodes for each offline model and analyzed the resulting distributions. We performed the Shapiro-Wilk test and the Mann-Whitney U

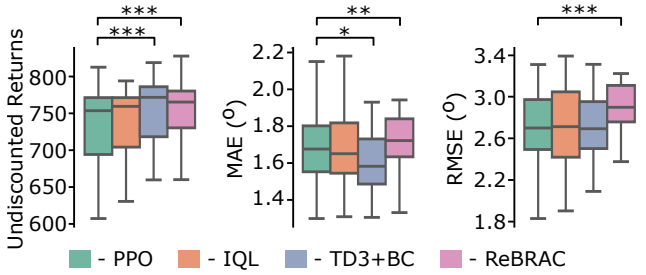

Fig. 4. Comparison of Return, MAE and RMSE Distributions across models. *p<0.05, **p<0.01, ***p<0.001 Mann-Whitney U test.

test using the SciPy python package, employing a significance level of 0.05.

III. Results

After computing the metrics for each model, we assessed normality using the Shapiro-Wilk test and determined that all metrics for all models were not normally distributed. Consequently, in Table IV, we present the median and interquartile range (IQR) of the MAE and RMSE across the hip, knee, and ankle joints. The overall distributions of these metrics are visually inspected in Fig. 4 and statistically analyzed using the Mann-Whitney U test to determine the significance of observed differences between models.

The results indicate that the TD3+BC and ReBRAC models achieved statistically significant improvements in returns compared to the baseline, while no significant improvement was observed for IQL. For MAE and RMSE, TD3+BC demonstrated improvements in both metrics, with the reduction in MAE being statistically significant. In contrast, IQL showed no statistically significant changes. Interestingly, while ReBRAC achieved higher returns, it exhibited a statistically significant decline in MAE and RMSE performance, suggesting a potential trade-off between maximizing returns and maintaining precise trajectory tracking.

Despite overall improvements in gait tracking, all models exhibited biomechanical anomalies at specific gait cycle points, likely inherited from the offline dataset. These include a pronounced hip oscillation near the end of the gait cycle, a prolonged knee flexion phase at 70–80% of the cycle, and high-frequency noise throughout ankle control.

Fig. 5 presents the trajectory tracking of each model, illustrating their ability to follow the desired gait pattern. OpenSim snapshots of TD3+BC's tracking throughout the gait cycle are visualized in Fig. 6, demonstrating its response to multi-joint control challenges. While TD3+BC achieved the best balance across joints, the observed anomalies highlight the influence of dataset artifacts on offline RL models, underscoring the importance of dataset quality in the future.

IV. Discussion

This study applied offline RL algorithms—namely IQL, TD3+BC, and ReBRAC—to train safe and effective control policies for lower-limb exoskeletons using a pre-collected PPO dataset. Our results demonstrate the feasibility of offline

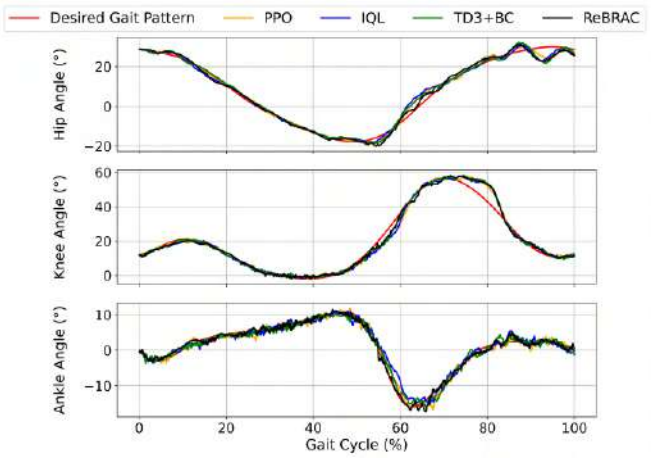

Fig. 5. Comparison of PPO (orange), IQL (blue), TD3+BC(green) and ReBRAC (black) in tracking the desired trajectory (red) for the hip, knee and ankle joints across a full gait cycle.

RL for exoskeleton trajectory control, with TD3+BC emerging as the best-performing model. This is consistent with the work of Li et al. [21], which optimized knee prosthesis impedance parameters via offline policy iteration. Our study extends offline RL to multi-joint gait trajectory tracking, relevant to rehabilitation for stroke and spinal cord injury patients [14].

A key advantage of offline RL is its *improved safety* over online RL, as training occurs without real-time exploration risks. This is particularly valuable in clinical applications, where direct policy learning poses significant safety and feasibility challenges. However, our findings also highlight a fundamental limitation: policies are constrained by dataset quality. The observed gait anomalies—hip oscillations, prolonged knee flexion, and ankle noise—suggest that our offline models inherited imperfections from the PPO dataset. Improving dataset diversity and quality is crucial to enhancing offline RL performance.

To address these limitations, future work should incorporate multiple subjects with varied impairments and walking speeds, introduce gait perturbations to assess adaptability, and explore transitioning from passive-assist to active-assist control for a more comprehensive rehabilitation scenario. Additionally, recent sim-to-real advancements [29] demonstrate that exoskeleton controllers trained entirely in simulation can successfully transfer to real-world devices, achieving significant reductions in metabolic costs across multiple locomotion tasks. Future work will involve real-world data collection to validate our approach outside simulation.

V. Conclusion

This study demonstrates the feasibility of offline RL for lower-limb exoskeleton trajectory control, offering a safer alternative to online RL. While TD3+BC showed the best performance, model effectiveness remained constrained by dataset quality. Future work will focus on improving data diversity, testing adaptability via gait perturbations, and validating models on real exoskeletons to bridge the gap between

Robotic-Assisted Leg Stretching Techniques Facilitated by a Powered Exercise Machine and Functional Electrical Stimulation

Steven Evangelos[1], Nicholas Rubino[1], Steven W. Brose[2], Victor H. Duenas[1]

***Abstract*— Flexibility training involving stretching aims to increase the range of motion (ROM) about a joint and mitigate factors that limit mobility. Stretching has been used for improving human performance and preventing injuries. Further, stretching can be used as spasticity treatment in people with spinal cord injury to provide relief from muscle spasms and improve passive ROM. Therapists apply manual stretching to participants; however, providing personalized and repeatable stretching forces is caregiver intensive. This paper describes the methods to apply three stretching techniques and determines the feasibility of implementing their protocols using a powered device and open-loop Functional Electrical Stimulation (FES) patterns. This paper develops a robust kinematic closed-loop controller to emulate the static, active-isolated (AIS), and proprioceptive neuromuscular facilitation (PNF) stretching techniques targeting the hamstring complex in which the human lies in a supine position. The robust electric motor controller rotates the leg from its initial position through a desired ROM using a rigid pivot arm actuated by a Bowden cable. When the leg reaches the target end ROM, FES inputs are applied for AIS and PNF stretching. Experiments were safely conducted in two able-bodied individuals to demonstrate the device's feasibility of implementing each stretching technique on the hamstring complex. A Lyapunov stability analysis ensures exponential tracking of the motor controller.**

***Index Terms*— Active-Isolated Stretching; Functional Electrical Stimulation (FES); Human-Robot Interaction; Proprioceptive Neuromuscular Facilitation (PNF); Static Stretching.**

I. INTRODUCTION

Flexibility describes the neuromuscular system allowing for muscular and connective tissue extensibility that enables a joint to safely achieve its full range of motion (ROM) [1]. Flexibility training involving stretching aims to increase the ROM about a joint and mitigate factors that limit mobility. In athletic applications, stretching exercises have been included in warm-up routines to improve human performance and prevent injuries [2]. In rehabilitative applications, stretching remains a primary treatment for spasticity in patients with spinal cord injury (SCI) and is a widely accepted standard-of-care therapy [3], [4]. Spasticity degrades the ability to functionally use voluntary muscle contraction for leg control, which impairs balance, body transfers, exercise, and ambulation [5], [6]. Leg stretching can enhance maximal performance in able-bodied individuals and improve quality of life for people with spasticity after SCI. Whether intended for athletic or rehabilitative benefits, a systematic framework of flexibility is needed to customize the implementation of different stretching techniques for people with varying movement and sensory capacities.

In this paper, the muscle to be stretched is the hamstring complex (i.e., the agonist). The three stretching techniques implemented in this paper and described in Section II include: static, active-isolated (AIS), and proprioceptive neuromuscular facilitation (PNF). Static stretching exploits the principle of autogenic inhibition to increase ROM [7]. AIS takes advantage of the principle of reciprocal inhibition by concentrically contracting the antagonist (i.e., quadriceps complex) for timed repetitions to produce a reciprocally inhibiting (i.e., lengthening) response in the agonist [1], [8]. PNF stretching uses the principle of Golgi Tendon Organ (GTO) activation of an agonist in a long position, followed by an immediate, slow, and passive increase in ROM [9].

Typically, stretching techniques are administered manually (i.e., hands-on) by a healthcare practitioner or trainer. Physical therapists and caregivers routinely perform manual stretching to provide relief from muscle spasms, maintain soft tissue extensibility, and improve flexibility. However, the demand for incorporating flexibility-based treatment protocols for patients in rehabilitative settings has been steadily increasing faster than the number of therapists that can be trained and made available to provide these treatments (e.g., due to staffing shortages). Further, challenges related to repeatability, consistency, and personalization have motivated the rehabilitation robotics community to generate novel, innovative solutions to facilitate on-demand stretching.

The technical challenges associated with developing a device and closed-loop controllers to implement the static, AIS, and PNF stretching techniques through human-robot interaction in a rehabilitative setting are safety and customization. Save the structural specifications in the physical design, the true measure of any device's feasibility for integration into a rehabilitative setting rests on the accuracy and precision with which the machine follows industry-accepted protocols/guidelines for how to effectively emulate the process of receiving manual therapy. Therefore, closed-loop feedback control methods are critical to ensure the safe, correct implementation of the stretching techniques and thus, ensure optimal performance and recovery.

People with SCI rely heavily on static stretching as a treatment for spasticity [4]. Instead of applying manual

forces, a powered machine can customize the rotation of the leg through a desired ROM. Further, these individuals are typically unable to voluntarily contract and relax agonists and antagonists, which inherently contraindicates manual AIS or PNF stretching techniques. In this paper, open-loop functional electrical stimulation (FES) inputs are applied to the antagonist (i.e., quadriceps complex) for AIS and to the agonist (i.e., hamstring complex) for PNF stretching, which could broaden and automate the scope of available treatments for people with SCI, without compromising safety. FES has been applied to characterize muscle fatigue during leg extension [10], combined with an electric motor for FES-cycling [11], and integrated with an exoskeleton for walking [12]. Traditional FES control facilitates concentric muscle contraction, and along with a robotic machine can produce torque about a joint for leg movement. Differently, this paper integrates FES with a powered machine to implement the stretching techniques in a supine position.

The main contribution of this paper is the design and implementation of a closed-loop kinematic motor controller and open-loop FES patterns for automated leg stretching of the hamstring complex using the static, AIS, and PNF techniques. Starting from a supine position, the electric motor rotates the leg through a desired ROM by exploiting the hip joint kinematics in the sagittal plane. Once the leg has reached the desired ROM, the motor maintains the leg in a static position. Then, a high amplitude FES pattern can be applied to the quadriceps complex (antagonist) for AIS, or a low amplitude FES pattern can be applied to the hamstring complex (agonist) for PNF stretching. Preliminary experiments in two able-bodied individuals were conducted to demonstrate feasibility of the proposed methods. A Lyapunov-based stability analysis is developed to ensure exponential kinematic tracking of the motor controller.

II. Stretching Techniques

The protocols governing the three stretching techniques implemented in this paper using the powered machine and FES are informed by the following standardized guidelines for manual treatment [1], [9], [13]:

Static Stretching. Once the hip joint arrives at the degree of hip flexion in the sagittal plane to elicit a muscle spindle response in the agonist, the joint is passively held in position, giving the body time to carry out the process of inhibiting the agonist so it can lengthen. One set involves a 60-second hold at the muscle spindle response angle of hip flexion in the sagittal plane.

Active-Isolated Stretching (AIS). Once the hip joint arrives at the degree of hip flexion in the sagittal plane to elicit a muscle spindle response in the agonist, the joint is passively held in position for 60-seconds. Different from static stretching, during the 60-seconds, active contraction of the (short) antagonist will be used to inhibit the agonist. Each repetition has a duty cycle of: 3-seconds of relaxed antagonist followed by 3-seconds of concentric contraction of the antagonist. Thus, one repetition is a 6-second process. One set involves 10 repetitions over 60-seconds.

Proprioceptive Neuromuscular Facilitation (PNF). Once the hip joint arrives at the degree of hip flexion in the sagittal plane to elicit a muscle spindle response in the agonist, the joint is passively held in position for 60-seconds. Different from static and AIS, during the 60-seconds, active contraction of the (long) agonist will be used to excite the GTO and create an inhibitory response. Each repetition has a duty cycle of: 10-seconds of relaxed agonist, 6-seconds of concentric contraction of the agonist, 20-seconds of increasing ROM to a new final position (where the final ROM is equal to the muscle spindle response ROM plus 10%), and 24-seconds of passive hold at the new final position. One set involves one repetition over 60-seconds.

III. Dynamics and Control Development

A. Dynamic Model

A leg rotating about the hip joint in the sagittal plane with the knee fixed in the extended position can be modeled as a single degree-of-freedom inverted pendulum as

$$J\ddot{q}+P(q,\dot{q})+G(q)+d(t)=\tau_{motor}(t)+\tau_{FES}(q,\dot{q},t), \quad (1)$$

where $J \in \mathbb{R}_{>0}$ denotes the uncertain positive constant corresponding to the lumped inertia of the leg and device, $q:\mathbb{R}_{\geq t_0}\to\mathcal{Q}$ denotes the measurable hip angular position, $\dot{q},\ddot{q}:\mathbb{R}_{\geq t_0}\to\mathbb{R}$ denote the measurable angular velocity and unmeasurable angular acceleration of the hip, respectively, $\mathcal{Q}$ is the set of hip angles, $t_0 \in \mathbb{R}$ is the initial time; $P:\mathcal{Q}\times\mathbb{R}\to\mathbb{R}$ denotes the effects of elasticity due to joint stiffness and the viscous damping effects in the musculotendon complex defined in [14]–[16]; $G:\mathcal{Q}\to\mathbb{R}$ denotes the effects of gravity; $d:\mathbb{R}_{\geq t_0}\to\mathbb{R}$ denotes unmodeled effects and external disturbances; $\tau_{FES}:\mathcal{Q}\times\mathbb{R}\times\mathbb{R}_{\geq t_0}\to\mathbb{R}$ denotes the torque evoked due to the applied open-loop FES input; and $\tau_{motor}:\mathbb{R}_{\geq t_0}\to\mathbb{R}$ denotes the torque applied by the motor about the hip joint, which is defined as

$$\tau_{motor}=B_e u_{motor}(t), \quad (2)$$

where $B_e \in \mathbb{R}_{>0}$ is a known motor torque constant and $u_{motor}:\mathbb{R}_{\geq t_0}\to\mathbb{R}$ denotes the motor current input designed in the subsequent subsection. The dynamic model in (1) satisfies the following assumption and properties that are exploited in the control design and stability analysis.

Assumption 1. *The additive disturbance d is bounded as $|d|\leq\zeta_d$, where $\zeta_d\in\mathbb{R}_{>0}$ is a known positive constant.*

Property 1. $|P(q,\dot{q})|\leq c_{p1}+c_{p2}|\dot{q}|$, *where $c_{p1},c_{p2}\in\mathbb{R}_{>0}$ are known constants [11].*

Property 2. $|G(q)|\leq\overline{g}$, *where $\overline{g}\in\mathbb{R}_{>0}$ is a known constant [17, Ch. 3].*

B. Kinematic Motor Tracking Controller

The kinematic motor tracking controller is designed to move the leg through the desired ROM for the three stretching techniques by following a desired hip joint trajectory in the sagittal plane denoted as $q_d:\mathbb{R}_{\geq t_0}\to\mathbb{R}$. To quantify the kinematic tracking objective, a measurable joint angular

position error $e : \mathbb{R}_{\geq t_0} \to \mathbb{R}$ and auxiliary filtered tracking error $r : \mathbb{R}_{\geq t_0} \to \mathbb{R}$ are defined as

$$e(t) = q_d(t) - q(t), \tag{3}$$

$$r(t) = \dot{e}(t) + \alpha e(t), \tag{4}$$

where $\alpha \in \mathbb{R}_{>0}$ is a selectable constant control gain. The desired trajectory q_d is bounded and continuously differentiable with bounded derivatives, such that $|q_d(t)| \leq \xi_{d_1}$, $|\dot{q}_d(t)| \leq \xi_{d_2}$, and $|\ddot{q}_d(t)| \leq \xi_{d_3}$, where $\xi_{d_1}, \xi_{d_2}, \xi_{d_3} \in \mathbb{R}_{>0}$ are known positive constants. Taking the time derivative of (4) and premultiplying by J, substituting for (1), (3) and (4) yields

$$J\dot{r} = J\ddot{q}_d + P(q, \dot{q}) + G(q) + d(t) - \tau_{motor} - \tau_{FES} + J\alpha(r - \alpha e). \tag{5}$$

Performing algebraic manipulation to (5) and combining terms that can be upper bounded by functions of the errors or by constants yields

$$J\dot{r} = \tilde{W} + N_d - \tau_{motor} - \tau_{FES} - e, \tag{6}$$

where the auxiliary signals $\tilde{W} \in \mathbb{R}$ and $N_d \in \mathbb{R}$ are defined as

$$\tilde{W} \triangleq P(q, \dot{q}) + J\alpha(r - \alpha e) - c_{p1} - c_{p2}\dot{q}_d + e, \tag{7}$$

$$N_d \triangleq G(q) + d(t) + J\ddot{q}_d(t) + c_{p1} + c_{p2}\dot{q}_d. \tag{8}$$

The auxiliary signal in (8) can be upper bounded using Property 2 and Assumption 1 as

$$|N_d| \leq \xi_d, \tag{9}$$

where $\xi_d \in \mathbb{R}_{>0}$ is a known positive constant. By using Property 1, (3) and (4), an upper bound can be obtained for (7) as

$$|\tilde{W}| \leq c_1 \|z(t)\|, \tag{10}$$

where $c_1 \in \mathbb{R}_{>0}$ is a known positive constant and $z : \mathbb{R}_{\geq t_0} \to \mathbb{R}^2$ is a composite vector of error signals defined as $z(t) \triangleq \begin{bmatrix} e(t) & r(t) \end{bmatrix}^T$. Given the open-loop error system in (6), the control input u_{motor} in (2) is designed as

$$u_{motor}(t) = k_1 r + k_2 \text{sgn}(r) + k_3 \|z\| \text{sgn}(r), \tag{11}$$

where $k_1, k_2, k_3 \in \mathbb{R}_{>0}$ are selectable constant gains and $\text{sgn}(\cdot)$ is the signum function. The closed-loop error system is obtained by substituting (11) into (6) as follows

$$J\dot{r} = \tilde{W} + N_d - \tau_{FES} - B_e(k_1 r + (k_2 + k_3\|z\|)\text{sgn}(r)) - e. \tag{12}$$

IV. STABILITY ANALYSIS

Theorem 1. *Given the closed-loop error dynamics in (12), the control input in (11) achieves global exponential tracking when $\tau_{FES} = 0$ in the sense that*

$$\|z(t)\| \leq \sqrt{\frac{\lambda_2}{\lambda_1}} \|z(t_0)\| exp^{-\frac{\beta}{2\lambda_2}(t - t_0)}, \tag{13}$$

provided the following gain conditions are satisfied

$$k_2 \geq \frac{\xi_d}{c_e} \text{ and } k_3 \geq \frac{c_1}{c_e}. \tag{14}$$

Proof. Let $V_1 : \mathbb{R}^2 \to \mathbb{R}$ be a positive definite, continuously differentiable Lyapunov function candidate defined as

$$V_1(e, r) = \frac{1}{2}e^2 + \frac{1}{2}Jr^2, \tag{15}$$

which satisfies the following inequalities $\lambda_1\|z\|^2 \leq V_1(z,t) \leq \lambda_2\|z\|^2$, where $\lambda_1 \triangleq \min(\frac{1}{2}, \frac{J}{2})$, $\lambda_2 \triangleq \max(\frac{1}{2}, \frac{\bar{J}}{2})$, and $\underline{J} \leq J \leq \bar{J}$, where $\underline{J}, \bar{J} \in \mathbb{R}_{>0}$. Let $z(t)$ be a Filippov solution to the differential inclusion $\dot{z} \in K[h](z)$, where $K[\cdot]$ is defined as [18], [19] and h is defined using (4) and (12) as $h \triangleq \begin{bmatrix} h_1 & h_2 \end{bmatrix}$, where $h_1 = r - \alpha e$ and $h_2 = J^{-1}\{\tilde{W} + N_d - \tau_{FES} - B_e(k_1 r + k_2 \text{sgn}(r) + k_3 \text{sgn}(r)\|z\|) - e\}$. The control input in (11) contains the signum function; hence, the time derivative of (15) exists almost everywhere (a.e.), i.e., for almost all t. Based on [20, Lemma 1], $\dot{V}_1(z,t) \overset{a.e.}{\in} \dot{\tilde{V}}_1(z,t)$, where $\dot{\tilde{V}}_1$ is the generalized derivative of (15) along the Filippov trajectories of $\dot{z} = h(z)$ defined as in [20] as $\dot{\tilde{V}}_1 \triangleq \bigcap_{\xi \in \partial V_1} \xi^T K \begin{bmatrix} \dot{e} & \dot{r} & 1 \end{bmatrix}^T (e,\, r,\, t)$, where $\partial V_1(z,t)$ is the generalized gradient of V_1 at (z,t), since $V_1(z,t)$ is continuously differentiable in z, $\partial V_1 = \{\nabla V_1\}$, $\dot{\tilde{V}}_1 \overset{a.e.}{\subset} [e,\, Jr] K \begin{bmatrix} \dot{e} & \dot{r} \end{bmatrix}^T$. Therefore, after substituting for (12), setting $\tau_{FES} = 0$ (i.e., FES input is not applied while the leg is rotated through the ROM), and canceling common terms, the time derivative of (15) can be expressed as follows

$$\dot{\tilde{V}}_1 \overset{a.e.}{\subset} -\alpha e^2 + \tilde{W}r + N_d r - c_e(k_1 r^2 + k_2|r| + k_3|r|\|z\|), \tag{16}$$

where $c_e \leq B_e \leq c_E$ and $c_e, c_E \in \mathbb{R}_{>0}$. By substituting (9) and (10) into the previous expression, cancelling common terms, and provided the sufficient gain conditions in (14) are satisfied, the following upper bound can be obtained

$$\dot{\tilde{V}}_1 \overset{a.e.}{\leq} -\alpha e^2 - k_1 c_e r^2 \overset{a.e.}{\leq} -\beta\|z\|^2, \tag{17}$$

where $\beta \triangleq \min\{\alpha, k_1 c_e\}$. Since $V_1 > 0$ and $\dot{V}_1 \overset{a.e.}{\leq} 0$, $V_1 \in \mathcal{L}_\infty$. Therefore, $e, r \in \mathcal{L}_\infty$ and thus, $z \in \mathcal{L}_\infty$, and $\dot{e}, \dot{q}, q \in \mathcal{L}_\infty$. Since $z \in \mathcal{L}_\infty$, then $u_{motor} \in \mathcal{L}_\infty$ in (11). Using (15) and (17), the exponential upper bound in (13) is obtained.

To account for the open-loop FES input in the stability of the motor controller when holding the leg in a static position at the end of the ROM, the subsequent analysis is provided. The closed-loop error system in (12) is output strictly passive (OSP) when $\tau_{FES} \neq 0$, i.e., when FES is applied, provided the sufficient gain conditions in (14) are satisfied. Using (17), the generalized time derivative of (15) can be further upper bounded as $\dot{\tilde{V}}_1 \overset{a.e.}{\leq} -\alpha|e|^2 - k_1 c_e |r|^2 + \tau_{FES}|r|$ and its integration yields $\int_{t_1}^{t} \tau_{FES}(\,)|r(\,)|d \overset{a.e.}{\geq} \tilde{V}_1(t) - \tilde{V}_1(t_1) + \alpha \int_{t_1}^{t} |e(\,)|^2 d + k_1 c_e \int_{t_1}^{t} |r(\,)|^2 d$, where $t_1 \in \mathbb{R} > t_0$, which can be used to prove that the closed-loop error system in (12) is OSP from input τ_{FES} to output r [21] since τ_{FES} is bounded due to the bounded open-loop FES input. ∎

V. EXPERIMENTS

This section presents the apparatus, FES patterns, experimental protocols, and results obtained with the custom powered machine depicted in Fig. 1. The experiments are

motivated to demonstrate the ability of the machine and FES to safely provide a user experience that is consistent with the protocols outlined for manual stretching of the hamstring complex using the static, AIS, and PNF techniques (as introduced in Section II). Three experiments (one for each flexibility technique) were conducted in two able-bodied participants (male, age 40 and male, age 24). The first experiment is a single static set. The second experiment is a single set of 10 AIS repetitions. The third experiment is a single set of one PNF repetition. Prior to the experiments, the participants provided written, informed consent consistent with IRB protocol at Syracuse University (IRB #: 22-404). The hypothesis is that the combination of a closed-loop robust kinematic motor controller and open-loop FES inputs can accurately follow industry protocols for static, AIS, and PNF stretching of the hamstring complex.

A. Apparatus

The apparatus depicted in Fig. 1 consists of a rigid pivot arm that supports the participant's leg and rotates in the sagittal plane about a pin aligned with the participant's hip joint (Fig. 1A). An optical encoder (US Digital) is affixed to the pin and is used to measure the hip angular position and compute the angular velocity (Fig. 1B). An offboard 24 VDC brushless electric motor (Maxon) using a Bowden cable and pulley system (Fig. 1C) applies torque about the hip by raising the rigid pivot arm that supports the participant's leg. A load cell (OMEGA LC201-300) is placed in series to measure the tension in the cable (Fig. 1D).

The motor controller designed in (11) is implemented using a desktop computer (Windows 10 OS, Microsoft) running a real-time target (QUARC 2.6, Quanser) using MATLAB/Simulink 2018a (Mathworks), and operating with a sampling frequency of 1 kHz. Data acquisition devices (Quanser QPIDe, Q8-USB) command motor inputs computed by (11) and collect data from the sensors. Software stop conditions limit the angular position and velocity of the pivot arm and an emergency stop button is available to the participant.

B. FES for AIS and PNF Stretching

Transcutaneous electrical stimulation was applied to the quadriceps and hamstring complexes for AIS and PNF stretching, respectively. Pulse width (70 μs) and stimulation frequency (60 Hz) were fixed while the pulse amplitude was varied using open-loop control (i.e., the stimulation pattern was predetermined). Current amplitude is controlled in a bipolar configuration to facilitate concentric contraction cycles of the antagonist and agonist for AIS and PNF stretching, respectively. Biphasic symmetric electrical stimulation was delivered from a current-controlled stimulator (Fig. 1E) (Hasomed GmbH, RehaStim).

For AIS, two 3" $\times$ 5" adhesive electrode pads (ValuTrode) are placed on the skin inferior to the proximal origin and superior to the distal insertion (above the knee) of the participant's quadriceps complex (Fig. 1F).

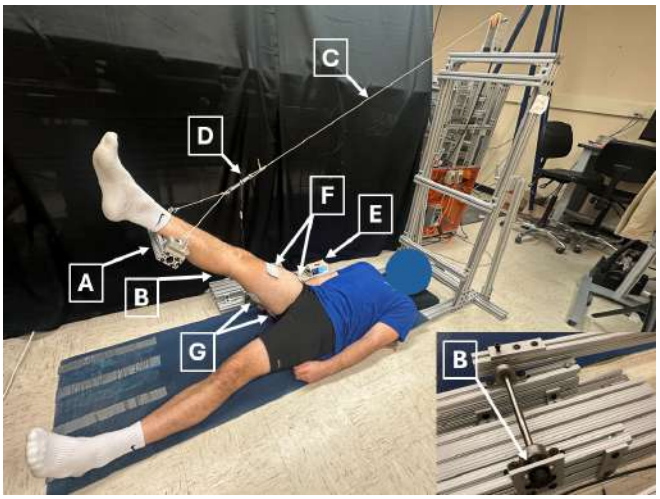

Fig. 1. A participant laying supine with the right hip being moved into hip flexion by the robust kinematic controller. A denotes the pivot arm. B denotes the optical encoder. C denotes the Bowden cable system. D denotes the load cell. E denotes the RehaStim FES module. F & G denote the FES electrode pad placement for AIS and PNF stretching, respectively. The sub-image shows the optical encoder from the participant's right side

For PNF stretching, two 3" $\times$ 5" adhesive electrode pads (ValuTrode) are placed on the skin inferior to the proximal origin and superior to the distal insertion (above the knee) of the participant's hamstring complex (Fig. 1G).

C. Protocol

Each experiment began with the participant laying supine on a thin, padded mat with the hip joint aligned to the rotational axis of the pivot arm. Using the kinematic motor controller defined in (11), the leg was rotated in tandem (slowly, as per industry standard guidelines) with the pivot arm about the hip joint in the sagittal plane from the horizontal (i.e., 0°) position to the desired end ROM and then held at that position until the end of the experiment (except in the case of PNF, where the kinematic controller increases the hip flexion angle by an additional 10% following FES-induced activation). The desired hip angular position, velocity, and acceleration, $q_d, \dot{q}_d, \ddot{q}_d$, are computed using hyperbolic tangent functions (two in the case of PNF) and their analytical derivatives.

For static stretching, five seconds after the robust kinematic controller is activated, the device begins to increase the angle of hip flexion in the sagittal plane to the target end ROM over 40 seconds – this rate of change in muscle lengthening of the agonist satisfies protocol guidelines to lift the leg slowly/passively. Once the leg reaches the target end ROM position, the device holds the leg static for 60 seconds.

For AIS, the leg is lifted similarly to the static case. However, once the leg is at the target end ROM position, FES is applied to the antagonist (i.e., quadriceps complex) with an open-loop high pulse amplitude with fixed pulse width and pulse frequency. The FES duty cycle for one set is consistent with the guidelines in Section II (see *Active-Isolated Stretching*).

For PNF stretching, the leg is lifted similarly to the static case. However, once the leg is at the target end ROM position for ten seconds, FES is applied to the agonist (i.e., hamstring complex) with an open-loop low pulse amplitude using fixed pulse width and pulse frequency. The FES duty cycle for one set is consistent with the guidelines in Section II (see *PNF Stretching*).

D. Results

For both participants, across all experiments, the kinematic controller gains were selected as $[\alpha,\ k_1,\ k_2,\ k_3] \triangleq [10,\ 0.0825,\ 0.015,\ 0.015]$. Fig. 2 shows the position tracking error e for each stretching experiment. Fig. 3 shows the desired q_d and actual q kinematic trajectories of each participant for each stretching experiment. Fig. 4 shows the open-loop FES patterns for the AIS and PNF stretching experiments.

As illustrated in Figs. 2-3, it can observed for all experiments that the kinematic controller was able to accurately follow the desired trajectory q_d.

For AIS, FES is applied for 10 antagonist contractions with minimal disturbance of the kinematic tracking. After the 10 FES-induced contractions, the experiment is concluded.

For PNF stretching, after the single set contraction of the agonist, the FES input is turned off and the kinematic controller tracks an increased target ROM over 20-seconds. Once the new position is held for an additional 24-seconds, the experiment is concluded. As depicted in Figs. 2-3, following the application of FES input, from 65-85 seconds, the kinematic controller was able to accurately increase the ROM by a factor of 10% over 20-seconds.

Fig. 5 shows the load cell tension and open-loop FES inputs of the AIS and PNF stretching experiments for Participant 1. The results in Fig. 5 illustrate an inversely proportional relationship between antagonist activation and load cell tension when using AIS and a proportional relationship between agonist activation and load cell tension when using PNF stretching. It can also be observed that following the (post-FES) PNF increase in ROM, the load cell tension remained at a magnitude consistent with the magnitude measured at the initial target ROM.

E. Discussion

The experimental results in the two able-bodied individuals present limitations to the statistical significance of the data: (i) the desired stretching trajectories q_d can be optimized to personalize the stretching techniques across participants, (ii) the sample size in this paper is small to achieve statistically significant results, which motivates future testing including people with SCI, and (iii) the design of a closed-loop FES controller is needed to customize the applied intensities across the participants (e.g., based on a percentage of a given participant's maximum voluntary contraction).

VI. CONCLUSION

In this paper, a closed-loop kinematic controller was combined with open-loop FES inputs to safely and consistently implement industry-standard guidelines for static, AIS, and PNF stretching of the hamstring complex using a custom powered machine. The closed-loop motor controller was developed to track a desired hip joint kinematic trajectory to reach a target end ROM and hold the leg at that position. Once the leg had reached the target end ROM, open-loop FES was applied in the AIS and PNF stretching experiments to the quadriceps and hamstring complexes, respectively. During the static stretching case, no FES was applied. The combination of the motor controller that rotates the hip to a desired ROM and maintains the leg in a fixed position (for static, AIS, and PNF) while FES is applied on the antagonist

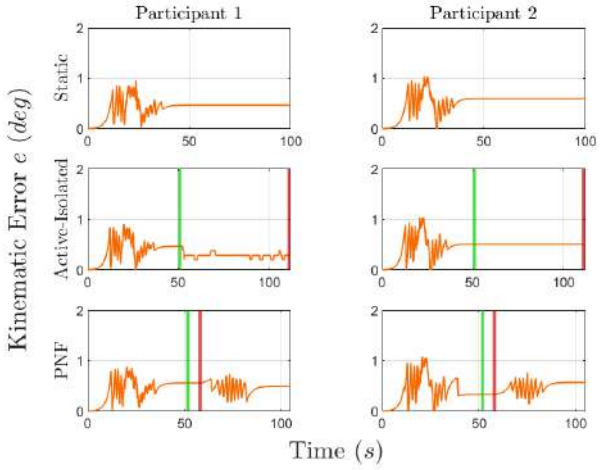

Fig. 2. The position tracking errors, e, for each experiment reported in degrees. The green and red vertical lines denote when the open-loop FES inputs were activated and stopped, respectively. Small perturbations in the kinematic error during the second half of PNF stretching were expected due to the applied FES on the hamstring complex and its interaction with the motor cable controller.

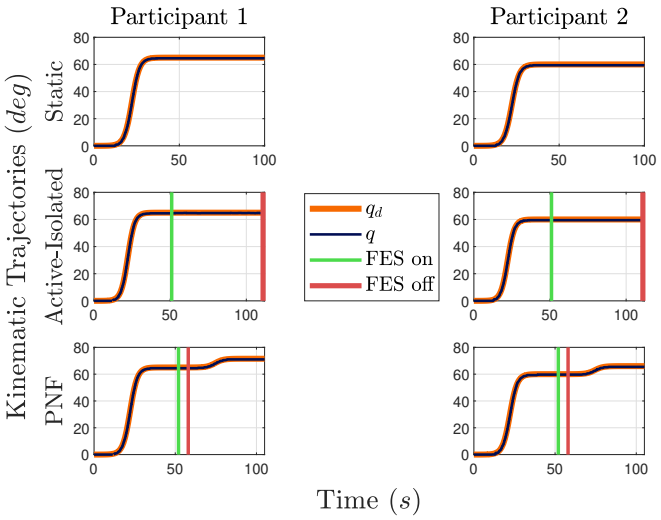

Fig. 3. The desired, q_d, and actual, q, kinematic trajectories from each experiment reported in degrees. The desired trajectory q_d was set to reach 65° and 60° for Participants 1 and 2, respectively. The trajectories q_d were determined for each participant in prior manual assessments using a goniometer. The green and red vertical lines denote when the open-loop FES patterns were started and stopped, respectively.

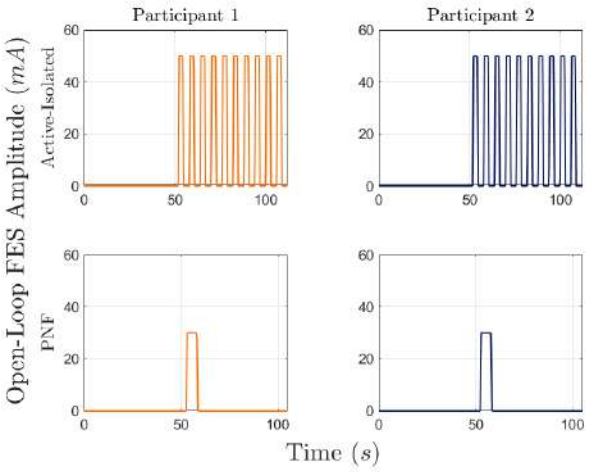

Fig. 4. The open-loop FES patterns for active-isolated stretching (AIS) and PNF stretching reported in milliamps (mA) for Participant 1 in orange and for Participant 2 in blue.

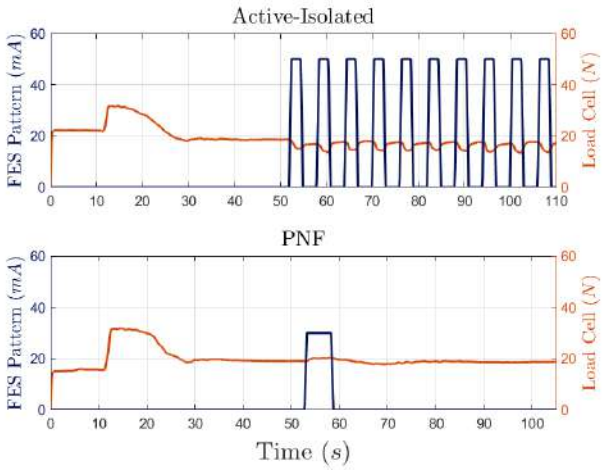

Fig. 5. The load cell measurements and FES patterns from Participant 1 during the active-isolated stretching (AIS) and PNF stretching experiments.

or agonist (for AIS and PNF, respectively) could reduce the labor-intensive burden of manual therapies and mitigate challenges related to staffing shortages in clinical settings. Preliminary experiments in two able-bodied individuals were conducted to show feasibility of the controller using each stretching technique. A Lyapunov-based stability analysis was developed to show that the electric motor controller achieves global exponential tracking.

A Novel Patient-Centered Robotic Rehabilitation Approach for Retraining Reaching and Grasping Functions for Individuals with Stroke

Aisha Raji, Cesar Marquez-Chin, Urvashy Gopaul, and Milos R. Popovic

Abstract— **This study introduces a novel robotic rehabilitation system for improving upper extremity function by retraining reaching and grasping in individuals with stroke. The system integrates a collaborative robotic arm equipped with a force sensor and gripper with functional objects to create a patient-centred approach that simulates real-world activities and stimulates sensorimotor activity during training sessions. The system constantly assesses the user's extent of reach and presents the individual objects as reaching and grasping targets at different positions within and slightly beyond the user's reach.**

Preliminary testing involved one participant without stroke and one individual with hemiplegia reaching and grasping 19 objects of various weights and textures. The results indicate that the participant without stroke reached objects in an average of 3.47 seconds with a mean grasping force of 3.28 ± 0.05 N, while the participant with stroke took 5.66 seconds, with a mean of 1.04 ± 0.02 N exerted to grasp objects.

Our findings suggest that the proposed robotic rehabilitation system may be suitable for improving reaching and grasping after stroke.

Keywords— Collaborative robot (cobot), upper extremity, reaching, grasping, stroke, robotic rehabilitation, Toronto Rehabilitation Institute – Hand Function Test (TRI-HFT), Range of movement.

I. Introduction

Stroke is a leading cause of long-term disability globally that severely impairs motor and sensory functions and reduces independence [1], [2]. Annually, over 15 million people experience a stroke, resulting an economic burden that exceeds $721 billion worldwide [3], [4]. Approximately 70% of stroke survivors experience upper extremity impairment [5], [6], [7]. Upper extremity function is vital for performing activities of daily living (ADLs) and enhancing quality of life. Rehabilitation plays a crucial role in restoring voluntary motor function, with several systematic reviews highlighting the importance of meaningful, mass-practiced, intensive (amount of time spent in therapy), and task-specific activities for improving motor function during rehabilitation [8], [9], [10].

Robot-assisted rehabilitation is a promising intervention that can provide consistent, repeatable, and intensive training opportunities while also reducing the physical burden on therapists [11]. Robotic systems offer precise control and adaptability, enabling therapy tailored to an individual's needs and progress. Furthermore, integrating motor, tactile, and proprioceptive training through interactive and functional tasks enhances neuroplasticity and promotes motor recovery [12].

Despite important advancements, there remains a need for robotic rehabilitation systems to focus on addressing both motor and functional recovery to facilitate the seamless translation of improvements into real-world ADLs [13], [14]. Some existing robotic devices incorporate game-based elements to engage patients; however, they lack the capability to imitate everyday activities, which is crucial for ensuring that improvements in reaching and grasping directly enhance functional independence [15]. Several studies have demonstrated the potential of robotic rehabilitation to improve upper extremity movement, especially among individuals with chronic stroke [16], [17]. However, current evidence suggests that the efficacy of robot-assisted rehabilitation is often similar to other upper extremity interventions [18], [19], [20], with improvements being either marginal or not clinically meaningful [19].

This work presents a novel approach to robotic rehabilitation that redefines the role of robots in delivering therapy. The system retrains reaching and grasping functions in individuals with upper extremity impairments by allowing users to explore three-dimensional space without restraints. It integrates a collaborative robotic (cobot) arm with force-sensing capabilities, a gripper, and functional objects from the Toronto Rehabilitation Institute – Hand Function (TRI-HFT) [21]. This integration facilitates a patient-centered approach by using real objects to assess each user's unique reach and strategically presenting them as targets within and slightly beyond this reach. By incorporating real-world tasks, the system provides meaningful sensorimotor inputs during training and encourages progressive motor engagement and sensorimotor adaptation by dynamically assessing the user's reach in three-dimensional space and presenting individual TRI-HFT objects as targets positioned on or just outside the user's reach. We tested the proposed protocol on neurologically intact individuals before testing on a person with a stroke that affects their upper extremity. This work presents preliminary data from two individuals – one without and one with a stroke - as part of a study to provide insights into how this system may support the transition of motor and sensation gains into functional everyday activities.

II. METHODS

A. System Specification and Setup

In this study, we used a UR5e cobot arm (Universal Robots, Denmark), which has six degrees of freedom, allowing each joint to move independently within a ±360° range and extend up to 85 cm from its base. The UR5e, with a payload capacity of 5 kg, was mounted on a table measuring 150 cm by 75 cm. We equipped the robotic arm with a 2F-85 gripper (Robotiq Inc., Canada) for object gripping and manipulation. This gripper has an adjustable grip force ranging from 20 to 235 N and can open up to 85 mm. For enhanced safety, we covered the arm with AIRSKIN module pads (Blue Danube Robotics GmbH, Austria). These pressure-sensitive pads require a minimum force of 5 N to stop the robot's movement.

We used 3D-printed objects of the TRI-HFT, including a mug, a sheet of paper, a book, a reusable plastic bag filled with golf balls, a soda can, a die, a sponge, a credit card, a wireless home telephone, a pencil, and nine rectangular blocks. The blocks were categorized into sets of three based on weight (100 g, 200 g, and 300 g) and surface friction (smooth, medium, and rough) [21].

Using SolidWorks (Dassault Systèmes, USA), we modified these objects to enhance the robot's picking and manipulation capabilities during rehabilitation exercises. The redesign involved creating external, internal, or handleless configurations to ensure compatibility with the gripper and facilitate smooth interactions between the objects, the robot, and the participants, as illustrated in Fig. 1. These modified objects were 3D-printed and stored on a custom-designed shelf mounted on the robot's table (Fig. 2), enabling the cobot to access them.

A. Rehabilitation Exercise Procedure

Participants sat on a chair facing the robot at a safe and comfortable distance from the table's edge. We provided participants with clear instructions and expectations, including a video demonstration to familiarize them with the procedure. We then configured the robot by selecting the affected upper extremity to be used throughout the session. An experimental session consisted of two phases (described next), in which the participant performed a series of tasks following visual cues. Ethics approval for this study was obtained from the Research Ethics Board (REB) at the University Health Network, Toronto, Canada. Participants provided written and informed consent for participation.

Phase 1: 3D Assessment of the Extent of *Reach*

In the first phase of the rehabilitation session, we conducted a one-time extent-of-reach assessment to evaluate each participant's three-dimensional workspace (range of movement (ROM)) – specifically focusing on the affected extremity in the individual with stroke. This assessment identified the maximum and comfortable reach limits across various axes, which were used to guide the subsequent phase of the session. The robot presented a rectangular block at the center of the table's edge without releasing it. When the "start exploration" visual indicator illuminated, we asked if the participants were comfortable with the block's position and adjusted it if necessary.

Participants then freely used their affected upper extremity to move the block vertically as high as possible on the z-axis and gradually draw the largest spiral possible while gradually moving the block towards the table surface. This movement captured their maximum reach in the x-, y-, and z-axes (lateral, anterior, and vertical). Figure 3 illustrates the setup and data recorded during this process. After the exploration, the "start exploration" indicator illuminated again, and the robot waited 10 seconds to ensure that the user had released their grasp before returning the block to the shelf.

Phase 2: Object Reaching and Grasping Task

In the second phase, the system randomly selected and adaptively presented objects for a reach-and-grasp task at two random positions within each participant's unique movement range, identified in the first phase. The sponge was the only exception, and it was used for a high-five-reaching task to increase the participant's motivation. When the "grasp object" indicator illuminated, the participant reached, grasped, and pulled the object until the indicator deactivated. The indicator turned off either after a force threshold of 5N has been exceeded or one minute (if the participant was not able to reach the target position).

We implemented a challenge mode to encourage participants to extend their reach beyond the measured range of movement. After the "grasp object" indicator deactivated at the second target position, the "challenge mode" indicator illuminated, prompting the participant to accept the challenge. If the participant accepted, the robot moved the object 5 cm outside the previously determined workspace. By reaching beyond arm's reach, the participants need to flex the trunk to reach the target. The "grasp object" indicator illuminated again at the challenge position, prompting the participant to grasp

and pull the object. Once the indicator deactivated, the robot dropped off the object and returned to its default home position. We use the 3D-printed sponge (Square 142 × 142 mm) to replicate a high-five gesture by providing a compliant surface for participants to tap, as illustrated in Figure 3b.

B. Data Analysis

We collected the data with a frequency of 500 samples per second and applied a low-pass filter to them with a cutoff frequency of 1 Hz to align with the frequency range of human motion [22], [23]. To evaluate the ROM, we rescaled the data using equation (1) and evaluated both the range of reach and force exerted on the object on each axis.

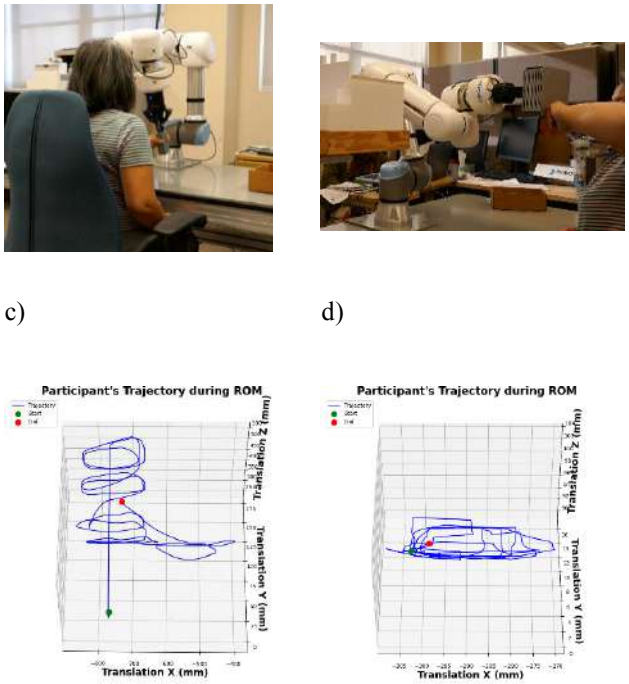
$$x_{normalized} = \frac{x - \sigma}{\sqrt{n}} \quad \dots (1)$$

where n is the number of data points recorded and σ is the standard deviation of the data.

In the second phase, the robot used the data from the first phase to calculate the maximal reaching workspace by selecting the outer edge of the path and the area of the workspace. We evaluated the mean grasp time as the interval between the object grasp cue and the participant's actual grasp, and we assessed the mean force exerted on each object as the force measured between the object grasp and release along each axis.

The standard error of the mean (SEM) was calculated using equation (2).

$$SEM = \frac{\sigma}{\sqrt{n}} \dots (2)$$



III. Results

The study involved two participants: one without stroke and one with left upper extremity impairment due to a stroke sustained seven years prior to participating in this study. Neither participant had previous experience with robotic rehabilitation, and both engaged in a single three-hour exercise session to evaluate the preliminary results of the system. The results presented here focus on their performance during the ROM exploration and object-reaching and grasping tasks.

A. ROM Exploration

Figure 3 illustrates the participant performing the tasks and the trajectory and performance data recorded during the extent-of-reach assessment, highlighting the three-dimensional spatial pathway with the start and end points. The results show that the participant without stroke covered a wider area and produced more defined, symmetrical spirals compared to the participant with stroke, who had a limited reach. This pattern may indicate that motor performance in the affected arm was constrained. These findings are supported by the data in Figure 4 and Table 1.

a) b)

c) d)

Fig. 3: a) Participant with stroke moving object with the affected hand during extent-of-reach assessment; (b) Participant with stroke performing high-five with the sponge; (c) and (d) show 3D visualizations of the recorded trajectories during the assessment for the participant —(c) without stroke (d) with stroke.

The table (150 x 75 cm) provides the spatial context for our analysis. Figure 4 and Table 1 show that the participant without stroke achieved a maximum range of 86.86 cm along the x-axis, with the smallest range of 32.15 cm recorded on the y-axis, which is consistent with normative data for horizontal reaches (80–100 cm) [24], [25], [26]. The individual with stroke reached a maximum of 30.93 cm along the x-axis and a minimum of 10.47 cm along the z-axis. This suggests that there is more restriction in the vertical movement and reduced variation in the area reached. Table 1 further presents the translation values captured during ROM assessment, with the mean and standard deviation values highlighting variability across all axes.

TABLE 1: POSITION RECORDED IN VARIOUS AXES DURING EXTENT-OF-REACH ASSESSMENT

Position	Range (cm) (without stroke)	Mean ± SD (cm) (without stroke)	Range (cm) (with stroke)	Mean ± SD (cm) (with stroke)
Translation X	86.86	54.03 ± 0.00	30.93	19.97 ± 0.00
Translation Y	32.15	16.88 ± 0.00	15.14	5.95 ± 0.00
Translation Z	54.75	25.85 ± 0.00	10.47	6.59 ± 0.00

a)

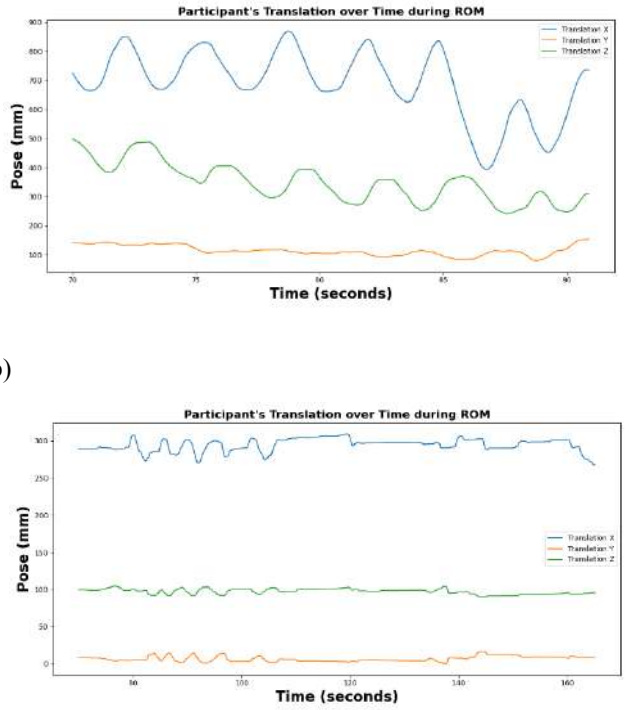


Fig. 4: 2D representation of reach in various axes during extent-of-reach assessment for the participant a) without stroke (b) with stroke.

The recorded force during ROM assessment is presented in Figure 5 and detailed in Table 2. The participant without stroke generated a total force of 6.47 N, with mean forces of 0.62 N, 2.28 N, and 0.381 N on the x-, y-, and z-axes, respectively, while the participant with stroke generated a total force of 1.38 N, with mean forces of 0.59 N, 0.39 N, and 0.06 N along the x-, y-, and z-axes, respectively. The relatively higher force exerted along the x-axis for the individual with stroke may reflect an increased effort to overcome the robot's internal resistance or muscle stiffness in the lateral direction.

TABLE 2: FORCES RECORDED IN VARIOUS AXES DURING EXTENT-OF-REACH ASSESSMENT

Force Axis	Range (N) (without stroke)	Mean ± SD (N) (without stroke)	Range (N) (with stroke)	Mean ± SD (N) (with stroke)
X	1.78	0.62 ± 0.01	0.76	0.59 ± 0.01
Y	4.11	2.28 ± 0.04	0.54	0.39 ± 0.01
Z	0.58	0.38 ± 0.01	0.08	0.06 ± 0.00
Total	**6.47**	**3.28 ± 0.05**	**1.38**	**1.04 ± 0.02**

B. Reaching and Grasping Task

The data recorded in this phase revealed notable differences between the participant without stroke and the participant with stroke. The participant without stroke spent an average of 2.47 seconds reaching objects, with a mean grasp time ranging between 1.31 to 3.32 seconds, as displayed on Table 3. Objects like the sponge, most blocks, and pencil required shorter grasp times, while the phone and credit card

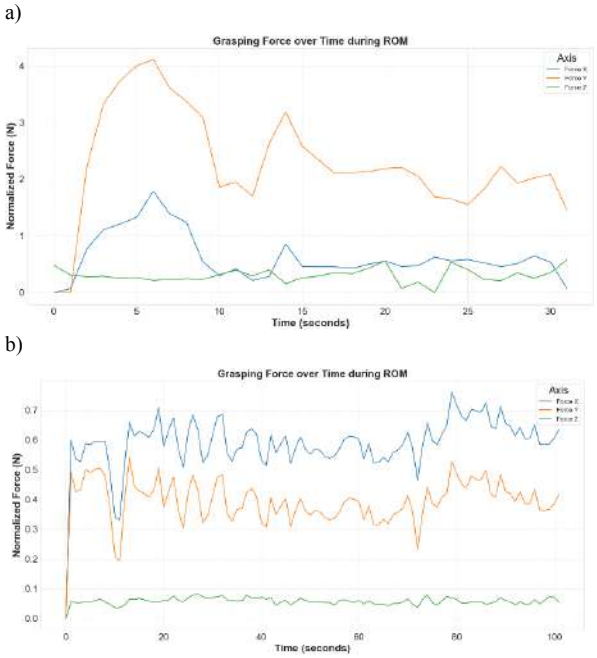

Figure 5: The grasping force exerted in various axes during extent-of-reach assessment for the participant a) without stroke (b) with stroke.

took slightly longer, their overall times remained within a manageable range, as shown in Figure 6a.

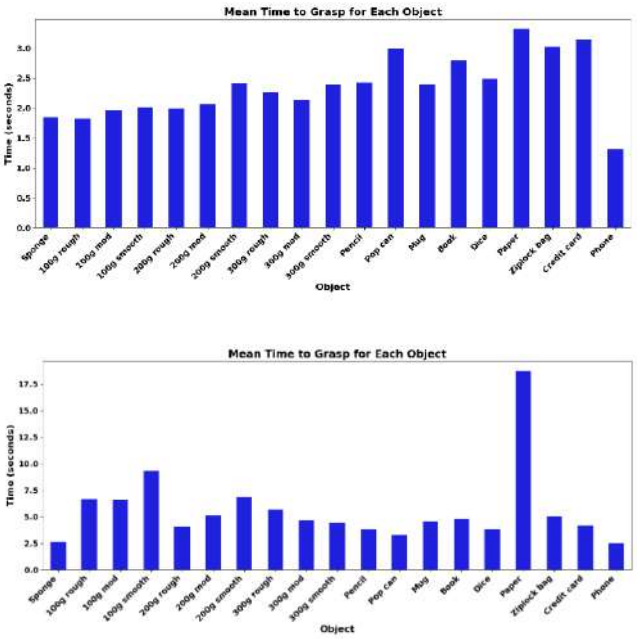

Fig. 6: Mean time to grasp each object for the participant a) without stroke b) with stroke

The participant with stroke had a longer mean time to grasp of 5.66 seconds, with a mean grasp time ranging between 2.65 to 19.59 seconds, as shown in Figure 6b. The characteristics of each object had a significant impact on performance. For example, the paper presented a considerable challenge due to its smooth texture and lack of rigidity, resulting in a grasp time of 45.31 seconds during the initial target presentation.

TABLE 3: MEAN TIME TO GRASP OBJECT AT VARIOUS TARGET POSITIONS (PARTICIPANT WITHOUT STROKE)

S/N	Object	Weight (gm)	Time to grasp (seconds)			
			Target 1	Target 2	Target 3 (challenge mode)	Mean
1	Sponge	178	2.01	1.43	2.10	1.85
2	100g rough block	100	2.08	1.38	1.99	1.82

7	200g smooth block	200	6.08	3.09	11.35	6.84
8	300g rough block	300	4.41	5.38	7.22	5.67
9	300g moderate block	300	5.04	4.48	4.27	4.60
10	300g smooth block	300	5.15	4.19	4.01	4.45
11	Pencil	7	5.07	3.48	2.74	3.76
12	Pop can	360	5.16	2.81	1.84	3.27
13	Mug	545	5.27	6.02	2.26	4.52
14	Book	316	8.96	2.04	3.32	4.77
15	Dice	5	5.58	2.59	3.22	3.80
16	Paper	14	45.31	10.21	3.26	19.59
17	Ziplock bag with golf balls	228	6.87	4.87	3.46	5.07
18	Credit card	3	5.77	2.60	4.14	4.17
19	Phone	215	5.01	2.64	Skipped	3.83
	Mean		**4.04**	**1.96**	**1.96**	**2.65**

However, by target 3, the grasp time reduced significantly to 3.26 seconds, suggesting the participant's adaptability and improved efficiency through learning and practice, as displayed on Table 4. The book and 100g smooth block also had a longer reach time (8.96 and 9.44 seconds) at the first target. This may be due to the initial unfamiliarity with the objects and their presentation distance and orientation. Notably, the participant without stroke mostly demonstrated a longer reach time during the challenging task, which may reflect that the participant was able to fully extend their arm during the ROM assessment, resulting in a target position that was more demanding to achieve.

Furthermore, the participant with stroke demonstrated decreasing time to grasp objects from Target 1 to Target 3 across multiple objects, indicating learning and adaptation. For example, smoother items, such as blocks, paper, and smooth blocks, exhibited a longer mean time to grasp, suggesting difficulty due to reduced friction. Nevertheless, the participant adapted their grasping approach to compensate for these challenges.

Figure 7 shows the translation and force changes for the sponge, which had the lowest mean reach time of 1.85 and 2.65 seconds, for the individual without and with stroke, respectively, and a high mean force of 0.93 N and 2.32 N. This

outcome may result from the absence of a grasping component in the sponge task, and the participant reported finding the task motivating.

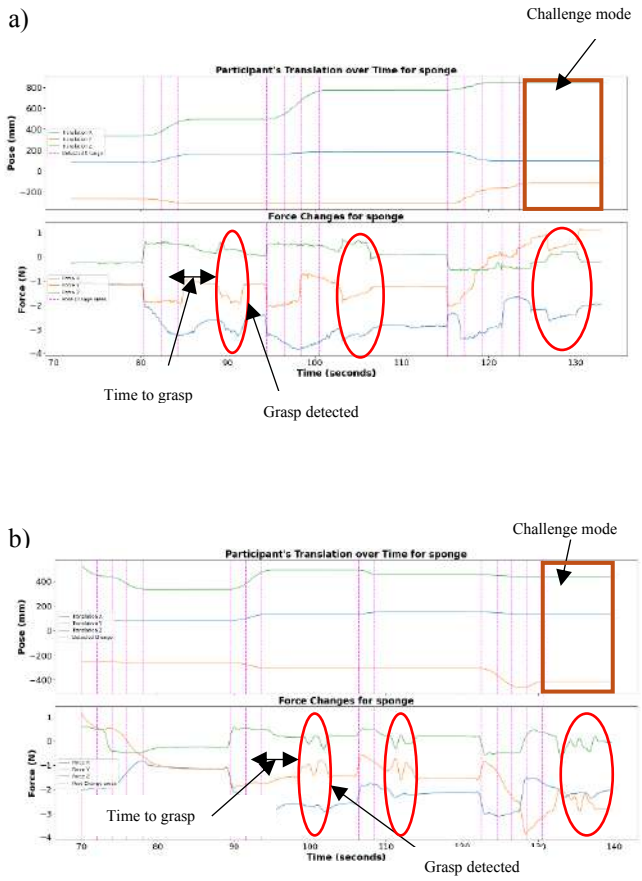

Figure 7: Target position and force changes during the task with the sponge for the participant a) without stroke (b) with stroke.

Figure 8 and Table 5 show the mean resultant force exerted on each object by the participant without stroke, indicating variations depending on object weight and texture. The highest force was 3.80 N, recorded for the 200g moderate block, while the lowest was 0.76 N for the pencil (7g). Force exertion also varied across different object textures, with higher forces mostly applied to rough and moderate-textured objects.

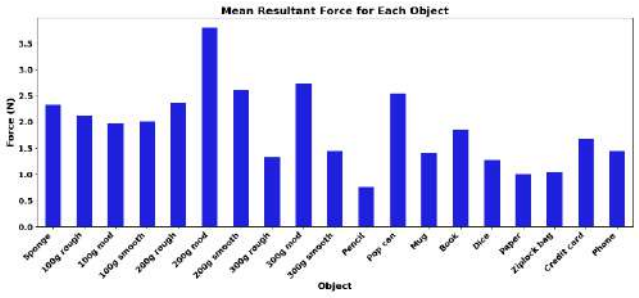

Figure 8: Mean Resultant Force Exerted on each Object (participant without stroke)

The participant applied higher forces during the challenge mode (target 3) for most objects. This may likely be due to the increased difficulty and the extended task duration (5 seconds), encouraging the participant to apply more force to maintain a secure grip and complete the task.

TABLE 5: RESULTANT FORCE EXERTED ON OBJECTS DURING EXERCISE (PARTICIPANT WITHOUT STROKE)

S/N	Object	Weight (gm)	Resultant force exerted (N)			
			Target 1	Target 2	Target 3 (challenge mode)	Mean
1	Sponge	178	2.10	2.01	2.87	2.33
2	100g rough block	100	1.47	1.99	2.90	2.12
3	100g moderate block	100	1.70	1.94	2.25	1.98

15	Dice	5	1.44	1.24	1.12	1.27
16	Paper	14	0.85	1.04	1.12	1.00
17	Ziplock bag with golf balls	228	1.13	1.44	0.58	1.05
18	Credit card	3	1.14	1.05	2.84	1.68
19	Phone	215	2.38	1.97	2.45	1.45
	Mean		**1.78**	**1.79**	**2.42**	**2.00**

Figure 9 and Table 6 illustrate the mean resultant force on each object by the participant with stroke, indicating lower force values and less variability compared to the participant without stroke. The highest force of 1.17 N was recorded for the mug, the heaviest object (545g), while the lowest force was 0.34 N on the paper (14g). Although heavier objects typically require greater force exertion, the participant did not exhibit a

clear increase in the force exerted across different objects, suggesting difficulty in adjusting grip strength.

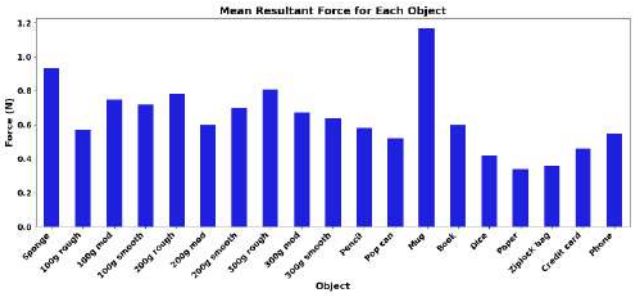

Figure 9: Mean Resultant Force Exerted on each Object (participant with stroke)

Force application was relatively low across all objects, with minimal adjustments based on weight and texture. Unlike the participant without stroke, who applied greater force to objects, the participant with stroke maintained a more uniform force. This may indicate reduced grip strength and a limitation in the participant's ability to adjust force based on object characteristics. Smooth objects like paper (0.34 N) and ziplock bag (0.36 N), posed challenges, likely due to the reduced friction and difficulty securing a stable grasp.

Additionally, the participant with stroke did not consistently increase the force exerted in the challenge mode**,** as observed in the participant without a stroke. This result may suggest difficulty in generating additional force, potentially due to muscle weakness. However, in the sponge task**,** which did not require grasping, the participant applied a higher force (0.93 N), indicating that challenges in generating force were more evident in grip-dependent tasks.

IV. Conclusion

This study introduces a new paradigm for robotic rehabilitation that redefines the role of robots in retraining reaching and grasping functions after a stroke. Unlike existing wearable exoskeleton robots such as the AGREE [27] and ARMin III [28] systems that attach directly to users and offer training modalities (passive, active assistive, assist-as-needed, or resistive) through predefined trajectories, activities displayed on screens, and counterweights for gravitational support, our approach minimizes joint misalignment by avoiding direct attachment to the user and simulates real-life scenarios without gravity assistance. Consequently, participants can engage in reaching tasks using diverse hand configurations that closely reflect natural movement, and our design facilitates finger movement practice to replicate everyday tasks more accurately.

We integrated functional objects into the training to imitate daily tasks and provide users with real sensorimotor inputs, including proprioceptive and tactile feedback. The system dynamically assesses each user's extent of reach and adaptively presents targets within and slightly beyond the measured ROM. This patient-driven strategy may enhance the relevance of training and help identify specific challenges that may be addressed in subsequent interventions.

TABLE 6: RESULTANT FORCE EXERTED ON OBJECTS DURING EXERCISE (PARTICIPANT WITH STROKE)

S/N	Object	Weight (gm)	Resultant force exerted (N)			
			Target 1	Target 2	Target 3 (challenge mode)	Mean
1	Sponge	178	0.79	0.94	1.06	0.93
2	100g rough block	100	0.82	0.45	0.44	0.57

	Mean		**0.66**	**0.62**	**0.64**	**0.64**

Preliminary results from two participants - one with stroke and one without - demonstrate the potential of this approach for upper extremity rehabilitation. For the participant without stroke, the system showed the capability of providing challenging tasks, as evidenced by the time taken to grasp objects during the challenge phase of the session. Additionally, the participant with stroke showed significant improvements in reaching time across all tasks, suggesting adaptability and motor learning. The decreased grasp times, particularly with initially challenging objects like the paper, may suggest

increased familiarity and skill development, which may be transferred into ADLs. Furthermore, the use of real objects provides the advantage of identifying specific areas where participants encounter difficulties, which could become targets for subsequent rehabilitation sessions.

However, challenges remain with smooth and lightweight objects, as exhibited by the extended grasp times for paper and smooth blocks, likely due to reduced friction. In addition, target placement and fatigue may have also influenced performance, particularly in the skipped trial with the phone. Further research will focus on evaluating the usability of this approach with a larger group of individuals with stroke, refining training protocols by gradually increasing task difficulty and reducing exercise duration, and implementing targeted interventions to address muscle stiffness in axes with limited ROM. Providing additional training with difficult objects may enhance dexterity and outcomes.

Although not all individuals with stroke may benefit from this system, our approach offers notable advantages compared to existing systems that rely on multiple layers of control and gravity compensation. By allowing participants to practice reaching and grasping tasks without restrictive attachments, our system promotes the performance of functional tasks with real objects in a more natural way. Furthermore, this paradigm may enhance neuroplasticity by increasing cortical activity in the motor and somatosensory cortices, thereby contributing to improved functional recovery. Additionally, our system creates opportunities to integrate complementary technologies for neurorehabilitation, such as functional electrical stimulation (FES), brain-computer interface (BCI), and other robotic devices. Combining our system with these modalities may enhance rehabilitation outcomes by leveraging the unique strengths of each system to improve recovery of individuals with stroke.

Design and Evaluation of a Single-Sided Mobility Assistive Exoskeleton (SMAEXO) for Hemiplegia

Xiaoyue Yan[1, 2], Wei Yun Yau[3], Isaac Okumura Tan[2], Longbin Zhang[2, 4], Youlong Wang[1, 2], Oliver Roberts[2], Seng Kwee Wee[5], Wei Tech Ang[1, 2]

***Abstract*— This study presents the Single-Sided Mobility Assistive Exoskeleton (SMAEXO), a novel, single-sided, multi-joint device designed to enhance mobility and rehabilitation for individuals with hemiplegia. SMAEXO provides active assistance at the hip and knee, combined with a passive, flexible ankle joint to prevent foot drop, ensuring comprehensive support throughout the gait cycle. Its innovative design optimizes reaction force support and weight distribution, promoting balance and reducing strain on the affected side. Additionally, its modular, customizable design accommodates diverse body dimensions and biomechanical needs, while safety features such as self-locking mechanisms, cushions, bumpers, and elastic components enhance user safety and comfort. The SMAEXO's usability, comfort, safety, and assistance were assessed through trials with eight able-bodied participants, including physiotherapists simulating stroke gait patterns. Participants reported the device as comfortable, safe, and effective, highlighting its benefits during level and slope walking and obstacle negotiation. Notable feedback included the need for enhanced ventilation, reduced device weight, and improved ease of donning and doffing. The results demonstrate SMAEXO's potential to deliver comprehensive multi-joint assistance for individuals with hemiplegia. This work contributes to advancing rehabilitation and assistive technologies for post-stroke individuals, enabling more effective and personalized mobility support.**

I. Introduction

Stroke, a leading cause of disability, often results in hemiparesis, affecting 65% of survivors with impairing gait [1]. Common issues include asymmetry, poor balance, and foot drop [2], requiring intensive rehabilitation to restore mobility. Traditional therapy is labor-intensive, requiring two physiotherapists per session, limiting scalability [3]. Exoskeletons offer a more efficient solution, providing consistent, automated support to enhance rehabilitation while reducing therapist workload [4].

Most lower-limb exoskeletons are bilateral, providing full mobility support by targeting the hip, knee, and ankle. Devices like Ekso Indego [5], ReWalk [6], and Rex [7] assist users with severe motor loss, such as spinal cord injury patients. However, their bulky design, high cost, and reliance on position control make them unsuitable for stroke survivors, who need responsive, tailored support [8].

For hemiplegic patients, unilateral exoskeletons offer a simpler, lighter alternative. Unlike bilateral devices, which restrict natural movement and disrupt gait symmetry [9], unilateral exoskeletons assist only the affected limb, enhancing mobility with less burden on the wearer.

However, the unilateral approach introduces its own challenges. The asymmetric structure of these devices can make it difficult to maintain balance, and the limited reaction force support hampers the generation of sufficient torque to adequately stabilize and propel the affected limb.

Furthermore, many unilateral exoskeletons assist only one joint, limiting their effectiveness for stroke-related multi-joint impairments. Knee devices like the University of Michigan's passive exoskeleton [10], the University of New York's active exoskeleton [11], and the REFLEX system [12] aid the knee for stance support and swing clearance. Similarly, ankle exoskeletons such as the ReStore Exo-Suit [13] and Northern Arizona University's device [14] improve plantarflexion and dorsiflexion but provide only partial support, neglecting impairments in other joints. Multi-joint unilateral devices such as HAL [15], AGoRA [16] and LitteStepper [17] attempt to assist multiple joints simultaneously but tend to be heavier, less user-friendly, and more challenging to integrate seamlessly with the user's intent.

In practice, existing unilateral exoskeletons still fall short of delivering seamless, multi-joint assistance while maintaining usability, comfort, and safety. These limitations underscore the need for a new generation of unilateral exoskeletons that can provide comprehensive, user-centered support for hemiparetic individuals.

To address these gaps, this work introduces the Single-Sided Mobility Assistive Exoskeleton (SMAEXO), a novel multi-joint device specifically engineered for individuals with hemiparesis. SMAEXO incorporates innovative features designed to optimize reaction force management and weight distribution, while ensuring that assistance at the hip, knee, and ankle joints is both effective and intuitive. The key contributions of this work include:

1) Development of the SMAEXO enables integrated assistance across the hip, knee, and ankle joints, providing comprehensive support to the affected limb. Optimized weight distribution and reaction force management strategies ensure that the device can effectively stabilize and support the user without compromising comfort, safety or ease of movement.

2) The performance of SMAEXO is validated through

This research is supported by ASTAR under the National Robotics Programme (NRP) BAU grant, Project - Assistive Robotics Programme (Award No: M22NBK0074).

a user study involving eight participants. This evaluation focuses on usability, comfort, safety, and effectiveness, offering valuable insights into SMAEXO's practicality and its potential to enhance the rehabilitation process for stroke survivors.

By offering a thoughtfully engineered solution that meets the unique needs of hemiparetic individuals, the SMAEXO has the potential to transform stroke rehabilitation.

II. System Overview

A. Architecture of SMAEXO

SMAEXO was developed through close collaboration with physiotherapists specializing in stroke rehabilitation and lower-limb exoskeletons. This consultative process ensured that the system aligns with the unique needs of individuals with hemiplegia, emphasizing usability, safety, comfort and comprehensive assistance. The device features a modular design comprising four primary components (Fig. 1):

- **Affected-side module:** Incorporates active hip and knee joints powered by quasi-direct drive (QDD) motors, which combine high-torque motors with a low gear ratio transmission (1:6) to deliver high bandwidth and backdrivability. Additionally, a passive ankle joint paired with a footplate is involved to prevent foot drop.
- **Unaffected-side module:** Features a passive hip joint that facilitates hip flexion/extension and abduction/adduction, ensuring natural movement on the unaffected side.
- **Back module:** Connects all modules and houses the control components and battery, strategically placing the battery on the unaffected side to optimize weight distribution and balance.
- **Vest harness:** Distributes device weight and reaction force evenly across the user's core, enhancing comfort and stability.

For safety and comfort, all joints incorporate both hard and soft limiters to restrict the range of motion (ROM) within the user's biomechanical capabilities. The soft limiters, implemented as joint buffers, absorb impacts when the joint approaches the hard limiters (Fig. 2 (b)). The joint buffers can be easily replaced to accommodate users with limited ROM. Additionally, all the leg bars are equipped with cuffs and cushions, as shown in Fig. 2 (d), these cuffs can be easily opened for quick donning and doffing and the major semi-axis, minor semi-axis of the cuffs can be easily adjusted to accommodate users with varying leg circumferences.

To further enhance adaptability and alignment, the SMAEXO features the corresponding adjustable mechanisms to allow tool-free adjustments for waist width, upper and lower leg bar lengths, and foot size, accommodating users of various body dimensions (Fig. 2 and Fig. 3 (a)). All adjustable mechanisms are equipped with reset springs to ensure the locked status for safety.

The main specifications of the SMAEXO system are summarized in Table I.

TABLE I
SPECIFICATIONS OF THE SMAEXO.

Items	Specifications
Motion Range (°)	Hip: (-20, 125); Knee: (0, 135); Ankle: (-40, 24)
Length Range (mm)	Upper Limb: 400–500 (Long), 300–400 (Short); Lower Limb: 380–480 (Long), 280–380 (Short); Hip Width: 335–435; Feet: 250–305
Hip and Knee Motors	Rated Torque: 12Nm; Max Torque: 37Nm; Ratio: 1:6; Weight: 0.759kg
Battery	Lithium Battery Pack, 24V 6Ah, Weight: 0.82kg
Weight (kg)	Total: 7.5; Affected-side Module: 3.3; Unaffected-side Module: 0.3 Back Module: 2.1 Vest Harness: 1.8

B. Efficient Reaction Force Management and Weight Distribution

Effective reaction force management is key to minimizing discomfort and enhancing usability. Double-sided exoskeletons like Ekso Indego [5], ReWalk [6], and Rex [7] achieve this through heavier self-weight and extensive user contact, enabling higher assistive torque but increasing bulk and reducing mobility. In contrast, lightweight exoskeletons face torque limitations due to weaker reaction force support. For example, Honda's SMA device provides 4 Nm of hip torque [18], while Samsung's GEMS, with a hip brace for additional support, reaches 12 Nm [19]. Unilateral devices like AGoRA improve torque and balance with bilateral configurations but increase mass to 17 kg [16].

The SMAEXO addresses these challenges by integrating innovative features for efficient reaction force management and weight distribution. Through a combination of an ergonomic vest harness and a flexible ankle joint coupled with a footplate, SMAEXO ensures effective stabilization and comprehensive assistance while maintaining a lightweight and user-friendly profile.

- **Ergonomic Vest Harness**

As depicted in Fig. 3 (a), the SMAEXO vest harness is designed to conform closely to the wearer's body. It consists

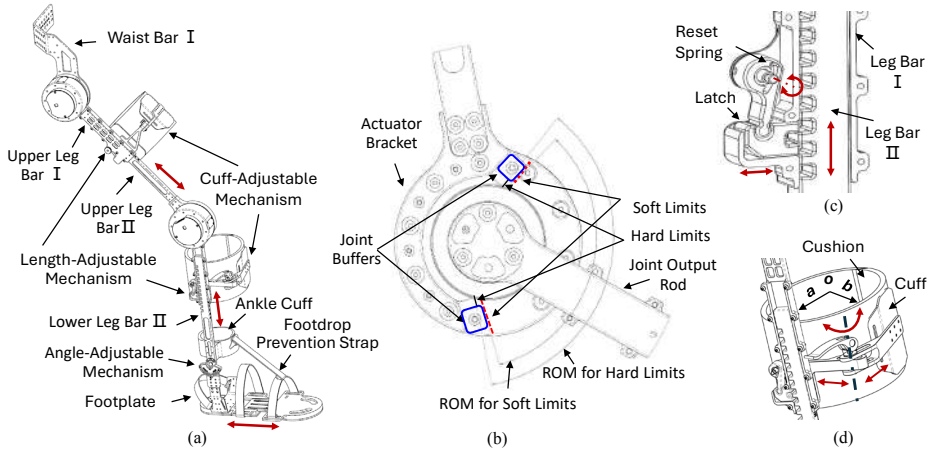

Fig. 2. The affected-side module of the SMAEXO. (a) Module with length adjustments (red arrows). (b) Joint with limited ROM, featuring replaceable buffers to absorb impact. (c) Length-adjustable mechanism with a reset spring for secure locking. (d) Cuff-adjustable mechanism with linear (a, b) and rotational adjustments for leg circumference and easy donning (red arrows).

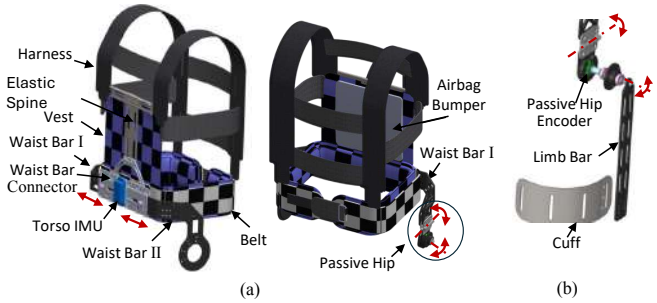

Fig. 3. The SMAEXO vest harness, back, and unaffected-side modules. (a) The back module, paired with the vest harness, includes an IMU for torso angle monitoring. (b) The unaffected-side module features a passive hip with an encoder to measure sagittal hip angles. Red arrows indicate linear adjustments for waist width and hip movement.

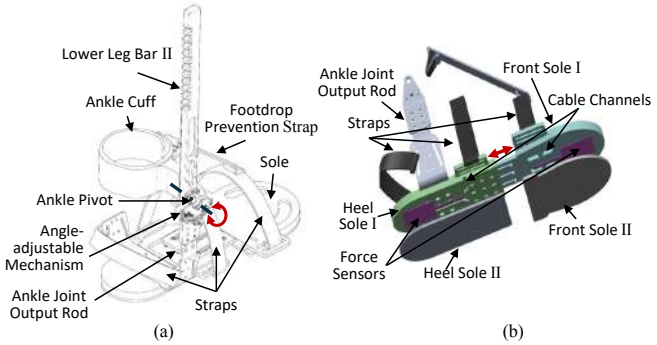

Fig. 4. The ankle joint and footplate of the SMAEXO. (a) The ankle joint connects to the footplate via an output rod and an elastic foot-drop prevention strap, which acts like a spring with adjustable tension for user adaptability. (b) The footplate features adjustable length via a sliding front sole I over heel sole I, accommodating various foot sizes. Embedded force sensors in front sole I and heel sole I are protected by an additional layer (front sole II and heel sole II). Integrated cable channels facilitate wiring.

of a vest integrated with a harness and belt, featuring an elastic spine made from flexible materials such as spring steel, which naturally adapts to the wearer's spinal curvature. To enhance fit and contact, an adjustable airbag bump is included, allowing compatibility with diverse body shapes and improving overall user comfort. This configuration efficiently utilizes the wearer's waist, chest, abdominal, and back muscles to stabilize reaction forces, reducing discomfort and enhancing mobility.

- **Flexible Ankle Joint**

Unlike most exoskeletons, such as Knee-Ankle-Foot Orthoses, ReWalk™ [6], and HAL [15], which use fixed ankle joints and rigid footplates to prevent foot drop and transfer weight to the ground, SMAEXO features a versatile ankle joint design that prioritizes both comfort and a natural gait. This innovative design adapts to individual user needs, facilitating improved mobility.

As depicted in Fig. 4 and Fig. 5, the SMAEXO ankle joint incorporates the following features: (1) An angle-adjustable mechanism, which can either be allowed to rotate within a controlled range or fixed at a specific angle. (2) A flexible footplate with force sensors at the heel and forefoot to detect gait events. (3) Effective weight transfer to the ground during stance without impeding force sensor functionality. (4) Integration with an elastic strap and ankle cuff to prevent foot drop during swing. (5) Adjustable footplate length to accommodate various foot sizes. (6) Construction using elastic and durable materials such as polyurethane (PU), rubber, and ethylene-vinyl acetate (EVA) for natural ground contact and durability. This configuration facilitates a natural gait while offering personalized adjustments to align with individual walking patterns and assistance needs, enhancing both comfort and mobility.

With its advancements in reaction force management and weight support, the SMAEXO achieves a maximum assistive torque of 25 Nm. This capability addresses the high torque demands of hemiplegia rehabilitation while ensuring user

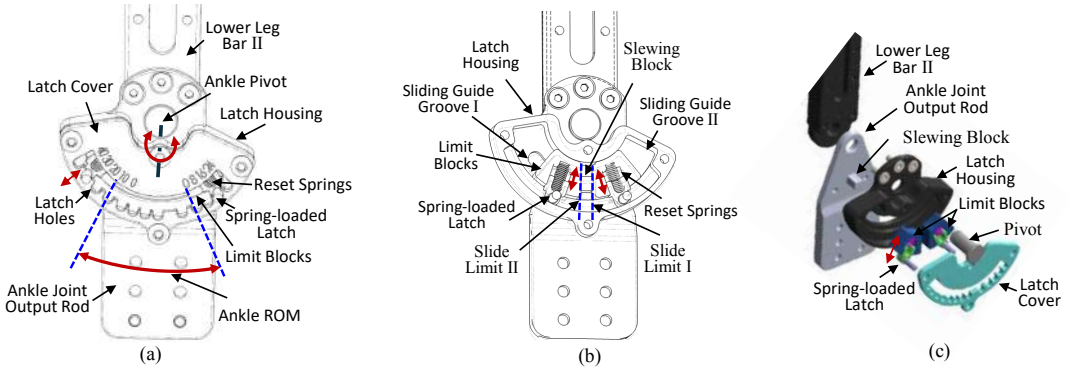

Fig. 5. The angle-adjustable mechanism of ankle joint. (a) Locked with limited movement. (b) Fixed at a specific angle. (c) Exploded view. The mechanism enables controlled ankle rotation or fixed positioning using a latch housing, sliding guide grooves, a slewing block, spring-loaded limit blocks, a pivot, and a latch cover. The limit blocks rotate along guide groove II and lock when the spring-loaded latch engages a latch hole. Unlocking releases the latch, restoring movement. The slewing block rotates within guide groove I and locks the ankle at a set angle when contacting both limit blocks.

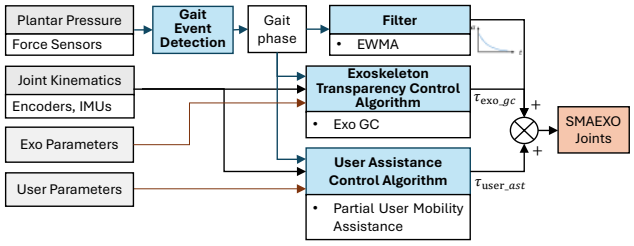

Fig. 6. Control block diagram of the SMAEXO.

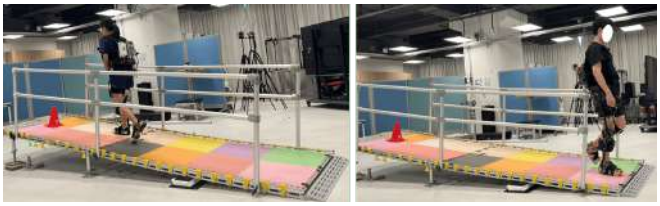

Fig. 7. Experiment setup.

comfort, providing an effective and user-friendly solution for mobility assistance.

C. Control Scheme

The SMAEXO utilizes a multi-level control strategy with a reliable and cost-effective sensor system to enhance its functionality. This system incorporates a torso IMU and encoders embedded in the hip and knee joints to provide accurate joint kinematic measurements. Foot pressure measurements from force sensors, combined with kinematic data, are employed to identify gait phases during various daily activities, including sit-to-stand transitions and walking on flat surfaces, ramps, or stairs. The control system leverages this gait phase information to implement exoskeleton transparency(e.g., Gravity Compensation) and partial user mobility assistance for optimized support and a better user experience. Additionally, exoskeleton and user parameters are tailored to meet individual assistance needs, while filters like the Exponentially Weighted Moving Average (EWMA) ensure a smooth torque profile throughout the entire gait cycle (Fig. 6).

III. Experiments

To evaluate the usability, comfort, safety, and assistance provided by the SMAEXO, eight able-bodied participants were recruited, including two physiotherapists specializing in lower-limb rehabilitation. During testing, physiotherapists simulated stroke gait patterns—including foot drop, stiff knee, circumduction, and weak knee—based on their experience to evaluate the exoskeleton's effectiveness from a patient's perspective. Demographic and anthropometric details of the participants are provided in Table II. All participants gave written informed consent after being briefed on the study's objectives and potential risks. The study protocol received approval and oversight from the Nanyang Technological University Institutional Review Board.

During the experiment, participants could take rest breaks, stop, or withdraw from testing at any time. The assessment consisted of two sessions (with and without the exoskeleton), each comprising three tasks. Participants repeated each task at least three times:

- 10-meter level walking;
- 4-meter slope with 8 degrees inclination up and down;
- Stepping over a 10 cm high, 12.5 cm wide obstacle.

In the second session, participants were familiarized with the exoskeleton for 30 minutes before testing. Investigators guided them on exoskeleton use and ensured acclimatization. Participants were instructed to report any discomfort or pain, which was documented and addressed.

At the study's conclusion, participants completed a questionnaire assessing the exoskeleton's usability, comfort, safety and assistance. All questions are rated 1 to 5, with 1 as "strongly disagree" and 5 as "strongly agree".

IV. RESULTS AND DISCUSSION

As shown in Fig. 8, participants appreciated SMAEXO's modular design and tool-free adjustments for easy donning and doffing. However, its unbalanced structure made maintaining a neutral position challenging, especially when seated. Physiotherapists noted that post-stroke users often require two assistants for stabilization. Incorporating a support frame could address this issue by providing stability during the donning process.

Participants considered the device's weight acceptable. During the stance phase, the SMAEXO effectively transferred weight to the ground, reducing the burden on the knee joint. However, physiotherapists raised concerns regarding hemiplegic users, as the unaffected leg bears the device's weight during the swing phase. This could potentially increase stress on the unaffected knee, particularly concerning for elderly post-stroke individuals who are more susceptible to knee issues, such as osteoarthritis. Further reducing the exoskeleton's weight is recommended to alleviate this strain.

The device was reported to be comfortable, with no instances of pain, itching, or irritation. The adjustable mechanisms enabled proper adaptation to various body dimensions, ensuring a snug fit that effectively engaged the user's core muscles for optimal reaction force management and weight distribution. However, two participants experienced slight perspiration on their backs after wearing the device for more than an hour, likely due to the vest and airbag bump. Incorporating breathable materials into these components could enhance comfort during prolonged use.

Regarding safety, participants indicated no concerns about falling or other safety issues during the trials, indicating that the SMAEXO's design effectively solved the weight distribution and balance challenges. However, one participant highlighted the potential risk of the footplate contacting obstacles or stairs if the straps were not tightly secured. This emphasizes the importance of ensuring that all straps are properly adjusted and secured to maintain safety during use.

Participants reported the SMAEXO provided adequate assistance during level and slope walking, as well as obstacle negotiation, reducing their effort. This shows the SMAEXO offered comprehensive joint support throughout the gait cycle by combining active hip and knee assistance with a passive, flexible ankle joint.

Compared to double-sided exoskeletons, the SMAEXO

demonstrated advantages in weight reduction and freedom of movement, while offering more comprehensive support than single-joint devices. Table III compares the main features of our device with commercial unilateral exoskeletons, HAL and LiteStepper. SMAEXO offers advantages in compact design, lighter weight, an intuitive and cost-effective sensor system, improved force management, and more flexible footplates for natural gait. However, challenges remain in minimizing the overall weight and improving the ease of donning and doffing, particularly due to the lack of a stable sitting pose without external support. Future iterations should focus on incorporating a dedicated support mechanism to address this limitation and further enhance usability.

Compared to double-sided exoskeletons, SMAEXO offers reduced weight and greater freedom of movement while providing more comprehensive support than single-joint devices. Table III compares its key features with commercial unilateral exoskeletons, HAL [20] and LiteStepper [17]. SMAEXO excels in compact design, lighter weight, an intuitive and cost-effective sensor system, improved force management, and flexible footplates for natural gait. However, challenges remain in further reducing weight and improving donning and doffing, particularly due to the lack of stable sitting posture without external support. Future iterations should integrate a dedicated support mechanism to enhance usability.

V. Conclusion

In this study, we developed the Single-Sided Mobility Assistive Exoskeleton (SMAEXO), a single-sided, multi-joint lower limb exoskeleton designed to enhance mobility in individuals with hemiplegia. SMAEXO actively supports the hip and knee while incorporating a passive, flexible ankle joint to prevent foot drop, ensuring dynamic assistance throughout the gait cycle. Its tool-free adjustments, optimized weight distribution, and reaction force management enhance usability, balance, comfort, and safety while minimizing strain on the affected side.

We evaluated usability, safety, comfort, and assistance with eight able-bodied participants during level walking, slope walking, and obstacle crossing. Participants reported the device as safe, comfortable, and effective, with no adverse effects such as itching or irritation, and found the assistance beneficial. However, areas for improvement were noted, including better cooling, reduced weight, and simplified donning.

This study is limited by a small and unbalanced participant sample, which may impact the generalizability of the findings. Future work will address this by conducting extensive testing with a larger, more diverse participant pool for robust validation.

Building on the these findings, we will advance to clinical trials to evaluate SMAEXO's effectiveness in post-stroke individuals. Comprehensive data analysis will inform design refinements to enhance functionality, comfort, and user experience. With continued development, SMAEXO holds the potential to significantly improve mobility and quality of life for individuals with hemiplegia.

Preference Augmented Q-Learning for Patient Exercise Scheduling in a Robotic Rehabilitation Gym

Varun R. Bharadwaj*, Benjamin A. Miller*, Vesna D. Novak and Chao Jiang

***Abstract*— Robotic rehabilitation gyms enable groups of patients to perform motor rehabilitation under the guidance of a single therapist. While software can help process and present patient exercise information in an easy-to-understand manner, certain characteristics like motivation and fatigue are harder to quantify using sensors. Human therapists are able to observe these characteristics without precise sensor measurements and use them to make intelligent patient-robot assignment decisions. However, actively observing every patient in the group and changing which robot they exercise with would distract the therapist from delivering effective therapy. To help with this, we propose a Preference Augmented Q-Learning assignment scheduler that learns to create patient-robot assignment schedules for group rehabilitation. The scheduler is trained to leverage expert assignment preferences and implicitly incorporate motivation and fatigue through expert guidance. The assignment scheduler was tested using 1000 simulated patient groups with its results compared against several baselines. Our assignment scheduler outperformed all tested baselines, except for schedules created by a simulated expert who had access to all the patients' characteristics and could predict future exercise outcomes. In simulation, the results show the effectiveness of incorporating expert preferences into reinforcement learning models to improve assignment scheduling without directly measuring hard-to-quantify factors.**

I. Introduction

Rehabilitation robots are designed to assist patients during motor rehabilitation, with results roughly as good as traditional aid delivered by a human therapist [1], [2]. More recently, the effectiveness of rehabilitation robots has sparked interest in robotic rehabilitation gyms: rehabilitation venues with multiple rehabilitation robots that enable multiple patients to exercise at the same time [3]. These robotic gyms enable a single physical or occupational therapist to oversee the exercise of multiple patients at once. Analysis software, such as HocoNet [4], can further aid therapists by keeping track of and consolidating the performance of every patient in the group. This consolidated data provide a clearer picture of individual progress and group dynamics. However, even with this information, therapists may face challenges in creating optimal group adjustments in real time due to the complexity and volume of data. By further analyzing trends in patient performance, the software could potentially suggest reassigning patients to different robots or exercises that are better aligned with their current skill level and needs. If implemented, such adjustments could help ensure that each patient focuses on exercises most beneficial to their rehabilitation goals.

A. Previous Work

Recent simulation research suggests that it is possible to train an automatic robotic rehabilitation gym scheduler to create group rehabilitation exercise schedules based on measured patient performance metrics, though the simulated environments were rather simplistic [5]–[9]. Initial simulations consisted of groups of patients performing exercises using different rehabilitation robots in fully observable, deterministic environments where results could be predicted before patients performed an exercise [7]. In this simplified environment, patient exercise scheduling was framed as a mixed-integer nonlinear programming problem and solved using optimization software to create exercise schedules.

More recent studies included stochastic environments where patients' skill levels were not measurable during a session (mirroring the impracticality of measuring a patient's true motor skill during a session) [5], [6], [10]. Instead, the patients' success rates (a measure of how well the patients performed their exercise) and their effort were measured. In such simplified environments, it was shown that a machine learning model could be trained to mimic a therapist's assignment decisions and produce schedules that outperform several baselines [5], [6].

However, these schedulers prioritized short-term over long-term skill improvement [5], [6]. Additionally, the simplified environment meant that all relevant variables were directly measurable. In real-life scenarios, certain characteristics like motivation and fatigue that influence skill improvement are hard to measure [11]–[13]. Without knowledge of these hidden characteristics, the schedulers would not be able to create optimal schedules in more complex environments. Our work aims to address this issue by developing a Preference Augmented Q-Learning algorithm that trains the scheduler via a combination of Reinforcement Learning (RL) [14] and direct therapist feedback.

II. Methodology

A. Simulated Robotic Gym Environment

Similar to previous studies [5]–[9], the robotic rehabilitation gym consists of J different robots and K exercises, where each of the J robots can be used to perform one of the K exercises. Each exercise additionally has three

*Both authors contributed equally to the work. This work was supported by the National Science Foundation under grant no. 2024813.

Varun R. Bharadwaj and Chao Jiang are with the Department of Electrical Engineering and Computer Science, University of Wyoming, Laramie, WY 82071 USA. {vbharadw, cjiang1}@uwyo.edu

Benjamin A. Miller and Vesna D. Novak are with the Department of Electrical and Computer Engineering, University of Cincinnati, Cincinnati, OH 45221 USA. mille7ba@mail.uc.edu and novakdn@ucmail.uc.edu

difficulty levels, where patient performance changes based on the difficulty of the exercise relative to the patient's skill level. The three difficulty levels serve to better model reality where rehabilitation robots can offer differing amounts of support or resistance [15]. Similar to a previous study [6], the difficulty for each exercise is always set by the expert so that each patient exercises at the difficulty best suited for their current skill level. Each robot can only be used by one patient at a time and a patient may only exercise with one robot at any given moment. Only one patient group at a time can use the gym, with a patient group consisting of *I* simulated patients. All patients in the group stay in the gym for an entire exercise session and each exercise session is divided into *T* equal blocks of time, called timesteps. Each patient in the patient group is assigned to exercise with a robot at the beginning of each timestep and cannot switch to a new robot until the start of the next timestep.

Ideally, real patient motor rehabilitation data would be used in this study. However, due to a lack of preexisting data and the difficulty of collecting the necessary amount, this was not feasible. Instead, we updated a patient motor rehabilitation data generator from our previous work [5], [6], [8]. The previous data generator modeled patient success rate, effort, and skill level, with these measurements being analogous to real performance metrics and patient characteristics (e.g., percentage of completed motion, amount of force/torque applied during the exercise, range of motion, etc.) that can be measured using sensors [5], [6], [8], [16], [17]. A patient's success rate and effort were generated based on their current skill level, while their skill improvement after a timestep of exercise was determined by their resulting success rate and effort. In our current work, the simulator was updated to better model a real rehabilitation gym where exercises can have different levels of difficulty and where patient motivation and fatigue can affect their performance.

B. Patient Characteristics and Performance Metrics

Each patient has a corresponding skill level for each of the *K* different exercises. This value is hidden during an exercise session, simulating real-life scenarios where it is difficult to directly measure a patient's skill level without a time-consuming series of tests (such as the Fugl-Meyer Assessment [10]). Skill level improves whenever they exercise with the corresponding robot. The amount of improvement is determined by how successfully the patient performed the exercise (their success rate) and how much work they put in (their effort). Exercising also affects a patient's motivation and fatigue, with their motivation changing based on how successful they were and their fatigue changing based on how long they have performed each exercise [11], [13], [18]. Motivation reflects a person's enthusiasm to engage in a task, whereas fatigue indicates their level of physical exhaustion.

1) Motivation: A patient's current level of motivation is determined by the patient's motivation in the previous timestep and change in motivation (denoted as Δ*motivation*). Δ*motivation* is proportional to the patient's exercise performance as shown in Fig. 1 (right) [11], [18]. We model

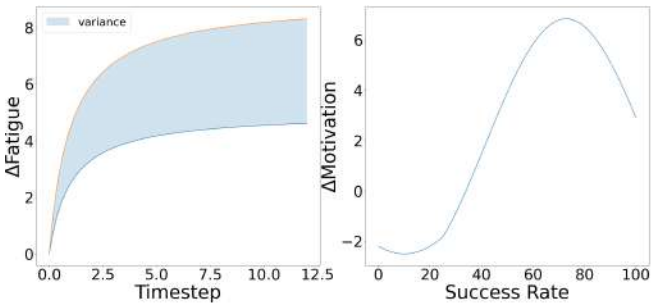

Fig. 1: Δfatigue vs number of timesteps a patient has performed an exercise (left) and Δmotivation vs success rate (right). The shaded region in the left plot represents the range of possible random values for the change in fatigue (Δfatigue) based on the time spent performing an exercise

motivation using the following equations:

$$motivation(t+1) \;=\; motivation(t) + \Delta motivation \quad (1)$$

with its values capped between 0 and 100.

2) Fatigue: Patients have separate levels of fatigue for each exercise. Performing an exercise increases the corresponding level of fatigue while decreasing the level of fatigue for all other exercises (as the patient is not exercising that specific muscle group) [12], [13]. Additionally, if a patient does not perform an exercise, the corresponding fatigue for all exercises decreases as well. A patient's overall level of fatigue is the sum of all of their exercise fatigues and a patient will refuse to exercise while their overall level of fatigue is greater than 100. A patient's change in fatigue is denoted as $\Delta fatigue_k$ where k denotes the corresponding exercise. $\Delta fatigue_k$ when a patient performs exercise k is shown in Fig. 1 (left). $\Delta fatigue_k$ when a patient does not perform exercise k is -0.05 $fatigue_k(t)$. Patient fatigue is modeled using the following equations:

$$fatigue_k(t+1) = fatigue_k(t) + \Delta fatigue_k \quad (2)$$

with a minimum value of 0.

3) Effect of Motivation and Fatigue: High fatigue and low motivation reduce patient performance [11]–[13], [19]. The overall effect that motivation and fatigue have on patient performance is modeled as a factor, α, representing the average of the fatigue and motivation, where motivation and fatigue are scaled such that alpha is between 0 and 1.

$$\alpha = \frac{(motivation/100) + (1 - fatigue_k/100)}{2} \quad (3)$$

This allows both fatigue and motivation to have an equal effect on patient performance.

4) Skill Improvement, Success Rate, and Effort: Patient skill improvement, success rate and effort are all modeled using stochastic equations, mimicking the uncertainty of patient exercise. These values (base performance metrics) are first calculated without factoring in the effect of fatigue and motivation. After all three are calculated, the effects of motivation and fatigue are accounted for by scaling the base performance metrics with the factor α. All three values are

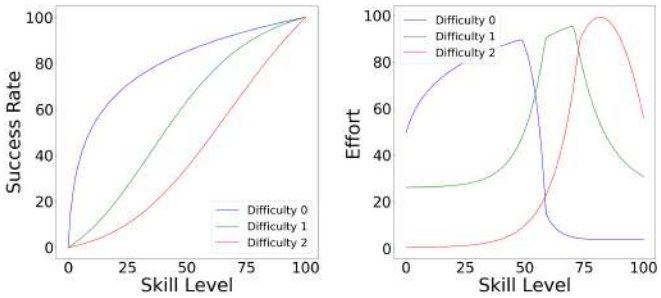

Fig. 2: Success rate (left) and effort (right) across different difficulty levels

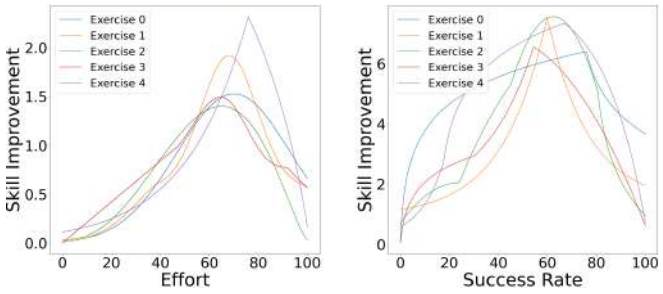

Fig. 3: Skill improvement from success rate and effort

capped between 0 and 100. Patient success rate increases with skill if difficulty level is kept unchanged (Fig. 2 (left)) [19], [20]. Similar to previous studies [6], [9], the skill level to success rate curve for the medium difficulty (difficulty 1) was roughly linear, but with a slightly higher growth in success rate at lower skill levels. The skill level to success rate curve for the low difficulty (difficulty 0) used a logarithmic curve such that patients always had a higher success rate compared to higher difficulties, with success rate increasing more rapidly at earlier skill levels before becoming roughly linear. The skill level to success rate curve for the high difficulty (difficulty 2) resembled an exponential function, such that patient skill level was always lowest at this difficulty. It then became roughly linear at medium to higher skill levels.

Similarly, a patient's effort varies according to their skill level in an exercise relative to the difficulty level of the exercise, where a patient exerts less effort if a task is too easy or too hard to perform for their current skill level (Fig. 2 (right)) [6]. Effort is lower when a patient's skill level is too low for the current exercise difficulty, modeling how patients cannot properly engage with an exercise if it is too difficult for them (e.g., patients with a lower skill level cannot move if a robot applies too much resistance) [6], [21]. Effort increases as the patient's skill level becomes more appropriate for the current difficulty, modeling how the patient becomes skilled enough to perform the exercise and thus works harder. Effort then starts decreasing as the patient becomes too skilled for the current difficulty, modeling how patients do not need to try as hard to complete the exercise.

Patient skill improvement before factoring fatigue and motivation directly depends on their success rate, effort, and exercise difficulty, with optimal improvement occurring when the exercise is moderately challenging (Fig. 3). The curves are based on the challenge point framework (a mathematical model describing the relationship between skill level, performance, and skill improvement), but modified to allow for different exercises to have different skill improvement curves [19], [20]. A patient's total skill improvement is modeled as the sum of improvements due to success and effort. Fig. 2 and 3 show the deterministic versions of patient-exercise characteristics and performance metrics. When simulating our gym, we add stochasticity to the patient-exercise characteristics and performance metrics. For success rate and effort, we first calculate their deterministic value and then add a random value sampled from a uniform distribution ranging from -2 to 2. For skill improvement, the stochastic values were chosen from a range from 0 to 20 percent of the maximum possible deterministic skill improvement for the exercise.

C. Assignment Scheduler

Our Preference Augmented Q-Learning algorithm is a two-stage assignment scheduler. The first stage uses a neural network to generate scores for patient-robot assignments and the second stage performs conflict resolution based on the scores from the previous stage. The scheduler aims to assign patients to robots at each time step, in such a way that the expected skill improvement of the group is maximized. Exact measurements of patient skill level, motivation, and fatigue are difficult to measure during an exercise session and thus cannot be used by the assignment scheduler, aligning with characteristics of Partially Observable Systems [10]–[13]. However, motivation and fatigue still affect the patient's exercise outcomes, and thus the assignment scheduler must learn how to account for them. To do this, we leverage expert knowledge and patient exercise history to infer about these factors while training the scheduler. The second stage, a binary constraint search tree [22], then finds the schedule that is expected to give the largest long-term skill improvement.

1) The Neural Network: The long-term benefit of each patient-robot assignment is estimated by a Deep Q-Network (DQN) trained using RL [14], [23]. The sparse nature of our environment (i.e., the lack of skill measurements) means that our neural network cannot be trained using a patient's true immediate skill improvement as the immediate reward. Additionally, the assignment scheduler must be designed and trained to account for the hard-to-quantify factors (fatigue and motivation). Hence, we leverage the expertise of a domain expert (such as a therapist) to guide the training of our model, and utilize the patient exercise history to infer about motivation and fatigue. While this work involves simulation, the data generation was designed to emulate how the data could be collected in the real world.

The inputs to the network are as follows:

- All of each patient's previously recorded success rates denoted by $Gh_{pi,rj} = \{g_{pi,rj}(1), g_{pi,rj}(2), ..., g_{pi,rj}(t)\}$

- All of each patient's previously recorded effort denoted by $Eh_{pi,rj} = \{e_{pi,rj}(1), e_{pi,rj}(2), ..., e_{pi,rj}(t)\}$
- The current timestep in the session, denoted by T_t
- The number of timesteps remaining in the session denoted by $T_r = T - T_t$.

$Gh_{pi,rj}$ and $Eh_{pi,rj}$ are the same size as the total number of timesteps in one session and are initialized to zeros. The current timestep in the session is used as an input, as motivation and fatigue directly affect patient performance and are affected by how long the patients have been exercising. On the other hand, using the remaining number of timesteps as an input helps the network know how far into the future it should plan for when assigning patients to robots.

2) Network Architecture: Our DQN's input layer has the same dimension as the feature vector $(Gh_{pi,rj}, Eh_{pi,rj}, T_t, T_r)$. We have two hidden layers with 128 and 256 neurons respectively. We have dropout layers in between all the hidden layers with a dropout probability of 0.27. All hidden layers use L2 regularization with λ = 10^{-5}. The L2 regularizer shrinks the weights to be small but nonzero coefficients, preventing one feature from dominating the model's predictions and improves generalization.

3) Training Data Generation: To generate training data, 10000 simulated patients each exercise in the gym alone for one exercise session, where a session lasts for 12 timesteps. During this training process, there are 5 robots in the gym and each robot is used to perform a different exercise. At the beginning of each timestep, two actions are selected: one by a simulated expert and one by our algorithm. The simulated expert provides the robot assignment they prefer based on the current patient performance metrics. Our simulated expert's scheduling policy is intended to be optimal: they always make the assignment that is expected to produce the largest skill improvement for the current timestep. To do this, the expert is given total knowledge of the patient's characteristics and performance metrics, including their current motivation, fatigue levels, and expected skill improvement if they perform each exercise. Importantly, this means that the expert has significantly more information than what our model will ever have. Our model either selects a random robot with probability ε or the robot it thinks is best. Allowing our model to pick a random robot ε percent of the time during training helps ensure that we have a wide variety of data to train our model and that our model explores actions it would otherwise not. ε starts at 100 percent and decays based on how much data has been generated. The simulated patient then performs the exercise selected by the algorithm. This causes the patient's success rate, effort values, fatigue, motivation and skill values all to change based on the previously described relationships.

4) Reward Design: During training, our model is given rewards based on the quality of its assignments. The network receives a reward based on three things: whether its selected assignment matches the expert's (the preference reward), the rate of change of patient success rate between consecutive timesteps, i.e., $g_{pi,rj}(t+1) - g_{pi,rj}(t) > g_{pi,rj}(t) - g_{pi,rj}(t-1)$ (success rate reward), and if the patient starts exercising at a higher difficulty level (difficulty reward). The total reward is the sum of all three and is denoted by L_{total}. If the assignment suggested by the model is the same as the expert's, we assign a reward $L_{\text{pref_r}}$ (preference reward) of 10, but if they are different we give the model a reward based on the equations shown below:

$$R_e = Q(s, a_e) + \sqrt{(Q(s, a_e) - Q(s, a_m))^2} \quad (4)$$

$$R_m = Q(s, a_m) - \sqrt{(Q(s, a_e) - Q(s, a_m))^2} \quad (5)$$

$$L_{\text{pref_r}} = \left[\left(\frac{e^{R_n}}{e^{R_e} + e^{R_m}} \right) * 40 \right] - 20 \quad (6)$$

Here, a_e represents the expert's preferred action, and a_m the action chosen the model. $Q(s, a_e)$ measures how good the model currently thinks the expert's action is, and $Q(s, a_m)$ measures the model's own action. Intermediate values R_e and R_m are used to calculate the preference reward, which is inversely proportional to the difference in Q-values between the two assignments. This encourages the model to align with the expert's preferences by rewarding similar assignments and penalizing dissimilar ones.

Along with human guidance, we also consider rate of change in success rate as well as their difficulty level in shaping our reward. If the change in a patient's success rate when they perform an exercise is larger than the previous time they performed the exercise, or if the expert assigns the patient to a higher difficulty, the model earns an additional reward of 5. This promotes actions that drive rapid skill improvement. After computing rewards, the success rate, effort, reward and selected action for the current timestep are stored. At the end of the session, the model is updated using the deep Q-learning algorithm [23] with the following loss function, where γ is the discount factor.

$$L(\theta) = \mathbb{E}_{s,a,s'} \left[(L_{\text{total}} + \gamma Q_{\theta'}(s', \arg\max_{a'} Q_\theta(s', a')) - Q_\theta(s, a))^2 \right] \quad (7)$$

D. Evaluation

1) Baselines: We additionally simulated six other scheduling philosophies to compare and evaluate the effectiveness of our assignment scheduler.

a) Simulated Expert: The simulated expert has access to all patient characteristics and performance metrics including motivation and fatigue, and can predict the expected immediate skill improvement for all patient-robot combinations at each timestep. The expert uses this knowledge to make assignments that are expected to be optimal at each timestep.

b) Immediate Best: Each patient is assigned to a single robot for the entire session. Each patient's robot is selected such that the expected skill improvement of the group after the first timestep is maximized based on each patient-robot combination's expected skill improvement. This is done by simulating a single exercise timestep for each patient-robot combination where all stochastic values are set to their expected (mean) result. This mimics a realistic scenario where a therapist may be able to predict which robots would be most immediately beneficial for each patient [1].

c) Two Immediate Best: Identical to "Immediate Best", but patients switch to their second-best robot halfway through the session. As skill improvement tends to slow down at higher skill levels, having patients change robots mid-session can encourage greater overall skill improvement.

d) One Best: Identical to "Immediate Best", but the entire session is simulated for each patient-robot combination instead of only a single timestep. As this baseline simulates the entire session to determine every patient's optimal robot, this baseline has knowledge of the expected future result of patient exercise (including motivation, fatigue and all skill improvements) and relies on post-hoc optimization. Hence it is not practical in a real-world setting.

e) Two Best: Identical to "Two Immediate Best", but the entire session is simulated for each patient-robot combination when deciding which robots are optimal. Again, this baseline has future knowledge and relies on post-hoc optimization, making it impractical. It serves as a theoretical best schedule under the condition that patients must switch robots once halfway through the session.

f) Random: This method assigns each patient to a random robot at each timestep as a sanity check to confirm that our approach is effectively learning and not performing randomly.

2) Patient Groups: 1000 simulated patient groups were created to test the effectiveness of our scheduler in creating group assignment schedules that maximize group skill improvement. Each group consisted of 5 patients and 5 robots (i.e., $I = 5$ and $J = 5$), where each robot could be used to perform a different exercise (i.e., $K = 5$). Each patient's initial skill levels were generated randomly between 0 and 100 and their initial success rate and effort were then generated based on these initial skill values. This is done before the simulated session officially "begins" and is analogous to an initial pre-session assessments of patient abilities. Each patient's motivation was randomized between 0 and 100. As patients have yet to perform any exercise, their initial fatigue values for each exercise were randomized between 0 and 20.

Each patient group exercised for one 12-timestep session for each different scheduler. During each session, patients performed scheduled exercises, and their characteristics were updated in the same manner as in training data generation.

III. Results and Discussion

Fig. 4 shows the performance of the different schedulers for 1000 patient groups. One-way repeated-measures Analysis of Variance on Ranks with post-hoc Tukey tests was conducted and showed that all schedulers are significantly different from each other at $p < 0.05$. The scheduler type had a large impact on patient group skill improvement, with the "Expert" performing the best, followed by our model and then "Two Best" (Fig. 4). This highlights the importance of intelligent, dynamic patient-robot assignment based on patient performance. This is further supported by the "Random" scheduler outperforming "Immediate Best" and "One Best" schedulers, which did not allow patients to change exercises.

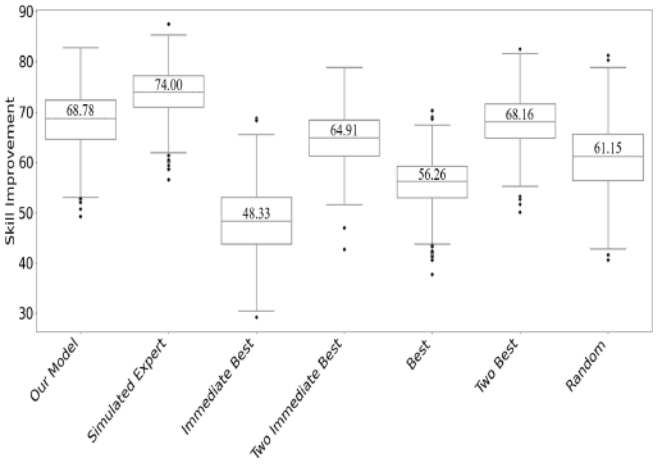

Fig. 4: Boxplot of the skill improvement for 1000 patient groups with different assignment methods. Top and bottom box edges represent 25th and 75th percentiles, whiskers extend to the most extreme observation within 1.5 times interquartile range from the nearest quartile, and circles represent individual outliers. Median values are labeled.

Importantly, our model produced the second largest median skill improvement even without access to patient motivation and fatigue values. This shows the benefit of human-in-the-loop feedback during data generation and model training. Without input from the expert, our model would lack any means to learn how harder-to-quantify characteristics like motivation and fatigue influence the choice of robots that a patient should exercise with. By leveraging expert knowledge, our model learned to make intelligent decisions without needing motivation or fatigue values. Additionally, our model performed better than baselines that could accurately predict the future ("One Best" and "Two Best"). This demonstrates that our model can effectively learn from the expert and optimize for long-term rewards.

A. Expanding the Scenario Simplifications

1) Therapist Feedback: Future work will address the simplifications in our simulated gym scenario. Specifically, reducing the therapist's involvement in data generation could be achieved by storing expert feedback and corresponding patient metrics. Once sufficient data are generated, new feedback could be auto-generated based on similarities in patient performance. Additionally, our current methodology depends on the expert to assign the correct difficulty level. This could be improved by adapting our network to output difficulty levels along with robot assignments.

2) Different Sizes of Rehabilitation Gyms: Only scenarios involving 5 patients, 5 robots, and 12 timesteps were tested in this study. However, real rehabilitation centers could have variable sizes. While our scheduler was designed to work for any number of patients, a new network would need to be trained each time a new robot is added or removed from the gym. Additionally, due to optimizing for a specific number of timesteps, the performance of the scheduler would likely suffer if it is used in other scenarios.

3) Number of Patients Needed for Training and Testing: The number of patients used to train and test our scheduler is likely impractical in the real world. However, only a small number of patient groups are needed to test the quality of the scheduler, and the current 1000 groups were used to reduce the effects of randomness in the gym model. Future work will focus on reducing the number of patients required to train our scheduler to better align with practical limitations.

4) Additional Stochasticity: Several other factors that were not modeled in this study likely affect patient performance and skill acquisition. While modeling these additional factors would be challenging, a preliminary analysis of their effects could be performed by increasing the amount of stochasticity in the simulation model. The increased stochasticity would roughly reflect the increased uncertainty due to additional unknown environmental factors.

B. Real-World Robot Gym Evaluations

While this study uses a simulated environment, the goal of the research is to eventually create an assignment scheduler usable in the real world. Indeed, a simplified version of the assignment scheduler could already be evaluated in a simplified robotic gym. For example, fifty healthy participants could be used to collect data by performing three simple exercises. Afterwards, groups of healthy participants could be brought into the simplified robot gym and exercise using schedules produced by the assignment scheduler.

While our model accounts for motivation, fatigue, and difficulty through expert-guided RL, it was not based on empirical data. The relationships between these hidden states and observable metrics rely on theoretical frameworks and prior studies rather than real-world validation. Additionally, motivation and fatigue were modeled such that they changed similarly for all patients. In reality, motivation and fatigue can vary between patients. Future work will better account for interpersonal differences and will evaluate the effectiveness of our scheduler in the real world. While real-world data is expected to have more stochasticity because of additional unmodeled factors, our machine learning algorithm should still be effective as it aims to capture the underlying logic of patient development based on expert feedback.

IV. Conclusion

Our work addresses the challenge of optimizing patient-robot assignments in a robotic rehabilitation gym where hard-to-measure patient characteristics, such as fatigue and motivation, have a large impact on patient performance. Unlike prior works [5]–[9] that ignore these hidden characteristics, our method factors in the hidden characteristics in exercise scheduling by leveraging a combination of RL and expert input. This allows us to optimize patient skill improvement and create more effective rehabilitation schedules compared to several baselines that had access to the hard-to-quantify characteristics. Practically, while this work was performed in simulation, it is a step towards developing a patient-robot assignment scheduler for real-world applications.

***Abstract*—Manual wheelchair users are prone to a more sedentary lifestyle due to their limited mobility and, therefore, decreased cardiovascular health. Regular assessment of their cardiovascular fitness can help with appropriate interventions and overall improvement in their quality of life. One way of assessing cardiovascular health of manual wheelchair users is the 6-minute push test (6MPT), adapted from the 6-minute walk test. In this study, 5 novice and 5 expert wheelchair users performed the 6MPT while wearing a heart rate monitor and VO_2 mask. Significant correlation (r=0.685, p=0.029) was found between the distance completed and the max value of the VO_2 recorded during the 6MPT. Additionally, a linear regression model was constructed and found statistically significant (F(1,8)=22.3, p=0.0015). The model can serve clinicians as a convenient and direct indicator of cardiovascular fitness for manual wheelchair users without the need of additional heartrate sensors or VO_2 mask.**

Keywords—cardiovascular health, 6-minute push test, VO_2, physical exertion, manual wheelchair users, oxygen consumption, heart rate.

I. Introduction

Cardiovascular fitness plays an essential role in the overall health and quality of life for manual wheelchair users [1], [2]. Poor cardiovascular health can hinder their mobility and functional independence [1], [3]. Regular movement and physical activity are important in limiting secondary health issues like pressure sores, musculoskeletal problems, and cardiovascular disease [2], [3], [4], [5], [6]. Understanding the maximal oxygen uptake (VO_{2max}), a key indicator of aerobic capacity and overall cardiovascular health, can provide insights into the physical demands and health conditions of those with mobility impairments [7], [8], [9], [10].

Traditional testing methods for VO_2 involve maximal exercise protocols, such as treadmill or cycle ergometer tests [11], which can be challenging for manual wheelchair users and may require specialized laboratory equipment and trained personnel. While accurate and reliable [11], [12], [13], these approaches are often expensive, require an extensive setup, add complexity to the testing process, and can be impractical for regular testing in a community setting [14]. These considerations can limit their usefulness in monitoring cardiovascular health over time for people with mobility impairments. This underscores the need for a simpler and easier field-based method to estimate VO_{2max}, specifically tailored to the functional abilities of manual wheelchair users.

One key way of measuring cardiovascular health in manual wheelchair users is the 6-Minute Push Test (6MPT), adapted from the 6-Minute Walk Test [15]. The 6MPT involves the manual wheelchair user propelling themselves as far as they can in 6 minutes [16]. The test provides insights into cardiovascular health and overall fitness levels [3], [7], [13], [17], [18], [19], which are essential for daily functioning and mobility. Literature has demonstrated that specific physiological responses, such as heart rate, speed, and distance covered during the test, correlate with VO_2 consumption [9], [10], [20], [21], [22], [23], [24]; however, to our knowledge, no formula has been derived for predicting VO_{2max} from the 6MPT. Predictive models of VO_2 could offer an accessible alternative to direct VO_2 testing, thus providing a valuable tool for ongoing cardiovascular fitness assessment.

In this study, we aim to develop a simplified equation to predict VO_2 based on the recorded parameters of the 6MPT. By establishing a predictive equation, this work aims to create a feasible, repeatable, and cost-effective method for healthcare practitioners to monitor aerobic capacity outside the laboratory, enhancing the monitoring and rehabilitation of wheelchair users.

II. Methods

This study was approved by the University of Wisconsin – Milwaukee Institutional Review Board (IRB#23.347).

A. Participants

The participants for this study were recruited under the following inclusion criteria; at least 18 years of age, physically able to propel themselves in a manual wheelchair, no record of epilepsy, claustrophobia or increased sensitivity to light and free from any upper extremity injury or surgery within the past year. Moreover, participants with health issues or medications relating to blood pressure, heart or

cardiovascular conditions were encouraged to consult their doctor before participating.

Ten participants were recruited for this study: 5 long-term wheelchair users that use a manual wheelchair for at least 70 percent of their daily mobility and 5 able-bodied controls, who never used a wheelchair before the study. At the start of each lab appointment, informed consent was obtained and the participant completed a demographics questionnaire. The demographics questionnaire reported; gender, age, height, weight, injury level (if applicable) and estimated weekly activity level. The participants weekly activity level was categorized as high (more than 3h/week), moderate (2-3h/week) or low (under 2h/week) based on weekly hours of activity. Participants demographics are presented in Table I.

B. *Experiemental Setup and Sensors*

- **Six Minute Push Test Setup:** The set up for the 6MPT was identical to the protocol described in our previous study [25]. In a long hallway, with a smooth floor, two cones were set up 30 meters away from each other in a straight line, see Fig. 1. Before beginning the 6MPT, participants were given the opportunity to practice propelling themselves in the testing location. The control group used the laboratory wheelchair (see Fig. 2) while expert wheelchair users participated with their own daily wheelchair.
- **VO_2 Tracking:** This study utilized the VO2 Master Analyzer (VO2 Master Health Sensors Inc., Vernon, BC, Canada) to record VO_2 output. The portable analyzer is secured to the participant with a Hans Roudolph facemask and adjustable headgear following the instructions provided, see Fig 2. Oxygen consumption is recorded by electro-galvanic oxygen and differential flow sensors throughout the duration of the 6MPT. VO_2 output data is used to analyze and compare the user's aerobic exertion throughout the test.

TABLE I. PARTICIPANT DEMOGRAPHICS: 5 NOVICE AND 5 EXPERT WHEELHCAIR USERS; SCI – SPINAL CORD INJURY, BMI – BODY MASS INDEX

#ID	Gender	Age	BMI	Injury Type	Weekly Activity
1	F	37	28.1	N/A	High
2	M	33	25.8	N/A	Moderate
3	M	41	31.2	N/A	Low
4	F	22	28.3	N/A	Low
5	M	18	21.5	N/A	High
6	M	27	31.9	T10 incomplete SCI	Moderate
7	F	23	22.5	Neuromuscular autoimmune	High
8	F	30	24.9	T3 Incomplete SCI	High
9	M	33	39.1	Spina bifida	High
10	F	31	39.5	Cerebral palsy	High

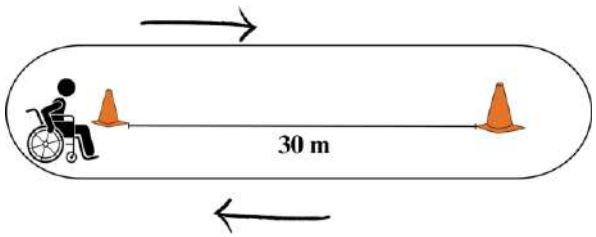

Fig 1. 6-Minute Push Test Setup: 30 meters long hallways marked with 2 cones. Wheelchair user starts on one end and pushes themselves around the cones as many times as possible in 6 minutes.

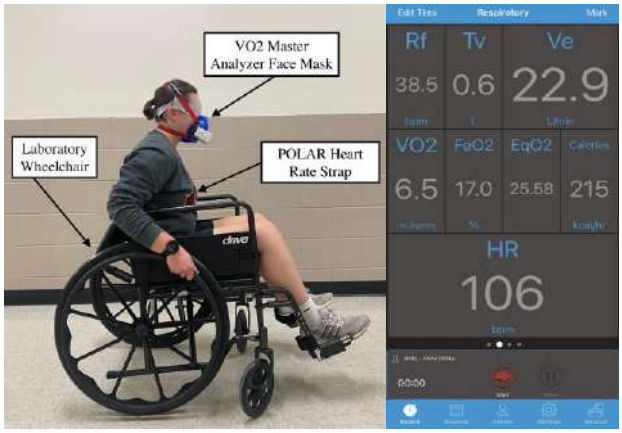

Fig 2. On the left, a picture displaying a novice wheelchair user set-up with the VO2 Master Analyzer, POLAR heart rate strap and laboratory wheelchair. On the right is a screenshot of the VO2 Master Manager Application (VO2 Master Health Sensors Inc., Vernon, BC, Canada) dashboard during a test recording.

- **Heartrate Monitoring:** A Polar H10 heartrate strap (Polar Electro Oy, Kempele, Finland) was provided with the VO2 Master Analyzer to record heartrate, see Fig 2. The Polar strap uses surface electrodes to measure the electrical signals from the heart during cardiovascular expenditure. The resulting electrocardiogram was used to evaluate physiological exertion throughout the test.

C. *Study Protocol*

Each participant was given a complete description of the study protocol. After informed consent was obtained and the demographics questionnaire was completed, the participant was equipped with a Polar heartrate strap, secured horizontally across the torso, just below the sternum. The participant was instructed to sit in an upright position, with their eyes open and no talking, while an observer recorded resting heartrate data for two minutes. Once completed, the VO_2 mask was secured on the participants' head before the start of the 6MPT. For each participant without a manual wheelchair, a lab wheelchair was provided to them.

The participant was positioned adjacent to the first cone, facing the second cone down the hallway and asked to propel themselves as fast as possible down the hallway, turning around the second cone and returning to the starting cone, repeating this until the end of the six-minute timer. Throughout the 6 minutes, the observer counted all

complete laps and provided verbal cues at the beginning, middle and end of the test.

At the end of the 6 minutes, the participant was instructed to safely come to a complete stop before the VO_2 mask and heart rate strap were removed. The participant was then asked to report their perceived level of effort during the 6MPT using the modified Borg Rated Perceived Exertion (RPE) scale [26], [27].

All participants received $25 compensation for their participation and signed a reimbursement form at the end of the study.

D. Data Processing

All heart rate and VO_2 data were recorded and processed into summarized reports for each participant by the VO2 Master Manager (VO2 Master Health Sensors Inc., Vernon, BC, Canada, 2024) application. Each report included the Max, Min and Average of the participant's heart rate, frequency of breath per minute, tidal volume, ventilation of oxygen, and fraction of expired oxygen recorded during the 6MPT.

Statistical analysis was performed to find any correlations between the collected variables. First, a Shapiro-Wilk test was conducted to assess the normality of the data for each variable, including age, gender, resting heart rate, max heart rate, distance, and max 6MPT VO2 max. The results indicated that the assumption of normality was violated ($p < 0.05$) for multiple variables. Consequently, a Spearman's rank-order correlation was used to assess the relationships between the collected variables and max VO_2, as it is a non-parametric test that does not require normality. All correlations were conducted using SPSS (version 29.0.1.0, SPSS Inc., Chicago, IL, USA), and statistical significance was set at $p < 0.05$.

Next, a linear regression analysis was conducted to further examine the relationship between the distance completed (m) and max VO_2 values (mL/kg/min) for the 6MPT for each participant. The regression model was fit using MATLAB (version R2023a, The MathWorks, Inc., Natick, MA, USA) with the following formula:

$$y = \beta 0 + \beta 1 * dist$$

where y represents the predicted max 6MPT VO_2 value and dist represents the distance completed during the 6MPT in meters. The model's fit was assessed using the Root Mean Squared Error (RMSE), R-squared, and Adjusted R-squared values. Statistical significance was evaluated with a significance threshold set at $p<0.05$.

III. Results

Descriptive statistics observed and calculated from the 6MPT data for all participants are presented in Table II. The first 5 rows present novice data while the second 5 rows consist of expert wheelchair user data. Fig. 3 shows an example of a VO_2 and heart rate data for participant 5 collected by the VO_2 mask and heart rate sensor, respectively.

TABLE II. Parameters Collected from the 6-Minute Push Test Data: 5 Novice and 5 Experienced Wheelchair Users; HR – Heart Rate, 6MPT – 6 Minute Push Test, RPE – Rate of Perceived Exertion

ID	Distance completed (m)	Resting HR (bpm)	Max 6MPT HR (bmp)	Max 6MPT VO_2 (mL/kg/min)	RPE [1-10]
1	420	44	93	18.7	3
2	405	85	158	18.8	8
3	360	89	175	9.7	3
4	480	74	198	21.4	7
5	435	59	130	16.9	3
6	1125	97	180	40.9	8
7	765	98	168	33.2	7
8	345	76	186	18.3	7
9	910	70	155	25.1	6
10	559	97	143	13.2	7
$\bar{X}$ (σ)	581 (265)	79 (18)	159 (31)	22 (10)	6 (2)

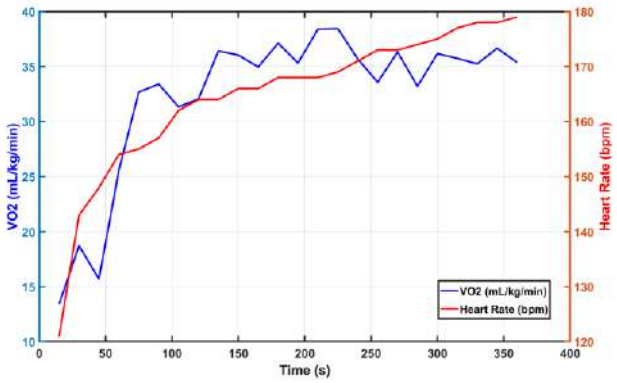

Fig 3. Example of a VO_2 and heart rate data for Participant 5.

Spearman's rank-order correlation found a strong positive correlation ($r=0.685$, $p=0.029$) for the distance completed during the 6MPT and the recorded max 6MPT VO_2 values. No other variables showed significant correlations with max 6MPT VO_2 in this analysis.

Further, a linear regression model was constructed to predict max 6MPT VO_2 based on the distance completed during the 6MPT. The intercept of the model ($\beta 0$) was 4.115 (SE = 4.042, $t=1.02$, $p=0.34$), and the slope coefficient for laps ($\beta 1$) was 0.030 (SE = 0.006, $t=4.72$, $p=0.0015$).

The model explained 73.6% of the variance in max 6MPT VO_2 ($R^2 = 0.736$), with an adjusted R^2 of 0.703. The RMSE was 5.08, indicating that, on average, the predictions deviated from the observed max 6MPT VO_2 by approximately 5.08 mL/kg/min. The overall model was statistically significant, $F(1,8)=22.3$, $p=0.0015$.

IV. Discussion

It can be observed from the recorded data (Table II) that 4 out of 5 experienced wheelchair users completed over

500m distance while all 5 novice users completed under 500m distance during the 6MPT. This outcome could be affected by the participants' everyday activity levels: 4 out of 5 expert wheelchair users reported high weekly activity compared to only 2 out of 5 in the novice group (see Table I). This difference can also be observed by the lower max VO_2 levels recorded during the 6MPT (Table II).

Additionally, 3 out of 5 novice users reported an RPE value of 3 – which is a fairly low perceived level of exertion despite being asked to use as much effort as possible. When asked about this, some novice users mentioned that their skill level limited their ability to achieve their maximum cardiovascular capacity. This is likely another reason for the occurrence of lower max VO_2 levels among novice users recorded during the 6MPT.

Statistical analysis found a strong positive Spearman's correlation between the distance completed and the recorded max 6MPT VO_2 levels ($r=0.685$, $p=0.029$). This relationship held for both novice and experienced wheelchair users. This suggests that the further the distance travelled during the 6MPT the higher the max 6MPT VO_2 value, which indicates a better cardiovascular health of the participant.

The following equation constructed from the overall model was statistically significant, $F(1,8)=22.3$, $p=0.0015$, indicating that the distance (m) completed during the 6MPT is a significant predictor of max 6MPT VO_2 (mL/kg/min):

$$\text{max 6MPT } VO_2 = 4.115 + 0.030 * \text{6MPT distance}$$

The predictive model was created to provide a foundation for an easily accessible and cheap means of monitoring VO_2 outside of traditional measurement methods. Since VO_2 has been recognized as the single best measure of aerobic fitness, estimating VO_2 throughout the 6MPT serves as a more direct assessment of cardiovascular health compared to measuring heart rate alone [8], [9], [11], [21], [22].

One of the limitations for the developed equation and observed relationship is the sample size and diversity of participant activity levels. Future studies can include a larger population with more diverse activity levels of the participants to ensure the robustness of the current model.

V. Conclusion

Our study demonstrates the foundation for estimating the VO_2 of manual wheelchair users from the results of the 6MPT. This has the potential to provide rehabilitation specialists and healthcare workers with a simpler means of assessing their patients' cardiovascular fitness without the need for specialized equipment and extensive procedures. Furthermore, by utilizing our equation, the cardiovascular health of manual wheelchair users can be more easily monitored on a regular basis and inspire prompt interventions to improve their quality of life.

***Abstract*— This research developed and integrated new mechatronic features to the Hand Extension Robot Orthosis (HERO) Glove soft exoskeleton to improve the assistive abilities of the device. The added features include low weight actuators, anchoring structures, force sensors, a camera and a cascaded computer vision driven Proportional Integral Derivative (PID) algorithm. Supporting electronics were developed to ensure that the integrated system can provide accurate grip force control based on situational awareness. The upgraded version of the HERO glove was evaluated and showed a 55% increase in grip strength, improved durability, and new force sensing and control capabilities as accurate as 0.1 Newtons. The algorithm uses computer vision software to recognize the object that the user intends to grip and then adjusts the target grip force commanded during autonomous gripping. This enhanced system, HERO Glove Insight is designed to overcome usability challenges in grasp stability and grip force modulation faced by stroke and spinal cord injury survivors when utilizing soft hand exoskeletons to enable their independence in home and community settings.**

I. INTRODUCTION

Chronic stroke survivors that receive three or more hours of high intensity upper limb therapy per day show substantial, clinically meaningful, gains in motor recovery [1], [2]. However, stroke survivors typically receive an average of just one hour of therapy per week after discharge [3]. Exoskeleton robots provide forces on the human's limbs to assist motion and provide haptic feedback, enabling people with impaired motor function to practice more engaging therapeutic tasks and accelerate their motor recovery [4]. Soft exoskeleton robots have potential to enhance the comfort, portability and inconspicuousness of their heavy, bulky, and difficult to maneuver exoskeleton predecessors, enabling extended use of exoskeletons in the clinic, home and community to deliver accessible high intensity rehabilitation and provide immediate benefits through assistance in everyday life [5], [6].

When portability is considered, the resulting soft exoskeletons utilize a small number of compact actuators and provide just enough assistive force to perform basic activities of daily living (ADLs), resulting in performance gains that are near the lower bound of being clinically meaningful [5], [7]. This has resulted in low usability ratings and technology abandonment and a need for enhanced mechanics that improve their assistive capabilities to enable greater independence.

Soft hand exoskeletons commonly utilize buttons, inertial measurement units (IMU) or pressure sensors to trigger grip assistance during unsupervised tasks at home, due to their intuitiveness, cost-effectiveness and predictable control operation [5], [7], [8] . However, button control requires use of the second hand and IMU and pressure sensor control require that the user has residual arm and hand motion. Further, these on-off control strategies do not modulate the grip force, resulting in large forces on fragile objects and suboptimal grasp postures for tool use. Myoelectric controllers utilize the user's electromyography (EMG) amplitudes to modulate the exoskeleton's velocity and assistive forces; however, these controllers are difficult to integrate into unsupervised home use cases as they require comprehensive electronics and extensive calibration and can cause unstable object interactions for users with motor control impairments [9], [10], [11].

There is a trend of integrating machine learning and artificial intelligence tools such as computer vision and smart sensing into real-world systems. This has allowed technology to surpass traditional barriers and offer new functionality in the next generation of automated systems, such as soft exoskeletons [12], [13]. More recently, the development of semi-autonomous control methodologies has opened opportunities for the development of human assistive technologies as well as human augmentation, with exoskeletons taking center stage in these [14]. Key challenges involved in developing these systems are the problems of perceiving the operating environment and capturing the dynamics of the human-in-the-loop system to achieve good control. Common strategies for overcoming these include using computer vision to describe the exoskeleton operating environment [15], [16] and control methodologies for force and position feedback systems [17], [18]. This enables independence by estimating the appropriate grasp posture and force regardless of muscle activation and ensure a reliable grasp through closed-loop control [19], [20]. Future works combining environmental awareness with assist-as-needed and myoelectric controllers could then be utilized to enable soft exoskeletons to enable independence in everyday life without sacrificing the user's rehabilitation goals.

This work was supported in part by NSERC CGS-M and AGE-WELL NCE Inc..

The study presented here focuses on integrating added systems to a Hand Extension Robot Orthosis (HERO) Glove to extend the functionality of the glove for safe and convenient at home use during rehabilitation. The paper is organized as follows, the design and integration of the added value feature for the glove are presented, a cascaded computer vision driven PID control algorithm is designed and tested on the upgraded HERO Glove, the results of the closed-loop gripping force control with situational awareness are shown and discussed and, future directions of development are recommended before concluding the paper.

II. Methodology

The HERO Grip Glove, an open-source portable wearable soft-exoskeleton was used as the base platform for this research due to its portability and customizability and to enhance its usability based on clinical trial feedback [21]. HERO Glove Insight incorporates mechanical, electrical and software modifications to the original device that were required to enhance the maximum grip force and allow for object-specific grip force control that are shown in Fig. 1.

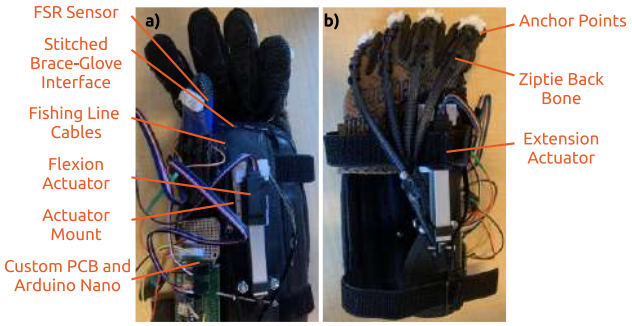

Fig. 1. HERO Glove Insight a) proximal and b) dorsal side views highlighting the modifications made to the original HERO Grip Glove.

A. Design

Mechanically, the HERO Grip Glove required improvements in its serviceability and robustness. To accomplish this, a mixture of custom and standard mounting brackets were designed to fix the linear actuators in place. Custom brackets were designed, and 3D printed using polylactic acid, then mounted to the wrist brace using threaded heat inserts and screws. This allowed the actuators and mounting brackets to be replaced with ease, while providing sufficient support. The end of the actuators are held in place using the mounting brackets and fixtures provided with the actuators. To improve the system's grip force, fishing line was routed from the front of the fingers and through custom designed and 3D printed anchors on the dorsal side of the fingertips. This modification redirects the pull force, so it is applied directly to the dorsal side of the fingertips and also keeps the proximal side of the fingertip more exposed for tactile sensation.

B. Sensing

The electrical and software components of the HERO Glove were updated to provide grip force control. The electrical subsystem was updated, and the microcontroller was changed from an Intel Curie board to an Arduino Nano BLE 33 Sense Rev 2. The microcontroller's onboard inertial measurement unit (IMU) provided the necessary sensor information for the HERO Glove's original control system as well as an RGB LED for providing the user with operation mode feedback. Additionally, a custom PCB was developed for sensor customizability and ease of assembly. A force sensing resistor (FSR Tekscan A101) and voltage divider circuit were added to provide grip force information. The location of the FSR was carefully selected after experimenting with different locations. The ideal position of the FSR was determined to be on the side of the interphalangeal joint of the thumb as it was observed that the research team would grasp objects at this location rather than the pad of their thumbs.

The added software features include the development of a library of functions to support object-oriented code and ease of development for future work. This library handles all the filtering, timing, control system and error handling functions. This is especially important as the HERO Glove is an open-source project and the development of the library which is self-contained allows for other developers to iterate on previous work.

A computer-vision system using the well-established open model You Only Look Once V3 (YOLO V3) [22] and Python open CV Library object identification routine was integrated into the control system. This is used to assign the correct setpoint for HERO Glove Insight's grip force controller, based on pre-defined object-specific grip force targets. The overall automation procedure begins by classifying the object that is in the field of view of a webcam (Logitech C920) and sending this information to the microcontroller's serial monitor, where the controller's setpoint is updated. In this article a stationary webcam was used. An important area of future development will be determining the ideal placement of the camera as well as determining the optimal number of cameras to use, as multiple cameras could provide depth perception and circumvent occlusions.

C. Calibration

Once the FSR sensor was installed and the mechanical changes were implemented, it was necessary to reduce the noise from the FSR sensors when the actuators were moving. To do this, a Kalman filter was designed with the noise covariance, measurement map scalar, process noise covariance, and error covariance values 1, 1, 0.1, and 1, respectively.

Calibration of the HERO Glove Insight was completed by commanding system to close fully around a Vernier Go Direct® isometric hand dynamometer used to measure grip force. Linear regression was used to model the relationship between the FSR sensor and dynamometer grip force readings. The results from the average of five trials of the filtered FSR sensor and hand dynamometer test are presented in Fig. 2.

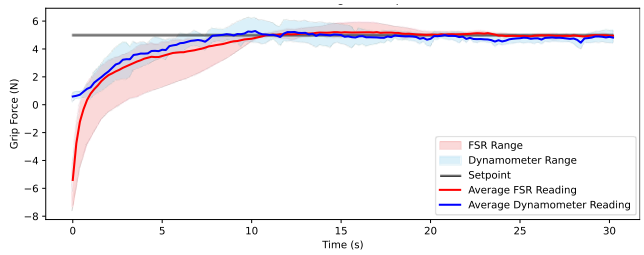

Fig. 2. FSR sensor comparison to hand dynamometer ground truth.

D. Control

To develop the transfer function for the HERO Glove Insight system, an open loop response was obtained by giving the flexion actuator a signal to provide maximum grip strength around the hand dynamometer. The filtered FSR readings were recorded and plotted using MATLAB to obtain the open loop response observed in Fig. 3.

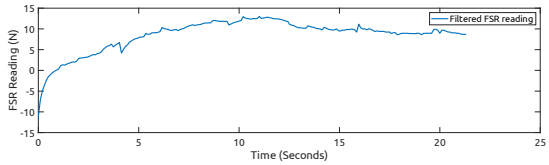

Fig. 3. Open Loop response of HERO Glove Insight at maximum grip force.

The transfer function was obtained using the general form of a first order system and the method described in [23] to obtain the transfer function of the open loop response.

$$G(s) = 1 / ((100)(4s+1)) \quad (1)$$

Using (1), a Simulink model was created and a PID controller was tuned using the PID tuning app. The PID controller was tuned to minimize overshoot and rise time.

The developed control system architecture is shown in Fig. 4., beginning by selecting the mode of operation. The IMU amplitude trigger is used to bring the system into the controlled state where the computer vision system identifies the object in front of the webcam. By identifying the object, the grip force setpoint is selected and HERO Glove Insight begins to grasp the object. The controller provides position commands to the linear actuator and the linear actuator has an in-built position controller, resulting in a nested feedback loop. The force control system operates at 5Hz and the computer vision system sends a new setpoint if the object changes.

E. Experimental Setup

To test the system's capabilities, the experimental setup shown in Fig. 5 and Fig. 6 was created. First, the user dons the HERO Glove, and the webcam is presented with the desired object. The HERO Glove system then begins to grasp the object. During this time, the FSR readings are saved in a CSV file using a Python script. This is repeated 7 times for each object.

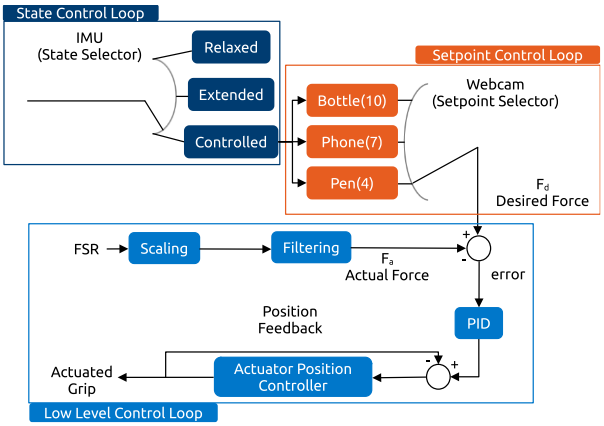

Fig. 4. HERO Glove Insight Control System Architecture.

Fig. 5. HERO Glove Insight experimental setup.

A water bottle, phone, and pen with pre-defined grip force targets of 10N, 7N and 4N, respectively, were selected as the objects for the experiments as they are common objects that people interact with every day and provide a benchmark that covers different sizes, geometries and grip force needs. These objects are easily recognizable in the pretrained YOLOV3 model. The subject in this experiment was familiar with HERO Glove Insight and kept their hand in a relaxed state to provide negligible additional input to the system during experimentation. In future works, many healthy subjects should be recruited that are unfamiliar with HERO Glove Insight to collect data and verify the system's performance.

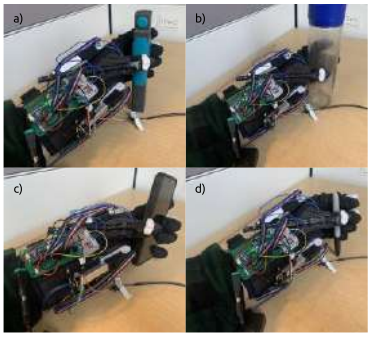

Fig. 6. Gripping orientation of selected objects for grasping tasks. a) Vernier isometric hand dynamometer. b) Glass water bottle. b) An iPhone 13. d) A sharpie marker. The orientations depecited in this image were the same orientations used to perform the grasping tasks for data collection.

III. Results

The computer vision classification system performed well. The accuracy of the class identification was approximately 98% and required less than 50ms to identify the objects. During the tasks, it was found that if no other objects were in frame of the webcam, YOLOV3 was very capable of identifying the object. The computer-vision system would classify the table causing an error during the experiment. To combat this, specific classes could be removed from the model or limits could be placed on the size of classifiable objects.

The water bottle gripping task yielded a 15% overshoot (4.27% standard deviation) with an average settling time of 27.4s (6.46s standard deviation). The results exhibited a negative force at the start of each trial due to the interaction between the sensor's tare function and the Kalman filter. The Kalman filter requires settling time prior to the collection of the data, but the data collection occurred as soon as the controlled state was entered. During each of the trials, when the system settled, the actuator would oscillate close to the setpoint generating a high pitch noise.

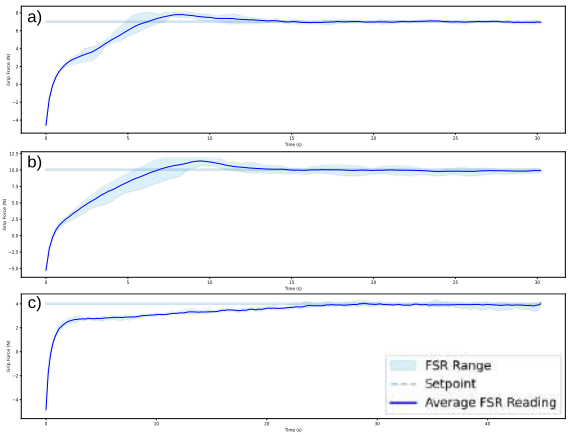

Fig. 7. Closed loop system responses of HERO Glove system grasping A) a rigid water bottle. B) a phone. C) a pen. Legend colours applies to each plot.

The phone gripping task yielded similar results with a 13.22% overshoot (2.85% standard deviation) and a settling time of 29.91s (0.7s standard deviation). While conducting these trials, the steady state oscillations caused an audible actuator response indicating the system was attempting to adjust to small changes in grip force. The negative force at the beginning of the data collection was also present.

The pen gripping task was strikingly different from the other two experiments, yielding a 4.29% overshoot (2.85% standard deviation) with a settling time of 42.8s (3.89s standard deviation). During these trials, the high-pitched noise from the actuator oscillation at the setpoint was minimal compared to the other experiments. A summary of the key characteristics of the grasping tasks are presented in Table 1.

TABLE I. Key Characteristics of Gripping Tasks

Metric	Average Reading		
	Bottle	***Phone***	***Pen***
Rise Time(s)	5.06 (1.09)	4.66 (0.62)	24.04 (8.24)
Settling Time(s)	27.40 (6.46)	29.91 (0.70)	42.80 (3.89)
Percent Overshoot(%)	15.00 (4.27)	13.22 (2.85)	4.28 (2.85)

IV. Discussion

Soft hand exoskeletons conform to the hand's anatomical structures and assist users in grasping a variety of objects. This article contributes anchoring techniques, sensing systems and an autonomous control architecture for soft hand exoskeletons. These features are integrated into the HERO Glove to evaluate their utility in increasing grip force output and applying object-specific grip forces without additional cognitive or physical load. HERO Glove Insight elevates the capabilities of soft hand exoskeletons and could be used as a rehabilitation tool that enables people to live independently and use their affected upper limb during everyday tasks in clinic, home, and community settings.

A. Enhancing Assistive Capabilities

Soft hand exoskeletons provide a range of grip forces, with fully portable systems providing under 20N and tethered systems reaching above 80N [24], [25], [26], [27]. Portable hand exoskeletons typically target assistance in activities of daily living; however, when integrating HERO Glove Insight into unsupervised home trials the users desired to perform a wider range of activities including instrumental activities of daily living, occupational and leisure activities [5]. The upgraded HERO Glove Insight provides 55% more grip force, increasing the force from 8.9N to 13.2N without modifying the power requirements or number of actuators. This increase allows us to fully assist 32% more activities of daily living and instrumental activities of living [28]. In addition to grip force, the grasping postures contribute significantly to the user's ability to complete a task [28]. The version of the HERO Glove Insight presented here does not control the grip type. To compensate for this limitation some fingers must apply larger forces to create a stable grasp. Further innovations could include increasing the number of actuators to command finger-specific loading profiles [7], [26], clutch mechanisms to command various grasp postures with a reduced number of actuators and differential mechanisms to evenly distribute the force across the fingertips without increasing the actuator count [29]. Integrating passive components, such as thumb support and support throughout the upper limb, could enable reach-to-grasp activities without considerable additions to device weight and control complexity [30], [31]. Further investigation of exoskeleton mechanics is needed to enhance device usability and acceptance in unsupervised home and community settings and restore pre-injury grasping behaviors and levels of upper limb activity.

The audible noise present during grasping is disruptive for the user and reduces the system's longevity. Constraining the change in grasp force will prevent the actuators from

adjusting aggressively to slight changes in sensor feedback. Additionally, the worm gear friction contributes heavily to the audible and signal noise generated by the actuator. This can be reduced by changing the material or gearing configuration. The noise from these actuators is 55dB. Numerous application studies [32] have reported audible noise as a problem, particularly in pneumatic systems but these studies do not include noise measurements. As a result, it is difficult to set a benchmark for the audible noise of soft exoskeletons. Future improvements to the HERO Glove Insight include a more fine-tuned control system to eliminate oscillations and subsequent audible noise as the user grasps the object.

B. Enabling Independence to Users Without Hand Function

In the development of HERO Glove Insight, a webcam camera was selected for its low cost, weight, and computational power. This contribution explores capturing situational awareness to provide force setpoints for the gloves control system. The next developmental step for this computer vision system is to mount the webcam to the user's shoulder or chest or Glove to track what the user is looking at and grasping and use the BLE capabilities of the microcontroller to communicate wirelessly with a device capable of running the object recognition model and use a model which recognizes more objects. This will enhance the portability of HERO Glove Insight for use in home and community settings and allow for the HERO Glove Insight to be usable in a larger range of scenarios. With improved situational awareness HERO Glove Insight will be able to interpret the user's intended grasp type by identifying the object and providing the correct output [15], [33].

The goal of the PID controller was to minimize the grip force overshoot and rise time relative to the object-specific grip force target. Observing the results presented in Table 1, the two larger objects, water bottle and phone, followed a much closer relationship to each other than the pen. For the pen task, the proportional gain was insufficient, resulting in a 24s rise time in comparison to less than 5s for the rise time in the other tasks. While the overshoot observed in each of the trials is not worrisome for rigid objects, more delicate objects could be broken if the overshoot is too high. The PID controller was a suitable proof-of-concept controller to evaluate the performance of the system, though future iterations should explore adaptive control schemes utilized in previous exoskeletons to provide more desirable transient responses [34], [35]. For instance, gain scheduling could be used to adjust the PID gains to create object-specific transient responses and model-predictive control could be used to personalize the model and controller to user's biomechanics and grasp orientation and reduce the oscillations of the gripping motion and thus the noise generated. As a higher voltage for this actuator model is not possible, a lower gear reduction could be used to increase the speed at the cost of the force provided.

C. Considering Users' Goals for Independence and Motor Recovery

Future works will explore the development of a model which includes the user in the loop. This will lay the foundation for developing a cooperative therapy mode which considers the user's goals, abilities and fatigue, such as in [34], where the assistance is only offered upon reaching the boundary of the user's working envelope and sensing a decrease in velocity. Using computer vision, the system could also monitor the progress of the user's grasping task to provide assistance only when needed. Other methods of optimizing grip on objects will also be explored, such as measuring slippage of the object, which could be accomplished by adding piezoresistive tactile sensors to the fingers [36].

D. Limitations

Current limitations of the research presented include reduced portability and small sample sizes. The current computer vision system is hosted on a computer and validated in uncluttered environments. The current iteration of the HERO Glove Insight is not optimized for weight. It currently weighs approximately 360 grams which is an increase of 210 grams from the previous version. To make the HERO Glove Insight more portable, the weight will need to be optimized, and the computer vision system added to the glove. This can be accomplished by using plastic fixtures for mounting the components instead of steel and by adding a harness for users to wear with the webcam. Healthy subject studies are required to validate the system's specifications ahead of portability refinements and clinical trials. Clinical trials then need to be conducted with a diverse group of participants with motor impairments after stroke and spinal cord injury to evaluate the safety, comfort and usability and effectiveness of HERO Glove Insight.

V. Conclusion

This research develops HERO Glove Insight, which integrates added value features to a HERO Glove. Improvements to the design have increased the maximum grip force and the system's robustness. Models of the sensor and transmission dynamics were derived and integrated with a computer vision-PID control system to provide automated object-specific grip force control. This system demonstrates opportunities that sensing and computer vision can provide to increase the functionality and ease of use of soft exoskeletons and identifies areas where future development and clinical trials are required to support safe and functional grasps for assistive and rehabilitation contexts.

Evaluating Feedback Modality Preferences of Power Wheelchair Users During Manual Robotic Arm Control

Breelyn Kane Styler[1] Lesong Jia[2] Henny Admoni[3] Reid Simmons[3] Rory Cooper[1,4] Na Du[2] and Dan Ding[1,4]

***Abstract*— Assistive robotic arms can extend a user's capabilities, but they can be hard to control because users do not always have good situational awareness at the robot's end effector. This study investigates whether explicit feedback about the robot's distance to task-relevant objects can help users manually control such robots more easily. Specifically, we investigate light and sound as feedback modalities. In a within-subjects study, users controlled a robot arm in a kitchen task. We compared a no-feedback condition with four feedback types: discrete light, discrete sound, continuous light, and continuous sound. We assess usability, performance outcomes, mental workload and user preferences. Our findings indicate that adding feedback improved task success; however, user preferences did not consistently align with performance metrics like task efficiency or success. Instead, preferences varied, revealing insights into user perspectives on each feedback modality.**

I. INTRODUCTION

Assistive technologies that enhance user functionality can provide non-verbal feedback for increasing task understanding and operation [1]. Specifically, manual operation of robotic arms is complicated by challenges such as depth perception, object alignment, and obstructed line of sight [2], [3], [4]. Line of sight is a further challenge for power wheelchair users, whose limited trunk control prevents them from repositioning their bodies to gain better visibility of objects during pick and place tasks. To address these difficulties, our work focuses on providing intuitive operation through unobtrusive light and sound feedback that enhances an operator's ability to perceive distance to objects. By improving control, we promote user independence which increases a user's engagement in everyday activities.

Recent research emphasizes the desire for better situational awareness and the importance of users feeling in control during arm operation [2]. However, for users with disabilities, who experience additional cognitive, visual, or hearing impairments, delivering situational feedback while maintaining the user's sense of control and minimizing distractions remains unclear. Auditory-visual interactions improve perception [5], and facilitate skill learning [6]. These modalities not only improve perception accuracy compared to others, such as haptic or temperature feedback [7], but offer familiar and intuitive communication channels.

Fig. 1: User manually operating robotic arm through a Keurig task.

Building on these insights, we investigated light and sound feedback in two forms: discrete and continuous representations. These modalities were used to convey proximity while maintaining manual robot arm control. We conducted five trials with power wheelchair users, testing no feedback and four distinct feedback methods. During these trials, we collected usability, performance, and workload metrics. Additionally, we gathered qualitative preference feedback throughout and between each condition to address the following four research questions:

1. **Usability:** *Do users find feedback-enhanced methods more usable?* Usability was assessed by comparing user rankings with System Usability Scale (SUS) scores, [8], gathered after each of the five conditions.

2. **Performance:** *Does the addition of feedback methods increase task efficiency and success?* To explore this, we measured task times and success rates across feedback conditions.

3. **Workload:** *Does feedback improve ease and intuitive use of the system by decreasing mental workload?* We evaluated this using NASA Task Load Index (NASA-TLX) workload assessments following each condition [9] .

4. **Preference:** *Do users prefer light or sound feedback more when grasping and placing objects?* User rankings and qualitative feedback during tasks provided insights into preferences for light versus sound feedback, as well as

discrete versus continuous feedback.

II. RELATED WORK

Situational awareness is an important aspect of user-centered design, particularly for assistive technologies supporting users with disabilities. In user interfaces, providing increased situational awareness enables operators to focus on task-relevant information, filter out distractions, and integrate current information to anticipate future states. In related work, this has been described as the operator's ability to understand the current state and project their understanding into future states [10].

Despite teleoperation being one of the oldest applications in human-assistive interaction, recent research highlights the lack of user-centered approaches, with teleoperation interfaces often restricted to expert use cases [11]. This further emphasizes the need to investigate interfaces that provide intuitive feedback for untrained users and improve understandability which is a key design guideline for human-robot interaction systems [12]. These systems should also convey their current state while minimizing cognitive demands, such as context switching between the environment and the interface [12].

Motivated by these previous studies, our work investigates the use of light and sound feedback. Visual and auditory modalities were chosen because they enhance perception [5], improve perceptual accuracy for users [7], aid in learning new skills [6], and serve as a preferred familiar communication method [13].

Auditory signals are commonly used to provide spatial awareness, as humans naturally rely on hearing for internal positioning [14]. Many assistive systems leveraging auditory cues focus on aiding users with visual impairments, such as providing spatial knowledge or localizing objects in space [15]. Examples include smart wheelchairs that use auditory cues to convey obstacle proximity, system status, or direction changes [16]. Additionally, non-verbal auditory signals, such as tones or broadband sounds, have been researched for their effectiveness in localization and communication tasks [17].

In contrast, there is a notable lack of research focusing on light-based feedback to convey object distance during robotic arm manipulation. Much of the existing work combines multiple modalities or explores haptic feedback [18]. While multimodal feedback methods can improve performance, this creates a gap in understanding individual user preferences and the effectiveness of individual feedback modalities, which is what our study aims to address.

Existing work on multimodal feedback often combines modalities, such as in powered wheelchairs, where sensors provide combined visual and auditory cues for navigation and obstacle avoidance [19]. Additionally, most research on robotic arm operation focuses on remote teleoperation interfaces, where the user is not physically co-located with the robot. These interfaces often aim to simplify free-positioning with techniques like point-and-click interfaces or constrained positioning for users with disabilities [20]. There is comparatively little focus on systems where the robotic arm is co-located with the user.

For systems that are in the same physical space as the user, research has focused on shared-control visualizations, emphasizing the importance of designing interfaces that improve predictability and legibility for the user [21]. Other studies examine multimodal feedback for co-located systems, such as tactile, visual, and auditory combinations [22]. However, there is still a lack of research isolating individual feedback modalities in these settings.

Our study provides a focused investigation where this contribution not only addresses gaps in user-centered feedback design but also offers insights into how specific modalities support operators with disabilities in direct-control assistive tasks.

III. SYSTEM DESIGN AND FEEDBACK CONDITIONS

A. System Setup

Users tele-operated a Kinova Gen3 robotic arm mounted on a table at the height of their power wheelchair positioned on the side opposite their dominant hand. An overhead camera was used to identify objects within the scene and was calibrated at the start of the trials relative to the robotic arm's base frame. To minimize movement, foam padding was placed beneath the pod holder and Keurig machine. Any residual movement was managed by the overhead camera, which continuously updated object positions using fiducial tags affixed to the pod holder and Keurig. Light feedback was provided through an LED ring on the robotic arm's wrist, and sound feedback through an external speaker. The task setup is illustrated in Figure 2.

The position of the end effector was translated into the overhead camera's frame by capturing four distinct poses of the end effector and applying the Umeyama Algorithm. This

Fig. 2: Overhead view of the task setup with overhead camera, pod holder, and Keurig. Fiducial tags mark objects in the scene, and the end effector tag is used at task start to calibrate the overhead frame into the robot arm's base frame.

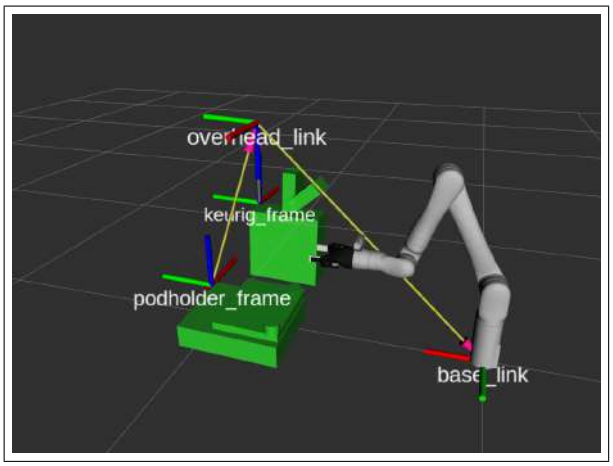

Fig. 3: Reference frames for the task.

calibration allowed the system to determine the position of all scene objects relative to the arm's base frame. A depiction of the reference frames is shown in Figure 3.

For providing light feedback, as shown in Figure 4, we wrapped the wrist of the robotic arm with a WS2812 LEDs light strip wrapped in silicone. This strip was wired to a ESP-WROOM-32 Arduino board with the wire cased and affixed to the arm's base via velcro wire wraps. An NVIDIA Jetson AGX Orin was used to communicate via Bluetooth (Tiny Bluetooth Library) to the Arduino (ESP32 BLE library) which sent signals using FastLED to control the lights. Light control was sent to the wrist LEDs via a function parametrized by color, brightness, and blink frequency.

For sound feedback, a sine wave function generator was used to generate a 300Hz wave file, a frequency chosen for its familiarity and relatively low pitch. This frequency is close to middle C (approximately 256 Hz) and falls within a range that is commonly encountered in everyday sounds. The file could then be played from the Jetson to a bluetooth speaker with a pitch factor setting from 0 to 1. For example, a pitch factor of 0.8 would be a frequency of 240 Hz. Audio control was sent to the speaker via a function parameterized by beep frequency, and pitch factor.

B. State Transitions

We provided users with five feedback conditions: no feedback, two light feedback options, and two sound feedback options. Each feedback modality (light and sound) included a discrete and a continuous condition. All feedback methods operated across four internal task states, *far from target*, *midway to target*, *near target*, and *action executable*, with feedback parameters varying according to both the task state (pod or keurig) and the feedback condition. These states and transitions are depicted in Figure 5.

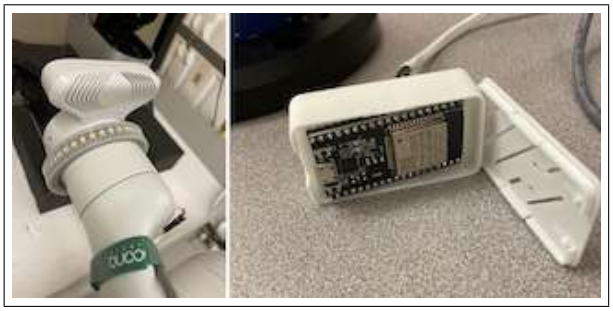

Fig. 4: Wrist light and arduino wired board.

In the pod-grasping phase, all four states were included. Transitions between states occurred based on the spatial relationship between the robotic end-effector links and predefined boundaries within the scene. These boundaries were established relative to the object's frame. Specifically, *far from target* encompassed the area outside the *midway to target* goal box. The *midway to target* area referred to the region within the first goal box. The *near target* state was defined as the region where the end-effector links intersected the inner goal box but the pod's line segment did not intersect the plane defined by the open gripper of the end-effector. Finally, the action executable state was achieved when the plane defined by the open gripper intersected the pod's line segment within the innermost goal box, Figure 5.

The line segment used to define the pod's position dynamically adjusted based on the gripper's orientation. For side and front grasps, the segment aligned vertically. For overhead grasps, the segment rotated to a horizontal orientation whenever the end-effector pitch in the base frame exceeded a specific threshold. This was determined by the roll angle in the end-effector frame, where the y-axis points out of the side: a roll of 90 degrees indicated a flat front or side grasp, while a roll exceeding 114 degrees positioned the end-effector overhead. Overlapping goal boxes were created for all pods in the holder; however, for consistent experiment starts, only two pods were available for retrieval, positioned at opposite ends of the bottom row.

In the Keurig pod-placing phase, only three states were used: *far from target*, *midway to target*, and *action executable*. Here, the definitions for far and midway remained the same as in the grasping phase. The *action executable* state was achieved when the end-effector links entered the innermost goal box.

C. Feedback Conditions

For the continuous feedback shown in the top graph, Figure 5, only the frequency of blinking (light) or beeping (sound) was adjusted. The light remained white with consistent brightness, while the sound retained the same tone. The frequency of blinking or beeping in the *far from target* and *midway to target* state increased linearly as the end-effector approached the target, normalized across a parameterized range. If the *action executable* area was triggered, the light or tone would go solid.

For discrete feedback, thresholds changed with each state, as shown in the bottom step graph of Figure 5. For sound, tones increased by a musical fourth, starting at 180 Hz (*far from target*), progressing to 240 Hz (*midway*), 300 Hz (*near*), and culminating in a distinct dinging sound for the final *action executable* state. For light, states transitioned

TABLE I: Demographic Information. Abbreviations include Spinal Cord Injury (SCI), Multiple Sclerosis (MS), Traumatic Brain Injury (TBI).

Diagnosis	Age	Cognitive Impairment	Hearing Loss	Vision Loss

SCI	64	No	No	forgot glasses

between white (*far from target*), yellow (*midway*), red (*near*), and green (*action executable*).

IV. METHODS

The study was completed in no more than two hours and approved as a minimal risk study under the Institutional Review Board of the VA Pittsburgh Healthcare System, protocol number IRBNet 1720292.

A. Participant Recruitment and Demographics

A total of 15 participants were recruited from the National Veteran Wheelchair Games, with two having scheduling conflicts, resulting in 13 participants for the study. Inclusion criteria was: 1) individuals over 18 years of age, 2) power wheelchair users, and 3) individuals with upper limb impairments that hinder daily manipulation tasks. Table I shows demographic characteristics of the thirteen Veteran participants. Seven were African American and six Caucasian with eleven identifying as male and two as female. Seven of the participants described having a cognitive impairment, two from a traumatic brain injury, two from stroke, and three from multiple sclerosis. Seven participants also described having a hearing impairment with the side indicated, three said this was from tinnitus. Despite these hearing impairments all participants indicated they could hear the sound feedback, we believe this was due to using a low pitch. Additionally, while many had glasses four participants indicated vision impairments with two forgetting to bring their glasses, one describing double vision, and the fourth describing mono-vision. Lastly, nine of the thirteen participants indicated some loss of sensation describing numbness in all or parts of fingers on their hands.

B. Study Design

The study followed a within-subjects, repeated-measures design in which each participant experienced five conditions. To control for order effects, the conditions were counterbalanced using a Latin Square design. The conditions included: no feedback, continuous light feedback (a blinking white light with a blink rate that varied with proximity to the goal), discrete light feedback (a light that changed color based on proximity to the goal), continuous sound feedback (a steady tone where the beeping rate increased as proximity to the goal decreased), and discrete sound feedback (a tone that changed pitch based on proximity to the goal).

C. Experiment Procedure

Participants began the study by providing informed consent and completing a demographic survey. The demographic survey collected details about participants' age, gender, diagnosis, and technology viewpoints. After completing the survey, participants underwent a 30-40 minute robotic arm training session. During this session, they were introduced to the joystick's four control modes: lateral end-effector movement, wrist roll and height changes, wrist orientation changes, and gripper opening and closing. To reinforce these controls, participants practiced moving the robotic arm to touch the investigator's hand at different spatial positions. They also completed three grasping tasks, which included a front grasp of a water bottle, an over-the-top grasp of a small cereal bowl, and a side grasp of a raised thin notebook.

Before each trial, the experimenter configured the feedback system via a setup file, explained the feedback modality to the participant, and ensured the participant could see the lights or hear the sounds. Once participants confirmed their understanding and readiness, they began the task. The primary coffee-making task required participants to retrieve a Keurig pod from the holder and place it in the top of the Keurig machine, as illustrated in Figure 6.

For consistency, participants were instructed to pick either of the two pods from the holder. If one pod was dropped, they were to proceed with the remaining pod. If both pods fell, the experimenter replaced them to ensure consistent start locations for the overhead system. Task success was defined as successfully grasping the pod without dropping it and placing it into the Keurig without it falling out.

D. Data Collection and Analysis

During each trial, task performance metrics, including task completion time and success rates, were recorded. To evaluate usability, participants completed the System Usability Scale (SUS) [8] after each trial. The SUS consists of 10 items rated on a Likert scale ranging from 'Strongly disagree' to 'Strongly agree,' with a total score ranging from 0 to 100, where higher scores indicate greater perceived usability. Participants also completed the NASA Task Load Index (NASA-TLX) [9] to assess workload across six dimensions: Mental Demand, Physical Demand, Temporal Demand, Performance, Effort, and Frustration. Therefore, each participant completed five SUS and five NASA-TLX questionnaires.

In addition to quantitative data, qualitative data was collected through video recordings and participant feedback. Audio recordings of participant comments were transcribed and analyzed to identify categories which included preferences, likes, and dislikes for each feedback modality. Participant rankings of the feedback conditions were also recorded at the completion of all trials.

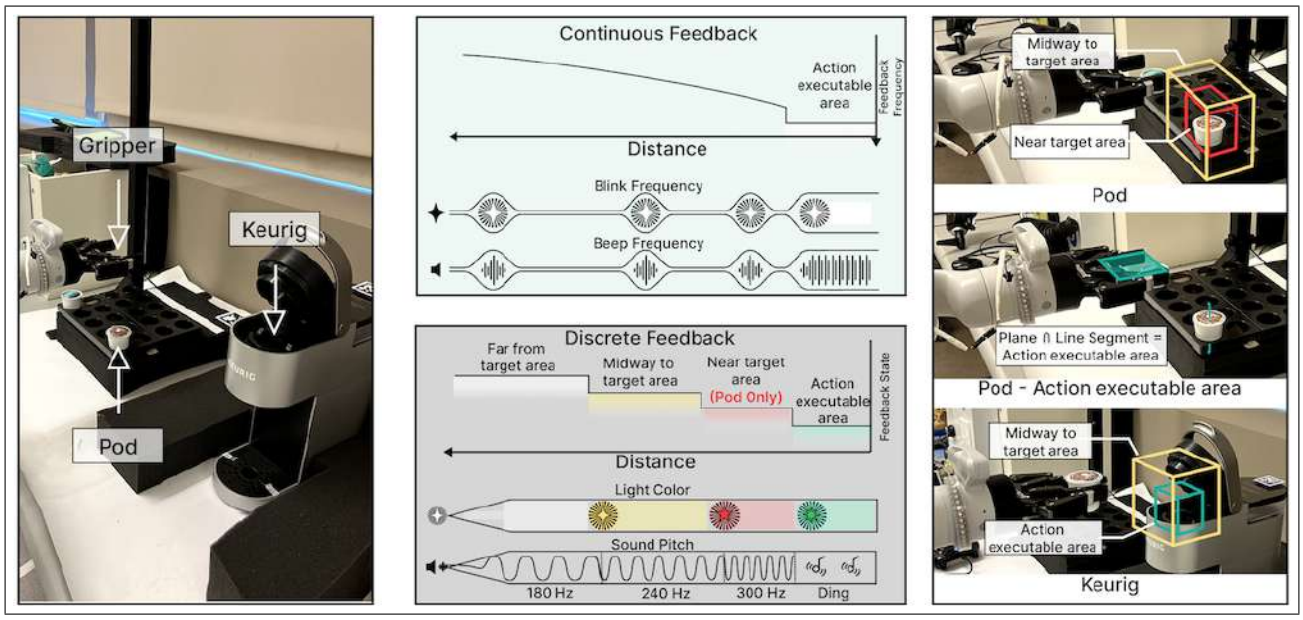

Fig. 5: States for continuous and discrete light and sound feedback.

Quantitative data was analyzed using IBM SPSS Statistics 29.0.2.0. Performance metrics, including task completion times and success rates, were first summarized using descriptive statistics. Pearson correlation coefficients were also calculated to explore relationships between success rates and other variables. To compare success rates across feedback conditions, Cochran's Q test was performed, as this test is suitable for binary data, such as success or failure outcomes. Task completion times were analyzed using a repeated measures ANOVA, which is appropriate for continuous, normally distributed data collected under multiple conditions within subjects.

For usability, differences in SUS scores across feedback conditions were analyzed using the Friedman Two-Way ANOVA by Ranks, a non-parametric test ideal for ordinal data in repeated-measures designs. The same test was applied to analyze the six workload dimensions of the NASA-TLX, as these measures are also ordinal and do not assume normality. Participant preference rankings of feedback modalities were analyzed using the Independent-Samples Kruskal-Wallis test, which is appropriate for comparing ordinal data across multiple groups.

Fig. 6: Two subtasks: grasping pod and placing pod in Kuerig.

V. RESULTS

A. Usability

No statistically significant differences or trends were found between usability scores and the feedback method, the user's ranked feedback preference, or the order in which the task was presented. Overall, usability scores grouped by feedback method had mean values greater than 68, as shown in Table II.

TABLE II: System Usability Scale Average per Feedback Condition.

	Mean SUS
No Feedback	80.2 ± 19.8
Continuous Light	78.8 ± 20.6
Discrete Light	82.1 ± 18.3
Continuous Sound	75.0 ± 22.0
Discrete Sound	79.2 ± 21.1

B. Performance

There was no statistical significant difference between the user's task success rate and ranked preference (favorite feedback method was not the most successful), and users did not succeed more with more practice (no order effect found for success), but there was a statistically significant difference among the success rates of individual feedback methods. In order of least successful to most successful, no feedback was least successful with four failures. Three of these failures occurred during pod grasping and one having to retrieve a second pod after dropping during Keurig placement. Discrete sound had three pod grasping failures, and continuous light with one grasping failure. A Cochran Q non-parametric test for binary results was performed with a calculated Q statistic

of 10.154(d=4) and a p-value of 0.038 indicating significant heterogeneity. Therefore, the addition of feedback methods did increase task success but this success rate did not seem to impact the users preference ranking. Success rates and task times were grouped by feedback method, as shown in Table III.

There was no statistically significant difference or trend among the feedback methods for overall task times. Nor were any trends found when grouping overall task times by user's feedback rank or the order tasks were presented. Therefore, the addition of feedback methods did not show evidence of increasing task efficiency. The task times grouped by feedback method are displayed in Table III. We did find a moderate negative linear relationship (pearson correlation $r(65) = -0.529, p < .001$) between total task time, and success rate (success rate increases as total time decreases).

C. Mental Workload

The NASA TLX workload evaluation included six workload dimensions. Results were analyzed based on the feedback method presented, the user's preferred feedback ranking, and task order. Of these dimensions, only the mental demand dimension showed a significant result, attributed to the order in which tasks were presented. Using Friedman's Two Way Analysis of Variance the results indicated a significant difference between task orders, $X^2(4) = 9.59, p = 0.048$.

The remaining five dimensions (performance, effort, temporal demand, physical demand, and frustration) did not show statistically significant differences when grouped by feedback method, users' preferred feedback rankings, or task order.

D. Feedback Preferences

Participants provided varied preferences for the five feedback methods, with no overarching trend favoring light over sound or discrete over continuous feedback. However, discrete color feedback emerged as the most preferred overall, while continuous beeping was the most preferred sound-based method.

Although statistical significance was not observed, a general trend toward color feedback as the most favored method was evident (Figure 7). After ranking all feedback methods, six out of thirteen participants listed color as their top choice. Of the remaining seven, three ranked color second, resulting in nine of thirteen participants placing color feedback in their top two preferences. This trend aligns with qualitative data, as several participants cited the intuitive nature of color changes which effectively signaled task progress. For example, one user noted, "I backed off, and it was yellow one time. Then once I backed off, the colors changed, and when it turned green, I knew I was right on point."

TABLE III: Performance Metrics per Feedback Condition.

	Success Rate	Mean Task Time (s)
No Feedback	0.69 ± 0.48	232.8 ± 114.5
Continuous Light	0.92 ± 0.28	257.8 ± 150.4
Discrete Light	1.00 ± 0.00	248.5 ± 104.6
Continuous Sound	1.00 ± 0.00	191.9 ± 090.5
Discrete Sound	0.77 ± 0.44	255.9 ± 145.1

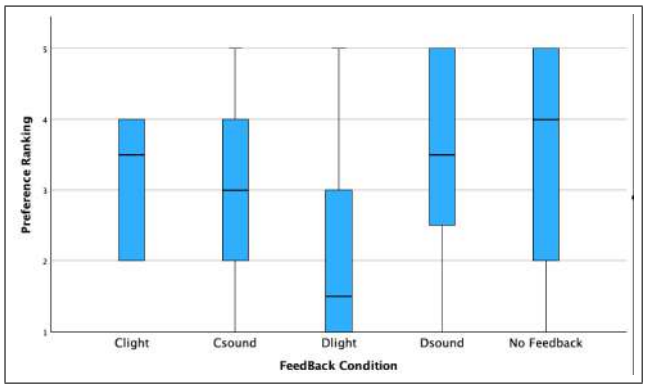

Fig. 7: Boxplots showing ranked feedback preferences grouped by feedback method.

When analyzing participants' top two feedback preferences, we found varied combinations. Four participants preferred visual feedback exclusively, ranking both color and blinking light in their top two. Two participants preferred sound feedback, selecting both beeping and tone. Four included no feedback among their top two preferences, while the remaining three participants had mixed preferences combining light and sound feedback. This variability suggests individual differences in processing visual and auditory signals during task execution.

In terms of light feedback, color changes were favored over blinking light by the majority of participants. Eight participants explicitly stated that they did not notice the blinking light, which limited its effectiveness. One participant explained, "The colors got my attention more than the blinking. I could kind of forget about [the blinking], ... but when the colors were changing I could really see that." This suggests that while blinking lights provided continuous feedback it may have been hard for the user to distinguish the range of information given, discrete color zones made feedback more salient and easier to interpret.

Sound feedback garnered mixed reactions. Six participants remarked sound feedback got their attention most. However, three participants described aspects of the sound, whether tone or beeping, as annoying, two of the six actually preferred sound because it captured their attention. One participant stated, "I liked the beeping the best because I'm used to it. I was a truck driver, and that 'beep, beep' gets my attention." Another participant also preferred the continuous sound due to familiarity: "I think because I got used to the car, I liked the going faster sound better." These quotes show users connect familiarity to preferences and feedback preferences are influenced by individual experiences.

When comparing discrete feedback methods, participants found color changes more intuitive and less intrusive than tone. While the tone conveyed proximity, three participants found it annoying, noting that the constant background sound was hard to ignore. One participant said,"Why do I like the color best? Because it's passive. The tone kind of got on my

nerves after a while ... a subtle hint versus like a dial tone." Although, one participant liked the tone during object pickup, with two others saying they prefer feedback more for pick rather than place tasks. This leads to further research with manipulation actions matching feedback needs for specific subtasks.

Several participants shared insights into broader feedback preferences and potential improvements. Six participants expressed a desire for feedback tied to the amount of pressure applied with the grippers which could enhance control. Additionally, three participants mentioned the importance of customization, with one explaining, "I think some people would like to customize the colors or sounds ... that would be up to the individual their likes and dislikes, man voice or woman voice, or for something more critical you might have a harsh voice."

Interestingly, three participants preferred no feedback because they felt it allowed them to focus better on the task. One participant noted, "I could concentrate better without the lights or sound by looking at the cup." However, the same participant acknowledged the benefits of feedback, adding, "I trust it more with the sound and lights." Another user that preferred the no feedback over other methods mentioned, "I definitely felt a lot more comfortable, but now I almost miss something telling me, 'hey', I did find that I was looking around a lot more, ... having something [feedback] is nice." This suggests a need to toggle feedback on or off.

Finally, there was no statistical significance between participants' feedback preferences and the task order in which feedback methods were presented. For example, the first task or last task's feedback method was not the method preferred most.

VI. DISCUSSION

A. **Usability** *Do users find feedback-enhanced methods more usable?* Usability, as measured by the SUS, did not vary significantly across feedback conditions or align with users' preference rankings. This result shows participants' preferences and their reported usability experiences did not always correlate.

B. **Performance** *Does the addition of feedback methods increase task efficiency and success?* The addition of feedback methods improved task success rates; however, this did not appear to influence users' preference rankings. Conversely, feedback methods did not show evidence of improving task efficiency, as task times remained statistically unchanged across conditions. This aligns with findings from related studies on auditory feedback, which reported no significant improvement in task completion time but noted a reduction in perceived subjective difficulty when auditory feedback was present [23]. Some participants in our study echoed this sentiment, stating they felt they had to "pay more attention" when feedback methods were absent.

C. **Workload** *Does feedback improve ease and intuitive use of the system by decreasing mental workload?* No specific feedback method demonstrated a significant reduction in overall workload as measured by the NASA-TLX. However, an order effect was observed within the mental demand dimension, suggesting that as participants became more familiar with the task, their workload decreased, independent of feedback modality. Participant comments about increased attention demands in the absence of feedback suggest that feedback may play a role in mitigating perceived workload, even if objective measures were not captured.

D. **Preference** *Do users prefer light or sound feedback more when grasping and placing objects?* User preferences were mixed, with an overall trend favoring discrete color feedback. Sound feedback was generally more effective for capturing attention, but gave diverse reactions: some participants valued it for its alerting nature, while others found it annoying. These findings are consistent with multimodal feedback in wheelchair navigation, which noted that "auditory feedback may be best for capturing attention," [24]. These auditory preferences aligned with work which found that broadband sounds (with varying frequencies) were preferred over constant, alarm-like tones due to reduced user annoyance [25]. In contrast, light feedback was favored for its subtlety, with discrete color changes being intuitive for understanding state transitions. However, blinking light feedback was often difficult to notice, likely due to challenges in distinguishing subtle changes in blink patterns for conveying distance. Participants typically preferred discrete light feedback over continuous blinking light, citing its clarity. Conversely, continuous sound feedback was favored over discrete sound for its familiarity. Some participants compared it to the beeping of a car in reverse. Even so, discrete sound was mentioned to be more effective for specific actions, such as object pickup.

E. *Limitations*

This study was limited to recruiting participants from a single venue, specifically Veterans, which may not be a full representation of the population. Additionally, the participant group was predominantly male, highlighting the need for greater female representation to ensure a more balanced perspective.

Another limitation is that the study setup required an overhead camera, which does not fully reflect a real-world deployment. However, our focus was on understanding user preferences for light and sound feedback, not system implementation. In practice, alternative camera placements such as a fixed home setup, a wrist-mounted pre-scan, or integration with a moving device localized within a fixed base frame could provide the necessary ground truth information.

VII. CONCLUSION

This study explored user preferences and the effectiveness of light and sound feedback modalities for enhancing usability, task performance, and intuitiveness while power wheelchair users manually moved a robotic arm through a coffee making grasping and placement task. While no single feedback method was universally preferred, discrete color feedback was the most favorable for many participants. User

preferences for feedback were not only varied but also task-dependent. Some participants emphasized the importance of context, favoring certain feedback methods for specific actions, such as object pickup over placement, while others gravitated toward feedback modalities that felt more familiar or aligned with their prior experiences.

Interestingly, the addition of feedback did not statistically improve task efficiency, but it did appear to enhance perceived situational awareness and task performance. This suggests that feedback's value lies more in supporting user experience and decision-making rather than directly accelerating task completion. Additionally, participants expressed a desire for customizable feedback, such as the ability to select specific colors or tones, to better suit their personal preferences. These findings show the potential advantages of multimodal feedback systems that can adapt to the user's preferences and the specific demands of the task.

Simulating Safe Bite Transfer in Robot-Assisted Feeding with a Soft Head and Articulated Jaw

Yi Heng San[1,*], Vasanthamaran Ravichandram[1,*], J-Anne Yow[1,2,*], Sherwin Stephen Chan[1,*], Yifan Wang[1], Wei Tech Ang[1,2]
[*]These authors contributed equally

***Abstract*—Ensuring safe and comfortable bite transfer during robot-assisted feeding is challenging due to the close physical human-robot interaction required. This paper presents a novel approach to modeling physical human-robot interaction in a physics-based simulator (MuJoCo) using soft-body dynamics. We integrate a flexible head model with a rigid skeleton while accounting for internal dynamics, enabling the flexible model to be actuated by the skeleton. Incorporating realistic soft-skin contact dynamics in simulation allows for systematically evaluating bite transfer parameters, such as insertion depth and entry angle, and their impact on user safety and comfort. Our findings suggest that a straight-in-straight-out strategy minimizes forces and enhances user comfort in robot-assisted feeding, assuming a static head. This simulation-based approach offers a safer and more controlled alternative to real-world experimentation. Supplementary videos can be found at: https://tinyurl.com/224yh2kx.**

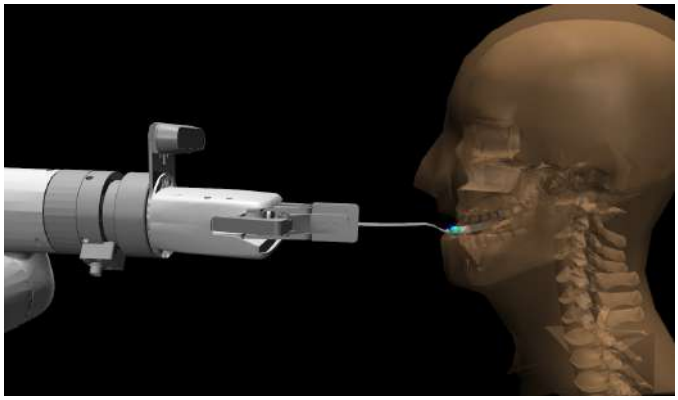

Fig. 1: Physical human-robot interaction simulation of bite transfer with contact forces between the spoon and the soft-body mouth shown by the blue and green spheres. The opacity of the head and skull is decreased to show the contact points.

I. Introduction

Robot-assisted feeding systems offer a promising solution for improving the quality of life of individuals requiring feeding assistance while also alleviating caregiver burden. However, implementing safe and effective bite transfer – the process of delivering food from a utensil into a user's mouth – presents unique challenges due to the close, physically interactive nature of the task.

Autonomous bite transfer has been proposed, with earlier works detecting the user's mouth pose and positioning the food in front of a care recipient's mouth [1], [2]. However, leaning forward for an outside-mouth bite transfer can be impossible or tiring for those with more severe upper body and neck mobility limitations, prompting recent works to study in-mouth bite transfer. To further enhance user comfort and safety, compliant controllers based on force feedback have been implemented, adjusting compliance during entry and exit phases [3] or classifying physical interactions using visual and haptic feedback to select a suitable controller [4]. Despite these advancements, current methods generally assume a fixed, pre-planned path and rely solely on force feedback to adapt to contact forces without adjusting bite transfer parameters such as insertion depth, exit angle, or exit depth.

Ensuring user safety is paramount in developing robot-assisted feeding systems, as direct physical contact risks excessive force, resulting in discomfort or even injury to sensitive areas like the mouth. Exploring different ways to perform bite transfer with real users is challenging due to ethical and safety concerns.

Human-in-the-Loop (HITL) simulation has been applied to assistive tasks that demand a high level of safety, such as assisted dressing [5] and exoskeleton control [6]. These simulations have proven valuable in enabling the development and evaluation of robotic controllers that involve physical Human-Robot Interaction (pHRI) and in some cases, facilitated the sim-to-real transfer of robotic controllers, particularly for complex pHRI tasks, such as learning and optimizing exoskeleton control [7]. However, most existing approaches rely on rigid-body skeletal [8], musculoskeletal [7], or primitive-shaped human models [9], which lack the ability to accurately model detailed physical interactions, particularly at the contact level. This limitation poses a significant challenge for tasks requiring precise contact modelling, such as robot-assisted feeding.

In robot-assisted feeding, particularly the bite transfer process, research in pHRI simulation remains sparse [10], [11].

The research was conducted at the Future Health Technologies at the Singapore-ETH Centre, which was established collaboratively between ETH Zurich and the National Research Foundation Singapore. This research is supported by the National Research Foundation Singapore (NRF) under its Campus for Research Excellence and Technological Enterprise (CREATE) programme.

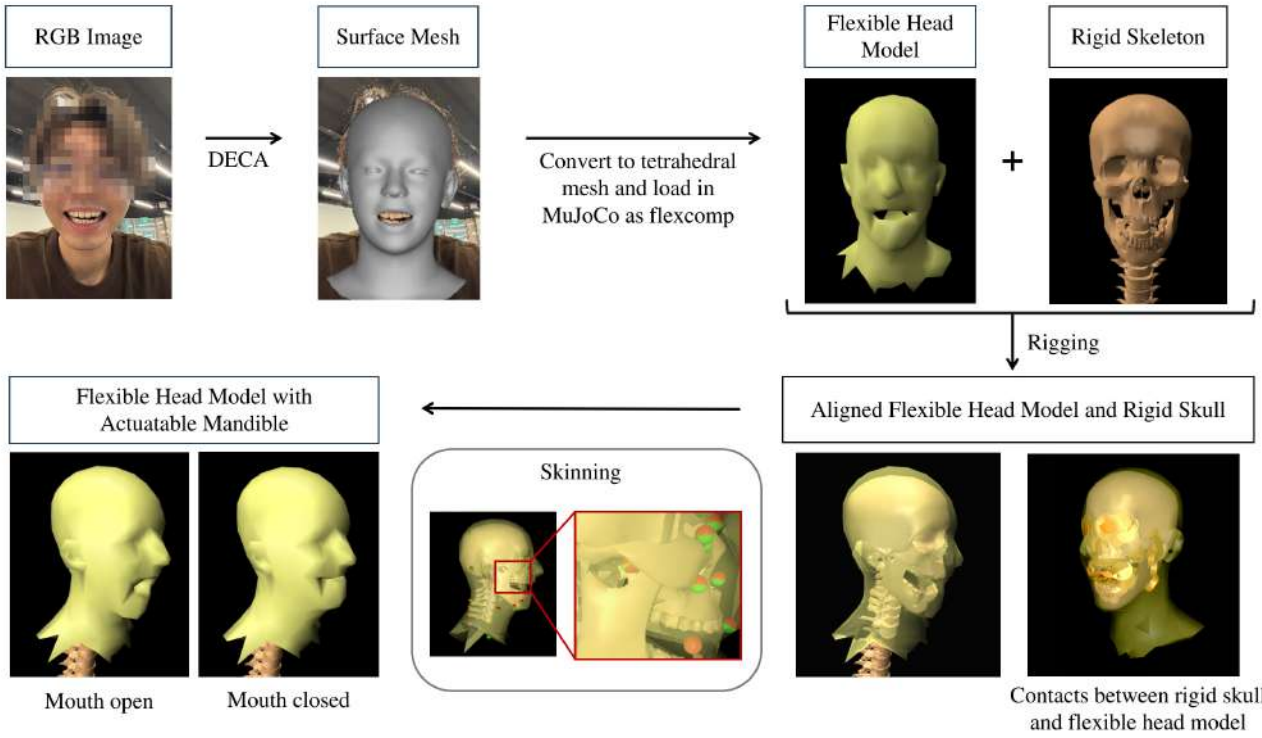

Fig. 2: Overview of our approach to model a head with soft-body dynamics. (Top) A flexible head model is generated from an RGB image through surface mesh reconstruction, tetrahedral meshing, and loading into MuJoCo as a flexible element. (Bottom) The flexible head model is combined with a rigid skeleton through rigging, and skinning is applied to bind the two. Contacts are detected and marked with yellow cylinders (bottom right), after which sites are created at the detected points, visualized using red and green balls (bottom center). Tendon elements then connect the sites to form a fully rigged and actuated head model. This setup enables realistic deformation, mandible actuation, and mouth movement simulations.

This gap is largely attributed to the absence of a high-quality face and mouth model capable of accurately representing the shape and motions involved in chewing and biting. To date, the only physics-based simulator attempting to integrate soft-body human modelling for assistive robotics is RCareWorld [11]. However, its human models are constrained to predefined configurations with fixed shape and mobility parameters, limiting personalization to individual users. While skinned biomechanical human models, such as those described in [12], have introduced deformable skin, they have largely overlooked the internal dynamics between the skin and the underlying skeleton in a physics-based simulation. Similarly, our previous approach [13], which manually rigged the skin and skeleton as a unified whole-body model using rigid `pin` elements, further highlighted these limitations. Although functional, this method introduced redundant contact forces during interactions, underscoring the need for a more sophisticated approach to model soft-tissue dynamics and natural interactions. These limitations highlight the need for a high-fidelity simulation framework capable of accurately modelling soft-body dynamics and human features, particularly the face and mouth, to enable detailed investigation of contact forces and motion dynamics in tasks such as robot-assisted feeding.

To address these gaps, we present a novel framework for simulating bite transfer using a soft-body human head model with an articulated mandible developed in MuJoCo [14]. This model enables the analysis of how variations in bite transfer parameters impact force distribution on the user, facilitating systematic experimentation without safety risks. By simulating these interactions, we aim to identify optimal bite transfer strategies that maximize user comfort by minimizing contact forces. Key contributions of this work include:

1) A method for creating a realistic, flexible human head model with a movable mandible from an RGB image, enabling the simulation of mouth opening and closing by controlling the joint of the rigid mandible.
2) Novel evaluation and analysis of bite transfer parameters to minimize contact forces and enhance user comfort.

These contributions provide a foundation for improving safety in robot-assisted feeding systems and modelling physical human-robot interactions more accurately.

II. Approach

To facilitate bite transfer parameter analysis in simulation, we developed a human head model in MuJoCo featuring soft-body contact dynamics. Using the `flexcomp` body element in MuJoCo, we constructed a volumetric, deformable head model that mimics the mechanical properties of human skin

and tissue. The head model was rigged with a rigid skull structure, enabling mandible actuation to simulate realistic mouth opening and closing motions. This section provides a detailed explanation of the human head model creation process.

A. Generation of Flexible Head Model

We take an RGB image of a human head and process it using DECA [15] to reconstruct a facial model, generating a rigid surface mesh of the head (Fig. 2). This surface mesh is then converted into a high-quality tetrahedral mesh using the method described in [16], which incrementally inserts triangles to create a volumetric mesh. The conversion to a tetrahedral mesh is necessary for compatibility with MuJoCo, which requires a volumetric representation of the mesh to create the necessary relationships across all vertices for soft-body dynamics. To improve computational efficiency, the mesh is simplified to produce a final model with 342 vertices.

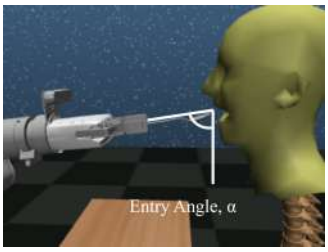
To define the soft body properties in simulation, the `flexcomp` elasticity attributes in MuJoCo were utilized to represent the mechanical behaviour of deformable materials accurately. The parameters used – Young's modulus and Poisson's ratio – were selected based on a combination of literature review of human soft tissue material [17], [18] (Table I) and the empirical testing of the functional requirements of the model. We used a Young's Modulus of 5×10^4 and a Poisson Ratio of 0.4. To ensure realistic mass distribution, we assigned a total mass of 5 kg to the flexible head model, consistent with the plausible range of human head mass reported in the literature [19]. This mass was evenly distributed across all vertices of the flexible head, while the mass of the rigid skull was set to near zero to avoid redundancy and ensure that the flexible head accurately represents the primary source of soft tissue mass.

TABLE I: Material Properties of Human Soft Tissues

Tissue Type	Poisson Ratio	Young's Modulus/kPa
Connective Tissue	0.3	2.25×10^5 - 1.5×10^6
Muscle	0.3 - 0.493	39 - 164
Fat	0.13 - 0.5	18 - 24

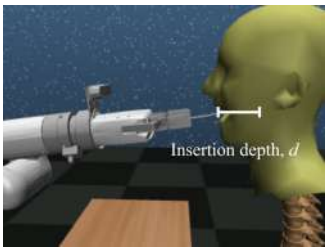
1) Rigging the Head Model: To enable mouth opening and closing movements, we utilized a rigid-body head and neck model from OpenSim [20] and converted it to a MuJoCo model [21]. The rigid skull consists of two components – the upper skull and the mandible. We created a six-degree-of-freedom (DoF) joint between these two bodies to simulate realistic mandible movement. We manually align the position of the skull inside the flexible head model due to the differences in the initial orientation.

2) Skinning: Skinning refers to the process of binding the flexible head model to the rigid skull by associating regions of the head's surface with specific parts of the skull, ensuring that movements of the skull result in corresponding deformations of the skin, as seen in the mouth opening and closing in Fig. 2. To model the internal dynamics between the soft skin and the skull, we mimicked the natural anatomical attachment of soft tissues to the underlying skeletal structure. Ideally, the flexible head would be attached to underlying muscles; however, in the absence of detailed muscle models for the skull, the flexible head was directly attached to the skeleton. In this context, the `tendon` element in MuJoCo was employed to represent fascia and connective tissues, which exhibit viscoelastic properties. These properties facilitate the independent yet cohesive motion of the skin in response to movements of the mandible. The `tendon` was created according to assigned pairs of `site` attributes on both the skin and the skull. All interaction forces between the skin and the skull were transmitted exclusively through the defined `tendon` elements.



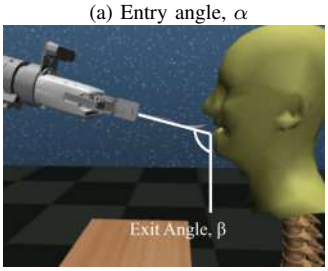
To determine the appropriate locations for the `tendon` elements, we analyzed the natural contact points between a rigid skull and a volumetric flexible head. After rigging the rigid skull and volumetric flexible head in MuJoCo, contact interactions between the surface of the skull and internal volume of the flexible head were identified. These contact points served as the primary indicators of potential locations where structural interactions between the skin and the skull should occur, ensuring stability during simulation runtime. Based on these contact points, the tendon elements were positioned by identifying the closest vertices of the soft head model to the contact points, effectively aligning the tendons with areas of natural contact.

With the detected set of contact points $C = \{c_1, c_2, \ldots, c_n\} \subset \mathbb{R}^3$ and the vertex set of soft body head model $V = \{v_1, v_2, \ldots, v_n\} \subset \mathbb{R}^3$, a linear search algorithm was applied to identify the subset of vertices $V_{closest} \subseteq V$ nearest to each contact point. To ensure the uniqueness of `tendon` element in each interaction area, the algorithm built an injective mapping $M : C \to V_{closest}$ by iterating through each contact point and calculating the Euclidean distance between that point and each vertex, represented as following:



$$M(c_i) = \arg \min_{v_j \in V \setminus V_{\text{closest}}} \|c_i - v_j\|_2, \quad \text{where } c_i \in C \qquad (1)$$

For each $v_k \in V_{closest}$, a pair of `site` attributes were created at the coordinates of v_k and assigned to both the rigid skull and flexible head. The `tendon` elements were used to link each pair of corresponding `site` attributes. These `tendon` elements were configured with adjustable viscoelastic properties and allowable stretching ranges, which were empirically determined through testing and refinement to ensure realistic behavior. Once the `tendon` elements were activated, default contact interactions between the rigid skull and flexible head were disabled. This ensured that the motion of the flexible head was driven exclusively by the `tendon` connections, with all interaction forces transmitted solely through these elements. By relying on tendon-driven dynamics, the head model exhibited predictable and controlled movements, entirely driven by the motion of the mandible.



The developed skinning method is novel in that it addresses the internal dynamics between the flexible head and skull, enabling realistic motion actuation and force transmission. In

Fig. 3: Bite transfer parameters modified in our experiments

our application, this integration enables precise control of the head model, facilitating detailed simulations of bite transfer in robot-assisted feeding systems. We believe that this method has the potential to be extended to other body parts in future work, enabling applications beyond head modeling, such as full-body modeling and biomechanical interaction studies, to support a broader range of research and simulation contexts.

B. Modifying In-Mouth Bite Transfer Trajectories

To analyse the physical human-robot interaction forces exerted on the user by a spoon during bite transfer, we defined bite transfer as a parameterized trajectory, as shown in Fig. 3. In general, bite transfer can be divided into 2 phases, the entry phase and exit phase [3]. We assume that bite transfer starts at a fixed initial pose p, defined by a fixed distance of $50mm$ away from the mouth pose. The spoon enters the user's mouth with an insertion depth d (Fig. 3b) and entry angle α (Fig. 3a) during the entry phase. After the user closes the mouth and a bite is detected, the spoon exits the user's mouth with an exit depth e (Fig. 3d) and exit angle β (Fig. 3c).

These parameters are then systematically adjusted within our simulation environment to observe their effects on contact forces exerted during bite transfer.

III. Experiments and Results

We conducted experiments in simulation to identify the optimal set of bite transfer parameters that maximise user comfort during bite transfer, defined here as minimising contact forces applied during the interaction.

A. Experiment Setup

We set up a simulated environment in MuJoCo [14] with the xArm-6 robotic arm (UFactory) grasping a spoon and the head model (Fig 1). We selected this robotic arm as we have access to the physical device for future experimental validation. However, our approach is not limited to this specific robot and can be adapted to other robotic arms. The starting pose of the robot arm is fixed throughout the experiment for consistency. After the spoon is inserted into the user's mouth in the entry phase, we actuated the mandible joint of the head model to simulate mouth closing. We assume the rest of the human body remains static, reflecting scenarios where patients have limited head mobility. This assumption simplifies the analysis and allows us to focus on the influence of bite transfer parameters on bite transfer interaction forces.

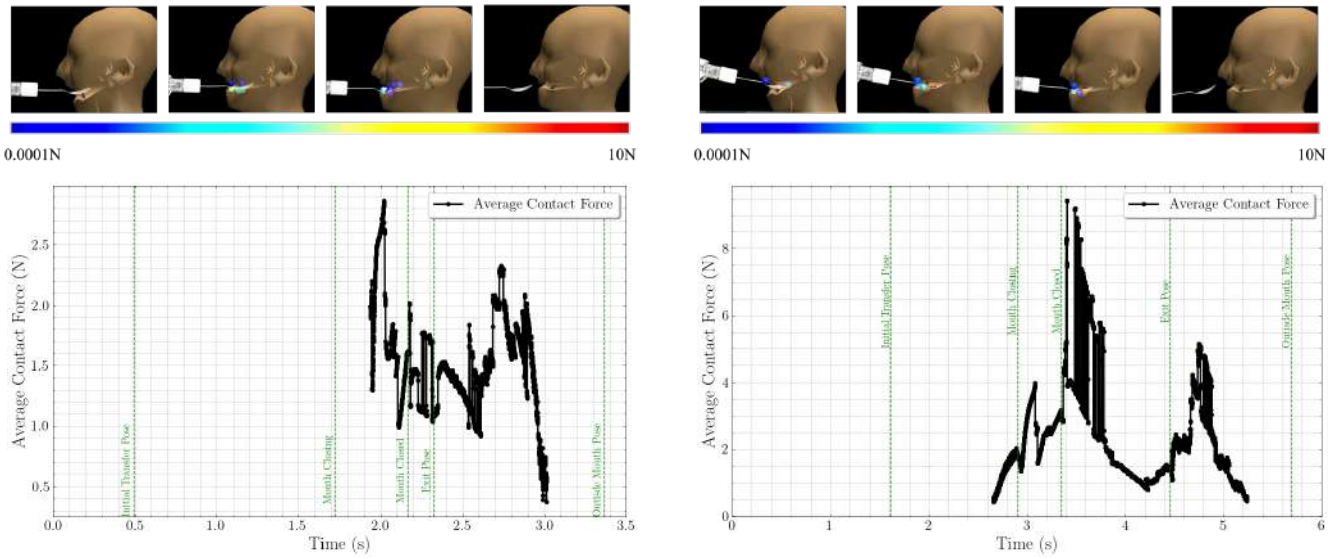
TABLE II: Bite Transfer Parameter Ranges and Increments

Phase	Parameter	Range	Increment
Entry	Entry Angle (α)	80° to 110°	10°
	Insertion Depth (d)	50 mm to 100 mm	10 mm
Exit	Exit Angle (β)	80° to 120°	10°
	Exit Depth (e)	0 mm to 40 mm	10 mm

To evaluate the impact of different bite transfer parameters, we measured the contact forces applied during the bite transfer phase. As multiple contact points could exist per time step, we compute the average force exerted per time step, denoted as f_t. The key metrics considered were:

- **Peak contact force**: the maximum average force f_t^{max} recorded during the interaction
- **Total contact force**: the summation of the average forces $\sum f_t$ applied throughout the bite transfer

The best parameters should minimize both peak and total contact forces. Peak force affects instantaneous user comfort, as high forces in a short duration can cause discomfort or injury. Total force, the cumulative force over time, impacts overall comfort as prolonged low-level forces that can still cause discomfort if sustained for extended periods.



We performed a series of trials to analyze bite transfer parameters, as detailed in Fig. 3. The parameters were first varied during the entry phase to identify the optimal settings, followed by similar trials for the exit phase. Table II summarises the specific parameter ranges and increments. These ranges were set based on human eating behaviour and the geometry of the spoon, where the spoon bowl length was 60mm.

B. Results and Analysis

The results of our experiments are shown in Figures 5 and 6.

1) Entry Phase: The simulation results show that both total and peak contact forces generally increase with greater insertion depths at entry angles of 100° and 110°. This is due to the larger contact surface between the spoon and the inside of the mouth as depth increases. The entry angle of 80° exhibits higher total and peak contact forces, especially at deeper depths, due to the tip of the spoon contacting the mouth more.

The lowest total contact force of 993.99N occurs at $\alpha = 90°$ and $d = 70$mm. Although the lowest peak contact force of 2.08N occurs at $\alpha = 110°$ and $d = 50$mm, the peak force of $\alpha = 90°$ and $d = 70$mm is only slightly higher at 2.89N.

(a) Bite transfer with optimal parameters ($\alpha = 90°$, $d = 70$mm, $\beta = 90°$, $e = 10$ mm)

(b) Bite transfer with suboptimal parameters ($\alpha = 100°$, $d = 80$mm, $\beta = 80°$, $e = 40$mm)

Fig. 4: Bite transfer in simulation: The top row shows screen captures of the bite transfer process, with contact forces visualized as coloured spheres, showing increased contacts in (b). The bottom row shows the corresponding contact forces over time. Note that the y-axis scales are different for clarity.

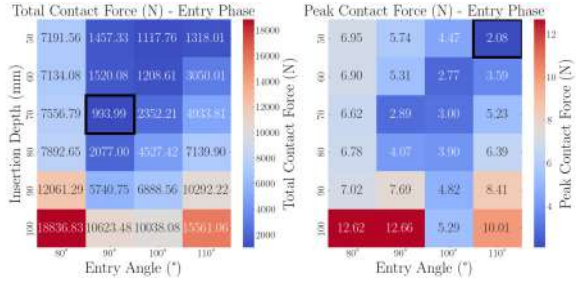


Fig. 5: Force Analysis Results – Entry Phase

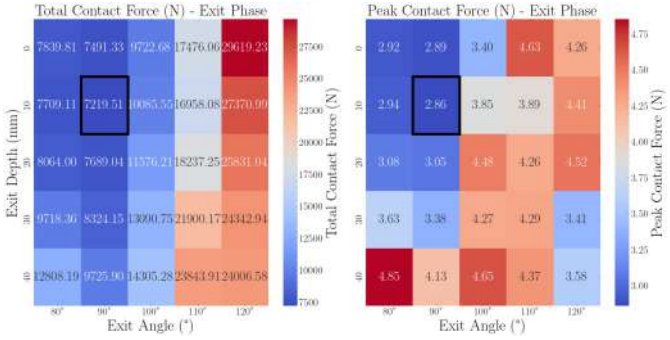

Fig. 6: Force Analysis Results – Exit Phase

This marginal increase in peak contact force of less than 1N is unlikely to be perceptible to a human. This minimal difference in peak contact force, combined with the substantially lower total contact force, makes $\alpha = 90°$ and $d = 70$mm the more optimal parameter set. The optimal entry angle suggests the spoon should be perpendicular to the mouth, while the optimal insertion depth should be slightly longer than the spoon bowl to minimize contact forces.

As shown in Fig. 4, the peak contact force for the entry phase occurs when the mouth is closing, which aligns with the expected increase in forces when the mouth interacts with the spoon.

2) Exit Phase: For the exit phase, the results indicate a general trend where the peak contact force increases as the exit depth e increases. Additionally, exit angles closer to 90° show lower total and peak contact forces. As the exit angle deviates further from 90°, the transition from the exit depth pose to the exit angle pose results in more rotation within the mouth, leading to increased forces.

Based on the results, the parameter combination that minimizes the total contact force with the mouth and maximises the comfort of the user is an entry angle $\alpha = 90°$, an insertion depth $d = 70$mm, an exit angle $\beta = 90°$ and an exit depth $e = 10$mm. Screen captures of the bite transfer process for both the optimal set of parameters ($\alpha = 90°$, $d = 70$mm, $\beta = 90°$, $e = 10$ mm) and a random set of suboptimal parameters ($\alpha = 100°$, $d = 80$mm, $\beta = 80°$, $e = 40$mm) are shown in Fig. 4 to better visualise the difference in contact forces for each stage of the bite transfer process. For the optimal set of bite transfer parameters, the peak contact force occurs during the entry phase when the mouth is closing, while the peak contact force occurs during the exit phase for suboptimal parameters.

Thus, from our experiments, we observe that having a simple bite transfer process of "straight-in, straight-out" given the same entry α and exit angle β of 90° minimises both the total and peak contact forces, and is most comfortable for the

user, with the assumption that the head remains stationary.

IV. Conclusion and Future Work

This paper presents a novel approach for modeling physical human-robot interaction in simulation, addressing a gap in assistive robotics. By leveraging MuJoCo's accurate contact dynamics, we developed a soft-body human head model with an articulated mandible. Our integration of the flexible head model with a rigid skull captures the internal dynamics between the skin and the underlying skeleton, enabling realistic motion actuation and force transmission.

Using this head model that accounts for soft-body contacts, we could capture detailed contact interactions between a spoon and the mouth during bite transfer. This capability enables systematic evaluation of bite transfer parameters, offering valuable insights into how variations in bite transfer parameters like insertion depth, entry angle, exit depth, and exit angle influence contact forces. These insights are important in improving user safety and comfort in robot-assisted feeding.

Nevertheless, the current approach assumes a static head during bite transfer, which overlooks the natural movements of the head in response to the spoon. Furthermore, the current model lacks a detailed oral cavity, tongue and lip actuation, which limits the realism of the simulated interactions. Future work will incorporate dynamic head and neck movements, and validate the simulation forces with real-world data.

Spatial Robust Whole-Body Dynamic Trajectory Optimization of a Lower-Limb Exoskeleton

Shahriar Sheikh Aboumasoudi[1,2], Ander Vallinas[1], Sjors de Bruin[1], Hakan Köroğlu[2], Herman van der Kooij[1] and Arvid Keemink[1]

***Abstract*—The goal of this paper is to design spatial (3D) robust reference trajectories for lower limb exoskeletons through optimization. Robustness is defined as the magnitude of the smallest force applied at the Center of Mass that cannot be rejected without violating joint torque or ground reaction force bounds. A larger robustness margin in the reference trajectory increases the capability of the controller to reject perturbations. A trajectory optimization problem was augmented by adding the maximization of this robustness metric to it. The augmented trajectory optimization is then employed to design dynamic trajectories for three different tasks. We demonstrated that our method increases the robustness metric value by comparing the results from the proposed method with a nominal trajectory optimization that does not take robustness into account. Moreover, the designed trajectories were implemented on a lower limb exoskeleton with a paraplegic user to show the feasibility of the proposed method. The user managed successfully to walk on level ground, perform side-stepping, and ascend stairs.**

I. Introduction

According to the World Health Organization (WHO), in the year 2021, there were more than 15.4 million individuals with Spinal Cord Injury (SCI), afflicted with partial or complete loss of motor functions [1]. Lower limb exoskeletons (LLEs) have emerged as a technological solution to help these individuals regain their ability to walk. Furthermore, it has been shown [2] that the repeated use of LLEs can mitigate secondary health complications related to SCI.

In the past few years, several commercial LLEs [3], [4], [5] and research prototypes [6], [7] have been developed. All these devices need reference trajectories to drive the individuals wearing them. In general, the methods employed to design the reference trajectories belong to one of the following design strategies, namely manual design, kinematic and reduced dynamic model optimization, Central Pattern Generator-based (CPG) method, and Hybrid Zero Dynamics (HZD), which will be explained below.

Manual design of reference trajectories involves adapting the joint angles of healthy humans to an exoskeleton. An example of this strategy is [8] where the authors used multiple prerecorded healthy gaits in the sagittal plane and a look-up table to transition between different trajectories. This strategy's inflexibility to changes in motion parameters such as speed, step length, etc. limits its widespread adoption.

With the advent of highly efficient and fast solvers, kinematic optimization strategy has gained popularity among the robotics community. Giannattasio et al. [9] considered four n-degree polynomials, each corresponding to one phase of gait for the joints in the sagittal plane, and solved a minimum-jerk optimization to find the polynomials of the swing phase. Other polynomials were designed to enforce a smooth transition between gait phases and kinematic constraints, such as maintaining contact during the double support phase. Mohammad et al. [10] proposed a three-stage gait generator that designs reference trajectories for the Center of Mass (CoM), the support leg, and the swing leg in the sagittal plane. Their goal is to minimize the CoM acceleration, keeping the Center of Pressure (CoP) close to the support ankle and minimizing the joint torque of the swing leg. Griffin et al. [11] designed the 2D swing foot trajectory of their exoskeleton in the cartesian space with the goal of minimizing jerk and then solved an inverse kinematic problem to obtain the reference trajectories for the hip and knee joint. However, they designed the reference trajectories in joint space for the support leg by keeping the knee straight. Zhang et al. [12] designed reference trajectories in the task space for an exoskeleton to ascend stairs and proposed a method to avoid singular configurations when solving the inverse kinematic problem.

The major shortcoming of the kinematic and simple dynamic model optimization is that it does not consider the full dynamics of the human-robot system, which could result in reference trajectories that are not dynamically feasible. An example of this is a reference trajectory that is kinematically compatible with the robot's mechanical structure but requires joint torques that are beyond the capacity of the actuators. Also, the designed trajectories in most cases are restricted to the sagittal plane.

A CPG is a biologically-inspired dynamic network that can generate patterns of rhythmic activity from non-oscillatory inputs. Sharifi et al. [13] took the Fourier transform of healthy gait and fed it to a system of adaptive CPGs that would generate the desired joint position trajectories. Additionally, they designed an observer to estimate the human-robot interaction torque that influences the desired trajectories further. Schrade

et al. [14] employed CPGs to design joint torque references for the sagittal model of an exoskeleton and to modulate its knee stiffness. Fang et al. [15] developed a lower limb exoskeleton with four Degrees of Freedom (DoFs), namely two hip and two knee joints, controlled by CPGs. They found the optimal parameters of the CPG by using a genetic algorithm and setting the fitness function as the error between the raw gait data and the output of the CPG. Despite the success in generating periodic motion using CPGs, none of the studies mentioned, conducted experiments with paraplegic patients.

Another powerful tool for trajectory generation in bipedal robots is HZD [16]. The key idea of this method is to introduce some virtual constraints that encode the desired behavior of the dynamical system and perform a feedback linearization to find the control law that ensures the satisfaction of the constraints. Furthermore, through an optimization routine, the system becomes invariant to impacts, meaning that the virtual constraints will be satisfied even when the bipedal robot makes and breaks contact with the environment. This method was used to enable a paraplegic user to walk in an Atalante X exoskeleton (Wandercraft, France) without using crutches, which is a remarkable achievement [17]. However, the feasibility of this method for lighter and simpler exoskeletons has not been explored.

Trajectory Optimization (TO) is a widely adopted method to generate trajectories in humanoids and quadrupeds [18], [19], [20]. TO is an optimization framework that can automate the process of trajectory generation while taking into account the dynamics of the system, as well as its kinematic and mechanical constraints.

Even though TO is an extremely potent trajectory design strategy, nominal TO does not address robustness, meaning that external perturbation forces on the system are not explicitly addressed. By increasing the robustness of the designed reference trajectories, the robot can recover from greater external perturbations forces. In this work, after defining robustness based on the work of Ferrolho et al. [21], we will incorporate it into TO. We will then utilize the resultant robust TO to design 3D reference trajectories for an LLE and verify the feasibility of the designed trajectories by conducting an experiment with a paraplegic user.

In short, the contributions of this work are twofold.

- Introducing a robustness condition into TO similar to [21] but in a less restrictive fashion and with the goal of improving balance robustness and using the augmented TO to design spatial (3D) trajectories to perform different tasks with an LLE.
- Implementing the designed spatial trajectories on an LLE with a paraplegic user to show their feasibility.

The paper is structured as follows. The theoretical background is explained in Sec. II, while Sec. III details the definition of robustness and how it can be incorporated into TO. In Sec. IV the implementation of the method is described. The results of the experiment are presented in Sec. V and a discussion of the results is given in Sec. VI.

II. Background

This section summarizes the dynamical model of a legged robot and TO as a method to plan its motion.

A. Dynamical Model

The dynamical equation that governs the behavior of a legged robot is

$$M(q)\dot{v} + h(q,v) = Su + J_\lambda^T(q)\lambda, \tag{1}$$

where $q \in \mathbb{R}^{n_q} \times SE(3)$ denotes the generalized position coordinates with n_q being the number of joints, v, $\dot{v} \in \mathbb{R}^{n_v}$ denote the generalized velocity and acceleration respectively, with n_v being the dimension of the generalized velocity. Matrix $M(q) \in \mathbb{R}^{n_v \times n_v}$ represents inertia, $h(q,v) \in \mathbb{R}^{n_v}$ shows the effect of Coriolis, centrifugal, and gravitational forces. Vector $u \in \mathbb{R}^{n_a}$ is the stack of joint torques with n_a being the number of actuated joints, $S \in \mathbb{R}^{n_v \times n_a}$ is the actuation matrix, $\lambda \in \mathbb{R}^{3n_c}$ is the vector of Ground Reaction Forces (GRFs) at n_c contact points and $J_\lambda(q) \in \mathbb{R}^{3n_c \times n_v}$ is the aggregated analytic Jacobian of the contact points.

B. Trajectory Optimization

TO is a framework for designing trajectories for a dynamic system to reach a desired final state from an initial state in a way that optimizes a certain objective while respecting a set of constraints. In this work, the continuous nonlinear TO problem is transcribed using the direct collocation method, where a series of time instants, called collocation points, are defined, and a set of optimization variables is assigned to each collocation point. Furthermore, the constraints and the objective function are discretized as well and are only evaluated at the collocation points. This way, the original time-continuous TO can be transformed into a nonlinear optimization problem, whose formulation is as follows:

$$\min_{Q,V,U,\Lambda} \sum_{k=0}^{N-1} \mathcal{L}_{n,k}\Delta t, \tag{2a}$$

$$\text{where } \mathcal{L}_{n,k} = \|u_k\|^2_{W_u} + \|\lambda_k\|^2_{W_\lambda} + \|u_{k+1} - u_k\|^2_{W_{\dot{u}}} + \|v_{k+1} - v_k\|^2_{W_{\dot{v}}} + \|\lambda_{k+1} - \lambda_k\|^2_{W_{\dot{\lambda}}}, \tag{2b}$$

such that

$$\begin{bmatrix} q_0^T & v_0^T & q_N^T & v_N^T \end{bmatrix}^T = \begin{bmatrix} q_{\text{ini}}^T & v_{\text{ini}}^T & q_{\text{fin}}^T & v_{\text{fin}}^T \end{bmatrix}^T, \tag{2c}$$

and for $i = 0, \ldots, N-1$:

$$M(q_i)\frac{(v_{i+1} - v_i)}{\Delta t} = -h(q_i, v_i) + Su_i + J_\lambda^T(q_i)\lambda_i, \tag{2d}$$

$$q_{i+1} - q_i - \Delta t B_{i+1} v_{i+1} = 0, \tag{2e}$$

and for $i = 0, \ldots, N$:

$$A_u u_i \leq b_u, \tag{2f}$$

$$A_\lambda D_j \lambda_i \leq b_\lambda \qquad \text{if } i \in \mathcal{C}_j, j = 1, \ldots, n_c, \tag{2g}$$

$$E_j J_\lambda(q_i) v_i = 0 \qquad \text{if } i \in \mathcal{C}_j, j = 1, \ldots, n_c, \tag{2h}$$

$$D_j \lambda_i = 0 \qquad \text{if } i \notin \mathcal{C}_j, j = 1, \ldots, n_c. \tag{2i}$$

In the above formulation, $\|.\|^2_{W_\star} = (\cdot)^T W (\cdot)$ and N is the total number of collocation points. Vectors q_i, v_i, u_i, and

λ_i represent the joint position, joint velocity, control input, and GRF respectively at time instant i, with Q, V, U, and Λ being the stacked vectors of these variables. Constraint (2c) enforces the initial and final desired configuration where q_{ini} and v_{ini} denote the initial generalized position and velocity respectively and q_{fin} and v_{fin} represent the desired final position and velocity respectively. Equations (2d) and (2e) show semi-implicit Euler integration of the dynamics, where Δt is the time step. We use quaternions to represent the spatial rotation of the floating base. Matrix $B_{i+1} \in \mathbb{R}^{(n_q+7)\times n_v}$ maps the generalized velocity to the rate of change of the generalized position that allows us to relate the rotational velocity to the rate of change of quaternions. Matrix A_λ and vector b_λ encode the constraints on the GRFs including the friction pyramid, which is an inner approximation of the Coulomb friction cone. Matrix $D_j \in \mathbb{R}^{3n_c\times 3n_c}$ selects the GRF components associated with the contact point j. Matrix A_u and vector b_u describe the bounds on the control input. Set $\mathcal{C}_j$ contains all the time steps that contact point j is in contact with the environment and n_c is the total number of contact points. When the contact point j is in contact, its velocity is set to zero through enforcing (2h). Matrix $E_j \in \mathbb{R}^{3\times 3n_c}$ is another selection matrix that selects those rows in the analytical Jacobian J_λ that are associated with the contact point j.

III. Proposed Method

Although TO is a powerful tool for motion planning of a dynamic system given its capability to take account of the system's dynamic and kinematic constraints, there is always this possibility that the designed trajectories only satisfy the constraints marginally. This means that a slight change in the environment or a mismatch between the robot and the model could make tracking the designed trajectory infeasible since one or more of the constraints might need to be violated to that end. To prevent such a violation and increase the margin of robustness against the model mismatch, some additional conditions can be incorporated in the TO formulation that will keep the designed trajectories as far away from the bounds as possible, especially the control input and GRF bounds.

Dai et al. [22] improved the robustness of reference trajectories against ground height uncertainty by minimizing the cost-to-go associated with the states in case of an untimely impact. Tucker et al. [23] designed robust reference trajectories for an exoskeleton utilizing discrete-time barrier functions to find the largest forward invariant set associated with a nominal limit cycle. In the present work, we will explicitly improve the robustness of the designed trajectories with respect to perturbation forces.

The definition of robustness employed in this work is a modified version of what is used in [21] and the notion of Smallest Unrejectable Force (SUF). In short, the idea is to find a solution (a control input sequence along with the associated state trajectories and GRFs) in the feasible domain of the variable space, that has the longest distance (in the Euclidean sense) from all the control input and GRF bounds. The equivalent mathematical representation of this idea is finding the largest inscribed Chebyshev ball within the feasible region by maximizing its radius. For further details, the reader is referred to [21].

By maximizing the SUF, the robot can withstand stronger perturbation forces without experiencing any change in its DoF's accelerations. We further developed this idea by restricting this requirement only to the robot's center of mass (CoM) and not all of its DoFs. This allows for a change in other joints' accelerations as long as the CoM's acceleration remains unchanged, which is less restrictive than the original method and still prevents movements of the CoM that would bring it to the edge of the base of support.

Consider the whole-body dynamics in (1) and the centroidal dynamics

$$A_G(q)\dot{v} + \dot{A}_G(q,v)v = w_g + J_{G,\lambda}^T(q)\lambda, \tag{3}$$

where $A_G(q) \in \mathbb{R}^{6\times n_v}$ represents the Centroidal Momentum Matrix (CMM) [24], $w_g \in \mathbb{R}^6$ is the gravitational wrench and $J_{G,\lambda}^T(q) \in \mathbb{R}^{6\times 3n_c}$ is the Jacobian transpose that maps the contact forces to the net force and moment on/around the CoM. If a perturbation force f_c at the CoM is applied to the system, a change in the accelerations, GRFs, and actuation appears in (1) and (3) with respect to no force being applied, giving

$$M(\dot{v}+\delta\dot{v}) + h = S(u+\delta u) + J_\lambda^T(\lambda+\delta\lambda) + J_c^T f_c, \tag{4}$$

$$A_G(\dot{v}+\delta\dot{v}) + \dot{A}_G v = w_g + J_{G,\lambda}^T(\lambda+\delta\lambda) + Rf_c, \tag{5}$$

where dependencies on q and v have been dropped for readability. In (4) and (5), terms with δ represent a change in the relevant quantity, f_c is the 3D perturbation force applied at the CoM, the matrix $R = \begin{bmatrix}0_{3\times 3} & I_3\end{bmatrix}^T$, and $J_c \in \mathbb{R}^{3\times n_v}$ is the Jacobian that maps differential CoM motion to differential generalized coordinate motions. It should be noted that the perturbed dynamics in (4) and (5) describe the dynamics of the system at the time instant the perturbation force is applied at the CoM. So there is a variation on the acceleration level but not on the velocity or position level. We desire no variation in the centroidal acceleration, which translates to having $A_G\delta\dot{v}$ equal to zero. By enforcing this requirement and subtracting (4) and (5) from (3) and (1) respectively, we arrive at the following system of equations:

$$\begin{bmatrix} A_G & 0 & 0 \\ M & -S & -J_\lambda^T \end{bmatrix} \begin{bmatrix} \delta\dot{v} \\ \delta u \\ \delta\lambda \end{bmatrix} = \begin{bmatrix} 0_{6\times 3} \\ J_c^T \end{bmatrix} f_c. \tag{6}$$

The underlying assumption implied by setting the change in the centroidal acceleration to zero is that there is an ideal controller that can react instantaneously to the perturbation; hence, we do not see the effect of disturbance on the velocity and position level. Even though such a controller might not be realizable perfectly in practice, reference trajectories generated in a way to respect (6) would possess an inherent robustness property. Designing a controller whose output resembles that of the ideal controller as closely as possible is outside the scope of this work.

To relate the change in the variables to the perturbation, we can write the perturbation force as $f_c = \xi\rho$ where the unit-length vector $\xi = f_c/\|f_c\|$ represents the direction and the scalar $\rho = \|f_c\|$ denotes the magnitude. Furthermore, we introduce gain matrices $K_a \in \mathbb{R}^{n_v\times 3}$, $K_\lambda \in \mathbb{R}^{3n_c\times 3}$, and $K_u \in \mathbb{R}^{n_a\times 3}$ that map the normalized perturbation force to acceleration, GRF, and control torque spaces respectively as follows:

$$\delta\dot{v} = K_a\xi, \tag{7a}$$
$$\delta u = K_u\xi. \tag{7b}$$
$$\delta\lambda = K_\lambda\xi, \tag{7c}$$

Substituting (7a)-(7c) in (6) results in the following equations:

$$A_G K_a = 0, \tag{8a}$$
$$SK_u + J_\lambda^T K_\lambda + J_c^T\rho - MK_a = 0. \tag{8b}$$

To add the robustness condition to TO, the formulation introduced in (2) needs to be augmented in the following way:

$$\min_Z \sum_{k=0}^{N-1} (\mathcal{L}_{n,k} - W_\rho\rho_k)\Delta t, \tag{9a}$$
such that for $i = 0,\dots,N-1$:
Initial and final configuration (2c), (9b)
Integration of the dynamics (2d), (2e), (9c)
and for $i = 0,\dots,N$:
$$A_{G,i}K_{a,i} = 0, \tag{9d}$$
$$SK_{u,i} + J_{\lambda,i}^T K_{\lambda,i} + J_{c,i}^T\rho_i - M_i K_{a,i} = 0, \tag{9e}$$
$$A_u u_i + \|A_u K_{u,i}\| \le b_u, \tag{9f}$$
$$A_\lambda D_j\lambda_i + \|A_\lambda D_j K_{\lambda,i}\| \le b_\lambda, \text{ if } i\in\mathcal{C}_j, j=1,\dots,n_c, \tag{9g}$$
Stationary contact point (2h), (9h)
Zero GRF for swinging contact point (2i), (9i)

where $Z = Z_n \cup \{K_{a,0}, K_{\lambda,0}, \rho_0, \dots, K_{a,N}, K_{\lambda,N}, \rho_N\}$ is the vector containing all the unwrapped optimization variables with Z_n being that of the nominal trajectory optimization (2), and i denotes times instants. The objective function (2a) needs to change to (9a), which contains $\mathcal{L}_{n,k}$ from (2b), the nominal cost, and an extra term that concerns robustness, where W_ρ is the weight assigned to this new objective. Constraints (9d) and (9e) need to be added to the nominal TO, while (2f) and (2g) have to be replaced by (9f) and (9g) respectively. These two inequality constraints ensure that the bounds on the control input and GRF still hold even in case of a perturbation. We follow [21] in solving K_u from (9e) in terms of K_a and K_λ, and replacing it in (9f), to reduce the number of variables in the optimization.

It is desired to maximize ρ without violating any of the optimization constraints, which translates to the robot being able to withstand greater perturbation forces without its CoM experiencing an acceleration change, feet slipping, or requiring joint torques that its actuators cannot deliver. The main difference between what we propose in this work and [21] is the addition of (9d) and the extra term in (9e) to the constraints. As mentioned, this stems from the fact that we no longer require zero variation in acceleration in all DoFs but the CoM. Our version is less restrictive and more practical since, the motion of CoM is more important for a balanced gait than that of individual joints as long as their motion respects the bounds.

IV. Experiments

To show that the trajectories designed using the proposed method are feasible and executable on an actual exoskeleton, we conducted experiments with a paraplegic user and showed that this method could be used to perform different locomotion tasks. In the following, we first briefly introduce the exoskeleton used in the experiments, then the locomotion modes are mentioned, and finally, the designed control pipeline to replay the trajectory on the robot is explained.

A. Exoskeleton and Software

We used the Symbitron exoskeleton [25] for the experiments in this work. This full lower-body exoskeleton features five DoF in each leg: hip ab-/adduction, hip flexion/extension, knee flexion/extension, ankle plantar-/dorsiflexion, and ankle in-/eversion with the first 4 DoFs being actuated and the last one being passive. The active DoFs are actuated with Series Elastic Actuators (SEA) allowing accurate torque tracking [26]. The robot's computer runs TwinCAT3, which provides real-time communication between the sensors and actuators based on the EtherCAT protocol. Furthermore, we designed a graphical user interface with Matlab R2022b (The MathWorks, Inc., Natick, MA, USA.) which allowed us to communicate with TwinCAT to send commands and receive sensor and actuator data.

B. Locomotion Modes

Three different tasks or locomotion modes were performed during the experiments, namely, level ground walking (LGW), stair ascending (SA), and side-stepping (SS). The step length during LGW was 25 cm and the step height (the minimum distance of the toe and the heel from the floor) was 10 cm. The staircase used for the SA task has exactly the same dimensions as that of the stair ascending task in the Cybathlon 2024 [27] competition with a stair depth and stair height of 27 cm and 17 cm respectively. During SS, the step width was 15 cm with a step height of 8 cm.

C. Control Pipeline

To enable the robot and the paraplegic user to perform these tasks, the following procedure must be performed. First, we use the formulation in (9) to design spatial robust trajectories for each task. The nonlinear optimization problem is constructed in Matlab R2022b using CasADi v3.6.6 [28] for finding gradients and Jacobians analytically and is solved by Ipopt [29].

The trajectories for LGW and SA contain three distinct steps: the opening, the intermediate, and the closing step. The opening is the first step that the robot takes from the initial (home) configuration, which takes it from a parallel to a staggered stance. The intermediate step is the next one

where the foot in the front and the foot in the back swap being the leading and the trailing foot. The closing step is the one that follows afterward and takes the robot from a staggered to a parallel stance, at the end of which the robot assumes the same pose as the home configuration. The intermediate step is designed such that the robot's configuration at the end of it is the mirror image of the robot's configuration at the beginning of the step. This scheme allows us to generate trajectories for any desired number of steps by simply mirroring the intermediate step and appending it to the trajectory as many times as needed to generate the reference for the robot, without solving a high-dimensional optimization problem. To endow this symmetry to the portion of the trajectory associated with the intermediate step, the following constraint needs to be added to the TO:

$$x_{l,T} = x_{r,2T}, \tag{10a}$$

$$x_{r,T} = x_{l,2T}. \tag{10b}$$

In (10a) and (10b), x_r and x_l denote the position and velocity states of the right and the left leg joints respectively and T is the duration of each step.

After obtaining the solution, the position and velocity trajectories are interpolated linearly since the low-level controller of the robot runs at 1 kHz and expects a torque reference each millisecond, whereas the continuous TO was discretized at 20 Hz (collocation points are 50 ms apart temporally).

The high-level controller comprises a state machine (SM) and a PD feedback control. Based on the user input, the SM decides which task should be executed and which reference trajectory must be tracked. The PD controller generates the desired torques to track the position and velocity references and sends them to the low-level controller of the robot, which ensures that the desired torques are generated by the actuators and delivered at the joints. The implementation is based on the feedback control that enables the robot to counteract against possible disturbances, thereby leading to a feasibility check of the reference trajectories. Besides positions and velocity trajectories, TO gives the feedforward torques as well. However, in this work, we did not use the feedforward torques and only utilized the state trajectories and had the robot track those trajectories by employing a feedback PD controller. The P and D gains for all joints are 800 Nm/rad and 5 Nms/rad respectively.

D. Experiment Protocol

We tested our proposed method by asking an individual with complete SCI (from now on referred to as the pilot) to wear the Symbitron exoskeleton and had them perform the tasks mentioned in Sec IV.B. The experimental protocol and the tasks to be performed were explained to the pilot and he gave informed written consent to participate in this study. All the procedures were approved by the Natural Sciences and Engineering Sciences Ethics Committee of the University of Twente, nr. 240878.

During the experiment, two spotters accompanied the pilot for safety, who were instructed not to interfere unless the pilot lost balance. Furthermore, we attached the robot to the ZeroG (Aretech L.L.C, Sterling, Virginia, USA), a body-weight support system that would catch the pilot and the robot in the case of loss of balance. The ZeroG was set to follow the pilot and exert a pulling force that compensates for 5 kg of weight, which is the lowest pulling force that needs to be maintained for the ZeroG to follow the pilot.

For each task, the pilot did a few trials to get familiar with the robot's motion. The best trial for each task was recorded and reported in this manuscript. The video recordings of the experiment are available online[1].

TABLE I
MEAN SUF (N) AND RMS OF CONTROL INPUT (NM) FOR ROBUST AND NOMINAL METHODS

Method	LGW		SA		SS	
	Cont.	SUF	Cont.	SUF	Cont.	SUF
Robust	**47.3**	**97.4**	**43.4**	**79.9**	**39.9**	**114.5**
Nominal	30.4	82.0	41.1	60.0	32.0	93.6

V. RESULTS

The pilot performed all 3 required tasks successfully after a few trials as seen in Fig. 1.

The weights used in the nominal TO (2) are as follows: we set W_u to $20\mathbf{I}_8$, W_λ to $0.05\mathbf{I}_{24}$, $W_{\dot{u}}$ to $\mathbf{I}_8$, $W_{\dot{v}}$ to $\mathbf{I}_{16}$, and $W_{\dot{\lambda}}$ to $0.1\mathbf{I}_{24}$. For robust TO (9) we set all the weights to zero except for $W_{\dot{v}}$ and W_ρ that are set to $0.05\mathbf{I}_{16}$ and 1 respectively. By setting all other weights to zero in (9), we are asking the optimization to emphasize increasing the robustness and smoothness of velocity reference trajectories. The latter is important for practical reasons as it would regulate the acceleration of the joints and make the motion of the robot more comfortable for the pilot.

The magnitude of the SUF corresponding to each task's reference trajectory is shown in Fig. 2. The magnitude of the SUF for both methods is similar during the swing phase but bigger for the robust trajectories during the Double Support (DS) phase. However, this greater robustness margin comes at the cost of higher joint torques.

Fig. 3 shows joint torques and positions associated with the robust and nominal methods. Table I summarizes the comparison between the two methods. The mean SUF and the RMS of joint torques are larger for the robust trajectories in all tasks. Furthermore, Table I shows that the side-stepping task has the highest mean robustness and stair ascending has the lowest.

On average, the optimization process to design reference trajectories for LGW, SS, and SA took approximately 9, 6, and 15 minutes respectively on a PC with an Intel i7-12700H, 2.3 GHz CPU, and 32 GB memory.

VI. DISCUSSION

In this work, we introduced a robust trajectory optimization method that can be used to design spatial (3D) dynamically

[1]https://www.youtube.com/channel/UCXIrttu3bMumesUIDPXPH_w

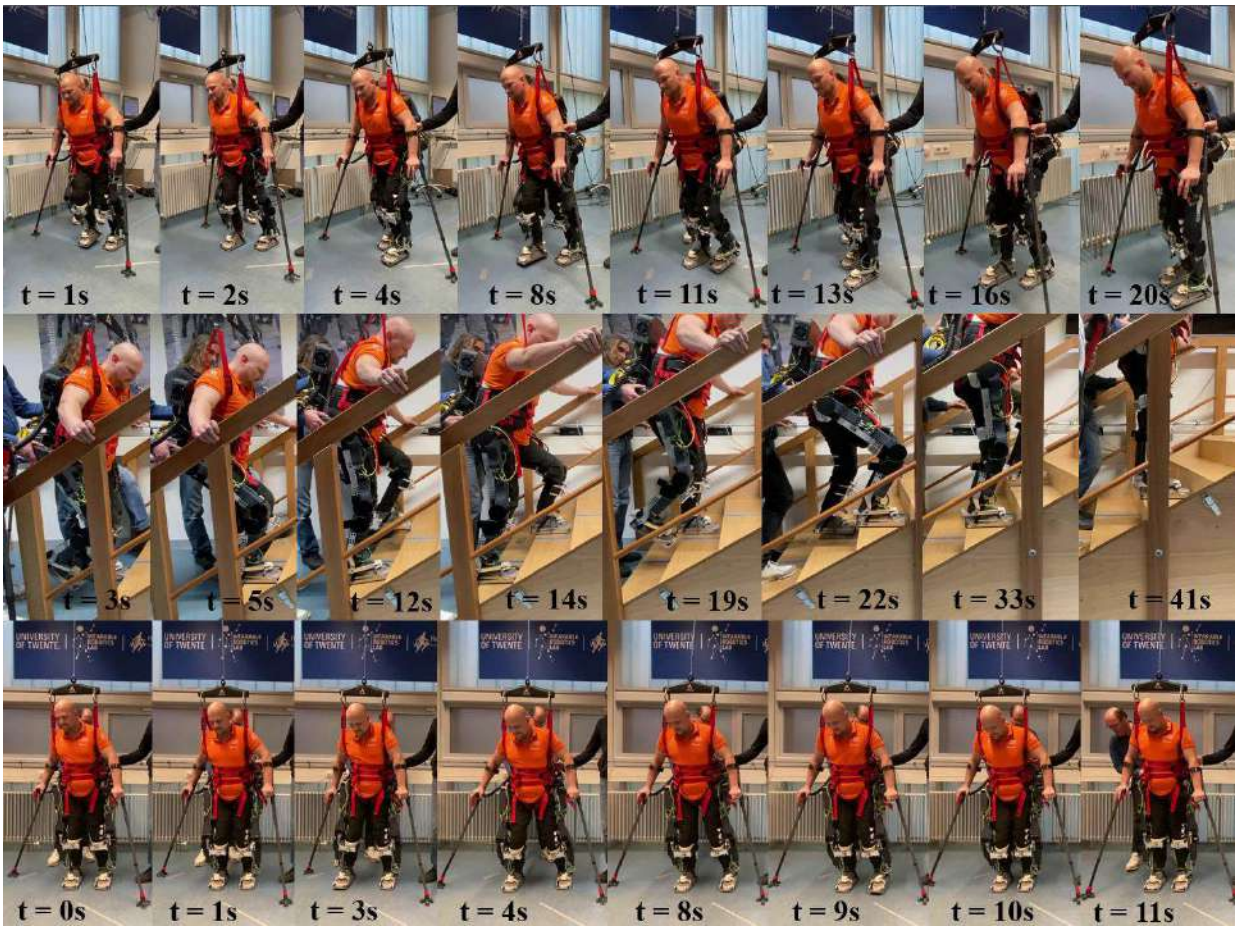

Fig. 1. The pilot performing the given tasks (LGW, SA, and SS from top to bottom) with the Symbitron exoskeleton. Everyone in the pictures consented to their face being visible.

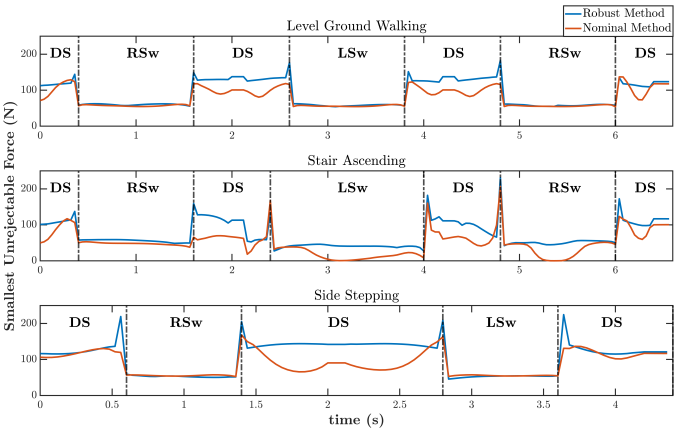

Fig. 2. A comparison between the magnitude of the SUF associated with the robust and nominal trajectories across different tasks. For each locomotion mode, various phases of gait are separated by dashed lines and labeled by DS, RSw, and LSw, which stand for Double Support, Right Swing, and Left Swing respectively.

feasible trajectories for an exoskeleton with a greater margin of robustness, i.e. an increased ability to withstand perturbations without undergoing any change in the acceleration at the CoM level. The difference between the robust and nominal trajectory optimization methods is evident from Fig. 3. The motion profile and the required control input are quite different between the two methods. Even though the robust trajectories would require higher joint torques, the increase in the balance robustness is far more valuable to an SCI patient as long as the joint torques remain within the bounds and the designed trajectories are non-aggressive, which is indeed the case here. Moreover, we showed the practicality and feasibility of the proposed method by implementing the designed trajectories on an LLE with a paraplegic user and having him perform different tasks including level-ground walking, side stepping, and stair ascending.

The robust optimization finds a trajectory with a higher mean SUF by modulating the GRF (while meeting the bounds on GRF and joint torques) since this is the force used to steer the robot's CoM motion. By exerting a higher vertical force on the ground, the maximum tangential force required to make

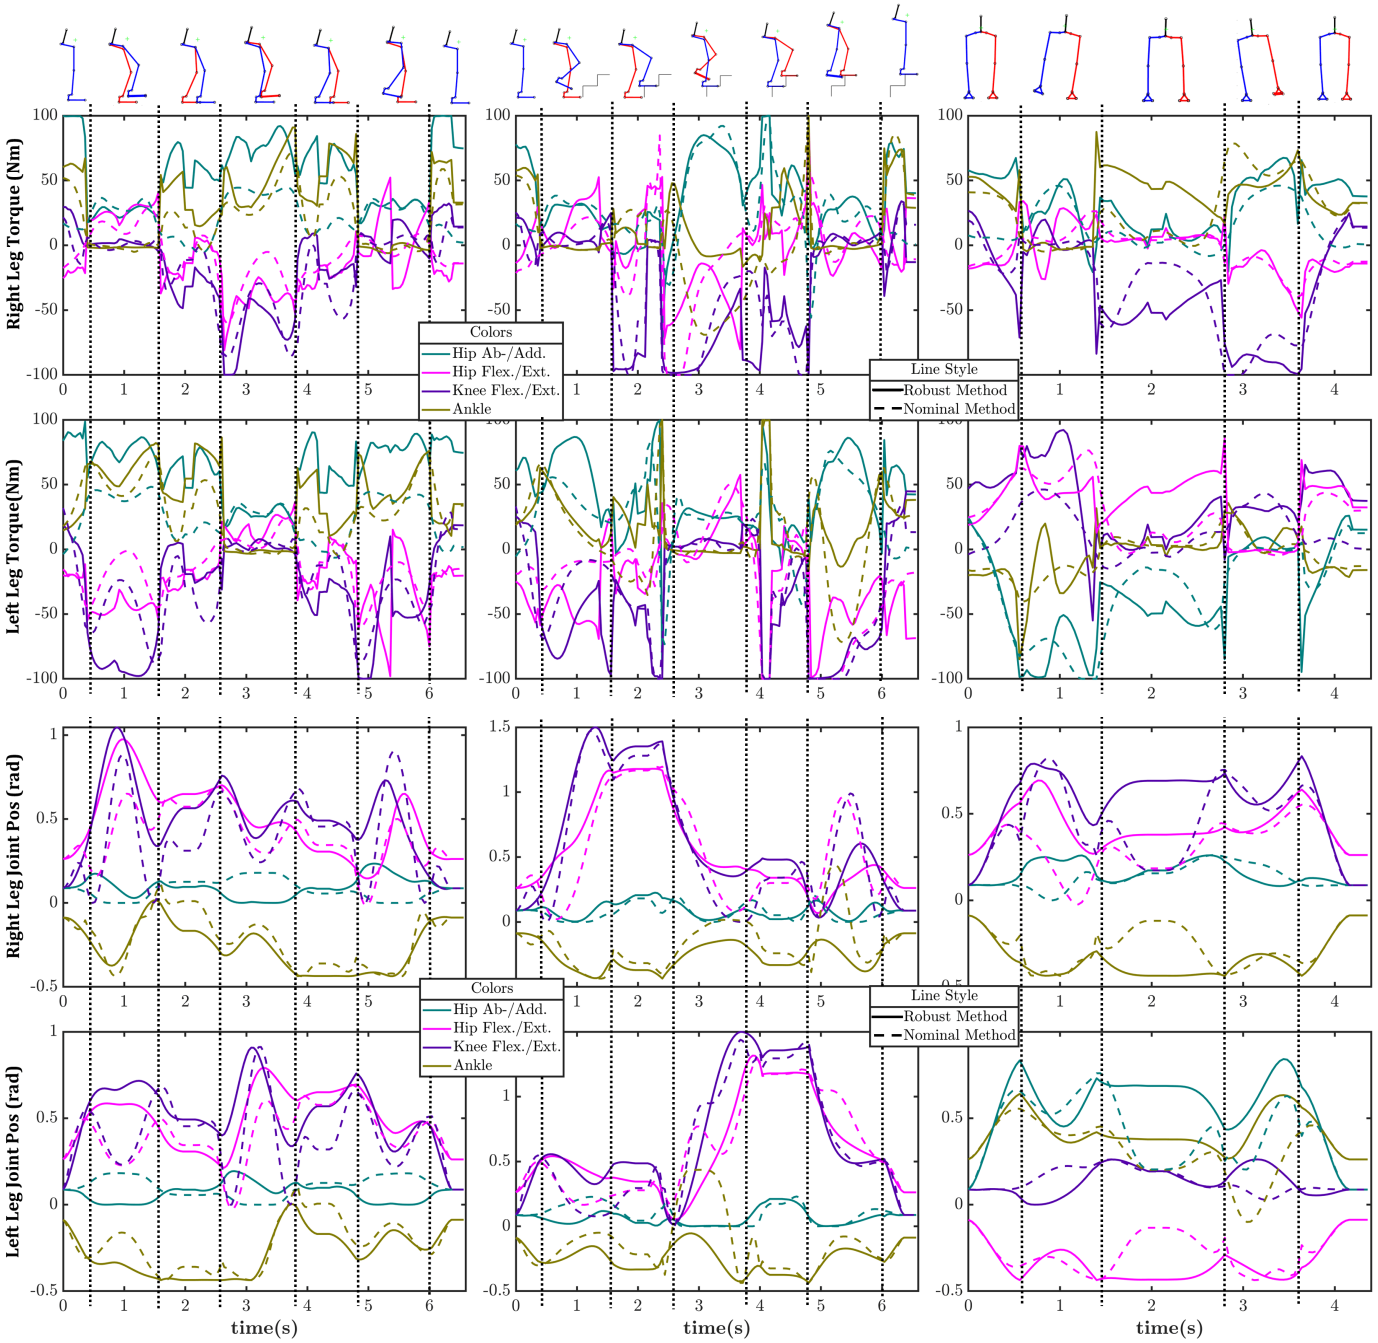

Fig. 3. A comparison of joint torque and position between the robust and nominal methods for different locomotion modes. The right leg is in blue and the left is in red. The stick figures above the plots show different phases of gait separated by the dashed vertical lines.

the contact point slip becomes higher. Therefore the robot can withstand perturbation forces with larger tangential components before the friction polynomial constraint is violated. We observed this behavior at the beginning of the DS phase. With the robust trajectory, the robot tends to stomp its foot on the ground to generate higher vertical GRFs, hence the higher peaks at the start of the DS phase for the robust method in Fig. 2. In the DS phase, the optimization has more freedom in manipulating the GRFs to increase robustness and that is why the difference in SUF between the robust and nominal methods is more noticeable in the DS phase than the other two gait phases.

The increased robustness margin becomes specifically important in scenarios where TO gives marginally feasible solutions and the margin of robustness is close to zero, such as in the case of stair ascending. By looking at Fig. 2, it can be seen that for the stair ascending task, the nominal SUF is very close to zero at some time instants, which means that a

small perturbation force applied at the CoM could result in a violation of either control input or GRF related constraints but the robust method increases the margin of robustness and yields trajectories that are further away from the bounds. However, the increased robustness comes with an increase in joint torques and behaviors such as foot stomping, which is not present in the nominal method. It must be noted that these behaviors can be mitigated by increasing the weight of the joint torque minimization objective and ground reaction force regulation with respect to the robustness weight.

Although the robust TO introduced in this work is a powerful method for generating trajectories for an LLE, the full potential of this method will be unlocked once it runs in an online fashion, which allows online modification of reference trajectories. A real-time implementation of this method or a simplified version of it along with a thorough analysis of balance and stability will be the focus of future work.

Force myography shows higher correlation to force output compared to ARV EMG features

Marek Sierotowicz[1], Claudio Castellini[1], and Khairul Anam[2]

***Abstract*— Force myography, or FMG, is an emerging technology which, despite not quite yet achieving the same maturity as surface electromyography, still shows much promise for the purposes of muscle activity-based human-machine interfaces. Compared to surface electromyography, FMG setups can be very cost-effective and robust, and they offer the fundamental advantage of not requiring direct contact between sensor and skin. These factors make FMG sensors an attractive option for the purpose of controlling assistive wearable robotics or prostheses, for instance. Electromyographic features have been demonstrated to lead the force output by a sizable margin, which can be taken advantage of in various applications. However, FMG as a modality is inherently correlated with muscular force, we hypothesize that it should also exhibit a higher correlation with measurable force output of the extremities in healthy subjects compared to commonly used electromyographic features. In this study, we set out to prove this hypothesis by performing a regression analysis evaluating how well isometric pressure exerted by fingers can be predicted based on FMG signals as opposed to electromyographic signals. Additionally, we demonstrated the effectiveness of a system that is particularly low-cost, which in conjunction with the robustness of FMG sensors, would make them an attractive solution to be used in resource-constrained settings.**

I. INTRODUCTION

In the field of Human-Machine Interfaces (HMIs), measuring muscular activity is an attractive solution for the purpose of inferring movement intention in the case of, e.g., prosthesis control, or current force output and direction in the case of wearable robotics. Force MyoGraphy (FMG) is a muscle activity measurement technique based on the monitoring of pressure exerted by bulging muscles during contraction [1]. Although FMG has been successfully used to control assistive robotic appliances in the past [2][3], it is still an emerging technology in the field of biosignal-based controls, and especially in prosthetic control. Possible reasons for this comparatively scarce adoption are vulnerability to artifacts due to external pressure being applied to the FMG sensors, or the lack of an anticipatory edge like that of certain features of electromyographic signals, as shown for example in [4].

As a sensor modality, FMG can provide measurements that are directly correlated with output force [5]. For comparison, surface electromyography (sEMG) measures neural activity which is mediated by electrochemical dynamics before causing muscle contraction and force output, thus leading to potentially lower correlation between commonly used sEMG features and force output, depending on the examined task [6] [7] [8] [9]. Furthermore, FMG sensor technology can be implemented at very low costs, compared to most sEMG sensors available commercially [6] [8] [10]. Various studies demonstrated how deep learning-based prediction algorithms can predict hand gestures even if relying on low-cost sEMG sensors [11] or few channels [12]. Nevertheless, Phillips and colleagues identify the necessity of sEMG for direct contact with clean skin surface as one of the obstacles to the wider adoption of myoelectric prostheses in low- and middle-income countries, where the majority of the amputee population needs to rely for their income on manual labor in environments where cleanliness might not be ensured [13]. Even though Phillips and colleagues do acknowledge that the complexity of electronic prostheses is in it of itself a limitation, since it leads to higher costs and complexities, they do specifically identify sEMG sensors as a limitation. Since FMG does not require direct contact to the skin, and because of the cost effectiveness and robustness of the sensors, force myography could be a factor contributing towards a wider adoption of electronic prostheses in low- and middle-income countries [3].

In this paper we present the results of a study implementing a comparison between a commercially available, low-cost sEMG sensorized armband with 8 channels, and a self-produced FMG sensor array. The signals from these sensors were used to predict individual finger pressures. We adopted a regression analysis between FMG sensor signals and the fingertip force output, and demonstrated how FMG signals show better correlation with the same output forces. The study is similar in methodology to those presented in [5] and [8]. The main difference with respect to those studies relies in the focus on low cost devices, with the intent of proving their potential usability in a constrained resource setting for applications such as prosthesis control. Additionally, we investigated the influence of fatigue on both sEMG and FMG.

II. METHODS

A. Setup

The setup consisted of a board featuring an array of Force-Sensitive Resistor (FSR)-based pressure sensors, a bracelet-mounted array of FMG sensors, and an EMG bracelet, as shown in Fig. 1. The FSR sensors allow to measure pressure from all fingers, as well as thumb flexion and rotation. The measurements are converted to a voltage ranging from $0\,\mathrm{V}$

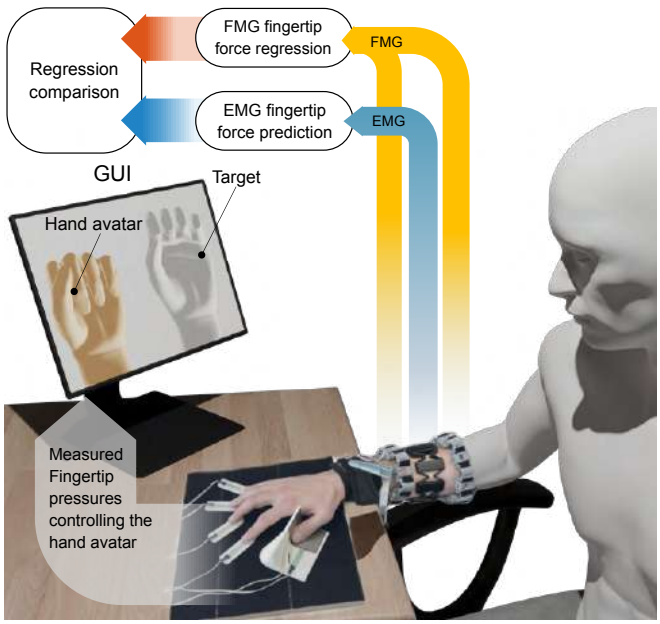

Fig. 1. Illustrative picture of the experimental setup. The hand was locked by means of a spanner, and the elbow was lying on an armrest. The participants were shown a target gesture which they had to match by controlling an avatar hand by pressing on FSR pads at their fingertips.

to 3.5 V by means of an amplification circuit. The same type of sensor is used to measure FMG signals on 13 channels. The FMG and fingertip force measurement setups both use the same data acquisition board, which samples at 400 Hz. For more details about the sensor technology used here, we recommend the sources [2], [5] and [6]. The sEMG was measured by means of a Myo armband (Thalmic Labs), which provides band-pass filtered EMG on 8 channels at a rate of 200 Hz.

B. Participants

A total of 13 able-bodied individuals participated in the study (8 males, 5 females, $1.77\,\mathrm{m}\pm0.11\,\mathrm{m}$, $76.92\,\mathrm{kg}\pm13.45\,\mathrm{kg}$, 27.92 ± 4.92 years old, 2 left-handed, 11 right-handed). The experiment was conducted with the permission of the ethical committee of the Friedrich-Alexander Universität Erlangen-Nürnberg (ID 22-278-S) and in conformity with the declaration of Helsinki in its latest revision of 2013. Each participant signed an informed consent form, and was extensively briefed by the experimenters about the study itself.

C. Experimental protocol

The participants were directed to control an avatar hand, shown in Fig. 1 in the GUI on the left, by pressing on the FSRs under their fingertips to follow a target. The target consisted of holding a given force output at the fingertips, consistent across all participants, for 7 s, which was displayed as a gesture of a target hand, shown in Fig. 1 in the GUI on the right. The participants had to match the gesture displayed by the target hand by pressing on the corresponding FSRs, which controlled the avatar hand. The total number of commanded force output configurations is 14, not counting the resting position, in a non-randomized order. Each participant performed 6 repetitions of the experiment. The fingertip pressure targets are shown in Fig. 2. The participants were instructed to never lift their fingers from the pads. The main reason for avoiding the extension of fingers as much as possible is that the pads would not have been able to measure that a force is being exerted. There was no attempt to avoid the co-activation of flexor and extensor muscles, on the other hand, as both sensor modalities were assumed capable of measuring both agonistic and antagonistic muscle activity.

D. Analysis

Prior to the analysis, all relevant signals, namely the 13 channels of the FMG, the 6 channels of the fingertip force measurement setup, and the 8 channels of the sEMG, were synchronized and brought to the same rate by means of a linear interpolation, using the timestamps of the sEMG as reference. The signals were additionally filtered (for the FMG and the fingertip force measurement, a sliding window filter of 50 samples width was used) and, in the case of the EMG, the Average Rectified Value (ARV) features were extracted using a sliding window of width 300. In order to eliminate the influence of transients, the signals were only considered starting 1 s after the commanded onset of contraction. Furthermore, for each finger, the measured fingertip force was only considered if the finger itself was required to exert pressure in a given time window. The reason for this decision is that the fingertip force pads can only measure downward pressures, and cannot monitor forces pointing upwards. Although the participants were instructed to never raise their fingers from the sensor pads, only when a pressure was actually required the downward force measurement can be considered reliable.

The prediction based on sEMG and FMG are compared based on Root Mean Square Error (RMSE) and Pearson's R^2 coefficient. Initial Kolmogorov-Smirnov normality tests indicated that neither the RMSE nor Pearson's R^2 are normally distributed. For this reason, Student's t-test was foregone in favor of a Wilcoxon signed-rank test in order to ascertain any statistical difference between the sEMG and FMG-based prediction of the fingertip pressure. The model's performance over repetition number was also monitored, as was done in [8]. Furthermore, any identifiable trends in the signals was gauged by fitting a linear regression model of the form $y = b + g \cdot t$ using time $t \in \mathbb{R}$ as independent variable, where $b, g \in \mathbb{R}$ are the model parameters, and y is the model estimate of EMG ARV features, FMG and fingertip pressure, depending on the case. For the fitting step, the model was fed the signals offset by their mean and normalized by their standard deviation, in order to allow for comparison of the proportional weight g between the models fitted on EMG ARV, FMG and FSR. Since the Kolmogorov-Smirnov test for normality showed that the distribution of the fitted parameter

g across all subjects and repetition is normally distributed, the appropriate form of t-test was used in this case.

For the purposes of analyzing fatigue, the progression of all signals was monitored over time. As a proxy for fatigue measurement, we considered the mean frequency of the raw sEMG. The mean frequency was calculated using a rectangular window. We elected to focus on the instances were the highest overall muscular contraction could be expected. Therefore, the mean frequency was calculated on the time windows where pressure was being exerted on all FSRs for each of the six repetitions. This is the case for target force output number 7, as shown in Fig. 2. Shifts in mean frequency over the course of the experiment were assessed on individual channels over all participants by means of a Wilcoxon signed-rank test between first and last repetition.

III. RESULTS

The signed-rank test shows significant differences between FMG and sEMG both in RMSE and R^2, with $p < 0.001$ in both cases in favor of the FMG-based prediction. Linear regression from FMG to fingertip pressure achieves RMSE of $0.221\,\mathrm{V} \pm 0.126\,\mathrm{V}$ and R^2 of 0.661 ± 0.170. Linear regression from sEMG to fingertip pressure achieves RMSE $0.253\,\mathrm{V} \pm 0.133\,\mathrm{V}$ and R^2 of 0.558 ± 0.189. Fig. 3 shows the distribution of RMSE and R^2 for EMG and FMG-based fingertip pressure prediction in the form of violin plots, with the corresponding box plots shown as well. Fig. 4 shows a representative plot of the used signals.

No significant effect of time on model performance could be detected. However, some significant changes over repetition number could be detected for the mean frequency on one of the sEMG channels, namely on channel 5, lying on the ventral side of the arm, across all participants. The mean frequency shows a decrease of $1.5\,\mathrm{Hz}$ in median between the first and last repetition (signed rank test on $n = 13$ shows $p = 0.0171$). No effects could be detected for any features in the time domain.

Looking at the progression over time of the various signals, the ARV features show the lowest slope over time. The FMG signal, on the other hand, shows a distribution of proportionality coefficients g with respect to time that significantly deviates from 0 (ttest, $n = 12$, $p = 0.03$). The same cannot be said for ARV features and the fingertip forces. However, both the fingertip force and the FMG show significantly higher correlation with time compared to EMG ARV features (right-tailed t-test, $p < 0.05$). Fig. 6 shows the boxplots of the gains g for FMG, ARV and fingertip forces, respectively, while Fig. 5 shows a representative case for the progression over time of all signals of interest during the instances where pressure is applied on all fingers.

Looking at the average levels calculated over the instances of pressure being exerted on all fingers, FMG exhibits highly significant correlation with the exerted forces over time ($R = 0.54$, $p < 0.0001$ without offsetting for individual means, $R = 0.53$, $p < 0.0001$ otherwise). In contrast, average ARV features show lower correlation with the average force output ($R = 0.16$, $p = 0.16$ without offsetting individual means, $R = 0.38$, $p < 0.001$ otherwise). Fig. 7 shows the average muscular activity signals over average force output across all participants and repetitions for the instances where all fingers were exerting pressure.

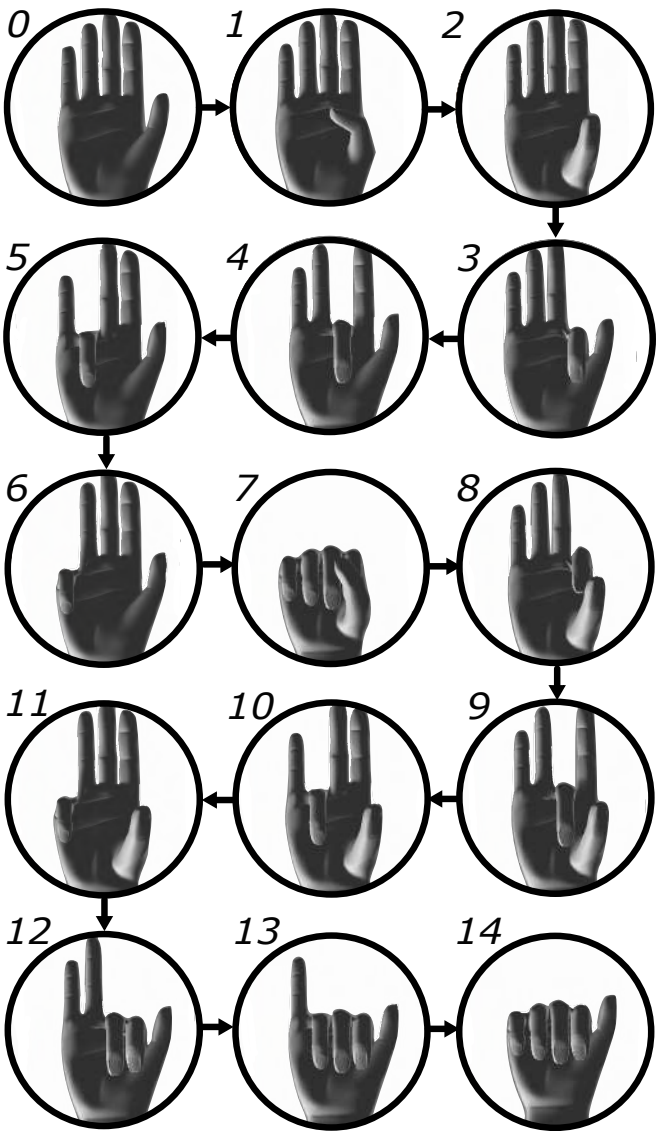

Fig. 2. Prompts shown to the participants. The flexion of the fingers symbolizes the required exertion of finger pressure. The fingertip pressure measured through the FSR pads underneath the participant's fingertips controls the avatar hand. The participants were prompted to have the avatar hand perform the same gesture as the target hand.

IV. DISCUSSION

The results indicate that FMG measurements are inherently better correlated with the force output achieved by the extremities moved by the monitored muscles, as compared to sEMG ARV features. The study specifically focused on low-cost equipment, in the hope of identifying a sensor solution

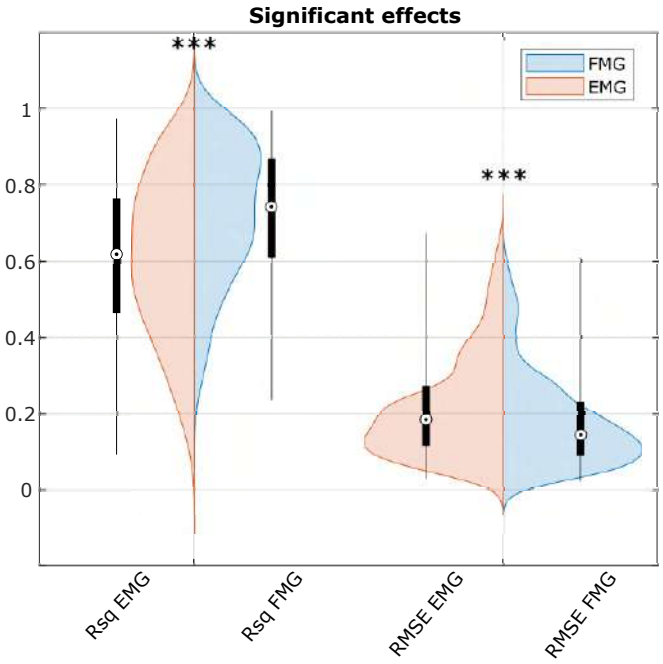

Fig. 3. Violin- and boxplots of R^2 and RMSE for FMG-based and EMG-based prediction. The significant effects are shown as well ($p < 0.001$ based on signed-rank test, $n = 468$ for both R^2 and RMSE).

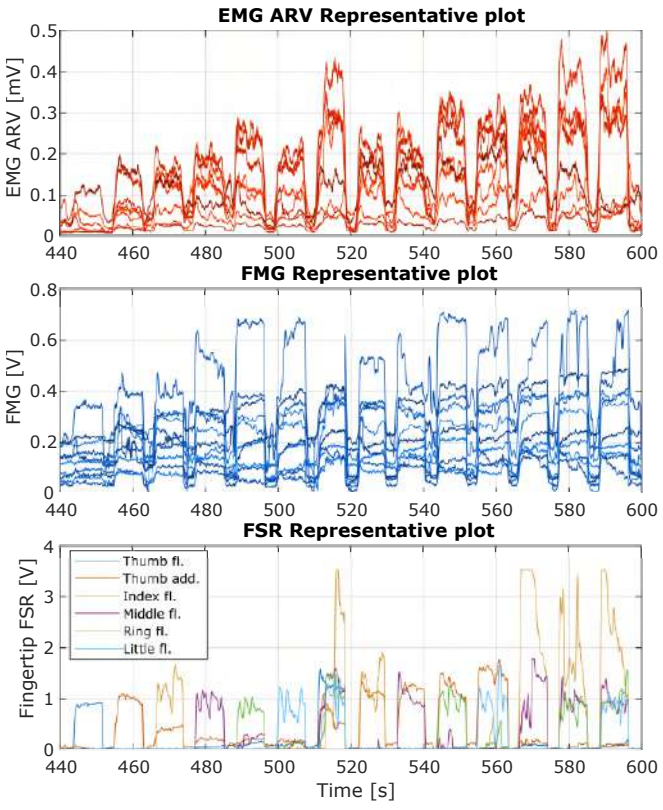

Fig. 4. Representative plot of the EMG ARV features, FMG voltages and FSR voltages correlating with fingertip pressure.

more suitable for resource-constrained settings. Previous studies were mainly concerned with comparing accuracy of hand gesture classification based on FMG and sEMG, or metrics related to classification such as Fisher's separateness index [6] [7]. Other studies [8] have focused on regression metrics, but found no significant difference between FMG and sEMG-based prediction. It is however true that some previous studies did confirm better real-time performance of FMG-based human machine interfaces in terms of task outcome metrics and path efficiency in target reaching tasks [14].

The more significant dependency on time of the FMG signals is worth further discussion. The main factors influencing measurable muscular activity during contractions are force output and fatigue, if absolutely no change in hand pose is assumed. The lowering in mean frequency would indicate that, overall, an increasing trend on fatigue can be inferred across all participants, especially considering that the ARV features do not seem to vary significantly over time [15]. Fingertip force is also not showing clear progression over time, and this is likely due to the fact that the fingertip forces were guided throughout the experiment. It is however possible that some effect is present, but the sample in this study makes the analysis statistically under-powered. An indicator in this sense is the fact that, while the dependency between force output and time is not significant, certain metrics are at the edge of significance, and furthermore the Pearson score for the linear regression model over time is significantly higher for the best-fit line of the FSR signals. This causes uncertainty as for whether the observed changes in average FMG signal is due to subtle changes in force output or due to other processes such as fatigue. While the progression of FMG over time seems to show an increasing trend overall, since only one model could be fit for participant, with the exclusion of one participant for which the measurement setup

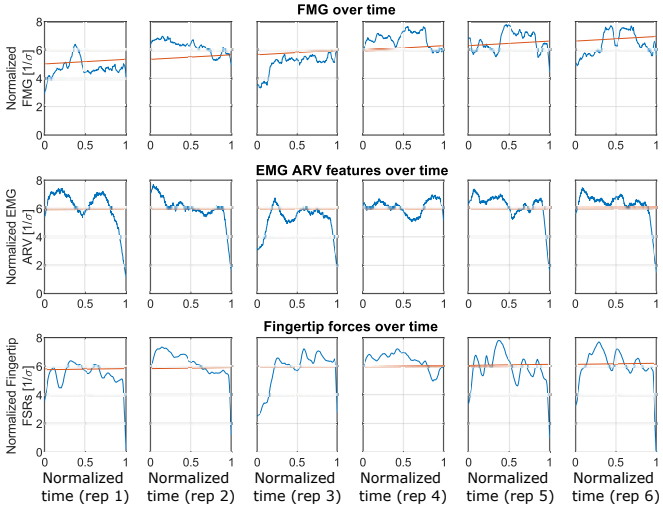

Fig. 5. Representative plot of the EMG ARV features, FMG voltages and FSR voltages over time (all in blue), as well as the best fit line (orange). The signals are shown over repetitions with time being normalized by the length of the repetition itself.

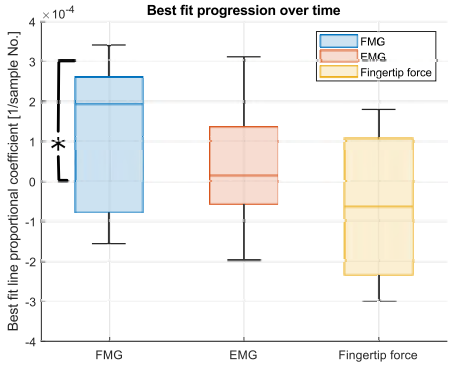

Fig. 6. Box plots of the gains g of the fitted linear regression models for FMG, ARV features from sEMG, and fingertip forces (n = 12), respectively. In this case, one participant was not considered, as the measurement setup was switched to a higher gain in the middle of the experiment, which would lead to an unreliable estimate of the g parameter.

was changed in the middle of the session, only $n = 12$ data points are available for this metric. The progression of FMG over time could be due to multiple causes. Nevertheless, since FMG shows high correlation with output force, it could reveal fatigue by, e.g., monitoring the decrease of force output over time under maximum voluntary contraction or under electrical stimulation [16]. This approach would likely be more reliable than time-domain EMG features, which show high variance across individuals as a response to fatigue [16], since the mechanisms coupling measurable electrical activation and force generation are more numerous than those connecting force output and muscle bulging. This would make it an interesting sensor modality to be adopted in, e.g., FES applications to monitor the progression of fatigue. Studies are in progress to assess this perspective application.

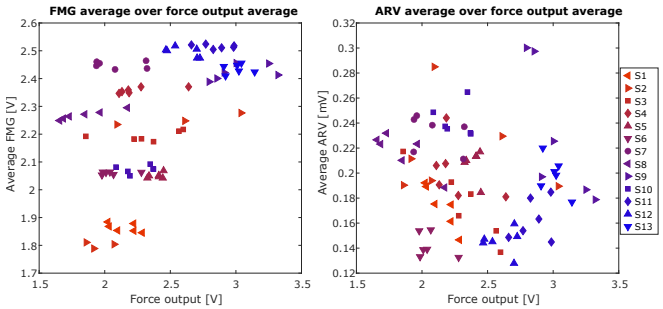

Fig. 7. Average muscular activity signals over average force output measurements across all participants and repetitions. Each color represents six repetitions of an individual participant. All 13 participants are represented in this plot.

A. Limitations

This study presents some principal limitations. As previously stated, the use of a mono-directional force measurement setup limits the reliability of our regression analysis to the instances where pressure is being detected. On the other hand, when the sensor is not being pressed, there is no guarantee that the participant is not actively exerting force upwards. Future studies should make use of a setup able to measure both downwards and upward forces, such as the FFLS [17]. Some adjustments in the posture of the hand throughout the experiment could not be avoided, and this could affect the regression from muscular activity to force output. FMG would be particularly affected by changes in posture, since the resting pressure could change across different hand poses. Furthermore, the experimental protocol was not aiming at causing fatigue, and therefore the only proxy for its observation is the progression of force output over time, the spectral features of the sEMG, which are limited by the relatively low sampling rate of the myo armband, and the reports of the participants. As for the comparison between the two muscular activity sensing modalities, the FMG sensor arrangement has more channels compared to the EMG bracelet used in this study, and furthermore the measurement sites for each modality differ. It is however worth mentioning that the sensor density was similar between the two sensor modalities (with an inter-sensor distance of circa $2\,\mathrm{cm}$). The sensor density would arguably have been a more determining factor given the density of the forearm's muscles. Both the FMG and the EMG bracelets had the same amount of sensors along the arm's circumference. An ideal solution would be one like that proposed in [18], but the mounting of the FMG sensors is of great importance, and potential trade-offs in designing such concurrent sEMG-FMG sensor mountings might be harder to navigate. The higher number of channels was also implemented as a precaution, since the adopted FMG amplifier design is prone to saturation, and needs careful mounting to ensure that the circuit is operating in its linear point. This can be achieved by carefully increasing or decreasing the resting tension of the bracelet. An alternate solution, which is currently being evaluated, is to shift the amplifier's operating point electronically using variable resistors. While the overall complexity of the sensor is increased, this solution can result in much broader usability, and because bracelet tension is not as crucial, it could also result in higher sensor spatial density being possible. Finally, the comparison between force output predictions performed here is limited to ARV features and linear regression, and it could be argued that a better choice in EMG features or the use of non-linear regression models could alter the results. ARV features are singled out in multiple studies, together with root mean square, as having particularly high correlation with both static and dynamic force output [19] [20] [21]. The choice of ARV features was furthermore motivated by the

intent of mimicking a real-time capable setup as commonly used in commercial prosthetic applications. While in most commercially available prosthetic applications single digit control is not available, the higher correlation of FMG to force output could still lead to benefits.

V. CONCLUSIONS

In this study, we provided evidence that FMG measurements show higher correlation with fingertip force output compared to ARV features obtained from a low-cost sEMG sensor. This, in addition to the greater robustness of the FMG sensors, on account of them not needing direct contact with the skin, could make them a conduit towards wider adoption of electronic, muscle activity-controlled prostheses in resource-constrained settings [13]. This statement is corroborated by the interest of various research groups in developing countries in FMG as a prosthesis control solution [3]. FMG sensors are indeed extremely cost effective and robust compared to most sEMG sensors, but it is also worth mentioning that FMG sensors are prone to artifacts due to external pressure being applied to the sensor. sEMG, on the other hand, is not as influenced by external forces. The fact that the present experiment is limited to an isometric exercise with the hand held in a constant position makes it hard to evaluate the influence of movement or external loads on the FMG-based force output calculation. Previous studies [2] have tested control loops based on such predictions in non-isometric scenarios, but did not compare it to the same computation obtained based on EMG measurements. The present study did not validate the quality of the prediction in real time, as was done, e.g., in [14] and [22], but is limited to a multivariate linear regression analysis. Future work should focus on the direct integration of FMG sensors in the robotic appliance they are supposed to drive, which is itself a non-trivial task, as force interactions between the robot, the sensor and the user could well lead to artifacts. The inclusion of the target population of patients will certainly be necessary.

Human-Interface Dynamics of Knee Exoskeletons with Lateral and Anteroposterior Attachment

Yichen Wang, José A. Montes Pérez, Robert D. Gregg, and Gray C. Thomas

***Abstract*— Assistive lower-body exoskeletons aim to improve quality of life for broad populations including older adults and people in physically exhausting manual jobs. By applying torque to augment human motion with backdrivable actuators, these devices can reduce human joint effort without restricting volitional motion. However, these backdrivable actuators are coupled by mechanical interfaces to soft tissues of the human body that together introduce resonator dynamics that can delay or diminish the torque assistance. Low interface stiffness and uncompensated dynamics can cause inefficient power delivery to the user, alter their perceived assistance and comfort, and destabilize feedback controllers. We hypothesize that the low stiffness in lateral strap interfaces, like those in the open-source M-BLUE exoskeleton, can be improved by mechanical redesign. Building on the open-source M-BLUE exoskeleton, this paper introduces an alternative interface design that loads the leg through anterior and posterior pads (normal loading) and straps, in which the pads provide extension assistance and the straps provide flexion assistance. We compare the interface dynamics of lateral and normal loading interfaces on N=10 human subjects using both quasi-static spring measurements and frequency response methods, finding the new design to be 85.7% stiffer ($p < 0.01$) for a range of leg poses and in both flexion and extension loading.**

I. Introduction

Lightweight, backdrivable lower-body exoskeletons that provide assistive torques have the potential to greatly improve quality of life for a large number of people struggling with physical disabilities, aging, or physical overexertion at work. Partial assistance exoskeletons can aid in many activities of daily living, for people who struggle with walking, using stairs, or lifting and lowering heavy objects [1]–[3]. For able-bodied people, exoskeletons can aid with material handling, repetitive movements, or awkward body positions at physically taxing jobs [4], [5]. Usage of exoskeletons can prevent injuries and fatigue, and increase worker comfort.

However, A core contributor to this efficacy is the manner by which the exoskeleton attaches to the human body. Soft tissue between rigid exoskeletons and our human endoskeleton system allows for relative motion and dynamic behavior. These dynamics are viscoelastic, and unfortunately time varying, nonlinear, and hard to predict for an individual [6], [7]. Thus they are typically left out of models [2] and lumped among the neglected factors that limit the performance of feedback controllers. In some cases, these dynamics can be quantified as a low-pass filter with respect to the actuator torque [8]. Generally speaking, the stiffer an interface the more closely it will resemble the rigid assumption and the less likely it will cause instabilities and time delays [9]. However, there is a lack of studies that quantify typical interface stiffness and dynamics for common exoskeleton configurations, or the extent to which it can be ameliorated through mechanical design.

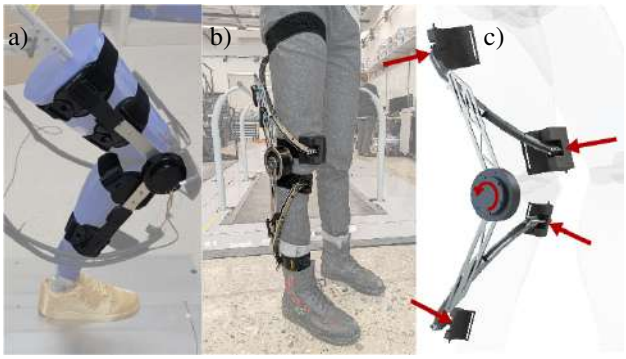

Fig. 1. **Exoskeleton attachments**—a) original attachment via lateral straps, b) new attachment in this paper, c) loading in the new system is via forces on the body (red arrows) that are normal to the surface of the leg.

The exoskeleton's attachment also impacts the efficiency of energy transfer from the exoskeleton to the user. Estimates suggest that in some cases, up to 50% of energy expended by the exoskeleton is used to compress soft tissue instead of doing work on the skeleton structure [10]. This inefficient energy transfer results in less effective assistance for the user, requiring larger torques powered by larger batteries to achieve the desired effect. However, there are limits to the amount of force the human body can tolerate [11].

While the rigidity of the exoskeleton interface is important, so are user comfort, generalizability, and ease of adjustment. Exoskeletons are commonly attached to the human with fabric straps [3], [12]–[14], which must be tightened to apply high pressure for increased rigidity [15]. However, this method becomes painful and uncomfortable for the user if the straps are over-tightened. Additionally, human soft tissue changes shape throughout the range of motion, causing an exoskeleton fitted at one particular body position to be uncomfortably tight or overly loose at others [16], which cannot be remedied by tightening straps. Instead of using straps, another attachment style molds rigid shapes to prominences on each user [17]. Human extremities have high local variations in stiffness that can be used to our advantage by carefully selecting the points of attachments [18]. Both

of these methods come at the cost of user generalizability, as an exoskeleton molded to one user may not fit another.

Exoskeletons that attach laterally to the joint and limb, such as the M-BLUE platform [5], [12] or clothing-integrated exoskeleton [13] developed under Skip and Arc'teryx have a simple design concept that is well-suited to a lightweight construction. Having attachments in the same plane as the joint movement dramatically eases re-fitting, and this low complexity enables a cheap, low-barrier-to-entry solution for research exoskeletons [12]. However, the lateral attachments convert applied flexion-extension force into a twisting moment around the femur and tibia-fibula (Figure 2), resulting in a significant mechanical deflection relative to compressive loading [19].

With attachment locations anterior-posterior to the limb (Figure 2, left), many exoskeletons have achieved more direct torque transmission at a weight penalty due to the heavier structures necessary to wrap around the leg and transmit force above and below the limb [14], [20], [21]. However, targeted research in human-exoskeleton interface dynamics is uncommon, and stops far short of quantifying the advantage in dynamic performance [22]. Research has analyzed skin compliance as a material property [18], but would require a complex simulation to relate to interface design. Exoskeleton-focused research offers some stiffness estimates for exoskeletons in special purpose tests (and have typically not measured the nonlinearity in the stiffness parameters) [8], [19], [20], [23]. A direct comparison of lateral and normal attachment strategies using a common exoskeleton platform and analyzing the dynamics of the mechanical interface would therefore aid mechanical designers in choosing an appropriate exoskeleton attachment style for their purposes.

This study investigates the interface dynamics of two versions of the M-BLUE exoskeleton platform, configured for lateral-strap and normal (anteroposterior) loading of the knee joint. In particular, we contribute: A) a sheet-metal and 3D printed plastic attachment design for normal loading attachment (Figure 1); B) quasi-static nonlinear spring measurements of both exoskeletons on $N = 10$ participants in three knee angle postures; C) frequency-response identification of the motor torque to exoskeleton deflection transfer function across subjects, exoskeletons, and extension vs. flexion loading, D) analysis of regressed nonlinear model coefficients for the quasi-static spring rate; and E) analysis of the dynamic stiffness differences arising due to the loading condition, knee angle, and exoskeleton design. We found the normal loading configuration to be consistently stiffer for all three tested leg poses and both loading directions ($p < 0.01$). In particular, we found an 85.5% increase in the quasi-static linear stiffness, 91.9% increase in the quasi-static progressive stiffness, and 85.7% increase in the average dynamic stiffness between 3 and 15 Hz.

II. Exoskeleton Interfaces

A. Interface Descriptions

Knee exoskeletons usually consist of an actuator connected to the person through attachments in the thigh link and shank link. Among many attachment methods, two main paradigms stand out.

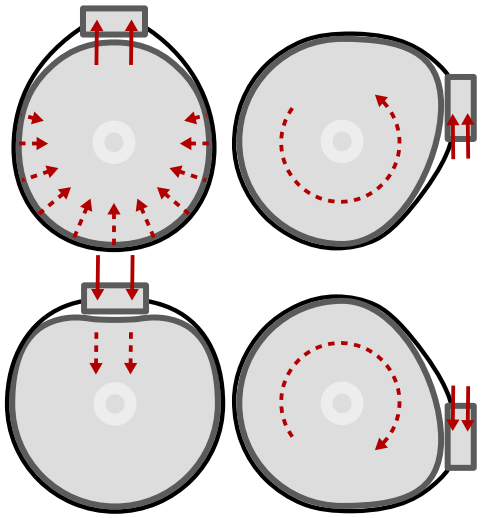

Fig. 2. **Normal loading (left) compared to lateral loading (right)** when applying knee flexion (top) and knee extension (bottom) on a cross-section of the leg. Deformation and deflections are exaggerated for illustrative purposes.

Lateral-strap loading exoskeletons (Figure 2, right) interface with the human through straps that surround the shank and thigh. The straps are then rigidly connected to the actuator through structures lateral to the limb. As the exoskeleton applies assistive torques, lateral forces applied to soft tissue causes twisting relative to the underlying bone. As the deflection becomes greater, the straps begin to compress the anterior or posterior of the limb, stiffening the connection. This interaction can be modeled as a nonlinear stiffness that grows as the deflection loads the straps and compresses the soft tissue against the skeleton. This series-spring and rotational effect results in an dynamic error between the desired and applied torque similar to a delay. Because humans are very sensitive to the timing of torques from exoskeletons [24], any disruption in torque application can be detrimental to the performance of the exoskeleton.

In contrast, normal-loading exoskeletons (Figure 2, left) transfer torques to the limb via pads placed anterior and posterior to the shank and thigh and straps around their circumference. The exoskeleton loads the limb by pressing into the soft tissue with pads or pulling on the limb with straps, depending on the torque direction. Relative to the lateral-strap configuration, this avoids the deflection due to torsion about the bone, instead compressing soft tissue immediately upon loading. Since it does not rotate soft tissue, we expect normal-loading exoskeletons to have a higher interface stiffness as well as a faster increase in stiffness.

B. Exoskeleton Mechanical Design

For the lateral strap exoskeleton, we used a modified version of the existing M-BLUE [12] exoskeleton. M-BLUE uses pads and straps from a T-Scope knee brace (Breg, Carlsbad, CA, USA) with sheet metal plates attaching to a

ActPack actuator (Dephy, Inc., Boxborough, MA, USA). In contrast from the original design of M-BLUE, we removed the aluminum uprights from the medial position. The configuration used in the experiments can be seen in Figure 4. This provides more comfort to the user in a bilateral configuration since the medial straps would often collide with one another when walking. Therefore, this is more representative of a deployed bilateral exoskeleton, and more similar to other exoskeletons of its class [13], [25].

We designed our normal-loading attachment system (Figure 1) with the goals of high interface stiffness, high structural stiffness, and high adjustability to a wide variety of body types. We chose to optimize the exoskeleton for applying extension knee torque, due to the fact that the knee joint applies a much higher peak torque in the extension direction than the flexion direction, especially in torque-demanding tasks such as stair ascent-descent [26]. Secondary goals that were important to the experiment were comfort while sitting down, and ease of donning and doffing. Some additional goals that we had which were less relevant to the experimental design but still important for a general use exoskeleton were reducing the weight of the exoskeleton, simple manufacturing by using common materials and accessible manufacturing techniques such as laser-cut sheet metal and 3D printing.

To ensure high interface stiffness, we placed two vertically offset pads for the shank and the thigh to effectively transmit a sagittal plane extension torque via pad compression alone (Figure 1). Because we chose to optimize the force application in the extension direction, we placed the proximal thigh pad posterior to the leg and the distal thigh pad anterior to the leg. Conversely, the proximal shank pad is anterior to and the distal pad posterior to the shank. Each pad is held in place by a inelastic strap that attaches it to limb, fixing it and the exoskeleton in place. The straps are chosen to have comparable materials to those used on the lateral-loading exoskeleton. When the exoskeleton applies a force in the extension direction, the pads compressed directly into the soft tissue, while in the flexion direction, straps surround and pull on the limb without rotation of the soft tissue. At design time, it was unclear if the two loading methods would result in different stiffness characteristics, and we hypothesized that a difference would be more pronounced than for the lateral straps of M-BLUE.

To be fit to a wide range of leg shapes, spacing between the pads needs to be adjusted. Our design achieved this through the integration of a C-shaped structural member that wraps around the leg and connects the pads. The angle of the C-shaped beam relative to the leg controls the sagittal spacing between the pads. As accurate relative vertical positioning of the pads is not necessary for a snug fitment, rotating the beam alone provides ample freedom of adjustment for user comfort. Cam handles placed on the joint between beams and the actuation arms enables fast loosening of the exoskeleton during fitment, and can be easily tightened once the pads and straps are applied and taut. Because the C shape is a key structural member of the exoskeleton, it is constructed of an aluminum and 3D printed plastic laminate for high bending stiffness and a low weight.

III. Experimental Methods

A. System Identification of Interface Dynamics

Exoskeleton tests are comprised of two two parts: a quasi-static loading test analyzes the soft tissue compliance at the exoskeleton attachments as a nonlinear spring, and a frequency response test analyzes it as a transfer function. Quasi-static loading represents the compliance of the attachment areas for torques that are applied at a low rate and represent steady-state stiffness. Dynamic loading represents interface dynamics when torques are applied at a high rate, and include factors of time-dependent effects and inertial recruitment. The exoskeleton might have different stiffness properties depending the type of loading (dynamic vs. quasi-static), the direction the torque is applied (extension vs. flexion), and the knee angle. Therefore, we designed an experiment that accounts for these variations by testing each separately (Figure 3).

In the quasi-static case, the soft tissue interface can be considered as a nonlinear spring attaching the exoskeleton to the underlying bone structure. To quantify the spring rate, we apply a low-frequency of 0.1 to 1 Hz and relatively higher amplitude of 10 Nm peak-to-peak signal to measure the nonlinear spring part of the system. We then use this data to calculate the deflection of the exoskeleton compared to the human. As the the human base of the system is fixed, any change in the encoder position of the motor represents a deflection of soft-tissue. The low frequency enables the motor to come to a complete equilibrium before the torque changes direction, and eliminates higher order inertial and damping effects from the measurement.

To quantify the stiffness during quasi-static loading we perform a least-squares regression that analyzes both the linear and nonlinear components of the spring behavior. In order to capture differences in dynamics resulting from loading directions, we regress separate flexion and extension models. The equations for the regression are then

$$\tau = \begin{cases} \begin{bmatrix} \theta & -\theta^2 \end{bmatrix} \begin{bmatrix} \alpha_1 \\ \beta_1 \end{bmatrix}, & \theta < 0, \\ \begin{bmatrix} \theta & \theta^2 \end{bmatrix} \begin{bmatrix} \alpha_2 \\ \beta_2 \end{bmatrix}, & \theta > 0, \end{cases} \tag{1}$$

where τ is the calculated torque of the motor, θ is the measured deflection of the exoskeleton with respect to the person, $\alpha_{1,2}$, represents the linear stiffness, and $\beta_{1,2}$ represent progressive stiffness. Because of soft tissue dynamics, the quasi-static tests observed a large amount of hysteresis. To accommodate for this hysteresis, which are not modeled in the regression model below, we binned the data into 100 equally distributed buckets according to the applied torque, and took the average of all data points within each bucket. The resulting 100 binned averages are then used as inputs for a least squares fit to the piecewise quadratic polynomial model mentioned above in (1). Piecewise models

are chosen to capture potential differences in stiffness in different loading directions as a result of asymmetry in loading through pads versus straps. A quadratic polynomial is an established modeling method for joint stiffnesses [27].

For the dynamical stiffness parameters, we consider the interface as a mass-spring-damper system. This means that there is a virtual mass that represents the exoskeleton which is attached to the human's bones via a parallel spring-damper. Since we are mainly interested in the spring component, we only quantify that aspect of the system. We do this by performing a system identification using a frequency sweep. Namely, we define the interface as a single input single output (SISO) system, with the input as the torque of the motor, and the output as the deflection of the motor encoder. A transfer function is defined with the gain being the output divided by the input, in this case, motor position over applied torque. Applied torque is calculated naively using the motor current, torque constant, and transmission ratio:

$$\tau = nK_m i, \tag{2}$$

where τ is the applied torque, i is the measured torque, $K_m = 0.105$ is the motor torque constant, and $n = 9$ is the transmission ratio. In order to account for possible differences in motor friction, inertia, and torque constant, the same motor is used for all experiments.

The dynamical loading test is broken down into an extension experiment and flexion experiment. Both tests use a smaller amplitude of 4 Nm peak-to-peak torque with a 2 Nm torque offset for flexion and a -2 Nm torque offset for extension. This torque range is lower than those typically applied during exoskeleton use, however we found larger amplitudes uncomfortable in the context of a frequency sweep test. The frequency for the dynamic test varies from 1 Hz to 50 Hz using a exponential interpolation following Equation 3 to measure the inertial and damping parts of the system. The exponential interpolation is defined as

$$\omega = \omega_0 \left(\frac{\omega_f}{\omega_0}\right)^{t/T}, \tag{3}$$

where ω_0 and ω_f are start and end frequencies, t is current time, and T is the end time. Each test lasts 60 seconds.

We used a closed-chain test posture (Figure 4) to isolate interface dynamics without allowing leg motion, similar to tests conducted by Shepherd et al. [8]. The subject is placed in a seated position, where the position of the hip is constrained by the body weight of the subject, and the position of the foot is constrained using a spring loaded device. The spring loaded device also functions as a cue for the subject to apply a force roughly equal to one quarter that of an average adult body weight, in order to stimulate a consistent level of muscle co-contraction during activities. Because the hip joint and the ankle joint are both constrained, the position and motion of the knee joint is also considered to be fixed.

For the dynamical system test, we process the resultant frequency domain information to estimate dynamic stiffness. Given that the data under 3 Hz are very noisy and data above 15 Hz are dominated by inertial behavior, we decided to limit our usable observations from 3 Hz to 15 Hz. We then define the effective stiffness that we use to compare the two exoskeletons as the average magnitude of the transfer function over this range.

We calculate percentage improvement in stiffness parameters (α, β, and the effective dynamic stiffness) from lateral strap to normal loading attachments as the average percent difference over all conditions. For two stiffnesses, s_1 and s_2, we define the percent difference as $2(s_1 - s_2)/(s_1 + s_2)$. To validate that our results are statistically significant we perform a one tailed T-test between the normal loading and lateral loading stiffness.

B. Experiment Protocol

People trace through a large range of knee angles throughout the range of motion of walking and daily tasks. During walking, the knee remains fairly extended, while in stair climbing is is more flexed, and in a sit-to-stand motion it is almost flexed to 90 degrees. To capture the dynamics at a range of knee angles, we conducted experiments for three knee angles within the range of motion represented in daily tasks [28]: 90 degrees, 135 degrees, and 180 degrees.

At the start of the experiment, the first tested exoskeleton is decided using a coin flip. Once the exoskeleton is fastened, we place the subject's leg between 90 degrees, 135 degrees and 180 degrees, the order of which is chosen using a random number generator. Once the leg is held at a particular angle, we run the quasi-static test, the dynamic flexion test, and the dynamic extension test in series. The quasi-static test is always conducted first to allow for lateral comparisons, while the two dynamic loading tests are randomized via a random number generator. Optional rest periods are provided between each leg angle, and a longer rest period is provided in the middle of the experiment to dismount and fit the remaining exoskeleton. After testing on the first exoskeleton, the motor is swapped to the remaining exoskeleton and aforementioned process repeated. We do not further randomize the two exoskeletons, since swapping the motor from one exoskeletons to another accelerates wear and tear.

Muscle stiffness changes when under co-contraction or applying force [29]. During most motion tasks, leg muscles are applying force, often to support the body against gravity or achieve a desired movement. In order to partially simulate this co-contraction while maintaining a safe experimental environment, we designed a spring loaded pedal device, on which we instruct the subject to step. The pedal applies a force of around 200N at max compression, roughly simulating half of the force applied through one foot when standing, based on the average body mass of American adults [30]. The subject is instructed to keep the pedal fully depressed against the hard stop, ensuring a minimum level of muscle force. The pedal also ensures the position of the foot remains constant and fixed throughout the experiments.

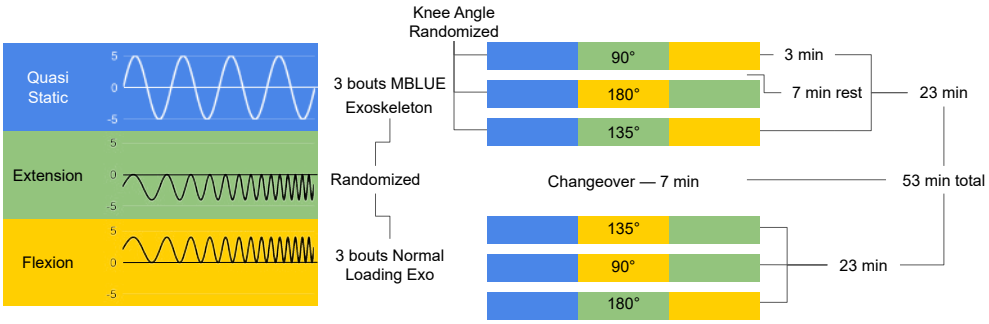

Fig. 3. **Experimental procedure**. Three tests are done per randomized leg position across both exoskeletons. Quasi-static test (blue) are done first for every trial and range from -5 Nm to 5 Nm of torque. Extension and flexion trials are then performed in random order and range from -4 Nm to 0 Nm and, from 0 Nm to 4 Nm respectively.

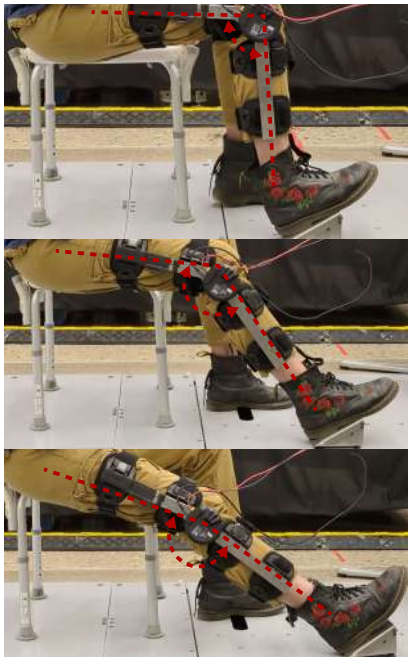

Fig. 4. **Experimental setup** illustrating three tested poses (90°, 135°, 180°), exoskeleton mounting, torque directions, and the spring-loaded pedal.

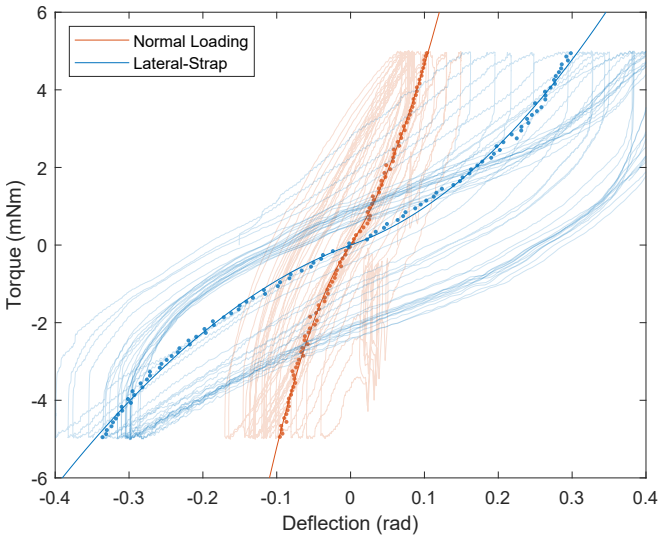

Fig. 5. **Quasi-static experiment results** of both the Lateral-Strap and Normal Loading attachments for one subject, showing the raw data (faint lines), binned averages (scatter plot in the middle), and piecewise quadratic regression (distinct line in the middle) used to approximate the data.

IV. RESULTS

A. *Quasi-Static Stiffness*

Pairwise t-tests show both linear and progressive components of stiffness are significantly higher for the normal loading configuration than the lateral-strap configuration for all loading directions and poses ($p < 0.01$). On average, the linear stiffness parameter α is 85.5% higher for the normal loading attachment, and the progressive stiffness parameter β is 91.9% higher. To visualize the goodness-of-fit we plot raw torque vs. deflection data for one subject at the 180 degree leg configuration in Figure 5. The regressed model (solid line) closely matches the binned data (scatter plot) for the 180 degree trial (Averaged R^2 value across all trials is is 0.982). While the rest of the data is obviated for clarity, the total fits for every subject across both exoskeletons and the different leg conditions (less opaque lines) and the average fit (solid lines) can be observed in Figure 6. We observe a higher slope in the normal loading case indicating higher stiffness. The increase in stiffness can be better understood by looking at the distribution of linear stiffness parameters $\alpha_{1,2}$ and progressive stiffness parameters $\beta_{1,2}$ in Figure 7. Despite the apparent discrepancies in distributions, we failed to find a significant difference in the coefficient of variation using an F-test in either the linear or quadratic parameters.

Surprisingly, we found that there was no significant difference between extension and flexion for the linear and progressive stiffness for either normal loading or lateral strap attachments. For the different knee angle conditions, we found that the linear quasi-static stiffness at a knee angle of 90 deg is higher than the stiffness at knee angles of 135 degrees and 180 degrees for both exoskeleton configurations ($p< 0.01$). A similar trend is yielded by a comparison of the quadratic terms of quasi-static stiffness. Quadratic coefficients at a knee angle of 90 degrees is higher than stiffnesses at both 135 and 180 degrees for both exoskeletons

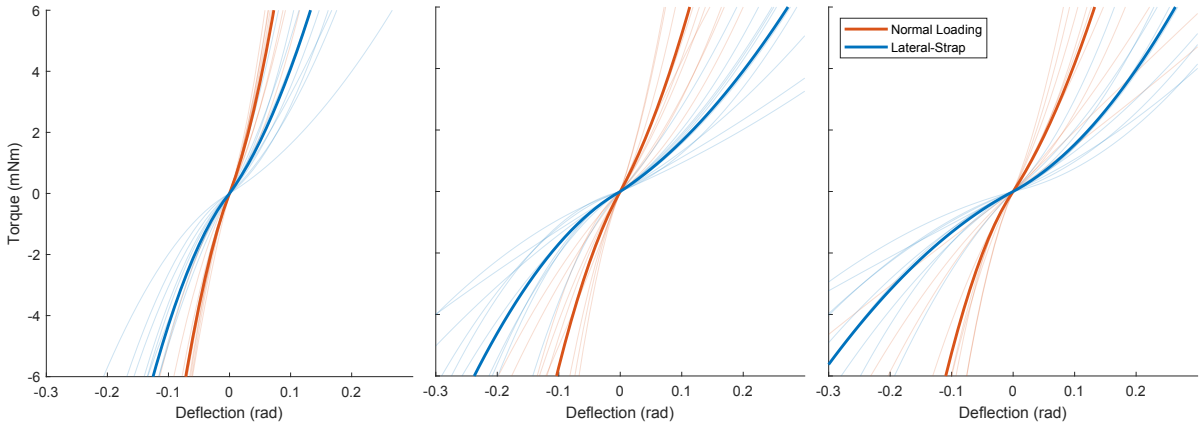

Fig. 6. **Comparison of output deflection vs. input torque** for 3 different knee angles: 90, 135, and 180 degrees. Lines shows piecewise quadratic regressions for each subject, and thick lines show the average of all subjects.

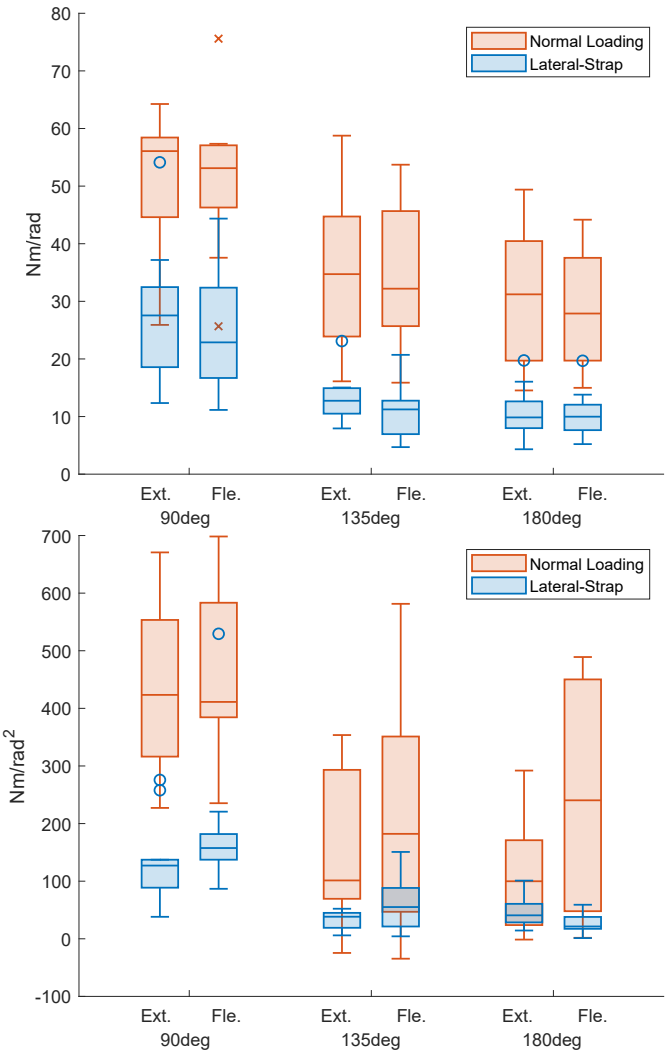

Fig. 7. **Quasi-static interface stiffness distribution** of the regression coefficients for extension α_1, β_1 (Ext.) and flexion α_2, β_2 (Fle.) of regressions (1) of Lateral-Strap vs. Normal Loading attachments in three different poses and two loading directions.

($p< 0.01$), and no significant difference is found between stiffnesses at 135 and 180 degrees.

B. Dynamic Stiffness

In line with the results for the quasi-static case, the normal loading exoskeleton design improved the dynamic interfacial stiffness compared to the lateral straps design ($p< 0.01$). We calculated the average percent difference of dynamic stiffness between the normal loading attachment and the lateral-strap attachment to be 85.7%. Representative Bode plots of the dynamic loading tests are shown in Figure 8, which also highlights the 3-15 Hz frequency window used to find the effective dynamic stiffness (average stiffness over the valid range) presented by the dotted straight line. We included two comparisons to illustrate a range of possible effective stiffnesses of the dynamic loading tests. A box and whiskers plot illustrates the consistency of the improvement from lateral strap to normal loading across the three poses and extension/flexion loading conditions (Figure 9).

There was no significant difference between the flexion and extension loading directions. We found that dynamic stiffness at 90 deg is significantly higher than stiffness at both knee angles of 135 degrees and 180 degrees for both exoskeleton configurations and both loading directions ($p< 0.01$), while there is no significant difference between stiffnesses at knee angles of 135 and 180 degrees. Dynamic stiffness for the Normal Loading attachment is consistently higher in extension than flexion ($p< 0.01$), while no difference is shown for the lateral-strap attachment. Similar to the quasi-static case, we found no significant difference in the coefficient of variance between normal loading and lateral-strap attachments.

V. Discussion and Conclusion

The normal loading exoskeleton resulted in stiffer interface stiffness across the quasi-static test and the dynamic test for all loading directions and knee angles ($p< 0.01$). In particular, we found an 85.5% increase in the quasi-static linear stiffness, 91.9% increase in the quasi-static progressive stiffness, and 85.7% in the dynamic effective stiffness.

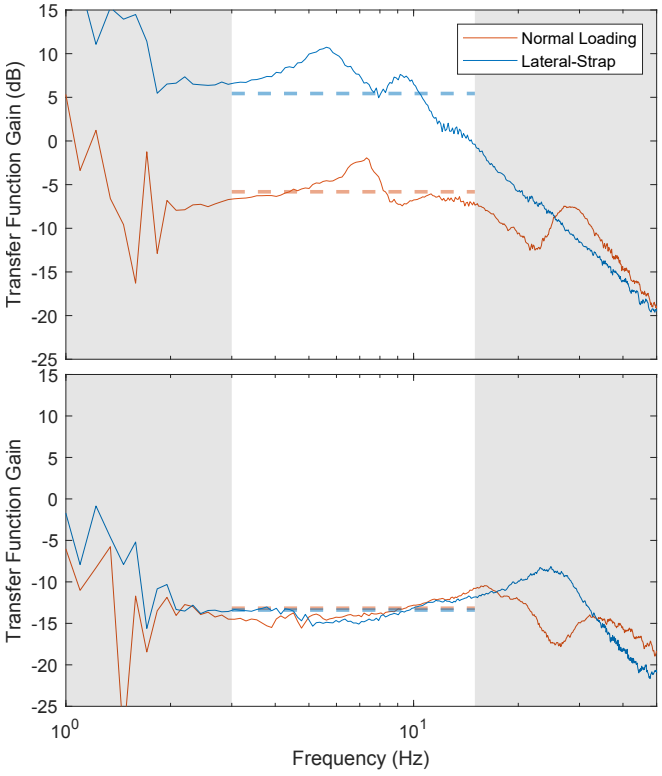

Fig. 8. **Dynamic compliance bode plots** showing extremes of gap between Normal Loading and Lateral-Strap stiffness for all experiments. An arithmetic average of the transfer function gain from 3Hz to 15Hz (highlighted area) is taken to represent the dynamic stiffness of the exoskeleton (dashed line). (Magnitude is in low-level device units of encoder tics per mNm.) Top graph is results from subject 10 at a knee angle of 90 degrees and in the extension direction. Bottom graph is from subject 6 at a knee angle of 180 degrees in the extension direction.

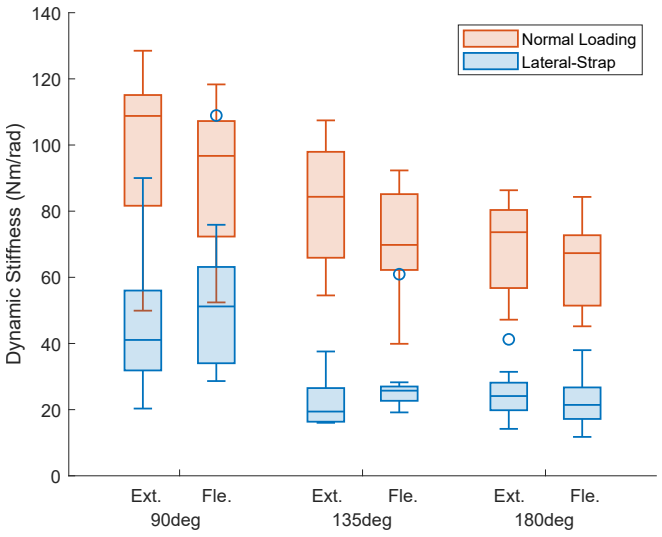

Fig. 9. **Dynamic interface stiffness distribution** between the two exoskeletons across three kinematic positions and across flexion and extension loading conditions. All 10 subjects represented in Box-Whisker plots. Ext. denotes loading in the extension direction, and Fle. denotes loading in the flexion direction.

Even though the normal loading attachment transfers force through straps in the flexion direction, the result was still significantly stiffer than for a comparable loading condition using the laterally attached exoskeleton. Moreover, we failed to find a statistically significant difference in the normal loading exoskeleton when loading in the flexion and extension direction. This reinforces our notion that a normal loading exoskeleton is stiffer due to more direct force transfer that avoids rotating tissue around an underlying bone.

Across knee angles, exoskeleton attachments, and loading directions, nonlinear stiffness terms represent a large amount of the total stiffness of both exoskeletons. At the end of the range of deflection, quadratic stiffness terms account for roughly half of all of the applied torque. The presence of progressive stiffness implies that tasks that have low deflection will result in less overall stiffness. For example, low-torque activities like level walking will be less stiff than high torques activities like sit-to-stand.

When comparing the linear stiffness in the quasi-static case to the dynamic stiffness we observe that the dynamic stiffness is generally larger. This is due to the fact that our analysis of the dynamic response assumes the system is linear, in which case the overall stiffness takes into account both the linear and quadratic term. Due to the large effect of the quadratic stiffness mentioned above, the linear term only represents a fraction of the overall stiffness represented in the dynamic test. Therefore, a one-to-one comparison between those values is not meaningful. However, we do note that they are in the same order of magnitude.

When comparing our results to the field, we see that at a knee angle of 90 degrees, the dynamic stiffness estimator had an average stiffness of 108.8Nm/rad in extension of 96.7Nm/rad in flexion. This is significantly lower compared to Shepherd et al.'s measurement of 327Nm/rad [8]. A few design differences in the tested exoskeletons may have resulted in this discrepancy: the Normal Loading attachment attaches to the shank directly, while Shepherd et al. attaches through both the shank and a foot plate; the Normal Loading attachment has a much lower system weight; and the Normal Loading attachment interfaces with the human body with a smaller area and thinner straps.

Despite the design of the experimental protocol, there are some variables that may not be well controlled and may skew the result of the experiment. For example, strap tightness was based on user comfort and not measured across different leg positions. Therefore there could be inter and intra-subject variations for each testing condition. The subjects are also not perfectly statically fixed during the experiment which can add noise to the measured deflection. The human subject may also move volitionally in response to slow loading, which is why we have excluded frequencies below 3 Hz from analysis in the dynamic test. The poses subjects are placed in may not be identical between experiments due to high variances in goniometer measurements of the knee angle [31].

Our modeling of the exoskeleton-human system might also have limited our explainability of the results. Inspection of bode plots reveal that most tests present with two dis-

tinct resonance peaks. Each peak corresponds to a specific resonance behavior, and we hypothesize that this is due to the two coupled mass-spring-damping systems that the exoskeleton-human interface can be abstracted into. As the exoskeleton is suspended by the thigh and shank attachments, oscillating forces resonate with the respective inertias, and result in the shape of the bode plot. Furthermore, quasi-static testing revealed a large amount of hysteresis in the interface behavior of the exoskeleton. Our analysis method obscures hysteretic parameters, but it may be useful to examine. We also do not analyze the phase model in the frequency domain, which may reveal dynamic hysteretic terms. Further research may be conducted to extract each parameter of the system and compensate for tissue dynamics in the controller.

Considered together, our experiments highlight the benefits of anteroposterior versus lateral human-exoskeleton interface attachments, as well as demonstrating an anteroposterior attachment design that is lightweight and relatively inexpensive to fabricate. Ideally, these results would inform design choices, especially for assistive exoskeletons that could benefit from feedback control and desire improved dynamic performance.

Green Means Go(Bot): Using an Assistive Robot to Encourage Independent Walking Practice by a Child with Motor Disabilities

Ameer Helmi[1], Tze-Hsuan Wang[2], Samuel W. Logan[2], and Naomi T. Fitter[1]

***Abstract*— For children with motor disabilities, a wide range of assistive technologies (such as exoskeletons, treadmill trainers, and body-weight support harnesses) exist to support learning to walk. However, after the onset of independent walking, few technologies are geared toward helping children with motor disabilities to practice walking and improve walking control. In this paper, we assess the ability of GoBot, a custom assistive robot with multiple game modes, to encourage one child with a motor disability to improve their amount, speed, and control of independent walking. We conducted a 12-session single-subject study and found that the child walked more and faster while engaging in lightly competitive races against a directly teleoperated GoBot, compared to during experiences in a standard of care condition. As a second and more exploratory element of our work, we equipped GoBot to autonomously play the common children's game red light, green light (RLGL) with the user as an entertaining way to motivate balance practice. Anecdotally, this RLGL activity led to some of the highest levels of child engagement. The preliminary findings of our single-subject study can benefit researchers working with assistive robots and physical therapists working with children with independent walking practice goals.**

I. Introduction

Children with motor disabilities typically experience delays in major motor milestones such as walking [1]. Research into improving children's ability to walk has primarily focused on helping children develop the skill of walking through physical therapy interventions with devices such as a treadmill trainer [2]. However, outside of adaptive physical education programs [3], few works have evaluated assistive-technology-mediated methods to support the continual improvement of children's amount and speed of overground walking after they develop the ability to independently walk. This gap is important; children with enhanced walking stamina and control are able to better participate in activities of daily living [4] and accomplish higher levels of physical activity [5]. In this work, we designed a proof-of-concept intervention with a custom assistive robot to help augment the methods available for encouraging a child with a motor disability to walk more, faster, and with more control.

Our custom assistive robot, GoBot, uses gamification in the presented interactions with the end user. Gamification of physical therapy interventions (e.g., with virtual reality [6]) is a common strategy for improving child engagement, but gamified motor interventions for children have primarily centered on treadmill training for children who are still learning to walk. One novel emergent method to motivate the practice of walking is the use of assistive robots; a robot's embodiment allows it to facilitate compelling gamified interactions in the physical world to keep children engaged during interventions. Two past efforts have shown the benefits of using peer-like assistive robots to improve motor practice by children with motor disabilities who are still using mobility aids [7], [8]. This promising initial work motivated us to research a robot-mediated intervention for a child who was beginning to walk independently, but required motivation to continue practicing aspects of walking such as stamina, speed, and control.

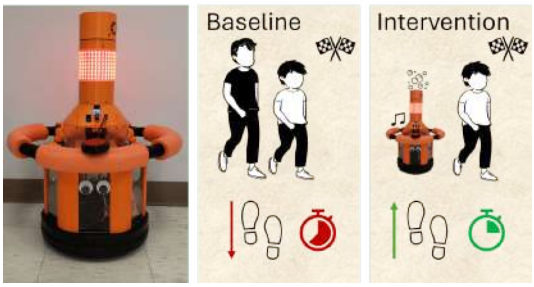

Fig. 1: *Left*: GoBot, our custom assistive robot with light, sound, and bubble rewards. *Center and Right*: Depiction of the key methods and results for our study phases.

Our main research goal in the presented work was to *evaluate if an assistive robot could motivate a child with a motor disability to improve their amount and speed of independent walking*. We used a GoBot robot [9], as shown in Fig. 1, that was equipped with racing and red light, green light (RLGL) game modes to conduct a 12-session single-subject study with a child who was focused on improving their independent walking. In this paper, Section II covers related work on the improvement of children's walking skills, gamification, and assistive robotics. Then, we elaborate on the robot design and the methods of the multi-month single-subject study in Section III. As conveyed in Section IV, our study results showed that the child tended to improve their amount and speed of walking while racing against the robot when compared with the baseline (i.e., standard of care) condition. Additionally, the child was able to successfully understand and play the RLGL game independently. Finally, we discuss the implications, strengths, and limitations of this work in Section VI. The main contribution of this work is early evidence that an assistive robot could help improve a child's amount, speed, and control of independent walking.

II. Related Work

Related work on improving children's walking skills, gamification strategies in pediatric interventions, and assistive robot design helped to inform the presented work.

[1]Collaborative Robotics and Intelligent Systems (CoRIS) Institute, Oregon State University, Corvallis, Oregon, USA. [helmia, fittern]@oregonstate.edu

[2]Disability and Mobility Do-It-Yourself Cooperative, Oregon State University, Corvallis, Oregon, USA.

When forming the presented work, we learned from our clinical collaborators that for some children with disabilities who are beginning to walk independently, physical therapy goals range from increasing the amount of walking to increasing speed and balance. Increasing levels of physical activity for young children is vital for health and carries benefits such as improving bone density and cardiometabolic health [10], [11]. Children typically perform the most physical activity in physical education (PE) programs at school, but adaptive physical education programs for children with disabilities continue to lag behind PE programs for children without motor disabilities [3], [12]. Outside of school programs, children with motor disabilities will engage in physical therapy interventions using rehabilitation technologies such as the previously mentioned treadmill trainer to improve motor skills [2]. Exoskeletons are another technology that could help young children (before and after the onset of walking) via different levels of support for walking more and faster, but these devices are cost-prohibitive and primarily tailored towards children still learning to walk [13], [14]. This leaves a gap for children with motor disabilities who need to improve their walking functions; they still need engaging interventions designed to help encourage the further improvement of walking. In our study design, we focused on improving our child end user's amount and speed of walking through lightly competitive races with a robot and enhancing their walking control via playing RLGL with the robot.

Keeping children engaged in any pediatric intervention is a key component of further enhancing motor gains. Researchers have focused on using gamification strategies with technologies such as virtual reality (VR) or biofeedback to encourage social and cognitive interaction during an intervention, but have primarily incorporated these technologies into assistive devices such as treadmill trainers. One team designed a VR soccer game to allow children on a treadmill trainer to walk and kick a virtual soccer ball [6] while another team designed a VR world for a child to experience while walking on a treadmill trainer [15]. Researchers have also developed biofeedback tools as another method for increasing engagement during treadmill training interventions. While the child is walking on the treadmill, changes in heart rate or breathing rate prompts visual or audio cues on a tablet or larger screen that are designed to celebrate walking more or faster and continue to encourage movement [16], [17]. While these tools could be used for a child walking with or without assistance on a treadmill, there are benefits to children walking overground, such as social and cognitive benefits that complement the motor gains [8]. This idea encouraged us to use assistive robots, a newer tool in pediatric interventions, as the external motivating factor to encourage child motor practice during overground walking.

Assistive robots can offer more motivation than similar types of technologies which are not embodied in the physical world [18], and have achieved preliminary success in child mobility encouragement. Assistive robots encouraging physical activity are often studied with older adult populations [19], but fewer works have investigated using robots to encourage physical activity for young children without motor disabilities [9], [20]. For children with motor disabilities, robotic treadmill trainers such as the Lokomat have shown success in providing direct support to a child's gait during treadmill training interventions [21], but these tools are focused on children still learning to walk. In our own related work, we found preliminary evidence that GoBot could encourage a child with a motor disability using a body-weight support harness (BWSH) to take more supported steps in the environment [7], while a different research team using a BWSH found promising results using NAO and Dash robots [8]. These benefits of using robots for motivation during physical activity interventions encouraged us to develop multiple game modes for GoBot and conduct a multi-month single-subject intervention designed to encourage a child with a motor disability to independently walk more and faster.

III. Single-Subject Study Methods

We conducted a single-subject study to evaluate if the presence of an assistive robot could motivate a child to independently walk more and faster during physical therapy, compared to in standard-of-care experiences. Our university ethics board approved the study (protocol #IRB-2020-0723).

A. Study Design

The study lasted for 12 sessions using a single-case ABAB withdrawal study design [22]. With this design, the study was divided into 4 phases: two 3-session baseline phases (labeled as "A1 and A2") in which the assistive robot was not present and two 3-session intervention phases (labeled as "B1 and B2") in which the assistive robot encouraged the child to walk. We alternated the baseline and intervention phases in an AAA-BBB-AAA-BBB pattern as further described below:

- *First Baseline - A1* (3 sessions): The child independently walked during races with a clinician or research staff, but no assistive robot.
- *First Intervention - B1* (3 sessions): The child independently walking during races with a teleoperated GoBot, which used its reward features (as further explained in Section III-B) to encourage the child.
- *Second Baseline - A2* (3 sessions): As in the first baseline phase, the child walked with a clinician/researcher.
- *Second Intervention - B2* (3 sessions): As in the first intervention phase, the child walked with the robot.

In alignment with the single-subject style of this work, the participant served as their own baseline, allowing us to observe the impact of introducing the assistive robot on the child's amount and speed of walking.

Each session lasted up to 30 minutes and occurred approximately every two weeks over a six-month period. These sessions took place between the participant's usual every other week physical therapy sessions.

B. Robotic System

We used a teleoperated GoBot (see Fig. 2) with flashing lights, bubble-blowing, and a library of sounds as motivating stimuli to encourage the child to walk during the robot races. Further detail on the early design of GoBot and its reward

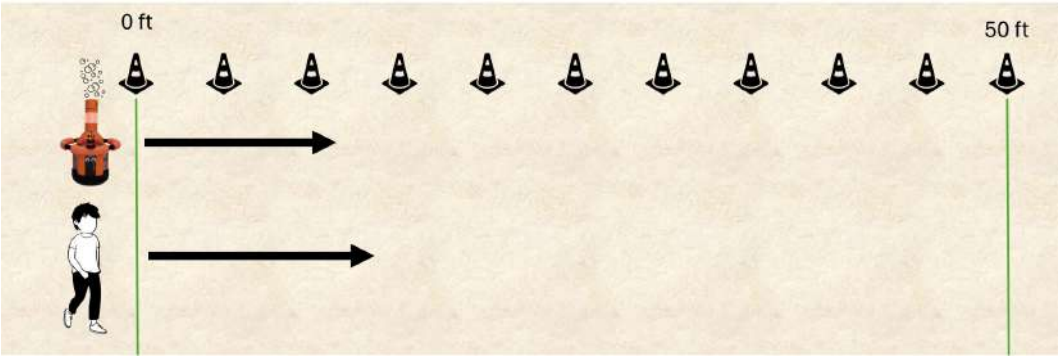

Fig. 2: Schematic of the robot races setup, including the child participant, robot, and cones for easily tracking distance walked. A complete "lap" was marked each time the child reached one extreme end of the cones.

features is available in our past work, e.g., [23]. Briefly, this robot has a custom reward hardware stack on top of a TurtleBot2 robot. It is capable of two-dimensional overground motion as well as the aforementioned reward features. The robot is orange to match the Oregon State University colors while also providing high-contrast and easy visibility.

C. Participant

Our participant was male and 7.1 years old. The participant has a diagnosis of multiple malformation syndromes with global developmental delay. At the start of the study, the participant primarily used wall walking and bottom scooting at home and was able to walk independently, but frequently required assistance. He communicated with single words, as well as through signs and gestures. The clinicians' goal was to improve his walking balance, endurance, and speed.

D. Procedure

Each study session was administered by one clinician and two research assistants. At the start of the study, the parents reviewed and signed an informed consent form and completed a demographics survey and a pre-study survey, as further explained in Section III-E. Before the start of a session, cones were laid out in a straight line at 5ft (1.5m) intervals to the side of the participant's walking course, ending at 50ft (15.2m) away. During intervention phases (B1 and B2), GoBot was placed alongside the child prior to beginning the session. A Canon camera recorded a front view while a GoPro Hero Black 7 recorded a side view. Four ActiGraph GT9X Link sensors were placed on the right and left ankle, right wrist, and hip of the child.

During the session, the child was tasked to race alongside either a clinician or research assistant (in baseline sessions) or GoBot (in intervention sessions) to the end of the cones. Each time the child reached the end of the cones, we noted a completed lap. At the end of each lap, we asked the child if they wanted to immediately turn around and start a new lap or take a break. During each lap, the child could request direct physical assistance from the clinician or parent in the form of holding one hand. A researcher noted the duration of each lap using a stopwatch. The researcher also recorded if the lap was completed independently or was assisted at any point by a clinician/parent. During the intervention phases, a researcher teleoperated GoBot to race alongside the child and used its features to encourage them to walk faster than the robot. Figure 2 shows a schematic of the study setup. Each session lasted 30 minutes.

At the end of a session, the sensors were removed from the child. Parents completed the post-session survey and were compensated $15 for each session. At the end of the study, parents completed the post-study survey. (These surveys are further explained in Section III-E.)

E. Measurements and Analysis

Measurements collected included *movement* data and *self-report* data. For each movement-based measurement, the data was analyzed for trends between baseline and intervention phases and the log response ratio (LRR) was calculated to compare each baseline and intervention phase. The LRR compares the intervention phase mean (M_t) to its preceding baseline phase mean (M_b) using the following equation:

$$LRR = ln(\frac{M_t}{M_b}) \quad (1)$$

LRR is commonly used in single-case work across domains such as ecology [24], special education [25], and behavioral psychology [26] to show changes in a measurement between the baseline and intervention. A positive LRR value indicates an upward trend for the measurement, an LRR value of zero marks no change, and a negative LRR value indicates a decline in the trend for the measurement. Larger LRR values represents a larger change between phases. For each of the movement-based measurements, we calculated the LRR value for the first intervention phase against the first baseline phase (i.e., B1 to A1; identified as LRR_1) and the second intervention phase against the second baseline phase (i.e., B2 to A2; LRR_2). We report each individual LRR value, as well as the overall mean LRR (LRR_M).

1) Movement-Based Measurements: This data included a count of ankle movements (calculated from the ActiGraph data recordings), the total distance of independent walking (transcribed during study sessions and later checked), the number of completed independent laps (live transcribed and checked), and the average duration of independent laps from each session (live transcribed and checked), as further elaborated below.

Ankle Movement Counts came from ActiGraph sensor data that was processed through an algorithm in related work [27] to compute a count of events that were likely

be *ankle movements*. We first used ActiLife v6.13.4 software to extract the recorded accelerometer and gyroscope data from the ActiGraph sensors. In this work, we focused on analyzing only the ankle sensor recordings since we were most interested in walking movement. The algorithm operates by first calculating the root mean square (RMS) acceleration and angular velocity from the raw ankle sensor recordings and then filtering the output by rejection ranges clarified in the related work [27]. After incorporating a 0.5-second window moving average filter, the algorithm identified an ankle movement starting when both the acceleration and gyroscope thresholds were exceeded and ending when the gyroscope data dropped below the associated threshold. We used the algorithm to calculate the total count of ankle movements for each session, including movement during both independent and assisted laps.

Independent Walking Metrics (i.e., total amount of independent walking, number of completed independent laps, and average duration of independent laps) came from live transcription during the study sessions by a researcher who actively monitored each lap. This live transcription data was then reviewed post hoc using video recordings; a video coder work with the original note-taker to ensure a 100% match rate in the coding. For both coding rounds, each lap was marked as completed fully independently (i.e., no physical assistance while walking) or assisted (i.e., holding one or both of the clinician's hands while walking). We only considered laps that were completed fully independently by the participant in the coding, as the the child's goals centered on amount and speed of independent walking specifically. We calculated the total amount of independent walking (in ft) by multiplying the number of laps completed fully independently by the length of the walking course (50ft). We also tallied the total number of fully completed independent laps for each session and calculated the mean duration of the fully independent laps during each session (in seconds).

2) Self-Reports: These inventories included demographic questions, pre-/post-study surveys, and a post-session survey.

Demographic questions collected child age, gender, diagnoses, and if the child was able to walk or crawl.

The pre-study survey included the following:

- All three components of the Negative Attitudes towards Robots Scale (NARS) [28], which the parents responded to using Likert-type scales from Strongly Disagree (1) to Strongly Agree (7).
- Trust Perception Scale-HRI (TPS-HRI) subscale items [29] rated as a percentage from 0 to 100. We used the 14-item abridged version.
- Free-response questions asking about the parents' prior experiences with robots.

At the end of each session, parents completed a survey which included Likert-type questions relating to the child's experience during each session. Specifically, parents answered the following custom Likert-type questions after every session:

- "How excited was your child today?" from Very Calm (1) to Very Excited (7)
- "What was the enjoyment level for your child?" from Very Unhappy (1) to Very Happy (7)
- "How well do you think your child interacted with others?" from Very Poor (1) to Very Well (7)

For intervention sessions with the robot, parents also answered the following Likert-type and free response post-session questions about their perception of the robot:

- "Do you think your child was engaged with the robot throughout the session?" from Strongly Disagree (1) to Strongly Agree (7)
- "Do you think robots can be useful to improve the well-being of children?" from Strongly Disagree (1) to Strongly Agree (7)
- "How do you think robots can be used to improve the well-being of children?"
- "In general, how did your child interact with the robot throughout the session?"
- "In general, what was your perception of the robot used in this session?"

At the end of the study, parents completed the same NARS and TPS-HRI survey items with additional questions asking about their final perceptions of the assistive robot.

IV. Single-Subject Study Results

The participant completed all 12 sessions and the assistive robot was fully functional for every intervention session. In this section, movement-based results are presented first, followed by self-report results. ActiGraph sensor results for session 8 were lost due to a recording error.

A. Movement-Based Results

The results of the study show that the child tended to increase their amount of independent walking throughout the study. Figure 3 shows the results for each measurement while Table I shows the LRR outcomes for each baseline and intervention phase combination. The participant completed at least one independent lap in every session. Although ankle count (including independent and assisted steps) results showed a decrease during the first intervention phase with the robot, independent walking distance generally increased during the first intervention phase's sessions. Step counts were generally high during the second half of the study, and LRR results showed a repeated increase in independent walking distance for the second intervention phase (when compared with the second baseline phase), although the second LRR value was not as high. The independent lap results closely mirrored the independent walking distance results. The highest number of completed laps occured during session 10 (a robot intervention session). Results also elucidated that the participant sped up their average duration of independent laps in the second half of the study. The child's fastest independent laps occurred during session 10, with the robot.

B. Self-Report Results

Self-report results for the per-session surveys are shown in Fig. 4. The parents tended to rate the child's excitement, enjoyment, and interaction level as above average for most

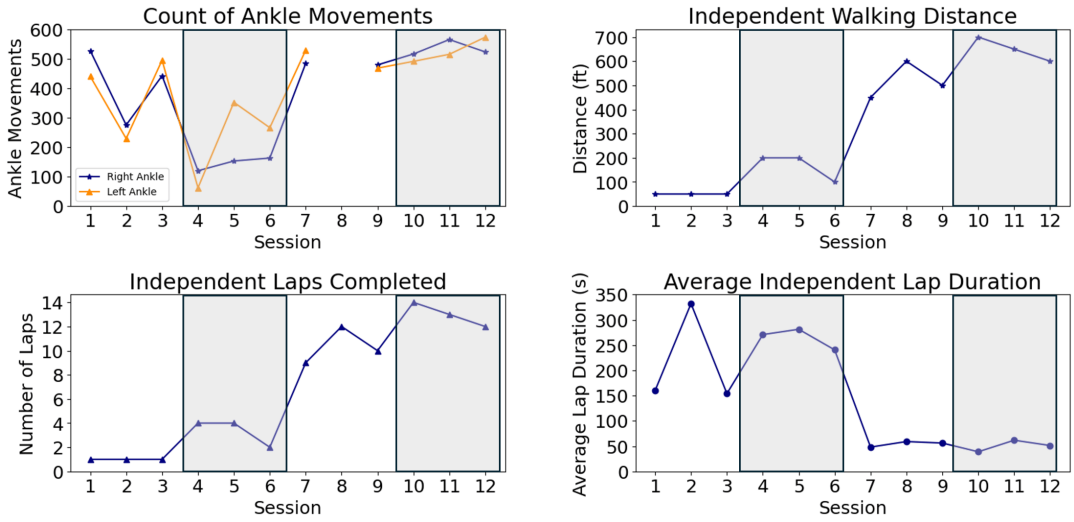

Fig. 3: Movement results by session, including the count of ankle movements, distance of independent walking, completed independent laps, and average duration of completed independent laps. The participant completed at least one independent lap in every session. The shaded area denotes the intervention phases.

TABLE I: Log response ratio (LRR) results, where a positive value indicates a higher intervention value (compared to the preceding baseline). Shaded values specify large increases in child movement (i.e., LRR > 1).

Measurement	LRR_1	LRR_2	LRR_M
Ankle Movements	-0.77	0.08	-0.20
Independent Walking	1.20	0.23	0.36
Independent Laps	1.20	0.23	0.36
Fastest Lap	0.2	-0.07	0.15

sessions, with the exception of session 3. Overall, the parents rated the child as being very engaged during intervention sessions with the robot ($M = 6.7$, $SD = 0.5$). For the NARS questionnaire, there was no change in the average ratings between the start and end of the study for the interaction component ($M = 3.6$, $SD = 0.9$ before; $M = 3.6$, $SD = 1.1$ after). There tended to be a decrease in ratings for the social component ($M = 3.3$, $SD = 1.1$ before; $M = 3$, $SD = 0$ after) and an increase in the emotional component ($M = 2.3$, $SD = 0.8$ before; $M = 3.3$, $SD = 0.8$ after). A decrease in ratings for each component of the NARS would indicate that the parent tended towards a more positive attitude towards robots for that component. Trust ratings tended to stay the same between the start and end of the study ($M = 78.0$, $SD = 11.4$ before; $M = 77.0$, $SD = 9.5$ after). Free-text responses from the parents offer insights into interactions with the robot. The parents noted that "[he] seemed more interactive with [GoBot] and I understand why because of mobility" and "[GoBot's] movement, lights, and bubbles kept him more engaged." For the final session, the parents responded that "he appeared to be competitive during racing and attentive during interactions."

V. Exploratory RLGL Interaction

Although we were able to evaluate walking amount and speed using the single-subject-style study, this interaction did not provide much of an ability to study motion control, another important part of motor development and practice.

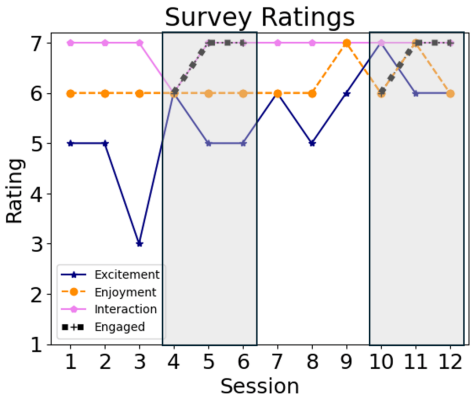

Fig. 4: Self-report results by session. Results include parent ratings of excitement, enjoyment, interaction, and engagement with the robot. Engagement questions were only distributed during intervention sessions.

Accordingly, we added a brief (exploratory) RLGL interaction to the close of intervention sessions as a way to begin to assess this interaction's viability for motor control practice. We chose to use RLGL for this child based on a collaborative discussion between the researchers, clinicians, parents, and child. The game includes a high stimulus-response agreement between green means "go" and red means "stop" while also encouraging starting and stopping movement control.

A. RLGL Interaction Methods

At the close of the intervention sessions, we presented the participant with the opportunity to play RLGL with the robot.

Gameplay Procedure: The participant could play RLGL with GoBot for up to five minutes (i.e., one or two games' duration). We placed GoBot 20ft (6.1m) from the starting mark and a researcher started the autonomous game mode, as further described in the next paragraph. Figure 5 demonstrates the setup for the game.

GoBot's RLGL game mode involved three states: *green light*, *red light*, and *game win*. Typically, the green light

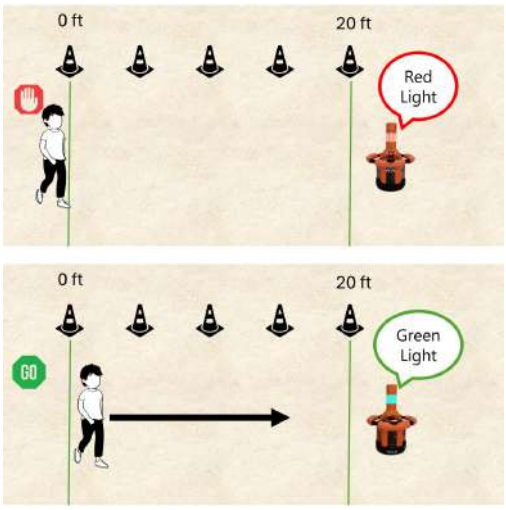

Fig. 5: Schematic of the exploratory RLGL setup.

and red light states alternated until the child reached the robot and pressed the robot's big red button, which activated the game win state. The green light state involved the robot turning away from the participant (i.e., the googly eyes looked away) while flashing the green lights, and saying "green light" out loud. In the red light state, the robot turned to face the participant, flashed the red lights, and said "red light" out loud. Based on the typical rules of the game, the child needed to move toward the robot during the green light state and to stop moving during the red light state. Both states alternated with a random duration in the range of 3-5 seconds. The game ended when the child pressed the robot's onboard button during a green light state. At that point, the robot indicated that the game was complete by flashing the green lights, blowing bubbles, and playing a cheering sound. The leftmost panel of Fig. 1 shows the robot in the red light state.

Measurement: During the RLGL game, a researcher took field notes which included observations, the number of times the game was played, and the percentage of games in which the child walked independently.

B. RLGL Interaction Results

Results from playing RLGL are shown in Table II. The child completed the game at least once every intervention session and displayed an understanding of the game by stopping and starting during the correct game states. In session 10, the child asked to play the game a second time before the session ended and walked independently during all time spent playing the game. The parents noted "his best interaction was during red light/green light" in session 10. Anecdotally, we also observed that the child would make a "stop" gesture with his hand during the red light phase and would point forward during the green light phase while making a train engine sound.

VI. Discussion

In this work, we evaluated how GoBot could motivate a child with a motor disability to independently walk more and faster by engaging in lightly competitive races. We found that the robot tended to encourage the child to independently walk more and faster, especially during the second half of the study. The largest change in independent movement was between sessions 6 and 7, perhaps due to an additional family member being present at session 7. However, the child continued to improve their levels of independent movement for the rest of the study, and the highest amount of independent movement/fastest independent lap overall occurred during session 10 with GoBot. The parents observed that their child was more engaged during intervention sessions and seemed motivated by the robot's reward features and mobility.

TABLE II: RLGL results from intervention sessions. The RLGL game was played at least once during each intervention session. For each session, the number of games played and the percentage of independent walking during the game was noted. Shaded cells denote sessions where the child played RLGL independently at least once.

Session	Games Played	% Independent
4	1	0
5	1	0
6	1	0
10	2	100
11	2	50
12	1	0

The RLGL game offered a different interaction premise to continue encouraging independent walking and balance. The child demonstrated an understanding of the game and asked to play a second time in sessions 10-11. The nature of RLGL encourages stopping and starting, which helped the child to practice balancing and starting to walk again. The presence of the button on the robot provided a clear goal for the child and facilitated celebration through bubbles and lights once the game was won. The majority of games played involved assisted movement, which may have been a result of the child being tired at the end of a session. There was no baseline comparison made against RLGL so further study is warranted to understand how the robot-mediated RLGL experience compares to other analogous experiences. The flexibility of GoBot to incorporate novel reward modules and different types of gameplay enables a plethora of interaction paradigms for children with unique needs.

A key *strength* of this work is its multi-month duration and preliminary demonstration that an assistive robot could motivate a child with a motor disability to independently walk more and faster. The robot races seemed to offer light competitiveness and encourage the child to move faster through the robot's mobility and rewards. A second strength is that the RLGL mode demonstrated that different robot paradigms can potentially motivate a child to work towards different goals, such as improving balance. A *limitation* of this study was the small sample size. The single-case design provided unique insights into this specific child's progress throughout the study, but further study with larger samples is needed to generalize the results. A second limitation is that we did not use any assessments such as the GMFCS [30] or collect self-reports from the child directly. Future work with this robot may include a focus on children with cerebral palsy, a more common developmental disability, and in gameplay

sessions with multiple children (i.e., group play).

We set out to understand whether an autonomous assistive robot could promote more independent walking for a child with a motor disability who was already walking. We conducted a longer-term successful single-case study and showed that the robot tended to motivate more and faster movement during robot races. Additionally, we found that the child understood and enjoyed playing the RLGL game with the robot during exploratory interactions, demonstrating potential for a future study focused on improving the child's balance, cognitive, and social abilities with RLGL. We encourage others in the assistive robotics space to consider ways that robots can help children to "start their engines" and play.

Novel method for setting population-specific joint torque assistance requirements with applications to exoskeleton design

Stijn Hamelryckx [1,3], Christopher van Vlerken[1,3], Louis Flynn[1,3], Mengnan Wu[1], Bram Vanderborght[1,2] and Tom Verstraten[1,3]

***Abstract*— This paper presents a novel methodology to calculate assistance requirements for wearable robotic devices (e.g., exoskeletons) using Maximum Voluntary Contraction (MVC) measurements. While other methods for determining assistance requirements focus on the kinematics and kinetics of specific tasks to be performed, our method determines the assistance needed for a population to reach the overall physical capabilities of another reference population. While applicable to any joint and population, we demonstrate its effectiveness on the lower limb joints of older adults. Unlike conventional methods that assume the need to provide 100% of the peak torque during the assisted task, our approach calculates the required assistance and identifies a 20–25% torque deficit for setting assistive torque requirements. This discrepancy underscores the importance of addressing the physical deficits of its users when designing assistive devices. As our method provides torque deficit as a function of joint velocity, the characteristics of the actuator can be chosen to match these deficits. Additionally, as the torque deficit is described as a function of joint angle, non-linear transmissions can be designed in future actuation systems of assistive wearable devices.**

Index Terms - Exoskeletons, Assistance Requirements, Elderly

I. Introduction

Exoskeletons can provide assistance or resistance to a specific human joint by applying an external torque. By doing so, exoskeletons can either assist, train, or augment a specific part of the wearer's body [1]. For the elderly, exoskeletons can allow the patient to maintain a high quality of life no matter the stage of muscle deterioration and can also be used for resistive training to slow down the rate of muscle mass loss.

The design of wearable robotic devices (e.g. exoskeletons) should consider both the intended use cases as well as the capabilities of the user [2]. For users with strength or mobility impairments, exoskeletons can provide assistive torque to a user's joints to help them accomplish various tasks. To maintain a high quality of life, the exoskeleton should support all important activities of daily life (ADLs), which are usually considered to be (slope)walking, stair ascent and descent, and sit-to-stand transitions [3]. Many diverse populations can benefit from wearable assistive devices, including persons who have had spinal cord injuries or strokes. As these populations have very different physical capabilities and assistance requirements [1], exoskeleton designers should more thoroughly understand the physical capabilities of the wearer in order to correctly dimension the actuator system and minimize the overall weight and size of the exoskeleton.

However, no systematic method exists to determine joint torque assistance level, which is important for actuator selection. Common practice [4][5][6] for calculating torque assistance levels is to take an arbitrary percentage of peak torques extracted from kinematic and kinetic datasets for specific populations and activities (e.g. [7] and [8]). Limitations of this method are that it assumes the same percentage deficit to all joints and does not consider the effect of joint angle and joint velocity on the torque generating capacity of the joint [7]. An alternative method [9] selects the actuator based on task requirements, but it does not consider the wearer's abilities. Another alternative method [10] proposes using simulations to determine assistance requirements, where muscle deficit is simulated by reducing the maximal isometric strength by an arbitrary percentage. However, since these deficits are simulated, it is uncertain if they represent actual populations. Furthermore, the muscle deficit is assumed to be the same for each muscle and exertion direction.

To address gaps in current methods for determining assistance levels, [5] proposes a methodology that takes into account both the wearer and task. They collect kinematic and kinetic data and calculate inverse dynamics to determine the joint torque during a specific task. This task-specific joint torque is compared with existing data on the maximum voluntary contraction (MVC) - a measure of the maximum force a muscle can generate during a voluntary contraction [11] - to understand how close to their physical limit the user is during the task. While this approach is promising, [12] showed that the MVC depends on joint angle and joint speed, which are not considered in [5]. Comparing task joint torques to MVCs without considering joint angle and speed can result in a significant overestimation of the person's physical "reserve." Furthermore, the torque-generating capacities of flexor and extensor muscles are asymmetric, highlighting the importance of understanding the biomechanical characteristics of the studied population [13].

In this paper, we propose a novel method to calculate joint assistance torque requirements for a wearable robotic device based on user capabilities that can be applied to any set of activities/tasks. We propose using MVCs measured at

[3]Flanders Make, 1050, Brussels, Belgium.

multiple joint angles and velocities and extrapolating them for the entire range of motion of interest based on the model developed in [12]. This model provides the peak joint torque as a function of joint angle and velocity. Our method differs from the one described in [5] as we do not use kinematic or kinetic data from a specific task. To demonstrate our method, we determine assistance requirements for a target population of unimpaired older adults with unimpaired young adults as the reference population.

II. Methods

Our method calculates joint torque assistance requirements to aid in actuator selection for a wearable assistive device. Torque deficits are calculated as differences in peak torques between a target and reference population across a range of joint angles and velocities. For this study, unimpaired younger adults were selected as the reference group and unimpaired older adults as the target group, but our methods can be used to compare any two populations. Unimpaired young adults were chosen as a reference group since this population has peak muscle mass and the highest level of locomotion capabilities [14].

We chose the range of joint angles and velocities based on common activities of daily living (ADLs) (I). Two sets of ADLs were considered for two cases of wearable assistive devices that support different levels of quality of life. The first case includes all movements for a high quality of life [3]: (slope)walking, stair ascent/descent, and sit-to-stand transitions. The second case includes only stair ascent/descent to allow comparison of our results to that of [5], which only examined these two tasks in unimpaired elderly adults.

TABLE I

Joint velocity and joint angle ranges for activities of daily living/stair ascent and descent used in the model based on kinematic data [8][7].

	Min velocity (°/s)	**Max velocity (°/s)**	**Min angle (°)**	**Max angle (°)**
Ankle	-225/-225	350/175	-30/-30	40/30
Knee	-500/-450	500/450	0/10	110/110
Hip	-250/-125	250/225	-20/-10	80/65

We obtained MVC measurements for our chosen populations from the dataset in [12]. The dataset was collected from 14 unimpaired younger adults (mean +/- SD ages: 19.6 +/- 1.2 years, weight: 67.5 +/- 8.6 kg, height: 167.7 +/- 8.7 cm) and 6 unimpaired elderly adults (mean +/- SD ages: 70 +/- 2.9 years, weight: 75.4 +/- 13.6 kg, height: 168 +/- 9 cm) with equal gender distributions for both populations. MVCs were measured using a Biodex System 3 dynamometer (Biodex Medical Systems , Inc. Shirley, New York, USA). Isometric and isokinetic measurements were performed on the hip, knee, and ankle. Isometric measurements were performed at six joint angles in both exertion directions (e.g. flexion and extension), with two repetitions per angle and direction. Concentric isokinetic measurements were performed at three velocities (60, 120, and 500 deg/s for the hip and ankle; 75, 150, and 500 deg/s for the knee). Eccentric isokinetic measurements were performed at one velocity (60 deg/s for the hip and ankle; 75 deg/s for the knee). Four repetitions were performed for each velocity and joint.

We input the MVC measurements to the model developed by [12] to obtain peak torques for each population across a range of joint angles and velocities. The torque model splits total torque into passive and active components [12]. The passive torque is based on exponential equations [15], while the active torque is based on the Hill model [16]. The model [12] uses MVC measurements as inputs and outputs peak torques (Equation 1 and 2). The active torque is found by: For $\dot{\theta} \geq 0$:

$$T_{Active}(\theta, \dot{\theta}) = C_1 \cos(C_2(\theta - C_3))\zeta(\dot{\theta}) \tag{1}$$

For $\dot{\theta} < 0$:

$$T_{Active}(\theta, \dot{\theta}) = C_1 \cos(C_2(\theta - C_3))\zeta(\dot{\theta})(1 - C_6\dot{\theta}) \tag{2}$$

With:

$$\zeta(\dot{\theta}) = \frac{2C_4C_5 + |\dot{\theta}|(C_5 - 3C_4)}{2C_4C_5 + |\dot{\theta}|(2C_5 - 4C_4)} \tag{3}$$

The model has six parameters, each of which has a physical interpretation. C_1 is the isometric peak torque (Nm/kg). C_2 is equal to $\frac{\pi}{\theta_{active}}$, where θ_{active} is the range of motion where active muscle force generation occurs. C_3 is the joint angle (radians) at which the peak torque occurs. C_4 and C_5 are the velocities (rad/s) at which the torque is 75% and 50% of the isometric peak torque, respectively; these parameters influence the velocity behavior of the model. Finally, C_6 is the ratio of eccentric to concentric torque, where a positive value indicates that the eccentric torque is higher than the concentric torque. We used mean C_i parameters from [12].

We calculated torque deficits of our target population - unimpaired elderly adults - by subtracting their peak torques from that of the unimpaired young adults. We also calculated power deficits as a function of joint angle, since power requirements are important for dimensioning the actuator of the wearable assistive device and its potential battery pack. To find the maximum power deficits for each joint angle, the following formula was used:

$$\delta P(\theta) = max(\delta T(\theta, \dot{\theta}_i)\dot{\theta}_i) \tag{4}$$

Power deficit ($\delta P(\theta)$) was found by multiplying the torque deficit ($\delta T(\theta, \dot{\theta}_i)$) by its corresponding joint velocity at each joint angle.

Torque and power deficits were calculated for males and females separately in case of gender effects. To compare our results to the common method of choosing an arbitrary percent torque deficit, the average torque and power deficits were divided by the peak torque of young adults, to find the percentage of deficit that occurs in unimpaired older adults.

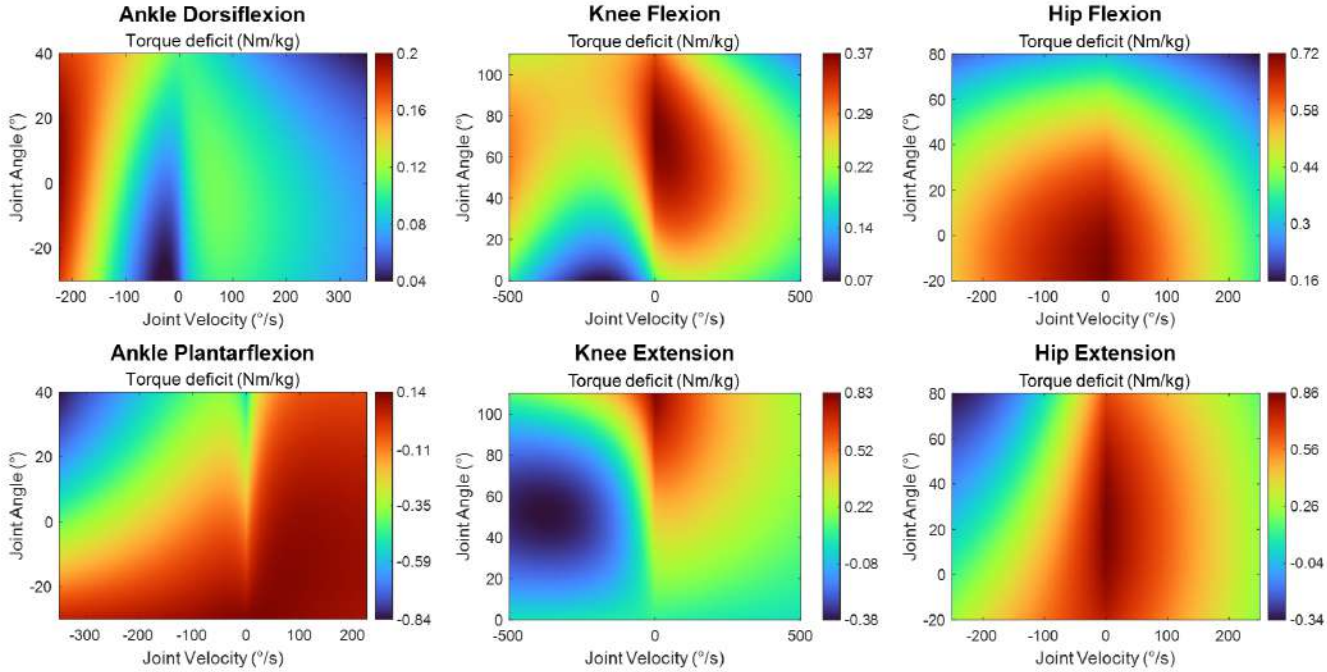

Fig. 1. The average torque deficits (normalized by body weight) as a function of joint angle and joint velocity for female unimpaired older adults across different exertion directions. The peak torque occurs at different joint angle and joint velocities for different exertion directions.

III. Results

A. Assistance requirements for older adults across activities of daily living

Our method yields different torque deficits for older adults depending on exertion directions (Fig 1). The largest deficit for dorsiflexion occurs at eccentric joint velocities at a joint angle of 5°. The largest torque deficit in plantarflexion is during concentric joint velocities and remains constant across joint angles. For both flexion and extension of both the knee and hip, the main deficit occurs at lower joint velocities, near the isometric condition. Peak deficits appear at joint angles of 70° and 100° for knee flexion and extension, respectively, and at -15° and 20° for hip flexion and extension, respectively. Although some values are different from previous work [17], our torque deficits are generally similar to previously reported ranges. We show torque deficits of 0.14 Nm/kg for ankle dorsiflexion whereas [17] found a deficit of 0.11 Nm/kg (torque normalized reported mass) for isokinetic MVC measurements. Ankle plantarflexion has a torque deficit of 0.23 Nm/kg while [17] reported 0.67 Nm/kg. Hip extension and flexion show torque deficits of 0.66 Nm/kg and 0.48 Nm/kg, respectively, compared to a reported deficit of 0.96 Nm/kg and 0.56 Nm/kg in [17]. Finally, the torque deficit in knee extension and flexion is 0.69 Nm/kg and 0.35 Nm/kg, respectively, compared to 0.93 Nm/kg and 0.51 Nm/kg from [17].

Older adults exhibit a reduction in torque capacity (positive torque deficit) across most joint angles and velocities compared to younger adults. However, a negative torque deficit—indicating greater torque capacity in older adults than in younger adults—is observed for eccentric torques in ankle plantarflexion, knee extension, and hip extension.

TABLE II

Power and torque deficits averaged across genders (n=6), considering all activities of daily living. Deficit values are normalized by peak values for young adults.

	Relative power deficit (%)	Relative torque deficit (%)
Ankle dorsiflexion	19.4	21.6
Ankle plantarflexion	11.3	12.9
Knee flexion	22.0	21.6
Knee extension	17.1	25.8
Hip flexion	20.8	23.4
Hip extension	13.5	22.9

Our trends for power deficits are sometimes different from those for torque deficits, especially for the hip and knee joints. For the ankle, both the highest torque and power deficits occur in the same exertion direction. However, for the hip and knee, the greatest torque deficit occurs in extension while the highest power deficit occurs in flexion; this is due to the fact that, at higher velocities, changes in velocity contribute more to power than changes in torque. Overall, maximum joint power deficits (Fig. 2) and joint torque deficits (Fig. 1) generally occur at similar joint angles. However, for the hip and knee, the highest maximum power deficits occur in flexion (60°) while the maximum torque deficits are observed in extension (100°). Similarly, the peak hip power deficit occurs at -15°, whereas the peak torque deficit occurs at 20° (Fig. 1). Average peak joint power

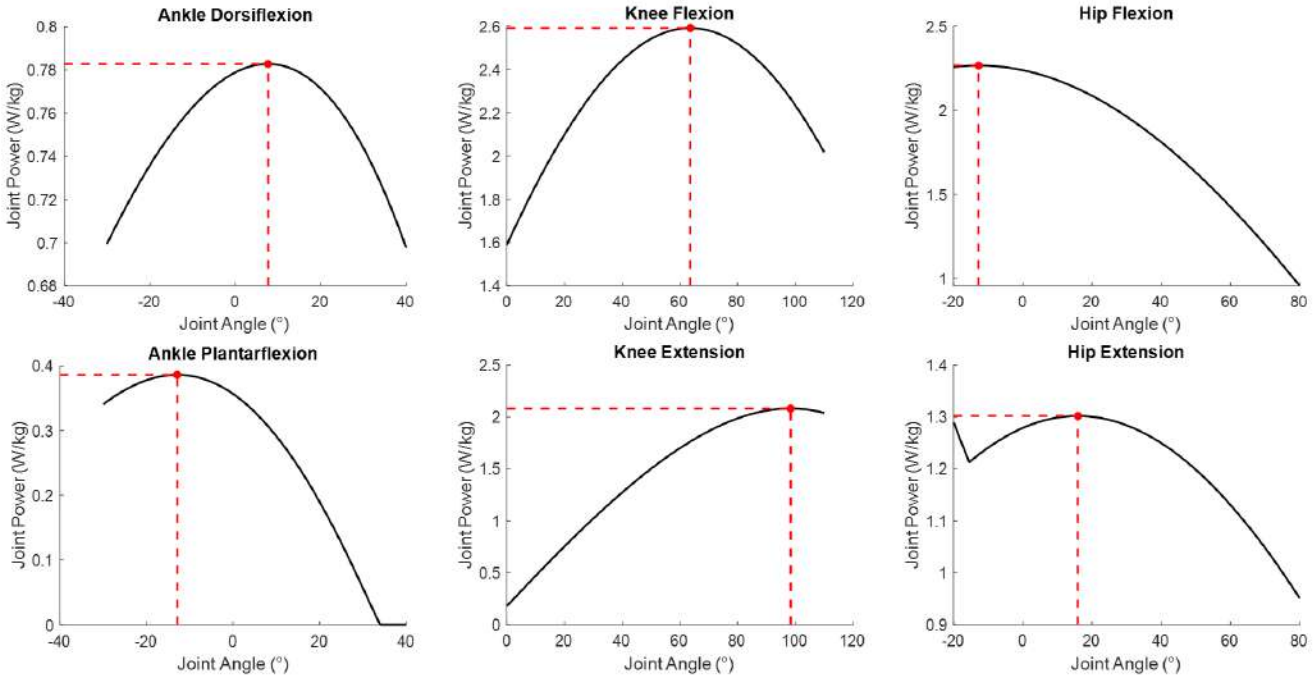

Fig. 2. Average joint power deficits (normalized by body weight) as a function of joint angle and joint velocity for female unimpaired older adults (n = 3) for different exertion directions. The red dot indicates the peak joint power deficit.

deficits are 1.2 W/kg for the ankle (which occurs during plantarflexion), 1.6 W/kg for the hip (during flexion), and 2.6 W/kg for the knee (during flexion).

Our results for power deficits also suggest potential sex-based differences (Table III), with females tending to exhibit higher deficits than males in both hip extension and flexion, consistent with the findings of [18]. Conversely, males tend to have a higher power deficit in ankle plantarflexion. Overall, for most joints and exertion directions a torque deficit of 20-25% was found (Table II). However, the deficit in plantarflexion was significantly lower at around 12%.

B. Assistance requirements for stair ascent and descent

TABLE III

AVERAGE MAXIMUM POWER DEFICITS FOR UNIMPAIRED OLDER ADULTS FOR EACH EXERTION DIRECTION FOR STAIR ASCENT AND DESCENT.

Joint Power (W/kg)	Female	Male	Average
Ankle Plantarflexion	0.39	0.91	0.65
Ankle Dorsiflexion	0.78	0.17	0.48
Hip Extension	1.3	0.76	1.0
Hip Flexion	2.2	0.71	1.5
Knee Extension	2.1	1.8	1.9
Knee Flexion	1.9	2.0	1.9

Power deficits for stair ascent and descent (Table III) are lower compared to those for all tasks required for a high quality of life, while torque deficits were similar for both cases. Our torque deficits are similar to values from [5]:we found a deficit 0.22 Nm/kg while they they found peak deficits of 0.2 Nm/kg in plantar flexion. While we found a deficit of 0.68 Nm/kg, they found a deficit of 1 Nm/kg in knee extension. For joint power deficits, we found a maximum deficit of 0.65 W/kg where they found 1 W/kg for ankle plantar flexion. Lastly, we found a power deficit of 1.9 W/kg for knee extension which they also found.For the hip, our results suggest that assistive power of 1.5 W/kg could be beneficial for older adults while results from [5] suggest that no assistance is needed. During stair ascent and descent, peak hip extension torque (0.8 Nm/kg) occurs at a joint velocity of 125 °/s and joint angle of 35°. The peak torque that an older adult can supply at this joint velocity and joint angle is 1.2 Nm/kg while young adults have a peak torque capability of 1.5 Nm/kg. Thus, older adults have less torque ”reserve” than younger adults at the point where peak hip extension torque is required.

IV. DISCUSSION

The validity of our method is supported by the agreement of our results with previous work [17][5]. Our torque deficits are similar to previously reported ranges, except for the ankle. A large plantarflexion deficit of 39% was reported in [19], but the older adults in the dataset we used [12] participated in a high level of physical activity (2-4 times per week) and were 5 years younger, on average, than the ones in [19]. As expected, older adults exhibit a reduction in torque capacity (positive torque deficit) across most joint angles and velocities compared to younger adults. The negative torque deficits we found may be due to the combination of relatively high eccentric torque capabilities in the elderly with substantial variability in MVC measurements and warrants further investigation. Our results show a lower magnitude

of torque deficits in eccentric contractions, aligning with the result that eccentric torque capacity is better preserved than concentric torque capacity in older adults found in [20].

Our results suggest that traditional approaches for estimating assistance requirements may lead to an overdimensioned actuation system, particularly for certain populations. While it is common practice to determine assistive torque requirements based on the kinetic demands of specific tasks, our approach quantifies the torque deficit of the user for each joint across any chosen tasks. Conventional methods typically result in torque requirements equivalent to 100% of the peak torque observed in the most demanding task [4]. In contrast, our findings indicate much smaller torque deficits of 20-25%.

Although they considered a different population, our results suggest that the assumption of equal deficits for all muscles in [10] is not valid. While most joints and exertion directions have similar deficits, ankle plantar flexion has a much lower deficit. This finding would heavily influence the exoskeleton design described in [10] and shows the importance of detailed knowledge of the effects of the impairment on joint deficits.

While the state-of-the-art method [5] determines assistance requirements based on torque required to perform a specific task in the same *manner* as a reference population, our more general method determines the assistance required for a reference population to reach the maximum physical *capabilities* of a reference population. The previous study [5] calculated assistance required for older adults to perform specific activities (with set combinations of joint angles and velocities) similar to young adults, while our method calculates the assistance required for any target population to reach the same physical capabilities as a reference population across joint angle and velocity combinations that can be chosen based on any activities. For stair ascent and descent, our results are generally similar to those of [5], except for the hip joint, where our results reveal potential benefits of assistance while the task-specific method does not show any assistance required. Furthermore, while their method requires time-series kinematics and kinetics measurements for each activity considered, our method requires only MVC measurements and allows the designer to select the range of joint angles and velocities based on any set of activities.

Another major advantage of providing torque deficit as a function of joint angle and joint velocity is that it allows the design of actuator systems for an assistive device to be matched to the specific characteristics of the user's deficit. By doing so, the actuator size can be reduced by allowing the actuator system to have a higher peak torque for a specific joint angle where it is needed and a lower peak torque but higher velocity for a different region of the ROM [21]. This type of design has already been used in prostheses, where the stiffness of the knee changes for different joint angles [22]. Our results may help optimize non-linear transmission systems, similar to what was observed in simulations from [23]. Non-linear transmission mimics human biological muscles, where the torque output of the muscle depends on the joint angle [24].

Demonstrating how our method can be used to set assistance requirements for an example population, our results show that a wearable lower limb assistive device for unimpaired older adults should be able to provide a peak ankle joint power of 1.2 W/kg, knee joint power of 2.6 W/kg, and hip joint power of 1.6 W/kg. Additionally, we found that the peak power and torque deficits for the hip and knee occur at different joint angles, which suggests the benefits of non-linear transmissions at these joints.

The choice of a reference group depends on the design intentions of the wearable robotic device. The designer can always opt for young adults as a reference population, envisioning an exoskeleton that would give the wearer ideal locomotion capabilities. Alternatively, for an example target group of sarcopenia patients, a reference group could be non-sarcopenic older adults to match the capabilities of a similar age group. An example of a slightly different approach to selecting "groups" in stroke patients could be to choose the target and reference "groups" as datasets from the paretic and non-paretic legs, respectively, of the same individuals. This would result in an exoskeleton that creates symmetric capabilities for both legs.

Two limitations of our method are that it cannot be used to control the assistive devices without additional information, and that MVC measurements are known to be variable due to factors such as encouragement [25]. Developing a controller based on our method requires additional kinematic and kinetic information on the wearer's task. One way to incorporate our method into a controller is by determining the assistance level based on the 'relative torque deficit.' This relative torque deficit is the torque deficit calculated by our method divided by the maximum torque capability of the reference population for a given joint angle and joint velocity. The relative torque deficit needs to be combined with kinetic data of the task to create a controller where the assistance level varies based on the amount of deficit a person has for a specific joint angle and joint velocity. MVC measurements are known to be variable, depending, for example, on encouragement to the person measured and variations between days. Best practices for collecting MVC measurements should be followed according to [25].

Finally, our results suggest potential differences in power deficits between males and females. However, as the dataset of unimpaired older adults utilized in this study includes only six participants (three per gender), this trend should be validated in a larger sample population.

V. Conclusion

In this study, we developed a novel methodology to set assistance requirements for exoskeletons based on physical capabilities. This method uses MVC measurements and was demonstrated on unimpaired older adults. We found that our results match previously found deficits from [17] and [5]. From our method, the torque deficit of healthy elderly

was found to be around 20-25%, contrary to traditional methods taking 100% of the peak torque of the task requiring assistance. This difference highlights the importance of understanding the underlying deficit of the user of the assistive device for the dimensioning of its actuator system. As our method provides torque deficit as a function of joint velocity, the characteristics of the actuator can be closely matched with those of the measured deficit. Additionally, as our method provides information on the deficit as a function of joint angle, non-linear transmission systems can be exploited to further reduce the size and weight of the actuation system. Our method found that the main power deficit at the ankle is in plantarflexion and is 1.2 W/kg and a peak torque deficit 0.23 Nm/kg. For the knee, flexion needs most assistance and has a power deficit of 2.6 W/kg and a torque deficit in extension of 0.69 Nm/kg. Finally, the hip has a main power deficit in flexion with 1.6 W/kg while the main torque deficit is in extension with a deficit of 0.66 Nm/kg. Due to the small sample size, the found results cannot be generalized over the entire healthy elderly population. However, the method shows promising trends that warrant further investigation in future research. This methodology can be used for any population and any joint.

A powerful customized fabric-based soft robotic glove for assistance and rehabilitation

Rui Chen[1*], Daniele Leonardis[1], Antonio Frisoli[1], and Domenico Chiaradia[1]

***Abstract*—Soft robotic gloves assist stroke patients in restoring hand function, and improve their ability to perform activities of daily living (ADLs). This study introduces a powerful, customized, fabric-based soft robotic glove designed for assistance and rehabilitation. The pneumatic fabric actuators were customized to achieve a configuration that aligns with the natural curvature of the flexed fingers when inflated. This ergonomic design ensures that the actuators provide precise and efficient torque assistance to the finger joints. Experimental results demonstrate that the glove actuator produces a block tip force of 19.1 N at 100 kPa. Moreover, at 97 kPa, the 73 g glove can grip an object weighing 3126 g, highlighting its robust assistive capabilities. Finally, preliminary tests conducted with healthy subjects performing grasping tasks showed that the soft glove effectively supports users in their daily activities.**

***Index Terms*—soft robotic glove; pneumatic actuator; hand assistance, exoskeleton.**

I. Introduction

Neurological disorders, such as stroke [1], incomplete spinal cord injuries [2], and muscular dystrophy, significantly impair hand functionality, often leading to the partial or complete loss of the ability to perform essential activities of daily living (ADLs) [3]. These conditions not only affect an individual's independence but also have a profound impact on their overall quality of life [4]. Consequently, effective rehabilitation strategies aimed at restoring hand function are critically needed. In this context, robotics has emerged as a promising field, offering innovative solutions that facilitate rehabilitation and provide controlled assistance to help patients regain functional capabilities [5].

Among various robotic aids, soft robotic gloves have gained attention as an innovative approach for hand rehabilitation and functional assistance. By utilizing soft materials and advanced actuation mechanisms, these gloves are designed to replicate the natural movements of the hand, thereby reducing the discomfort and physical constraints commonly associated with rigid exoskeletons [6], [7]. Recent advancements in material science have enabled the integration of diverse materials, including polymers [8], elastomers [9]–[13], and fabrics [14]–[18]. The use of these soft materials and actuation allows for natural joint movements, which are essential for effective rehabilitation.

Despite notable advancements in the development of soft robotic gloves, several challenges persist, particularly in the areas of customization, ergonomic fit, and user comfort [9]. Many current designs employing single-chamber pneumatic actuators face difficulties in achieving precise alignment with the user's finger joints [12], [19]. Such misalignment may lead to unintended torque distribution across different joint positions, potentially diminishing the efficiency and comfort of force transmission to the anatomical structures of the user's hands [20]. Although modular approaches incorporating rigid components have been developed to enhance customization, these designs often increase the overall weight and complexity of the system, potentially compromising its comfort and simplicity [21], [22].

To address these challenges, this study presents a novel powerful, customized, fabric-based soft robotic glove. At 100 kPa, the actuator generates a maximum block tip force of 19.1 N. The glove, weighing only 73 g, successfully grips objects up to 3126 g at the pressure of 97 kPa, demonstrating its powerful assistive capabilities. The customized fabric-based pneumatic actuators are engineered to conform to the unique dimensions of an individual's hand and finger joints. By aligning actuator segments precisely with the finger joints, the glove not only offers an ergonomic fit but also enhances comfort and effectiveness during hand flexion.

This innovative approach improves the precision of assistive forces applied to each finger while preserving the lightweight and flexible characteristics essential for creating a natural-feeling assistive device. The development of this customized fabric-based soft robotic glove presents a way for personalized and effective rehabilitation solutions that can adapt to the specific needs of each user.

II. The Customized Glove

A. Glove Design

As highlighted in the literature, finger sizes vary significantly among individuals, and gloves tailored to the user's specific finger dimensions are more ergonomic, minimizing misalignment. Assuming that the glove's actuator is customized according to the finger's flexion state after inflation, such tailored actuators can deliver a safer and more accurate assistive torque to the joints. Therefore, we propose a customized, soft robotic glove, as illustrated in Fig. 1.

The glove consists primarily of five custom-fabricated pneumatic actuators and a fabric glove that interfaces with the user. Each actuator corresponds to one of the five fingers of the hand. Each finger actuator is equipped with an independent air supply line, enabling theoretical individual control of finger flexion. This design allows for task-specific assistance and

rehabilitation, providing tailored support to meet the requirements of specific activities or therapeutic goals. The tip of each actuator features a finger sleeve, which aids in determining the finger's position, while the opposite end of the actuator is secured to the fabric glove using Velcro straps. The glove itself is fastened to the user's hand with additional straps and Velcro. Notably, this glove is extremely lightweight, weighing only 73 g, making it lighter than other existing fabric soft robotic gloves [14] (99 g), [16] (128 g), [18] (107 g).

B. Customization Process

Customization is achieved by tailoring the fabric-based pneumatic actuator according to the finger's flexion contour, and the process of customizing one finger is shown in Fig. 2. The process begins with measuring the outer contour of the finger in its flexed position (Fig. 2(a)). Next, the two thermoplastic polyurethane (TPU)-coated fabric layers (40D double-sided TPU-coated ripstop fabric, Adventure Expert) are laser cut (VLS350, Universal Laser Systems) and heat-sealed to create the pneumatic actuator based on the measured contour (Fig. 2(b)). Two pneumatic actuators are then thermally sealed with a bottom layer to create a customized, symmetrical fabric-based actuator (Fig. 2(c) and (d)). A finger pocket and Velcro are sewn onto the customized pneumatic actuators in preparation for integration with the fabric glove (Fig. 2(e)). When inflated, the customized fabric pneumatic actuators should align well with the finger's flexion configuration (Fig. 2(f)).

The process is repeated for each finger, ensuring the actuators match the specific dimensions of all five fingers. Afterward, the actuators are positioned onto the fabric glove, where they are securely attached to provide uniform flexion support across the hand. The customization process is now

complete.

The elastic strap and Velcro-based open design of the soft robotic glove significantly simplify the donning and doffing process, offering exceptional user-friendliness, particularly for individuals with impaired hand muscle control. The pneumatic actuators are attached to the fabric glove via Velcro, allowing for positional adjustments that improve the glove's adaptability to varying hand sizes. While the glove is tailored to a specific hand size, it accommodates a range of hand dimensions effectively. Specifically, the recommended hand length—measured from the tip of the longest finger to the crease beneath the palm—should deviate no more than ±5 mm from the designed size.

Importantly, the flexible design of the customized fabric-based pneumatic actuators allows for tailoring based on various degrees of finger flexion or even extension. This adaptability makes it possible to design the glove to support different hand postures and functionalities.

III. Experimental Evaluation

A. Block Tip Force

The block tip force is a widely used parameter for soft gloves, as it quantifies the assistance force provided during grasping [17], [18], [23]. Similar methodology for measuring block tip was used to evaluate the block tip force in this work, and a test platform for the customized pneumatic actuator was set up, as shown in Fig. 3(a). The actuator is placed laterally on the actuator support, with one end fixed to the support and the other end in contact with a force sensor (LSB205, Futek). The actuator's flexion acts against the sensor when it is inflated, generating reaction force. The actuator's curvature is constrained by a top surface, and its height is controlled by a height block, based on design. The nonlinear effects caused by the curvature are minimized by constraining the top surface of the actuator [20]. The experimental test platform has actual dimensions of 220 mm in length, 40 mm in width, and 96 mm in height, including the height of fix platform.

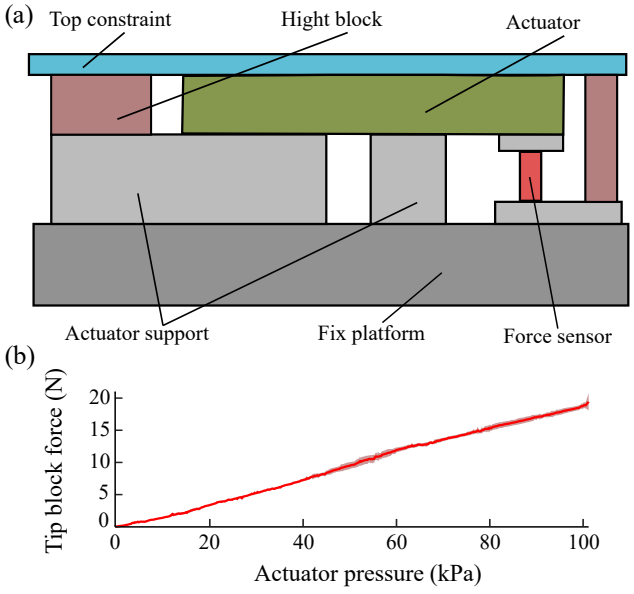

Fig. 3. Measurement of block tip force. (a) Experimental setup for block tip force. (b) Experimental results of block tip force.

The block tip force of the thumb actuator was measured at actuator pressures ranging from 0 to 100 kPa at a frequency of 50 Hz, with data smoothed using a moving window of size 10. The final result was obtained as the average of three repetitions. The actuation pressure was provided by a commercial air compressor (F6000/50, FIAC) and regulated using a pneumatic regulator (IR1000A, SMC).

The experimental results of the block tip force are shown in Fig. 3(b). The block tip force increases proportionally with increasing actuator pressure. The thumb actuator generated a maximum block tip force of 19.1 N at an actuator pressure of 100 kPa. The actuator is capable of generating a higher maximum block tip force compared to existing work at the same actuation pressure [17] (14 N), [18] (10 N), estimating from the picture).

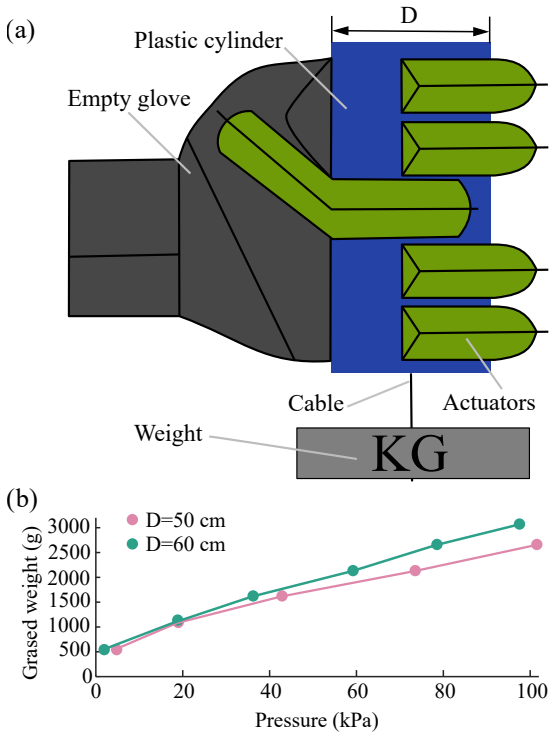

Fig. 4. Evaluation of grasp strength. (a) Experimental setup for grasp strength. (b) Experimental result of grasp strength.

B. Grasp Strength Evaluation

Experiments were conducted to evaluate the grasping strength of the soft glove (Fig. 4(a)). In this setup, a plastic cylinder with a diameter (either 50 mm or 60 mm) is placed inside the fixed empty soft glove. The lower end of the cylinder is connected to a weight via a cable. During the experiment, the pressure is first applied at its maximum level and then gradually reduced until slippage occurs between the glove and the cylinder. The pressure at the point of slippage is recorded.

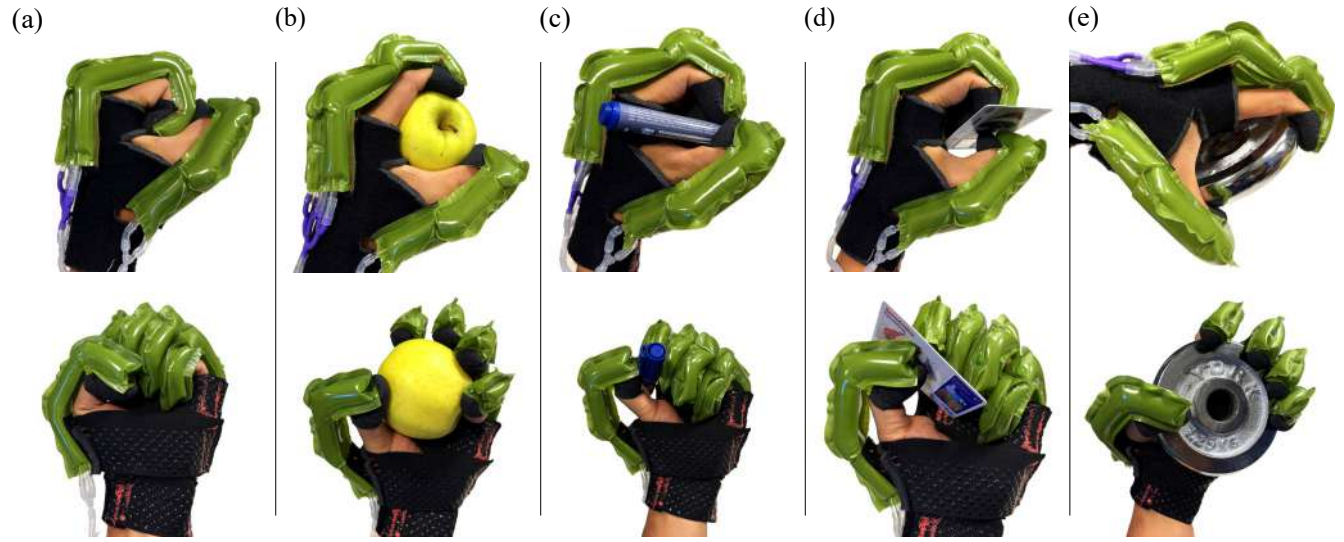

Fig. 5. Grasping various objects in daily life. (a) Grasping nothing. (b) Grasping an apple. (c) Grasping a marker pen. (d) Grasping an ISO card. (e) Grasping a weight.

This procedure is repeated three times for each weight, and the average pressure is used as the final data point.

The experimental results are shown in Fig. 4(b), where the grasped weight is plotted as a function of pneumatic pressure for two cylinder diameters (50 mm and 60 mm). The data reveal a nearly linear relationship between the weight being grasped and the pressure required, indicating that the glove can generate progressively greater grasping forces as pressure increases. Notably, the glove's ability to maintain a grip on a 60 mm cylinder exceeds that of the 50 mm cylinder at equivalent pressures. For instance, at 97 kPa, the glove can hold a load of 3126 g with the 60 mm cylinder, whereas it requires 101.3 kPa to hold 2706 g with the 50 mm cylinder. The output force is sufficient for a wide range of daily tasks (usually not more than 1000 g), demonstrating the glove's potential as an assistive device for individuals requiring enhanced hand strength [24].

Interestingly, even at very low pressures (approaching 0 kPa), the glove can still maintain a grasp on approximately 5 N. This residual force may be attributed to the glove's customized shape according to flexed finger, which provides minimal initial gripping force due to its structural bias toward flexion.

C. Grasping Various Objects in Daily Life

Experiments were conducted on a healthy subject to evaluate the performance of the soft glove in grasping various objects. Four daily objects were tested: an apple (188 g), a marker pen (16 g), an ISO card (85.6 mm x 53.98 mm x 0.76 mm), and a 1132 g weight, representing a ball-type object, a small cylinder, a daily card, and a heavy object (Fig. 5(b)-(e)). The healthy participant was first asked to open their hand with the deflated glove, palms facing up. The objects were then properly placed in the hand, and the soft glove was pressurized to 50 kPa. The subject was instructed to relax all hand muscles during pressurization to eliminate any intentional contributions from the user. Finally, the participant was asked to turn their hands over with palms facing down to test their ability to grasp the object.

Upon pressurization, the glove successfully grasped all the test objects. The smaller (thinner) the object, the better the fit between the glove and the subject's hand. The experiments demonstrated that the glove is capable of effectively assisting with gripping a wide range of objects commonly encountered in daily life.

D. Preliminary User Study

Preliminary tests were conducted on healthy subjects to evaluate the assistance effects of the soft glove by comparing muscle activation patterns during object grasping tasks with and without glove assistance.

Four male subjects (aged 28 to 34) participated in the evaluation. The glove, designed for a hand length of 200 mm, was matched to participants with a hand length of $200 \pm 5\,\mathrm{mm}$. At the start of each session, participants were briefed on the procedure and provided written informed consent.

The test simulated a common daily-life grasping task. Participants lifted an object (50 mm diameter, 1001 g weight) from a starting position, moved it to a target location (300 mm distance), returned it to the starting position, and placed it down (Fig. 6(a)). This task was repeated 10 times under two conditions: with and without glove assistance at a pressure of 60 kPa. A 5-second rest period was given between repetitions. Participants wore the glove on their left hand and controlled its activation manually with their right hand. Task order was randomized to minimize bias.

Muscle activity was recorded at 2222 Hz using surface electromyography (sEMG) sensors (Trigno Quattro Sensor, Delsys Incorporated) placed on six forearm muscles: extensor digitorum (ED), extensor carpi radialis longus (ECRL), abduc-

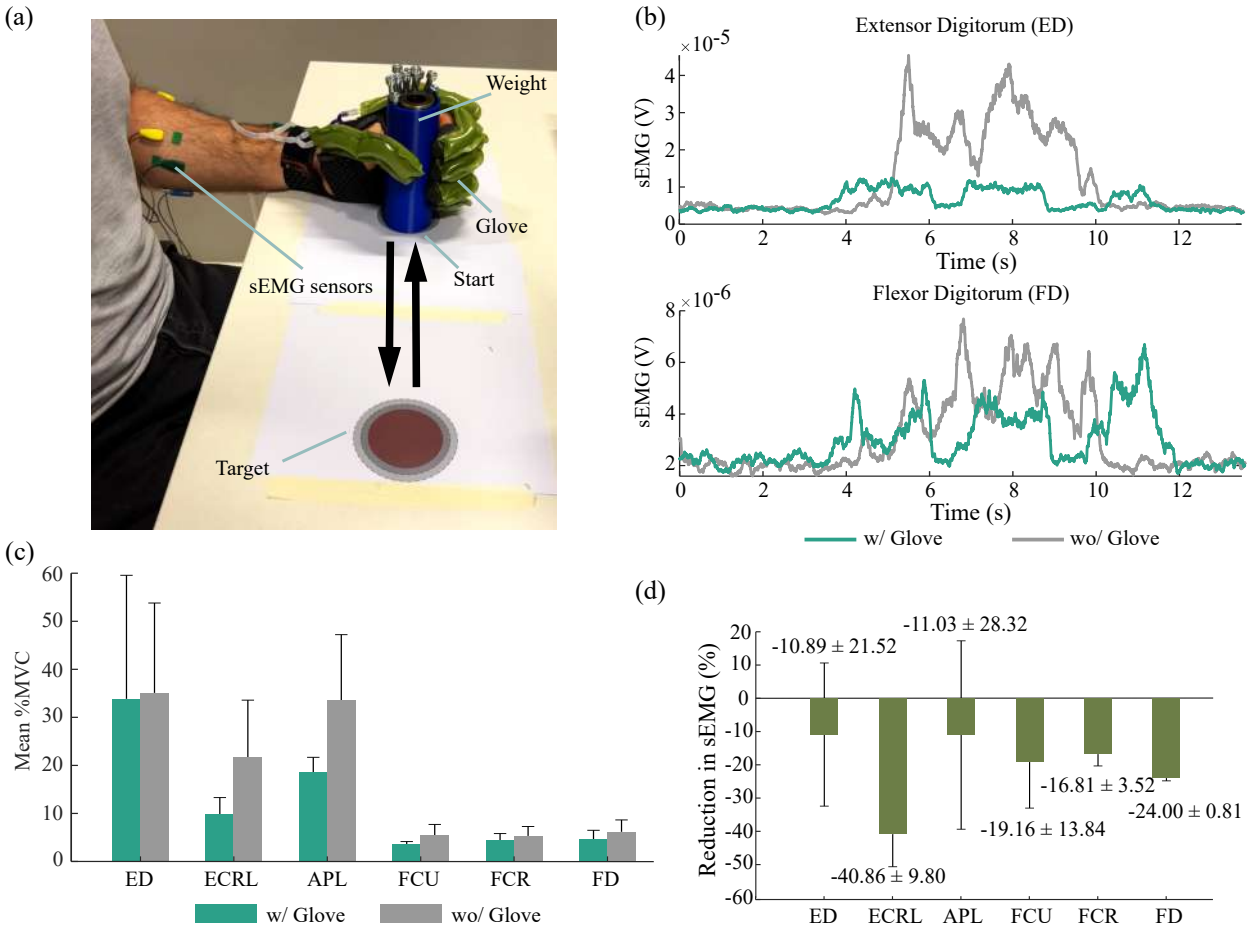

Fig. 6. Preliminary tests on healthy subjects. (a) Experimental setup. (b) sEMG data plot of ED and FD. (c) RMS of sEMG signals for all evaluated muscles. (d) Percentage reduction of muscle activity in compared conditions.

tor pollicis longus (APL), flexor carpi ulnaris (FCU), flexor carpi radialis (FCR), and flexor digitorum (FD). A maximum voluntary contraction (MVC) test was conducted at the start of each session to normalize muscle activity for cross-subject comparison.

The sEMG signals were processed using a band-pass Butterworth filter (20–450 Hz), followed by noise reduction, rectification, and smoothing with a moving average filter (0.2-second window). Signals were normalized to MVC, and the root mean square (RMS) values were calculated to quantify muscle activation [25].

For illustrative purposes, the SEMG signals of the FD and ED muscles from one representative participant are presented in Fig. 6 (b). The results consistently demonstrate reduced muscle activity with glove assistance compared to the unassisted condition, highlighting the glove's ability to mitigate muscular effort required during grasping tasks.

Aggregate results for all participants (Fig. 6(c)) revealed reduced muscle activity across all evaluated muscles when using the glove. Notably, the ECRL and APL muscles showed the largest reductions in average activity. Although slightly higher extensor activity was required to open the deflated glove during grasping and releasing, this was outweighed by the glove's ability to provide significant assistance during the grasping phase. Reduced flexor muscle activity during object-holding also indirectly decreased opposing extensor activity, confirming the glove's overall effectiveness in minimizing muscular exertion.

The percentage of the averaged reduction in muscle activity is detailed in Fig. 6(d). The ECRL exhibited the greatest reduction ($40.86 \pm 9.80\%$), followed by FD ($24.00 \pm 0.81\%$), FCU ($19.16 \pm 13.84\%$), and FCR ($16.81 \pm 3.52\%$). Reductions for ED ($10.89 \pm 21.52\%$) and APL ($11.03 \pm 13.84\%$) were more variable, likely due to muscle distribution complexity and task-specific variations.

Overall, these findings demonstrate that the glove effectively provides assistive forces, reducing the muscle activity required for grasping tasks and enhancing ergonomic support.

IV. Conclusion

In this study, we present a lightweight, fabric-based soft robotic glove designed for assistance and rehabilitation. By customizing pneumatic fabric actuators, the shape of the inflated actuators conforms to the natural flexion of the fingers. This ensures that the torque applied to the wearer's finger

joints is ergonomically precise. The customization and personalization of the glove enhance its safety, comfort, and overall effectiveness in providing assistance.

Experimental testing of the actuators and the glove demonstrated the impressive gripping capabilities of the customized design. Preliminary trials conducted on healthy participants further validated that the glove effectively aids wearers in performing gripping tasks.

While preliminary experiments were conducted solely on healthy subjects in this study, future research will focus on evaluating the glove's performance in diverse patients (different ages and degrees of hand function impairment), assessing its therapeutic effectiveness and suitability for clinical use. Additionally, future efforts will aim to optimize both the functionality and the structure of the glove, with plans to add a finger extension function and potentially incorporate abduction assistance for the thumb, as well as to achieve a more precise pinch.

ACKNOWLEDGMENT

The work was supported by the European Union. Domenico Chiaradia was supported by the Next Generation EU project ECS00000017 'Ecosistema dell'Innovazione' Tuscany Health Ecosystem (THE, PNRR, Spoke 4: Spoke 9: Robotics and Automation for Health), and Rui Chen was supported by MSCA-DN / Project 101073374 - ReWire. Assessment Scores for Patients with Central Neurological Conditions in Rehabilitation: a Systematic Review

Silvia Campagnini, Kaan Borekci, Kyle Embry, Arun Jayaraman

***Abstract*— In rehabilitation, evidence-based practice relies on evaluating patients' standardized outcomes to manage care plans and resources; however, the selection of tools to use is globally inconsistent. Alternatively, emerging technologies can measure high-resolution biomarkers, but their implementation remains a challenge. Given the amount of measures, interest in new scoring systems of patient health synthesizing multi-source data is rising. Emerging research in rehabilitation lacks standardized guidelines and psychometric validation of these scores. Hence, this review systematically examines the methods used for developing and validating patient assessment scores in rehabilitation. A systematic search included studies on the development and validation of scores to assess adult patients with central neurological disorders in rehabilitation. Nineteen studies were synthesized. In the score development, simpler methods and input data were more common (11 studies used statistics, 12 clinical data). In the validation, the heterogeneity in reference standards and tests in scores' psychometric analysis highlights the need for evidence and standardized processes in this field. Clinically relevant information is crucial for implementable scores able to guide clinical decision-making and care strategies. Future studies should adopt exploratory approaches, analyzing various input data, methods, and psychometric properties' impact on the score capability to assess patient health.**

***Index Terms*— Central Nervous Disorder, Outcome Assessment, Psychometrics, Rehabilitation, Score, Systematic Review.**

I. Introduction

Evidence-based practice is a fundamental concept in rehabilitation, where a patient's care is guided by complex decision-making based on their individual characteristics and institutional guidelines [1]. A necessary part of this process is assessing the patient's health status and tracking it over time. These patient assessments are used to design treatments, measure the impact of treatments, and manage care resources including long-term services and reimbursement [2].

Currently, patients are assessed using a broad set of standardized outcome measures in clinical rehabilitation [3]. These measures can be classified under the International Classification of Functioning, Disability and Health (ICF, [4]) and represent a common clinical language for communication across different institutions and healthcare professionals to understand and treat their patients. However, there are broad institutional inconsistencies about which measures are collected, and given concerns about high clinician workloads and the time and costs of frequent assessments [5], it is impractical to collect them all [3]. As a result, there is a continued desire to evaluate existing and new assessments for their ability to capture comprehensive patient outcomes.

A wave of research is exploring alternative patient assessments derived from technological devices (e.g., wearable sensors), neuroimaging, and biological/genetic analyses. These methods have demonstrated promise for providing complementary biomarkers correlated with patients' diagnosis, disease severity, and prognosis [6]. Such assessments could provide objective and high-resolution data about mechanistic and physiological changes, offering a potential solution for easier implementation across different settings/institutions [7].

Given the diversity and volume of data now available from these different sources, there is increased interest in developing and validating new types of assessment scores to easily and reliably evaluate patients. Big data analytics are becoming more common to synthesize and extract clinically meaningful information from these massive, multi-source data volumes and generate new assessment scores [8]. A primary goal is to simplify the process of obtaining comprehensive and accurate information about a patient's health or disease state, which can be used to design effective, individualized rehabilitation interventions and support efficient management of healthcare resources [9]. To date, this work has been primarily focused on acute medicine (i.e., emergency departments, intensive care units, and imaging) [10], [11], [12], while the rehabilitation field is beginning to see the emergence of the first examples [13], [14], [15], [16].

Among the few studies available, the methodologies used to develop a scoring systems are very heterogeneous (e.g., statistical transformation of input data [15], machine learning -ML- [16], or item response theory -IRT- [13], [14]) and there are no clinically accepted guidelines to support the process. Additionally, the validation of these scoring systems (i.e., analyzing their psychometric properties to examine their ability to capture a desired characteristic) is often overlooked. A study examining the 2017 measures list from the Center for Medicare and Medicaid Services (CMS) Quality Payment Program reported that only 37% of 271 measures were deemed valid [17]. Additionally, developing a patient assessment score without validating its psychometric properties potentially endangers its usability in clinical practice, creating frustration in healthcare professionals toward a non-trustworthy tool, increasing assessment time and costs, and

This work was funded by Shirley Ryan AbilityLab. K.B. is with the Dept. of Biomedical Engineering, Northwestern University, Chicago, USA.

ultimately compromising patient recovery [17].

Thus, the objective of this work is to systematically review available methodologies employed in developing and validating patient scoring systems during rehabilitation, with a specific focus on patients with central neurological injuries/disorders. The review examines the methods utilized for the development of scores, the type of input data used, and their validation based on psychometric properties, in order to examine eventual gaps and properly direct future research.

II. Methods

This systematic review was performed following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [18]. The protocol was registered on PROSPERO (ID CRD42024506880).

A. Selection criteria

To favor systematic search and transparency and reproducibility of the results, the selection criteria for the records in this review were designed following the Population, Intervention, Comparison and Outcome (PICO) framework, suitable for quantitative clinical studies.

The population included adults (age$\geq$18 years) affected by a central neurological injury or disorder. Only records in the rehabilitation field were retained; when the study setting was unclear, records that included patients onset$\geq$30 days after injury/diagnosis (targeting post-acute care) were retained.

The intervention was the development and validation of a new score for patient assessment. A score was defined as a univariate and objective measure obtained by condensing data related to patient health, impairment, or function through a numerical and synthetic value. No constraint was posed on the type and amount of input data. Records were excluded if they only presented the development of a score, without validating it through analysis of at least one psychometric property.

Studies with any type of comparison (or no comparison) and any type of outcome were included. Study protocols, conference abstracts and proceedings, reviews, and overviews were excluded. Additionally, records not in English or whose full text could not be retrieved were excluded.

B. Search

A systematic search of papers, by means of a search string, was conducted on the 9th of May 2024 in the following databases: PubMed, Web of Science, Scopus, and CENTRAL. The search string was designed on six concepts, two of which derived from the population criterion (central neurological disorder and rehabilitation setting) and four by the intervention type (score, new development, validation, and patient assessment) (**Figure 1**). A parallel search was also conducted in the Public Reporting section of the CMS website [19]. The search was manually conducted by a CMS expert (A.D.), utilizing the above-mentioned criteria.

All studies were screened first by title or abstract, then by full text; the screening phases involved initial semi-automatic procedures (The MathWorks, Inc. 2021, MATLAB version: 9.10.0 R2021a), followed by manual screening (Rayyan [20] and ASReview version 1.6.3 [21]).

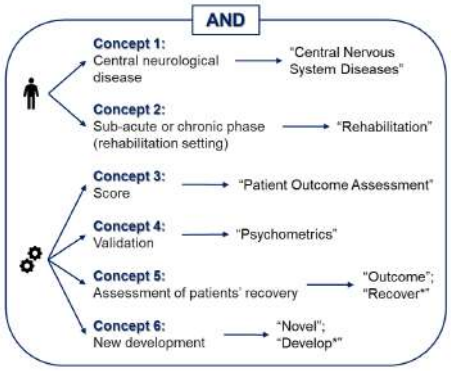

Fig. 1. String search concepts.

C. Risk of bias assessment

The Quality Assessment of Diagnostic Accuracy Studies-2 (QUADAS-2) [22] tool was used to assess the risk of bias in the included studies. Since no optimal tool exists for evaluating both the development and validation of scores, QUADAS-2—typically used for assessing diagnostic test studies—was chosen to emphasize the validation aspect and, consequently, the clinical applicability of the scores. This tool evaluates the risk of bias across four key domains: patient selection, index test, reference standard, and flow and timing.

D. Data collection and synthesis

In accordance with the PICO framework, the following were extracted from each study: *study characteristics*, *score development*, and *score validation*. A narrative description of the results was synthesized.

III. Results

A. Search results

A total of 8087 papers were retrieved from databases and 28 technical reports from CMS website (**Figure 2**). Overall, 19 studies were analyzed in the systematic review, including 18 papers and one technical report.

The most common reason for excluding papers was a non-rehabilitation setting (52.8%), followed by an intervention (30.4%) or diagnosis (11.2%) outside the scope of this review. Most technical reports were also excluded due to an intervention outside of scope (81.8%).

B. Risk of bias

The risk of bias analysis reported "Some concerns" for all the 19 studies, except for the study by Magliacano et al. [16], which reported an overall "Low" risk of bias. The domains most often reporting "Some concerns" across studies were the *Reference standard*, followed by *Flow and timing*.

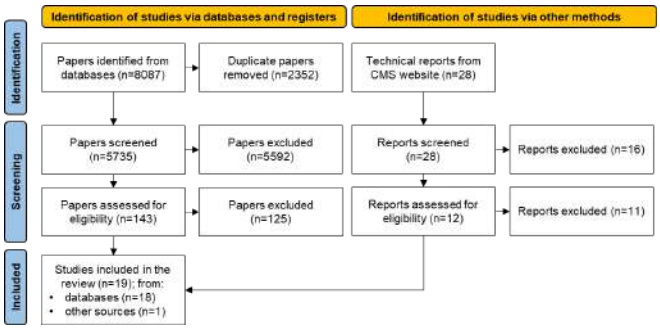

Fig. 2. PRISMA chart.

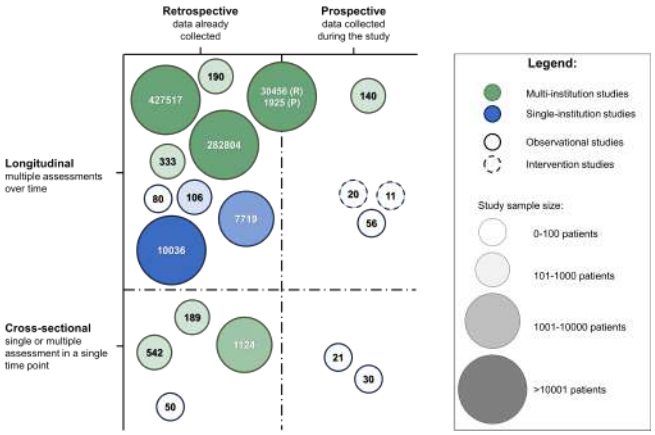

Fig. 3. Characteristics of the 19 included studies. Study design can be either retrospective or prospective, and either cross-sectional or longitudinal. One study used both retrospective and prospective data for the score training and validation, respectively. Dimensions/shades, colors, and line styles represent the sample size, the presence of one or more centers, and the presence of intervention of the included studies, respectively.

C. Study characteristics

Most studies were published between 2013 and 2023, with one record focused on the development of a score for co-morbidities on individuals with stroke published in 1997 [23]. **Figure 3** summarizes the study design and sample size of each included study. There were a similar number of single- and multi-institution studies (9 and 10, respectively), and most studies (12) were retrospective by design. One study [23] proposed the development of a score for the assessment of co-morbidities on a retrospective sample and externally validated it on a prospective one. Retrospective longitudinal studies were characterized by higher sample sizes with one study using a sample of below 100 participants (80 [24]), three studies having more between 100 and 500 participants (106 [23], 190 [25], and 333 [16]), and four over 5000 participants (7719 [13], 10036 [14], 282804 [26], and 427956 [27]).

Two studies with the highest sample sizes performed development and validation of mobility and self-care scores [27] and discharge function score [26] by aggregating average data across patients (i.e., institution-level analysis). Conversely, all the other studies used the data from each individual patient to develop and validate their scores (i.e., patient-level analysis). Lastly, while the majority of the studies utilized data collected during traditional rehabilitation and therapeutic care, two studies utilized data collected during experimental therapy, including upper-limb bilateral tasks in virtual reality [28] and walking tasks with functional electrical stimulation [29].

Concerning the patient populations, four studies included participants with multiple diagnoses, five with stroke, five with disorder of consciousness from traumatic and non-traumatic brain injury (TBI), two with TBI, one with multiple sclerosis, one with dementia, and one with traumatic spinal cord injury.

D. Score development

A total of 30 different scores were developed in the 19 studies, with 13 studies developing one score, three studies developing two scores [27], [30], [23], two studies developing three scores [29], [24], and one study developing five scores [31] to assess functional ability levels on individuals with spinal cord injury. Following their review, the scores were classified using the ICF model [4] (**Figure 4, Panel A**). Specifically, a first and second-level classification were provided, i.e., specifying the health-related domain and its sub-components.

In 14 studies, the methodological steps included pre-processing the input data before computing the score, whereas no pre-processing was applied in the remaining five studies. Pre-processing included feature extraction (5 [28], [29], [32], [33], [34]), feature weighting (1, through principal component analysis [24]), missing data imputation (2, through fixed value [26], [27]), and feature selection (7).

Methods used to develop the scores were categorized as ML, IRT, or statistics. Statistics was further categorized into either cut-off calculation, statistical regressions, or statistical manipulation such as data transformations or scaling. ML was further classified into supervised or unsupervised ML (**Figure 4, Panel B**). A total of 10 studies utilized one methodology only, six [31], [34], [30], [27], [28], [26] and three [35], [33], [24] used a combination of two and three methodologies, respectively. A total of 11 studies utilized only statistics.

The source of input data used for score development was initially classified as instrumental, biological, or clinical (**Figure 4, Panel C**). Most studies utilized one data source (12 clinical, 2 instrumental data), two had a combination of clinical and instrumental data (from markerless motion capture [28], surface electromyography, and stereophotogrammetry-based gait analysis [29]), and one included clinical, instrumental, and biological data (from electroencephalography and somatosensory evoked potential, as well as neuron-specific enolase [33]). Clinical data was further categorized into personal information, pathology description, standardized outcome measures, Patient-Reported Outcome Measures (PROMs), and other clinical descriptions such as co-morbidities.

Among the 14 studies considering scales or questionnaires, i.e., standardized outcome measures or PROMs, 10 studies developed scores from these data at an item-specific level, while the remaining four used the total scale scores. Lastly, none of the included studies considered dynamic information

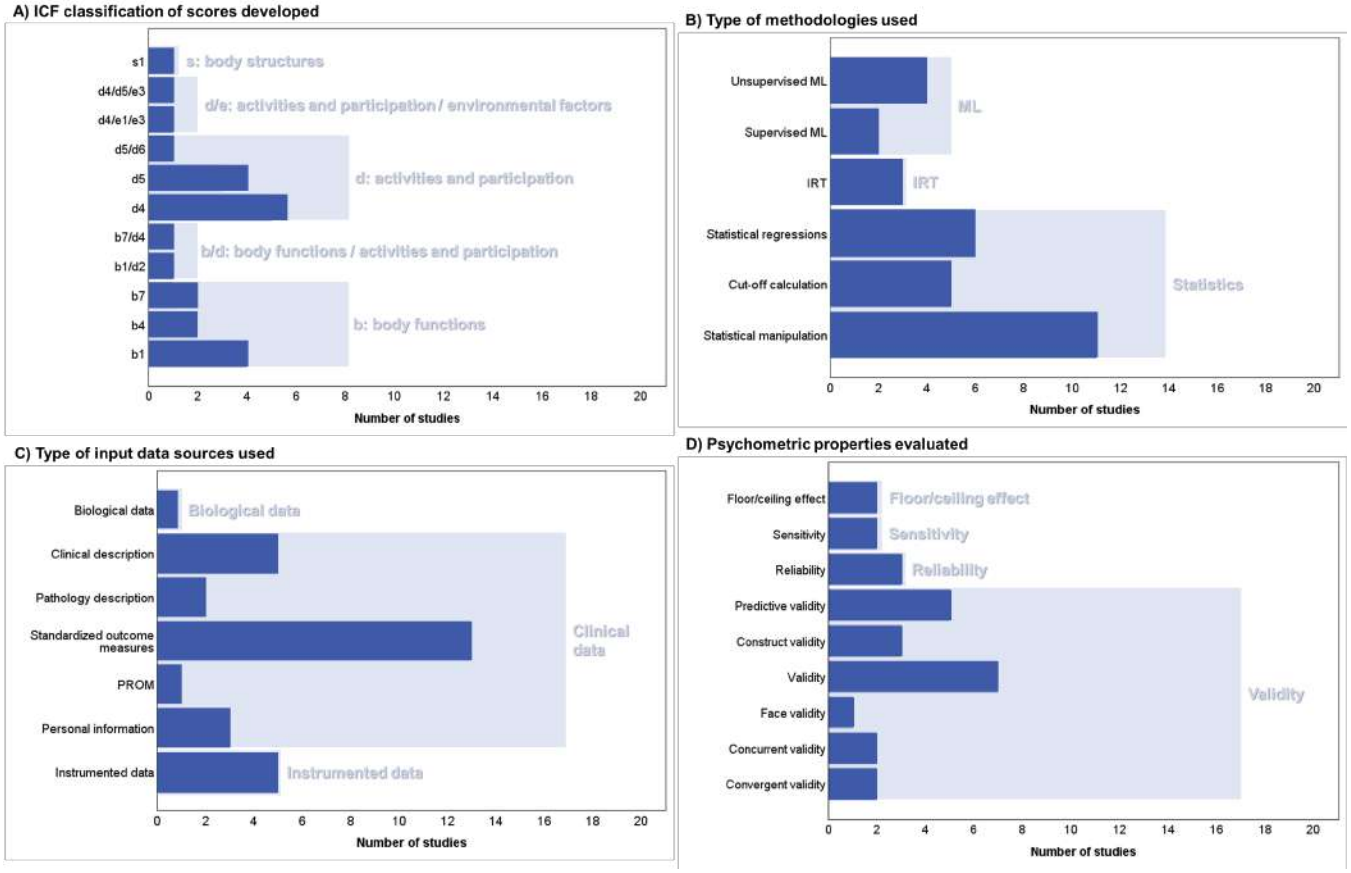

Fig. 4. Bar charts related to the ICF classification of the developed scores (Panel A), methodologies (Panel B) for the development of scores, data sources (Panel C), and psychometric properties evaluated (Panel D). Light-blue bars represent macro-categorization of these domains, dark blue bars refer to sub-categorizations.

over time, but instead relied on a unique assessment over time, even in the cases of instrumental data sources.

E. Score validation

The following psychometric properties were analyzed: validity, reliability, sensitivity, and floor and ceiling effect; the first was further categorized into concurrent validity, convergent validity, face validity, construct validity, and predictive validity (**Figure 4, Panel D**). Additionally, in a few studies (7), the type of validity tested was not reported. Most studies (13) evaluated only one psychometric property, four studies analyzed two properties (2 sensitivity and floor/ceiling effects [13], [14], one construct and convergent validity [36], one reliability and construct validity [27]), and two studies validated the score on three psychometric properties (one face validity, reliability, and convergent validity [26] and one concurrent validity, predictive validity, reliability [23]).

A total of 60 different reference standards were used across all studies as a benchmark for comparing the scores during their validation. The number of reference standards used for each score validation ranged from a minimum of 0 to a maximum of 8. The majority of reference standards spanned multiple ICF domains, specifically 9 in body functions, activities and participation, and environmental factors (b-d-e) and 20 in body functions and activities and participation (b-d). Five reference standards were in the domain of body functions only (b) and five in the domain of activities and participation only (d). The remaining 18 reference standards did not enter the ICF classification, as demographic or administrative factors such as age, sex, length of stay, etc., were selected. In three studies, at least one analysis did not use a reference standard due to the nature of the psychometric property assessed (reliability, construct validity, and face validity [26], [27], [23], which do not require one). The analysis of the psychometric properties on each score-reference standard pair led to a total of 94 validation analyses across all studies.

IV. Discussion

The aim of this systematic review was to examine recent advancements in the development and validation of patient assessment scores in the rehabilitation field. The ultimate goal of this work was to understand current practices, identify gaps, and guide future work to ensure patient assessments are clinically meaningful (**Figure 5**).

There has been arguably more success in introducing new scoring systems based on synthesized data in acute care settings [10], such as when characterizing critical conditions [11] and reporting results from complex imaging [12]. On the contrary, in rehabilitation, this is still an emerging field, with no cohesive processes for bringing together data from new sources to assess patient health or recovery. The presence of

limited research in rehabilitation was confirmed during this systematic work by the great heterogeneity of terminology used across studies (with the terms "score", "index", and "scale" often intertwined). Additionally, there was no single risk of bias tool that could appropriately evaluate potential sources of bias both in the development and validation of these scores. In this work, we selected the QUADAS-2 tool, which mainly analyzing the risk of bias arising in the validation process. Having a unified framework introducing definition of terms and appropriate tools for the analyses of the scoring system would be beneficial for the analytical rigor and consistency in both the development and validation phases of scoring systems. Such a framework would not only standardize the evaluation process but also improve the reliability and comparability of results across studies.

The characteristics of the included studies showed that retrospective designs are more common and often connected to larger data volumes (**Figure 3**). Furthermore, the presence of dedicated digital infrastructures and strong inter-institutional collaboration emerge as critical factors for the development of scalable and generalizable scoring systems. Scores derived from extensive data availability have the potential to deliver valuable insights at both the patient and institutional levels (e.g., Deutsch et al. [27] and Acumen-Technical Report [26]). Hence, patient-specific scores can aid in the local optimization of rehabilitation plans, while institution-level scores can support global resource management strategies.

Most studies used one source of input data only, with clinical data being the most common (**Figure 4, Panel C**). These numbers could be the result of the retrospective nature of the included studies, and the reduced costs and complexity represented by the utilization of data already in use in the clinical practice. In fact, even across clinical data, standardized clinical outcome measures were the most common data source, given their widespread use in current practice. Conversely, PROMs were incorporated less frequently, perhaps due to their subjective nature and variability in their design and administration [37], [38], [39], or the challenge of acquiring these patient-reported measures for some individuals with neurological injuries, since since their cognition, communication, sensation, and other relevant factors might be affected.

Most studies employed simpler, statistical methods (**Figure 4, Panel B**) during score development. Contrary to expectations, with the exception of Chung et al. [28], these methodologies were generally used when multiple input data sources were combined. On the other hand, ML approaches were more frequently chosen when a larger number of input features or bigger sample sizes were available. Importantly, none of the studies in this review examined or compared the performance of multiple methodologies, nor did they assess how the choice of method influenced the outcome of the score. This is a critical point, as the resolution and final characteristics of a score are fundamental for a reliable and precise assessment of patients and they largely depend on the methodology used in the score development. Therefore, for future research, we encourage the use of multiple methods,

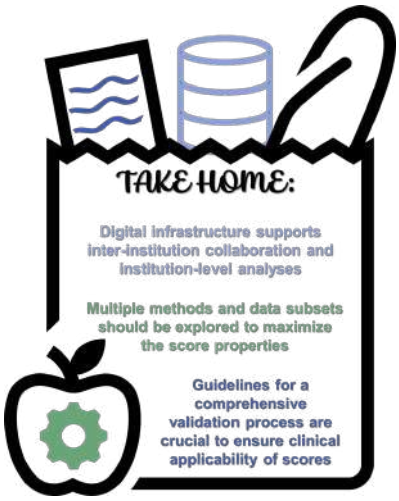

Fig. 5. Take home messages of the study.

starting with simpler approaches to maintain control and interpretability of the results (e.g., with simple statistical methods or manipulations). Then, depending on the characteristics of the input data, IRT and/or ML could be applied. It is essential to consider the advantages of each method: statistical methods offer simplicity and interpretability and allow for more elaborated modeling of the relationship among input features (e.g., mediation, moderation, etc...), while ML excels in managing large volumes of data and multisource information. IRT, on the other hand, is particularly suited for exploring the relationship between input features and latent traits, including non-linear ones, providing valuable insights into the underlying structure of the data.

Similar considerations should be made regarding the selection of psychometric properties and reference standards during the validation process. The goal of validation is to assess how well the score reflects the patient's health or recovery and to determine whether external factors influence this assessment. This process is crucial for the successful implementation of the score in clinical practice, where it can play a key role in decision-making and the selection of appropriate care strategies. However, in this review, the majority of studies (14 out of 19) only evaluated validity, often without specifying the type of validity used (**Figure 4, Panel D**). Moreover, a broad range of methods and reference standards were employed to validate the scores. Future research should focus on validating a comprehensive set of psychometric properties and selecting sets of multiple reference standards across different ICF domains and sub-categories. This is particularly important for scores that assess more complex, higher-level ICF domains (e.g., activities and participation), where the influence of external factors is likely to be more impactful.

V. Conclusions

This work summarized the current state of the art concerning the development and validation of patient assessment scores during rehabilitation from central neurological disorders/injuries. This review highlighted how this field is still in preliminary stages and deeply intertwined with a process of

digitalization and data-driven reorganization of healthcare facilities. Standardized processes for both the development and validation of scores are lacking. Hence, it is recommended for future studies to adopt an explorative approach, evaluating how different input data subsets, methodologies, and reference standards impact on the psychometric properties of the scores.

***Abstract*—We have previously proposed a novel tethered ankle exoskeleton AN-EXTRA-Push. It operated by exploiting the posterior movement of the leg on the treadmill to stretch an elastic tendon. The exoskeleton was controlled using an electromechanical brake.**

The objective of this case study with one healthy and one hemiparetic subjects was to test the feasibility of AN-EXTRA-PUSH, modified in such a way that one end of the elastic tendon is permanently attached to a fixed point, eliminating any control.

Subjects walked on a split-belt treadmill under 4 experimental conditions: one unassisted and at three different assistance levels. The healthy subject repeated the experimental procedure at three different walking speeds. The hemiparetic subject walked at a constant self-selected speed.

In healthy subject, AN-EXTRA-PUSH assistance caused a decrease in peak biological torque accompanied with an increase in exoskeleton torque in the ankle joint. Biological power remained similar across conditions with the additional exoskeleton power contributing to increased total power generation. Exoskeleton torque and power increased with higher walking speeds.

In hemiparetic subject, AN-EXTRA-PUSH did not affect biological torque and power, however, it added torque and power to reach higher totals.

These preliminary results show that the proposed actuator- and control-less version of AN-EXTRA-Push is feasible and warrants further research.

***Index Terms*—ankle, exoskeleton, walking assistance, rehabilitation, control**

I. Introduction

The muscule-tendon complex of the ankle joint plays a vital role in generating mechanical power for propulsion during healthy human walking. The majority of this power is spent in a short sub-phase of a gait cycle named push-off. The key elements of the ankle muscle-tendon complex in this process are *m. triceps surae* and Achilles tendon, that work in series and both contribute to ankle platarflexion torque generation. During the stance phase, muscle fascicles of *m. triceps surae* remain relatively isometric, while the Achilles tendon stretches and stores elastic energy [1]. The tendon then supplements the force created by the contracting muscles during push-off, which results in efficient production of a high burst of positive power. In terms of power, both the tendon and muscles contribute in roughly equal parts [2].

Part of the need for power generation at the ankle can be offloaded onto ankle exoskeletons. These robotic devices have shown the potential to improve human walking economy and endurance, but their effectiveness is significantly dependent on the timing and power of the delivered assistance [3], with needs varying from person to person. An important aspect of ankle exoskeleton development is therefore the search for optimal control. Currently, the leading approach towards individualized assistance relies on human-in-the-loop optimization (HILO) [4].

Modern control methods in general require dedicated, high-performance hardware with high-computational power and ample time to arrive at optimal settings for a single optimization parameter, most notably metabolic cost. However, various other factors such as users' comfort and, in case of neurologically-impaired subjects, also high variability in walking patterns may further complicate the optimization process. Further development of HILO-based control approaches foresees utilization of high-scale personalized musculoskeletal modelling that would allow for off-line training of HILO controllers through simulations using the real-time walking data, thus even further increasing demands on technology, which in turn may drive modern exoskeletons further away from practical use. Even if we assume that the described approach may in the future become feasible for individualized use in able-bodied subjects, it seems that great variability

This research was supported by the Slovenian Research and Innovation Agency under research program number P2-0228.

surrounding gait of various neurologically-impaired populations would preclude successful implementation in clinical applications.

On the other hand, there have been successful implementations of entirely passive ankle exoskeletons that were able to reduce metabolic cost of walking in healthy individuals at certain speeds while requiring no control (e.g. [5]), however with an important limitation that they could not inject additional energy during the push-off, which greatly limits their practical potential, especially in rehabilitation. Considering the ability of active ankle exoskeletons to inject substantial amounts of energy and the ability of passive ankle exoskeletons to recoil timely during the push-off there is a question whether would it be possible to conceive an ankle exoskeleton that could deliver desired amount of additional energy into the biological push-off, similarly to active exoskeletons in a semi-active way and at the same time that would, similarly to entirely passive exoskeletons, not require any control.

Inspired by the elastic nature of ankle plantarflexor muscle-tendon complex, we have previously proposed a novel device: ANkle EXoskeleton using TReadmill Actuation for Push-off assistance (AN-EXTRA-Push) [6]. AN-EXTRA-Push is an ankle exoskeleton that combines features of active and passive exoskeletons. It is a tethered device, which allows for lightweight design, similar to passive exoskeletons, while offering additional power for generating torque, which it harnesses from a moving treadmill. The only actively controlled part of the device is a brake that, while disengaged, allows for free movement of the tether that is tensioned only by a soft constant force spring, and while engaged, fixes one end of the tether in place. Posterior movement of the foot on the treadmill throughout stance phase then stretches the elastic tendon of AN-EXTRA-Push, loading it with energy. Using a combination of coaxial spools of different radii, the force is transferred to a rigid tendon at the back of the device, where it pulls on the foot and the shank, creating plantarflexion torque. In our previous studies, we have observed that omitting a brake might be a feasible modification to the device, which would even further simplify AN-EXTRA-PUSH, rendering it completely actuator- and control-less.

The objective of this study was to test the feasibility of AN-EXTRA-PUSH, modified in such a way that the elastic tendon is permanently attached to a fixed point. In a case study with a healthy human volunteer and with a subject with hemiparesis we provide first preliminary results showing that the proposed ankle exoskeleton exhibits performance that is comparable to SoA HILO controlled powered ankle exoskeletons.

II. Methods

A. AN-EXTRA-Push

The device used in this study is a modified version of AN-EXTRA-Push, roughly described in the introduction and previously presented in [7] and [8]. Schematic representation of its operation is shown in Fig. 1. One end of the elastic tendon is fixed on a point in front of the treadmill. The other end is split in two and wound around a structure of coaxial spools attached to the shoe at the back of the orthosis. A rigid cable is wound around a spool of a smaller radius on one end and attached to a cuff on the shank on the other end (see Fig. 1 A). In stance phase, the leg is moved posteriorly by the treadmill and the ankle is dorsiflexed. This stretches the elastic tendon, generating force. The force is transferred to the rigid cable at the back of the device, amplified to five times its magnitude due to the structure of coaxial spools, where it pulls on the foot and the shank, creating plantarflexion torque (see Fig. 1 B). After push-off initiation, the ankle plantarflexes rapidly, releasing the majority of the energy stored in the elastic tendon. Any remaining energy pulls the leg in the anterior direction in swing phase. At the start of the next gait cycle, the device is essentially reset and ready to assist in the next step. Fig. 2 shows the current version of AN-EXTRA-Push prototype that was used in this study.

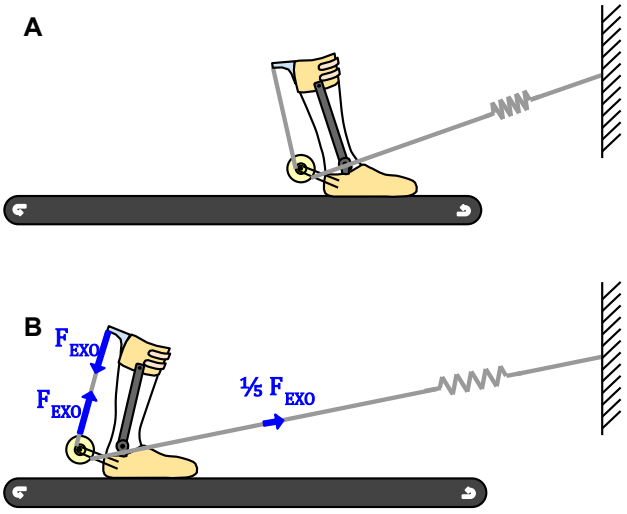

Fig. 1. Schematic representation of AN-EXTRA-Push and exoskeleton forces during its operation. A) No forces are present at heel strike. B) The leg was pulled posteriorly by the treadmill, stretching the elastic tendon. Forces in the rigid cable at the back of the device are 5 times the force in the elastic tendon due to being transferred over the spools of different radii.

B. Study participants

One healthy adult male and one adult male suffering from left-side hemiparesis participated in this study (healthy subject – age: 27 years, height: 179 cm, weight: 89 kg and post-stroke subject – age: 53 years, height: 179 cm, weight: 99 kg). The study was approved by National Medical Ethics Committee of the Republic of Slovenia.

At the time of study, subject with hemiparesis was receiving treatment at University Rehabilitation Institute Republic of Slovenia, following a stroke 8 weeks prior. He was an independent ambulator (FAC score 4) who exhibited limited push-off generation capabilities.

C. Instrumentation and data acquisition

Participants walked on a custom-built split-belt treadmill. They wore AN-EXTRA-Push on their left leg. The left part

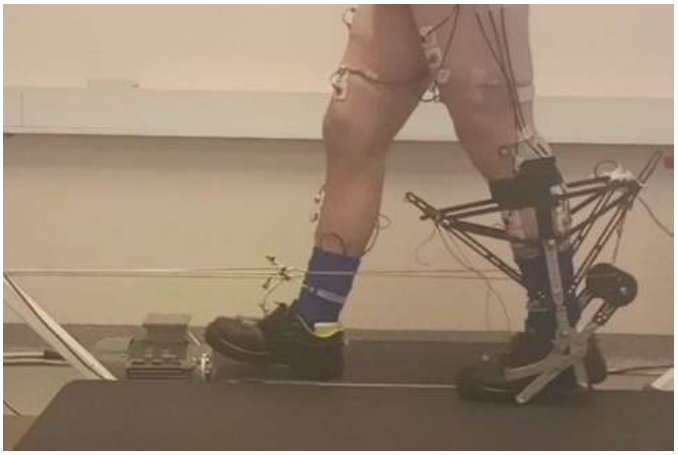

Fig. 2. A photograph of the prototype, taken during one of the experiments.

of the treadmill stood on four force transducers (K3D120, ME Systeme GmbH, GER) that measure ground reaction forces (GRF) with a frequency of 250 Hz.

Gait kinematics were measured using motion capture cameras (Optitrack, NaturalPoint, Inc., USA). 18 reflective markers were placed on the body of the participant, 16 of them following the Plug-In Gait lower-body marker set. Kinematic measurements were sampled at a frequency of 120 Hz. AN-EXTRA-Push was equipped with a force sensor (U9C, HBM, GER) that measured the force in the rigid cable at the back of the device. A Beckhoff CX5020 embedded PC was used to record the force sensor data.

For the healthy subject, surface electromyography was measured for six muscle groups: *m. soleus, m. gastrocnemius lateralis, m. tibialis anterior, m. vastus medialis, m. biceps femoris, and m. rectus femoris*. Pairs of 3.5x4 mm electrodes (3M, Maplewood, USA) with inter electrode distance of 4mm were placed atop appropriately prepared skin surface above muscle bellies. Data was sampled using TelemyoMini 16 (Neurodata, Vienna, AUT) at 1 kHz.

D. Experimental procedure

Both subjects had no previous experience with walking with AN-EXTRA-Push. In this experiment, they walked under 4 different experimental conditions: while wearing AN-EXTRA-Push, but without the tendons being connected (Unassisted) and in three different active assistance conditions (Weakest –elastic tendon implemented with one elastic rope, Medium – two elastic ropes in parallel and Strongest – three elastic ropes in parallel). Each elastic rope had a stiffness of 35 N/m.

The healthy subject repeated the experimental procedure at three different walking speeds: 0.4 m/s, 0.8 m/s and 1.2 m/s. The subject suffering from hemiparesis walked at a constant self-selected speed of 0.5 m/s.

Each measurement consisted of about 2 minutes of walking which amounted to at least 44 completed strides (more at higher speeds). Measurements were done in the following order: Unassisted, Weakest, Medium, Strongest. They were recorded one after another with a minute long break in between them.

E. Data processing

Raw marker data were processed in Motive 2.2.0 software (NaturalPoint, Inc., USA). Marker trajectories were smoothed using the built-in filtering algorithm. Joint angles were calculated using the Plug-in Gait kinematic model. Ground reaction forces, center of pressure positions, and exoskeleton force values were filtered using a Butterworth filter (4th order, 7 Hz). Using a Newton-Euler inverse dynamics algorithm, joint torques and powers were calculated, taking into account the additional weight and inertia of the exoskeleton attached to the left leg.

EMG signals were first filtered using a 20-140 Hz band-pass and 49-51 Hz notch filter, then rectified and filtered using a 150 ms moving average filter. Each subject's EMG signals were normalized relative to the peak muscle activity during the unassisted condition at the highest recorded walking speed to compare muscle activation across conditions.

Data were segmented into gait cycles. Left heel strike was chosen as the beginning of a stride. A heel strike event was marked when the vertical ground reaction force exceeded 30 N. The last 30 strides during each experimental condition were used for the analysis.

III. Results

A. Healthy subject

Figures 3-5 show kinematics, kinetics and EMGs around the ankle joint for all experimental conditions at three gait speeds. In comparison to unassisted walking, AN-EXTRA-PUSH causes a decrease in peak biological torque accompanied with an increase in exoskeleton torque in the ankle joint. Overall, the sum of biological and exoskeleton ankle torque remains comparable to Unassisted experimental condition, indicating that volitional human effort decreased with increased assistance. This is reflected in a decrease of peak soleus and gastrocnemius muscle activation throughout the stance phase.

This is followed by an increase in the activation of tibialis anterior in the initial swing phase, which is probably a consequence of residual energy stored in the elastic tendon that drives foot towards plantarflexion during the initial swing. The residual tension in the elastic tendon dissipates throughout swing phase as the foot once again approaches the front of the treadmill.

At walking speeds that are low (0.8 m/s, Fig. 4) and very low (0.4 m/s, Fig. 5) for a healthy human, the subject did not retain the same joint kinematics across conditions as well compared to while walking at a more comfortable speed of 1.2 m/s (Fig. 3). At the slower two speeds, the biological power remained similar across conditions with the additional exoskeleton power contributing to increased total power generation at the ankle despite minimal changes in total ankle torque.

Exoskeleton torque and power increased with higher walking speed, although not linearly. The relative contributions of

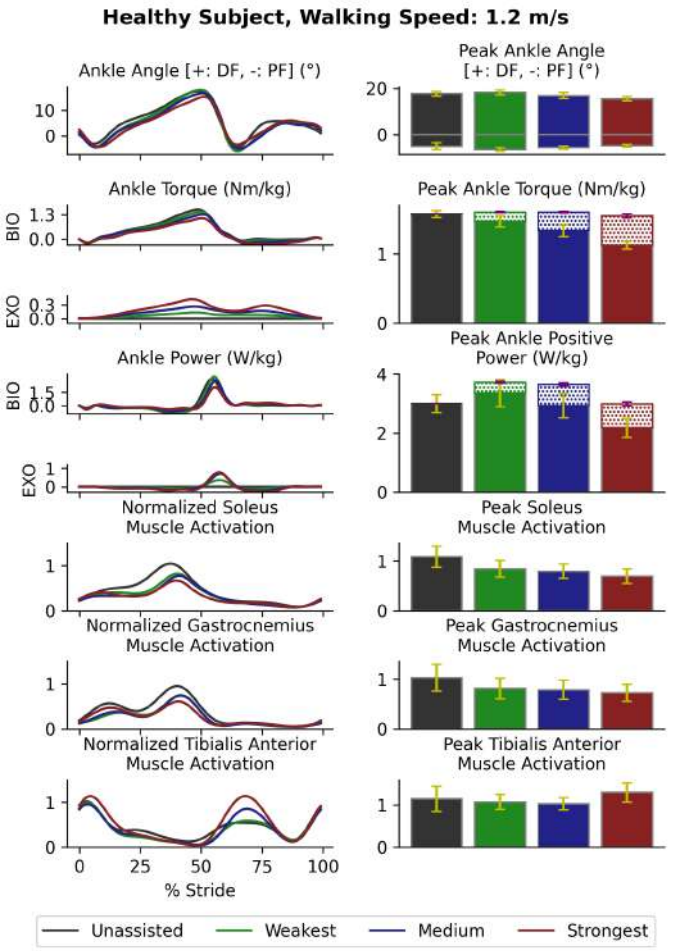

Fig. 3. Results for the healthy subject walking at 1.2 m/s. Trajectories for an average stride are shown on the left. On the right, bar charts depict peak values of the measured quantities. For peak ankle torque and positive power charts, the base section represents biological contributions (solid color), while exoskeleton contributions (hatched region) are stacked on top. Yellow and purple error bars indicate the variability of biological and exoskeleton contributions respectively.

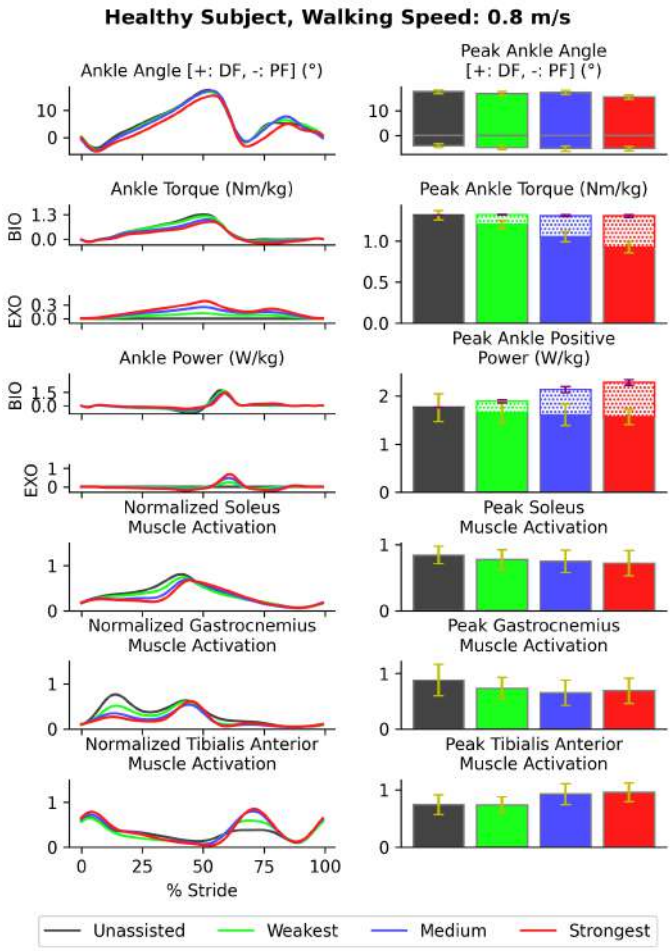

Fig. 4. Results for the healthy subject walking at 0.8 m/s. Trajectories for an average stride are shown on the left. On the right, bar charts depict peak values of the measured quantities. For peak ankle torque and positive power charts, the base section represents biological contributions (solid color), while exoskeleton contributions (hatched region) are stacked on top. Yellow and purple error bars indicate the variability of biological and exoskeleton contributions respectively.

the exoskeleton assistance to torque and power generation at the ankle was larger at lower speeds.

Inter-stride variability is only indicated by the error bars on the bar charts on the right side of the figures 3-5 to preserve the readability of the average trajectories on the left. Exoskeleton torque and power were applied consistently, their relative variability (coefficient of variation) being about the same compared to relative variability of biological torque and power.

B. Subject with hemiparesis

Figure 6 shows kinematics and kinetics for all experimental conditions. AN-EXTRA-PUSH largely did not affect biological torque and power, however, it progressively added torque and power, resulting in an increase in peak effective ankle torque of approximately 20 % and around 50 % increase in peak effective positive ankle power at the highest level of assistance compared to the Unassisted condition.

IV. Discussion and Conclusions

The effects of providing push-off assistance during gait with this actuator- and control-less version of AN-EXTRA-Push match how an assistive ankle exoskeleton should function based on the literature and our pre-experiment expectations. The healthy subject had an intact neuro-muscolo-skeletal system and was thus capable of exploiting the additional ankle plantarflexion torque and power. He was able to maintain a substantially similar walking pattern while offloading some of the volitional effort onto the device, which manifested in lower biological torque generation and plantar flexor muscles activation. The effect is most clearly visible in the reduced *m. soleus* activation, which is to be expected, since AN-EXTRA-Push functions directly in parallel to *m. soleus*.

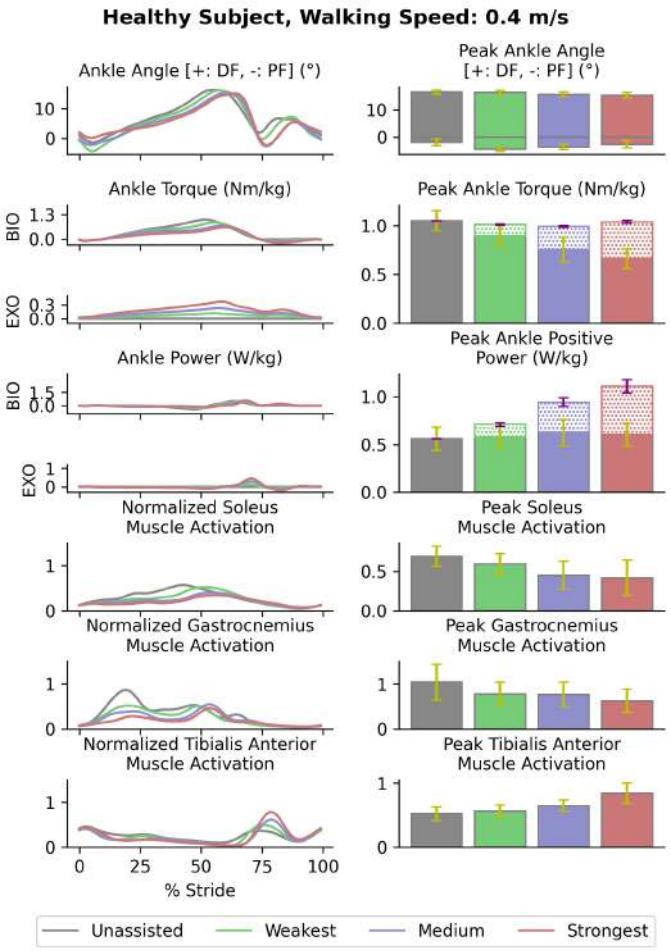

Fig. 5. Results for the healthy subject walking at 0.4 m/s. Trajectories for an average stride are shown on the left. On the right, bar charts depict peak values of the measured quantities. For peak ankle torque and positive power charts, the base section represents biological contributions (solid color), while exoskeleton contributions (hatched region) are stacked on top. Yellow and purple error bars indicate the variability of biological and exoskeleton contributions respectively.

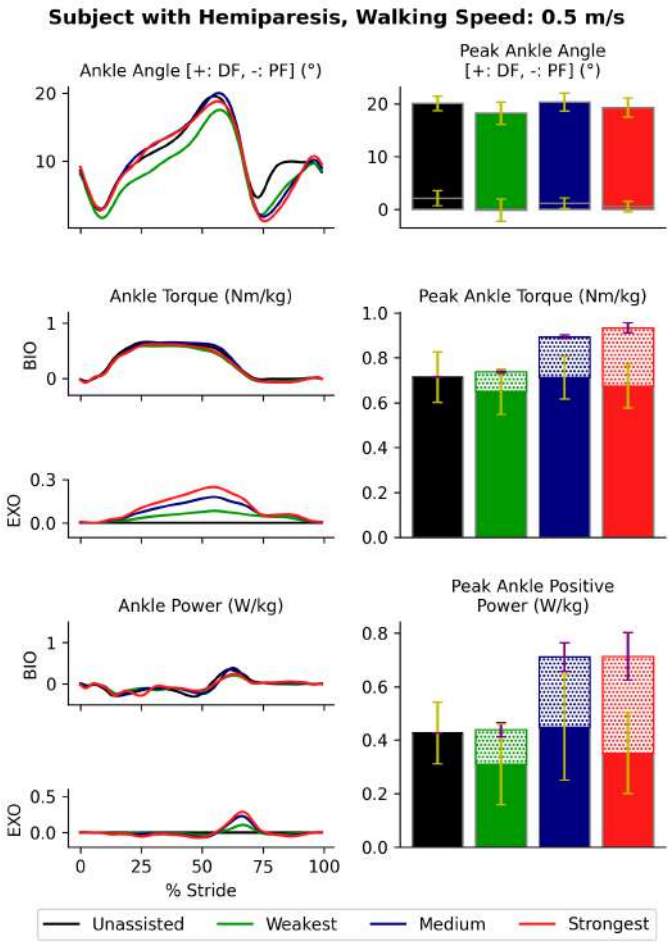

Fig. 6. Results for the post-stroke subject walking at 0.5 m/s. Trajectories for an average stride are shown on the left. On the right, bar charts depict peak values of the measured quantities. For peak ankle torque and positive power charts, the base section represents biological contributions (solid color), while exoskeleton contributions (hatched region) are stacked on top. Yellow and purple error bars indicate the variability of biological and exoskeleton contributions respectively.

Previously to the study, the subject suffering from hemiparesis had by himself been unable to generate the plantar flexion torque necessary for healthy-like push-off during walking. The subject continued to exert near-full volitional effort into walking (the biological torque and power were largely unchanged throughout the experiments). The device appears to have helped supplement their torque generating capabilities and approach healthy-like kinetics.

In both healthy and post-stroke subject experiments, the assistance was delivered during the appropriate time window. For healthy subject, this is reflected in the peak reduction of biological ankle torque and power which coincides with the peak torque and power in the unassisted condition. These peaks don't coincide as well for the post-stroke subject since his torque trajectory is abnormal and fails to reach the peak value in late stance, when plantarflexion torque is most needed to push off.

Inter-stride assistance variability is proportional to inter-stride variability of biological quantities. Since the assistance could partially adapt to large changes in walking speeds across the experimental protocol, it appears that AN-EXTRA-Push was able to adapt its assistance to the small changes in walking pattern in real-time. Put another way, a unusually longer stride is immediately supported by more exoskeleton assistance, which is to be expected based on the mechanical design of AN-EXTRA-Push. This means that AN-EXTRA-Push is likely to provide appropriate assistance even to users with highly variable gait patterns that typically occur with neuro-muscular impairments. This stands in opposition to exoskeletons that optimize their assistance pattern to a steady state gait.

After pushing off and transitioning to swing phase, the force exerted by the still partially stretched elastic tendon necessitates some active dorsiflexion torque by the user. Both the healthy and post-stroke subject were able to actively

compensate for that.

The two case studies were intended to demonstrate proof-of-concept and check that the simplified AN-EXTRA-Push design performs to expectations. Specific results showing how the two subjects responded to assistance with AN-EXTRA-Push should not be generalized, especially to patient populations. Inherent adaptation of AN-EXTRA-Push observed across different speeds and stride to stride differences, however, is an encouraging sign that increases our confidence that such approach is feasible and warrants further research.

By harvesting the energy from the moving treadmill, AN-EXTRA-Push is not limited to low power assistance like contemporary passive devices. While powerful, timely assistance does not require precise control of an actuator as with state of the art active ankle exoskeletons. Instead, it is achieved passively due to its biomimetic design.

In rehabilitation, time to find appropriate control parameters is a commodity that we cannot afford. Training sessions are typically limited to at most half of an hour; additionally, complex systems that need substantial knowledge to be operated are not desirable in clinical settings. Technical solutions that are simple, easy to don/doff and intuitive for use are likely to be accepted by primary users and therapists.

As such the proposed ankle exoskeleton may be perfectly suited for use in a treadmill-based training of walking in various neurological populations as it is easy to use and delivers extra push-off power in synchrony with volitional human efforts in every step without a need for time-consuming optimization of control parameters. Unlike the HILO controlled ankle exoskeletons that, once properly trained, require stationary gait in order to be successful our approach delivers timely assistance in each step regardless of the inherent step-to-step variability of the push-off initiation of a human, which is of paramount relevance in neurological populations.

Tailoring ankle-foot orthoses stiffness to end-users' needs: which performance variables matter?

Sejin Yi Yoo[1,†], Emma A. Gille[2,†], Jorge Gómez[1], Eduardo Rocon[1], Ignacio Martínez-Caballero[3], Edwin van Asseldonk[2], and Cristina Bayón[1,*]

***Abstract*— Ankle Foot Orthoses (AFOs) are devices designed to assist or rehabilitate gait. The stiffness of the AFO is an important parameter that needs to be tailored to the end-user's characteristics. However, the lack of clinical guidelines for optimizing AFO stiffness has led to inconsistent outcomes and low user satisfaction in existing experimental approaches. This inconsistency may stem from two reasons: (1) the limited number of variables considered by these methods, which may fail to capture the full complexity of gait; and (2) the variability in the relationship between stiffness and gait variables among users. To address these challenges, we propose a user-tailored optimization framework that identifies and incorporates relevant gait variables based on individual needs and preferences. In this pilot study, we explore key performance variables in two participants with cerebral palsy (CP), analyzing the results using XGBoost and SHAP values. Our findings highlight the importance of multiple performance variables in capturing gait complexity and reveal that the most relevant variables differ between participants. This study underscores the potential of personalized approaches to improve AFO optimization and user outcomes.**

I. INTRODUCTION

Ankle foot orthoses (AFOs) are devices frequently used to assist or rehabilitate gait in people with motor or neurological disorders [1]. These devices provide support to the ankle joint, correct gait deviations, and effectively reduce energy cost when walking. To maximize the benefit of an AFO, it is important to tailor its stiffness to the end-user's needs, as the stiffness highly influences the final user's performance [1], [2], [3], [4].

Optimal stiffness varies depending on the user's capacity [5], [3], the task [6] and the terrain type [7], among other factors. Therefore, objective data on user performance under all these different conditions would be useful to inform clinical-decision making in prescribing new AFOs [8]. However, clear clinical guidelines to determine a personalized value of the AFO's stiffness are lacking [8], and available experimental methods still face challenges like long measuring times and lack of inclusion of user preferences [1].

Human in the loop optimization (HILO) is a method aiming to optimize AFO stiffness based on an objective function that most often targets metabolic cost [9]. This target variable is computed indirectly from breath by breath measurements of carbon dioxide and oxygen. Nevertheless, metabolic cost requires a long measuring time, and even when a reduction in metabolic cost is achieved via HILO, this improvement is not reliably perceived by the user [10]. This can be explained by the fact that users prioritize several aspects of gait simultaneously, with metabolic cost not being the highest priority. Therefore, trying to optimize a single physiological measurement (i.e., metabolic cost) without considering other variables and user preferences, may not yield the desired results in terms of user satisfaction and acceptance [10].

Gait domains, aside from effort, that may also be relevant for optimization include kinematics, spatio-temporal parameters, balance, and muscular control. Variables related to these domains are typically not used in combination, limiting the understanding of gait performance [9]. When considered together, the combination is often partial, constrained by the use of predefined decision schemes [11]. These decision methods assess the performance of each target variable at different stiffness levels and rank optimal stiffness based on the first target variable. In case of a tie, they use subsequent variables one by one to make a decision. The hierarchy of target variables in these decision schemes is manually selected by researchers, potentially leading to high variability in the results between participants [11].

Tankink et al. [12] highlighted the importance of selecting the appropriate cost function (including the objective and variables), as different choices can highly influence the results and, in turn, affect the ability to design personalized features that suit the individual. This emphasizes that a "one-size-fits-all" approach may be suboptimal. Therefore, optimization of AFO stiffness should be improved by incorporating a tailored multi-variable hierarchy that aligns with user's priorities.

To propose an alternative approach that better captures the complexity of gait, it is necessary first to analyze how different gait variables are influenced by stiffness on an individual basis and how these results differ between users. Variables with weaker correlations to stiffness may be less effective for optimization and could therefore be excluded, reducing the number of sensors required and potentially increasing user comfort. Optimization can then focus on the most relevant variables while incorporating user preferences. This study introduces a method for identifying key variables using an explainability technique based on Shapley Additive

Explanations (SHAP) values, integrated with an artificial intelligence model utilizing Extreme Gradient Boosting (XGBoost). We tested this method in two pediatric participants with cerebral palsy (CP) using the inGAIT-VSO device [13].

II. METHODS

This section first details the methods employed for feature (or variable) selection, which form the core of our proposed approach. Subsequently, we describe the methods used to pilot this approach with two participants diagnosed with CP.

A. Feature selection

1) Performance variables: To take into account different aspects of gait, we defined five domains: 1. Kinematic Properties, 2. Spatio-Temporal Characteristics, 3. Balance and Stability, 4. User Perception and Physiological Demand, and 5. Muscular Control (Table I). Within each domain, specific performance variables were selected to comprehensively assess both functional and physiological aspects of user performance, with a particular focus on the ankle joint. We based our selection on previous literature [14] and prioritized variables that could be measured using wearable and onboard lab equipment, aiming to minimize duplication and redundancy within and between domains.

For the Kinematics domain, we computed the angle between foot and shank at heel strike, and the peak ankle dorsiflexion (DF) observed during the stance phase for every gait cycle (Table I). Within the Spatio-Temporal domain, walking speed, the percentage of the stance phase duration, and the walk ratio (understood as the ratio between step length and cadence) were computed every gait cycle as variables representative of pace, rhythm and coordination respectively. Additionally, the stance duration variability was determined every 20-meter walking segment by looking at the standard deviation of the percentage of stance phase durations computed along that segment. For the Balance and Stability domain, we computed the trunk lateral motion as a form of compensation mechanism every gait cycle, and the step time asymmetry (STA) every 20-meter segment. Trunk lateral motion was derived from the root mean square of the lateral acceleration as done in [15]. The STA was computed using the formula presented in [16]:

$$\text{STA} = \frac{\sum_{i=2}^{n}(ST_i - ST_{i-1})}{2n} \tag{1}$$

where ST_i is the step time of the step i in milliseconds, and n is the total number of steps on the corresponding walking segment. For the domain User Perception and Physiological Demand, we computed the Physiological Cost Index (PCI) [17] every walking segment as:

$$\text{PCI} = \frac{\text{HR}_{\text{walk}} - \text{HR}_{\text{rest}}}{\text{walking speed}} \tag{2}$$

where HR_{rest} and HR_{walk} are the heart rate measurements at resting and during walking, respectively. Moreover, the Borg's scale [18] was used to report user's perceived effort. Finally, for the Muscular Control domain, we computed the co-contraction index (CCI) during stance phase as presented in [19]:

$$\text{CCI} = \sum_{i=1}^{101} \frac{\text{EMG}_L(i)}{\text{EMG}_M(i)}(\text{EMG}_L(i) + \text{EMG}_M(i)) \tag{3}$$

where i represents the individual time points of stance phase (0–100%, or 101 data points), and $\text{EMG}_L(i)$ and $\text{EMG}_M(i)$ are the normalized activations of the less and more active muscles at point i, respectively. This was computed using the antagonist muscles, tibialis anterior (TA) and gastrocnemius medialis (GM).

2) Classification model for feature importance: A classification model was developed to predict the stiffness level based on the values of the different performance variables, with an XGBoost algorithm selected for its implementation. This model enhances the basic gradient boosting method by passing residuals from each decision tree to the next, hierarchically (Fig. 1). It offers the benefit of being well-suited for high-dimensional datasets and includes inherent regularization to prevent overfitting [20]. The purpose of training this model and employing an explainability framework was to identify the variables that were significantly affected by stiffness. To train the XGBoost model, observations of each performance variable were obtained across a range of stiffness levels (see section II-B). The values of the variables, estimated each trial or walking segment, were repeated according to the number of gait cycles within each respective trial or walking segment.

To quantify the contribution of each variable to the predictions, SHAP was employed [21]. SHAP values explain the contribution of each individual variable to the overall prediction. The SHAP value of a variable is calculated by assessing the effect of excluding that variable from the prediction process. If removing the variable has no effect on the result, its SHAP value will be 0, indicating the variable's irrelevance to the prediction. Different combinations of variables were tested to account for interactions between features, ensuring accurate calculation of SHAP values. The XGBoost model for classification and SHAP for result explanation were performed individually for each participant in the following pilot study.

B. Pilot study

1) Variable stiffness orthosis: The inGAIT-VSO is a pediatric-focused Variable Stiffness Orthosis (VSO) designed for children with CP [13], [6]. It features a non-actuated mechanism that provides a non-linear ankle angle-torque curve, active during both the stance and swing phases. The stiffness curve can be manually adjusted according to user/clinician preferences to impact the user's gait. The inGAIT-VSO is sensorized and allows for data capturing without needing sophisticated lab equipment. For a detailed description of the inGAIT-VSO, refer to [13].

2) Participants: Two participants with CP participated in a pilot-study to test the optimization model (weight 31 $\pm$ 7 kg, height 1.365 $\pm$ 0.025 m, age 9 $\pm$ 0.5 years old) (Table II). Participants met the following inclusion criteria:

TABLE I

SUMMARY OF PERFORMANCE VARIABLES AND THEIR CORRESPONDING DOMAIN, GAIT ASPECTS AND COMPUTATION INTERVAL

Domain	Gait Aspect	Performance Variables	Computation Interval
Kinematics	Amplitude	Strike angle dorsiflexion (deg)	Gait cycle
		Peak ankle dorsiflexion (deg)	Gait cycle
Spatio-Temporal	Pace	Walking speed (m/s)	Gait cycle
	Rhythm	Stance duration (%)	Gait cycle
	Variability	Stance duration variability (%)	Walking segment
	Coordination	Walk ratio (cm·min/step)	Gait cycle
Balance	Body compensation	Trunk lateral motion (m/s^2)	Gait cycle
	Asymmetry	Step time asymmetry (ms)	Walking segment
User Perception	Effort	Physiological cost index (beats/m)	Walking segment
		Perceived effort (Borg's scale)	Walking trial
Muscular Control	Smoothness	Co-contraction index (–)	Gait cycle

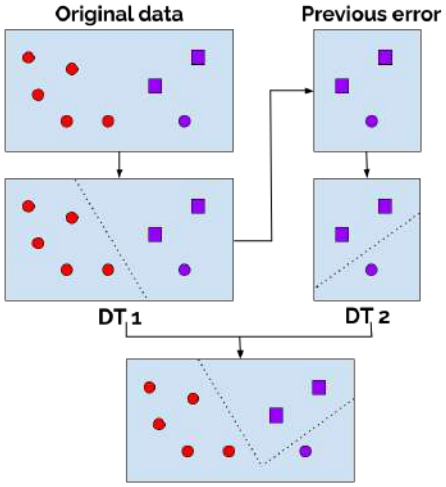

Fig. 1. Schematic illustration of functioning of XGBoost models. Original data has two classes circles and squares. The first decision tree (DT1) gives an imperfect classification. The errors or residuals from DT1 are fed as input to the next decision tree (DT2). DT1 and DT2 are combined to give the final prediction

aged 5–17 years, predominantly spastic uni- or bilateral CP, Gross Motor Function Classification System (GMFCS) [22] levels I–III, sufficient cognitive ability, and the capacity to complete the walking protocol. Flexible equinus deformities or drop-foot were preferred, with Ashworth scale scores ranging from 1 to 3. Exclusion criteria included leg surgery in the previous 6 months or botulinum toxin A injections in the previous 3 months, significant musculoskeletal deformities, unhealed skin lesions, gastrocnemius shortening $>10°$, or visual impairments or behavioral issues that could hinder protocol performance. The Local Ethics Committee at Hospital Infantil Universitario Niño Jesús (HNJ) gave the approval (R-0064/23) and ensured the study was conducted in alignment with the Declaration of Helsinki. Participants and their families were informed accordingly, and parental consent was obtained before participation.

The pilot involved a single session per participant of about 2h. Initially, participants were assisted in putting on

the inGAIT-VSO, and were given the opportunity to walk with the equipment and report any discomfort. After a brief familiarization with the device, they performed five trials of two-minute walking tests (2mwt) [23], walking back and forth along a 20-meter straight corridor, while they were instructed to walk as fast as possible without running. For each trial, the inGAIT-VSO was set to a different stiffness level: (1) no stiffness (spring disconnected), (2) low stiffness (0.2 Nm/kg as peak restoring torque at 12 deg of DF), (3) medium stiffness (0.4 Nm/kg at 12 deg of DF), (4) high stiffness (0.6 Nm/kg at 12 deg of DF), and (5) very high stiffness (0.8 Nm/kg at 12 deg of DF). The value of 12 degrees of DF was chosen in accordance with previous literature [13], [24] as it is the approximate maximum value reached during stance in healthy gait.

To minimize fatigue-related bias, the order of trials (i.e., stiffness levels) was randomized for each participant. Participants were allowed to rest as needed between trials.

C. Data acquisition

During the 2mwt trials, a combination of sensors was used to compute the required performance variables exposed in Table I. Magnetic encoders (AS5048b, AMS-OSRAM AG, Premstaetten, Austria) integrated in the inGAIT-VSO recorded the ankle angle in the sagittal plane at 100 Hz. Force-sensitive resistors (FSRs, FlexiForce A502, Tekscan Inc, MA, USA) embedded within the insoles were used to detect heel strike and toe-off events also at 100 Hz [13]. Two GaitUp sensors (Physilog, Lausanne, Switzerland) were

attached to the shoes to monitor foot movements sampled at 128 Hz. Surface electromyography (EMG) electrodes (Trigno Delsys, Natick, MA, USA) were bilaterally placed on the TA, GM, soleus (SOL), and gastrocnemius lateralis (GL) muscles to register muscle activity with a sampling rate of 1926 Hz. An inertial measurement unit (IMU) was attached to the trunk of the participants at the sternum height, and recorded torso motion at 100 Hz. Finally, a smartwatch (Versa 3, Fitbit, San Francisco, USA) was used to measure heart rate at 1 Hz. Participants also reported their perceived effort after each trial using the Borg's scale [18].

D. Data processing

Data from the sensors of the inGAIT-VSO, EMG sensors, IMU sensor, and smartwatch were processed using MATLAB 2021b (MathWorks, Natick, MA, USA). Data from the GaitUp sensors were processed using GaitUp Lab (Physilog, Lausanne, Switzerland).

EMG data were pre-processed to remove noise and artifacts. This involved band-pass filtering (30-300 Hz), full-wave rectification, and low-pass filtering (3 Hz). The resulting linear envelopes were normalized to the maximum activation observed in the no stiffness walking trial. After pre-processing, all data were resampled to the same frequency and synchronized. The data were then segmented into gait cycles using heel strike events detected by the FSRs. Each gait cycle was linearly interpolated, resulting in 300 data points per cycle. Variables were calculated as described in Section II-A.1 with a computation interval specified in Table I.

III. RESULTS

Data acquisition during the pilot sessions proceeded smoothly for both participants, enabling computation of performance variables for each trial (Fig. 2). Visual inspection revealed that some variables exhibited greater response with respect to stiffness levels (Fig. 2). The increase in stiffness corresponded to the decrease in the maximum ankle DF values in both participants. Perceived effort showed a slight increasing trend in CP02, while no clear pattern emerged for CP01. For CCI, both participants showed higher values for the left side compared to the right.

Upon training an XGBoost model for each participant, SHAP values representing the contribution of each variable to stiffness prediction were computed (Fig. 3). SHAP values were calculated for data at each stiffness level, and values were stacked to observe the overall contribution of each variable.

Variables did not consistently hold the same level of influence across participants and stiffness levels. For CP01, the SHAP values revealed that peak ankle DF had a dominant influence on the model's predictions, with the remaining variables contributing substantially less. In contrast, for CP02, the PCI was the most impactful variable, though the influence on the prediction was evenly distributed among other variables, each belonging to a different gait domain. Regarding differences between stiffness levels, SHAP values

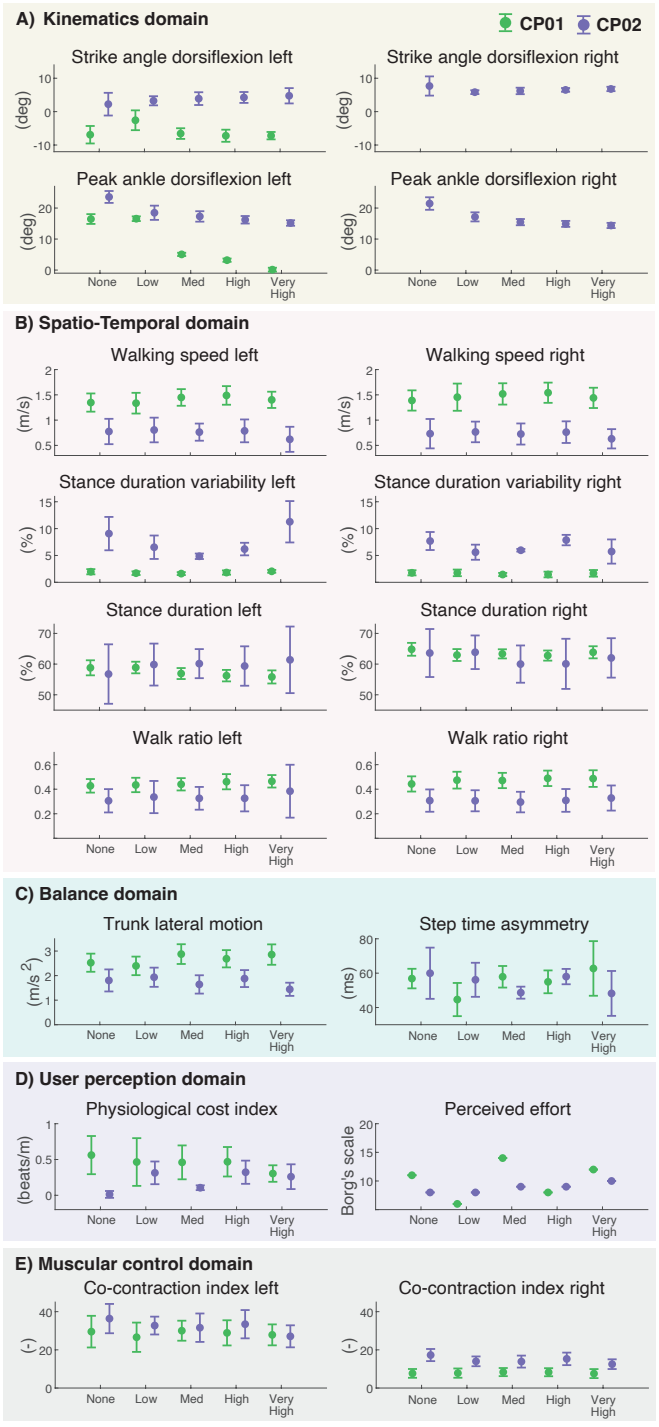

Fig. 2. Means and standard deviations for the different performance variables calculated for CP01 (green) and CP02 (purple). Variables for the Kinematics domain on the right side were not computed for CP01, as the participant was hemiparetic and only wore the AFO on the left side.

for PCI in CP02 were lower at very high stiffness compared to lower stiffness levels. Lastly, some variables were not relevant for any participant. For example, the SHAP values for the walk ratio (both on the left and right sides) were close to 0 for both participants. Walking speed, CCI and trunk lateral motion also had a minimal contribution.

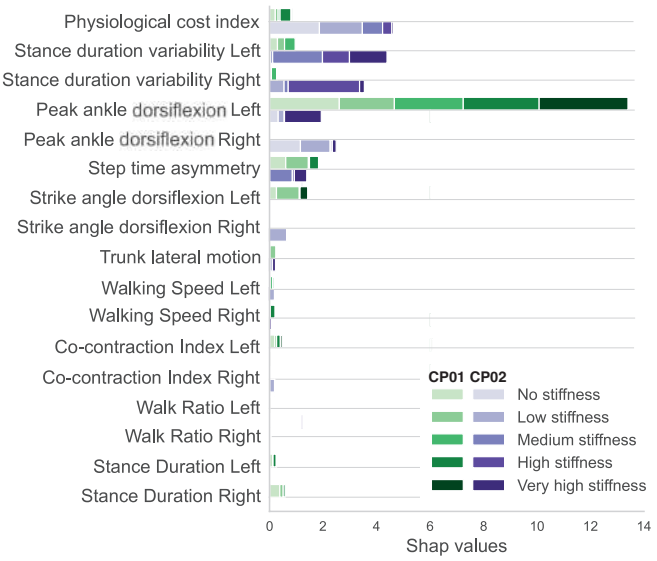

Fig. 3. SHAP values for CP01 (green) and CP02 (purple). The bars are formed by stacked SHAP values obtained for each stiffness level, and represent the impact on stiffness prediction, with larger bars indicating greater influence.

IV. DISCUSSION

In this work, we proposed a series of performance variables reflecting different aspects of gait and explored their relevance for stiffness in a pilot study with two participants with CP using the inGAIT-VSO. Key findings showed a different distribution of the influence of performance variables on stiffness predictions between participants. This could explain why optimization effectiveness varied across participants in previous studies that relied solely on a limited set of predefined variables [11], [9]. These findings highlight the importance of having customized cost functions that move away from "one-size-fits-all" approaches.

Looking just to the variables with the largest contributions in both participants, we observed that they differed, as for example, the PCI had the largest contribution for stiffness prediction in CP02, but the same variable had a low impact in CP01. This variability also extended to other variables in our study, with the top-ranking SHAP values for CP01 not being as relevant for CP02 and vice-versa.

For CP01, there was a clear dominant variable: the peak ankle DF left, side in which this hemiparetic participant worn the inGAIT-VSO. However, for participant CP02, there was a more uniform distribution across six variables (i.e., PCI, stance duration for the left and right sides, peak ankle DF for the left and right sides, and STA), being these the primary drivers for prediction. Excluding any of these variables, which belonged to different gait domains, would result in the loss of valuable information regarding gait characterization in this participant. These results in CP02 highlight the potential pitfall of relying on a reduced number of variables or domains that might not be enough to capture the complexity of gait.

Our findings using SHAPP values indicate that the stiffness optimization problem should: 1) account for multiple variables to capture the diverse domains of gait, and 2) be customized for each user, as the impact of individual variables can vary significantly between users. However, while this pilot study identified performance variables most sensitive to changes in stiffness, optimizing stiffness solely based on these variables –which primarily reflect the user's physical characteristics– may not be sufficient, as it does not guarantee that the resulting stiffness configuration aligns with the user's personal preferences. To address this limitation, future research should also incorporate user preferences into the optimization process. This would allow the optimal stiffness value to reflect the best solution, considering both the user's physical state and personal preferences. However, aligning user preferences with clinical goals can be challenging. Previous studies have highlighted divergences between the priorities of healthcare professionals and those of patients [8], [25], [4]. Therefore, future research should aim to strike a balance between these two aspects to ensure both clinical efficacy and user satisfaction.

Lastly, the current study protocol requires individual testing for each stiffness level, which may be impractical in a real-world clinical setting. However, with a larger dataset, it may be possible to infer the effects of each stiffness configuration without directly measuring each one. This approach could simplify the testing protocol, making it more practical for clinical use.

A. Study limitations

The first acknowledged limitation is the involvement of only two participants, limiting the generalization of the findings. However, even with two participants we proved the need for an individualized stiffness optimization. Future work will include a larger sample size to strengthen conclusions and potentially simplify the protocol.

A second limitation was the variation in the computation intervals for the different variables. Three of the 11 variables were extracted per walking segment, while one was calculated only once per trial, leading to repeated values across observations (i.e., gait cycles). This might have introduced some bias.

The Borg's scale to estimate perceived effort was excluded from predictions due to bias in registering this variable. Specially for CP01, ratings consistently increased with the (randomized) trial order, suggesting that this participant compared the new rating with the one of the previous trial.

Lastly, the study focused on kinematic and temporal domains but excluded kinetics, as measuring them requires assessment of forces along the 20-meter corridor. The ankle torque measured with inGAIT-VSO was also excluded to avoid bias in SHAP values, as it directly relates to the AFO stiffness. The inclusion of kinetics and other joints' kinematics in the future could provide deeper insights.

V. CONCLUSION

This study aimed to identify relevant optimization variables and observe how they varied between users. Our

findings show that multiple variables were classified as important, supporting the hypothesis that relying on a single variable is insufficient to capture the complexity of gait. Additionally, the variability in relevant variables between participants highlights the need for individualized optimization. Taking this research a step further, future studies aim to incorporate user and clinician preferences to achieve a more personalized optimization. This would yield higher levels of user satisfaction and acceptance.

ACKNOWLEDGMENT

This work has been carried out with the financial support from the Dutch Research Council NWO (Veni-TTW-2020, 18079). Authors would like to acknowledge all participants of the study.

Encoding Desired Postural Synergies in a Single-Actuator Soft Robotic Prosthetic Hand Through Finger Joint Stiffness Modulation

Alireza Mohammadi, Ki Hoon Han, Monireh Ahmadi Bani, Jaimie , Silvia Ursula Raschke, Ying Tan, Peter Choong, and Denny Oetomo

***Abstract*— This paper presents the design and analysis of a single-actuator robotic prosthetic hand based on soft flexure joints, enabling the encoding of desired postural synergies of fingers through their joint stiffness modulation. Finger movements are coordinated using a simple whiffletree mechanism, which simultaneously pulls all tendons, with the synergy determined by the varying stiffness of the flexure joints. A forward quasi-static model is developed to predict joint angles based on tendon displacement driven by the actuator, assuming known joint stiffness values. Then, an inverse model is introduced to compute the required stiffness of finger joints for achieving a desired postural synergy. The proposed design is validated through simulations and real-world experiments on a 3D-printed soft robotic prosthetic hand. The hand successfully demonstrates a postural synergy that produces both pinch and power grasp types. This approach provides a lightweight and mechanically simple solution for robotic prosthetic hands with single actuator, enabling desired postural synergy while maintaining functionality and adaptability for grasping tasks.**

I. INTRODUCTION

Soft robotic hands have received significant attention in recent years due to their inherent safety, lightweight design, and cost-effective fabrication enabled by 3D printing [1]. These characteristics are particularly beneficial in the field of prosthetics, where safety, comfort, affordability are essential to meet the needs of users [2].

Various actuation systems and force transmission methods have been employed in the design of soft robotic prosthetic (bionic) hands. Actuation approaches include pneumatic systems [3], shape memory alloys [4], and DC motors [5], while transmission mechanisms often rely on tendons, gears, or pulleys [6]. Among these, tendon-driven mechanisms actuated by DC motors are the most prevalent due to their high power-to-weight ratio and lightweight design [7].

In tendon-driven bionic hands, achieving a variety of grasp types typically requires multiple actuators, with each actuator responsible for controlling an individual finger or joint [3]. While this approach enables precise and independent movements, it often results in prosthetic hands that are bulky, heavy, and complex to manufacture and maintain. Such characteristics can significantly reduce the appeal of these hands, especially for users who prioritise lightweight and compact designs such as paediatric users [2].

To address the challenges associated with multi-actuator prosthetic hands, several studies have explored highly underactuated designs that use a single actuator to drive multiple fingers. These designs rely on carefully engineered transmission mechanisms and underactuated finger design with spring or flexure joints [8] to return the finger to the original position after flexion. In [9], [10], a direct actuation system was utilised to move all the fingers simultaneously, enabling basic grasping functionality. While this approach simplifies the mechanical design, the mechanism provides only a single grasp type and lacks adaptability.

In [11], a continuum differential mechanism combined with passive thumb movement was employed to enable a grasp adaptable to objects of varying shapes and sizes. In [12], a combination of coalesced whiffletree differential mechanism, a locking mechanism that switches between power and tripod grasps, and manual repositioning of the thumb enables three distinct and adaptive grasp types. However, this will require intervention from other intact hand to switch between different grasp types.

The SoftHand Pro [13] employs a single actuator to control 19 joints, utilising the concept of postural synergies to coordinate finger movements. Elastic tendons and a differential transmission mechanism enable the hand to adapt to various object shapes. The finger synergies, derived from experimental studies on grasping objects of different shapes and sizes [14], provide the hand with multi-grasp capabilities, such as power and precision grips. However, reliance of the design on multiple tendons in the finger joints and elastic components introduces mechanical complexity, requiring precise calibration to ensure consistent performance.

In this paper, we present a single-actuator robotic prosthetic hand with soft flexure joints in the fingers. The design achieves the desired finger synergy by modulating stiffness of the flexure joints, enabling the hand to produce desired coordination of the fingers. The stiffness modulation is achieved by altering the geometrical parameters of the flexure joints in the fingers. While previous studies, such as [15], have explored stiffness modulation to achieve a desired trajectory for a single finger, our work extends this concept by investigating how joint stiffness can be optimised to achieve the desired synergy among multiple fingers. A whiffletree

transmission mechanism drives all tendons simultaneously, with finger coordination dictated by the varying stiffness of the flexure joints.

We first develop a forward quasi-static model to predict the joint angles of the fingers as a function of the tendon cable length pulled by the actuator, assuming predefined joint stiffness values. Using this model, we then introduce an inverse model to calculate the required joint stiffness values necessary to achieve a desired finger synergy. Through simulations, we validate that for a desired synergy providing two grasp types of pinch and power, the required stiffness values for each joint can be determined to achieve the intended functionality. This is further demonstrated through real-world experiments using a 3D-printed hand fabricated with flexible materials and integrated with a whiffletree mechanism, driven by a single servo motor. The proposed approach simplifies the design while enabling the encoding of desired synergies to perform a wide range of grasping tasks.

II. Forward Quasi-static Modeling

This section provides a detailed kinematic analysis of the tendon-driven soft bionic hand, actuated by a single motor in combination with a whiffletree mechanism, as illustrated in Fig. 1. The mechanism consists of four links, each arranged in parallel to distribute forces evenly across the fingers.

The proposed design incorporates two flexure joints per finger: the metacarpophalangeal (MCP) joint and the proximal interphalangeal (PIP) joint. To simplify the design without compromising the generality of the proposed control method, the distal interphalangeal (DIP) joint is assumed to be fixed. We also assumed that the friction between the tendon cable and the elastic finger is negligible. Each flexure joint is modeled as a torsional spring with a fixed axis of rotation, as depicted in Fig. 2.

A. Quasi-static modeling of the fingers

Modelling the flexure joints as torsion springs, Hooke's law expresses the force applied by the tendon and the angular displacement, θ_{ij}, of the *ij*-th joint as:

$$\begin{aligned} \tau_1 &= k_{ij}\theta_{ij}, \\ F_i * r_{ij} &= k_{ij}\theta_{ij}, \\ F_i &= \frac{k_{ij}\theta_{ij}}{a_{ij}\sin(\angle J_{ij}B_{ij}A_{ij})}, \end{aligned} \tag{Eq.1}$$

where F_i is the actuation force acting on the *i*-th finger and r_{ij} is the perpendicular distance from the *ij*-th joint rotation axis, J_{ij}, to the tendon, $\overrightarrow{A_{ij}B_{ij}}$.

The torsional stiffness, k_{ij}, is dictated by the geometrical parameters of the flexure joint including a_{ij}, b_{ij}, and ϕ^0_{ij} as well as the Shore hardness of the material (more details in [5]). Additionally, a_{ij} and b_{ij} denotes the magnitude of $\overrightarrow{J_{ij}A_{ij}}$ and $\overrightarrow{J_{ij}B_{ij}}$, which remain constant during bending. Note that the angular displacement is constrained to $0^\circ \leq \theta_{ij} \leq \phi^0_{ij}$ due to the joint itself resisting further bending once it reaches ϕ^0_{ij} (angle ϕ_{ij} at relaxed state). Thus, applying

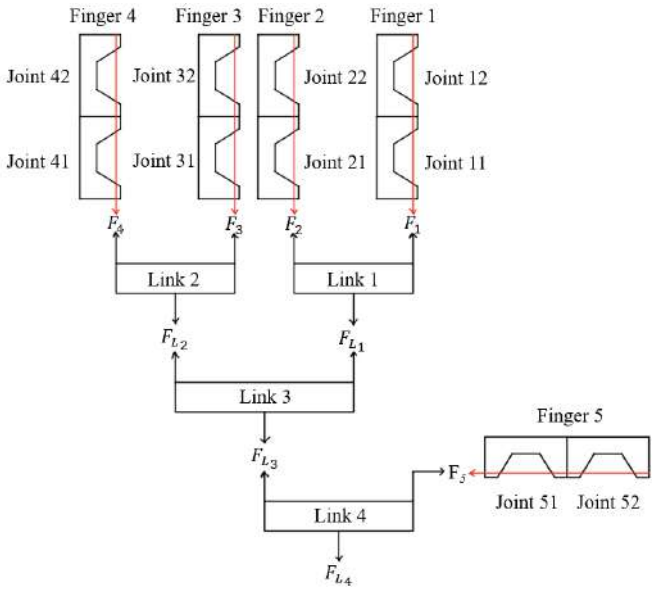

Fig. 1: Schematic diagram of simplified two-joint single-actuator driven soft bionic hand. The red lines illustrate the tendons used to transfer the actuation force to each joint.

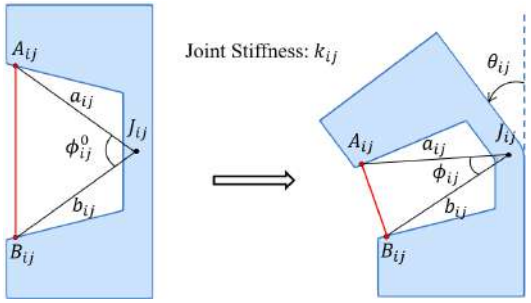

Fig. 2: Schematic diagram of a single *ij*-th joint with geometrical parameters a_{ij}, b_{ij}, and ϕ^0_{ij} for stiffness modulation

the laws of sines and cosines to Eq.1 gives the generalised equation that relates the actuation force and the joint angle displacements for any *i*-th finger:

$$\begin{aligned} F_i &= f(k_{ij}, \theta_{ij}, a_{ij}, b_{ij}, \phi^0_{ij}) \\ &= \frac{k_{ij}\theta_{ij}\sqrt{a_{ij}^2 + b_{ij}^2 - 2a_{ij}b_{ij}\cos(\phi^0_{ij} - \theta_{ij})}}{a_{ij}b_{ij}\sin(\phi^0_{ij} - \theta_{ij})} \end{aligned} \tag{Eq.2}$$

for $i = 1, 2, 3, 4, 5$ and $j = 1, 2$.

Moreover, the relationship between the total length of the tendon corresponding to the *i*-th finger and the angular displacements of its constituent joints, θ_{ij}, can be described using the law of cosines for the triangle $\Delta A_{ij}J_{ij}B_{ij}$, as follows:

$$l_i = \sum_{j=1}^{2} |\overrightarrow{A_{ij}B_{ij}}| = \sum_{j=1}^{2} \sqrt{a_{ij}^2 + b_{ij}^2 - 2a_{ij}b_{ij}\cos(\phi^0_{ij} - \theta_{ij})}.$$

Consequently, the change in length of the tendon associated with the *i*-th finger, as induced by the actuator, can be

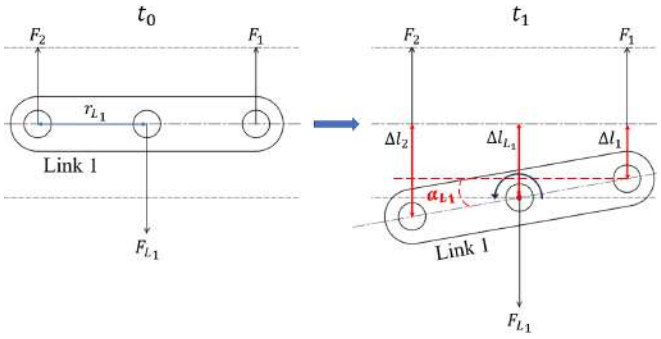

Fig. 3: Schematic diagram of the simplified primary linkage system.

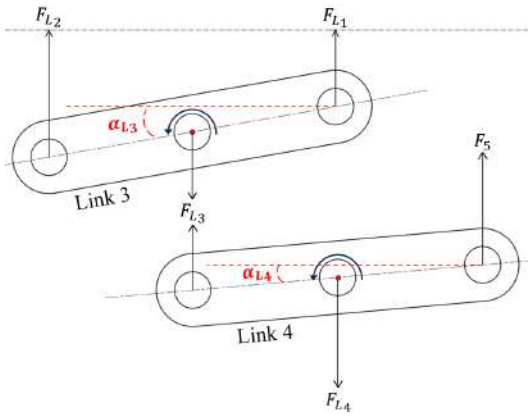

Fig. 4: Schematic diagram of the simplified secondary linkage system

expressed as:

$$\Delta l_i = l_i^0 - l_i, \tag{Eq.3}$$

where l_i^0 denotes the length of the wire of *i*-th finger at its relaxed position with θ_{ij}^0 being the initial offset of joint angular displacements. Δl_i is the length of tendon pulled for a given *i*-th finger. Thus, Eq.3 represents the relationship between the joint angular displacements and the length of tendon cable displaced for each finger.

B. Quasi-static modeling of the linkage system

1) Primary linkage system modeling: Primary linkage system refers to the links that are only connected to the fingers, i.e., Link 1 and Link 2 (refer to Fig. 1). A pair of fingers are actuated through tendons attached to a shared link, represented using a simplified two-dimensional geometry, as illustrated in Fig. 3. Focusing on Link 1, and assuming that Finger 1 has higher stiffness than Finger 2, the entire link will rotate about its central pivot point when the tendon located at the centre is pulled. Due to its lower stiffness, Finger 2 will experience displacement first, causing Link 1 to rotate by an angle α_{L_1} from its equilibrium position. It is important to note that the deviation angle α_{L_k} for any arbitrary link is expected to be small, as the tendon displacement for each link is constrained by the size of the palm. This assumption allows all tendons to be considered as remaining vertical throughout the travel of the links.

Assuming the link is symmetrical about its centre lines, the centre-to-centre distance between the outer holes and the centre hole will be equal, i.e., $r_{L_1} = r_{L_2}$. Subsequently, the quasi-static forward modeling of Link 1 can be described as:

$$+\uparrow \sum F_{vertical} = 0 : F_1 + F_2 = F_{L_1},$$

$$\circlearrowleft + \sum M_{pivot} = 0 : F_1 = F_2 = \frac{F_{L_1}}{2}.$$

Hence, referring to Eq.2, the following relationship must hold true:

$$f_{ij} = f(k_{ij}, \theta_{ij}, a_{ij}, b_{ij}, \phi_{ij}^0) = \text{Constant}, \tag{Eq.4}$$

for $i = 1, 2$ and $j = 1, 2$.

Furthermore, the relationship between the displacement of the bottom tendon, Δl_{L_k}, and the top tendons, Δl_1 and Δl_2, can be described as:

$$\begin{aligned} \Delta l_{L_1} &= \Delta l_1 + r_{L_1} \sin \alpha_{L_1} \\ &= \Delta l_2 - r_{L_1} \sin \alpha_{L_1}, \end{aligned} \tag{Eq.5}$$

where:

$$\alpha_{L_1} = \arcsin\left(\frac{|\Delta l_2 - \Delta l_1|}{2 r_{L_1}}\right). \tag{Eq.6}$$

The maximum theoretical angle of α_{L_1} is when the link has rotated fully vertically. This remains true irrespective of which finger has greater stiffness. Using the properties of inverse trigonometric functions, where $\sin(\arcsin x) = x$, for $x \in [-1, 1]$, Eq.5 can be simplified as:

$$\begin{aligned} \Delta l_{L_1} &= \min(\Delta l_1, \Delta l_2) + \frac{|\Delta l_2 - \Delta l_1|}{2} \\ &= \max(\Delta l_1, \Delta l_2) - \frac{|\Delta l_2 - \Delta l_1|}{2}. \end{aligned} \tag{Eq.7}$$

Therefore, Eq.4 and Eq.7 form a system of equations that obtains the constituent joint angles θ_{ij} for Fingers 1 and 2 for a known length of the wire displacement of Link 1. The same analysis approach can be applied to Link 2.

2) Secondary linkage system modeling: The secondary linkage system refers to the links that are situated within the palm that are only or partially connected to other links, i.e., Link 3 and Link 4. This section addresses the modeling of these links and hence completes the forward quasi-static modeling of the entire underactuated bionic hand. The configuration of the secondary linkage system, Fig. 4, is similar to that of the primary linkage system (Fig. 3).

Similar to the analysis of a link shown in the previous subsection, the quasi-static forward modeling of Link 3 can be described as:

$$+\uparrow \sum F_{vertical} = 0 : F_{L_1} + F_{L_2} = F_{L_3},$$

$$\circlearrowleft + \sum M_{pivot} = 0 : F_{L_1} = F_{L_2} = \frac{F_{L_3}}{2}.$$

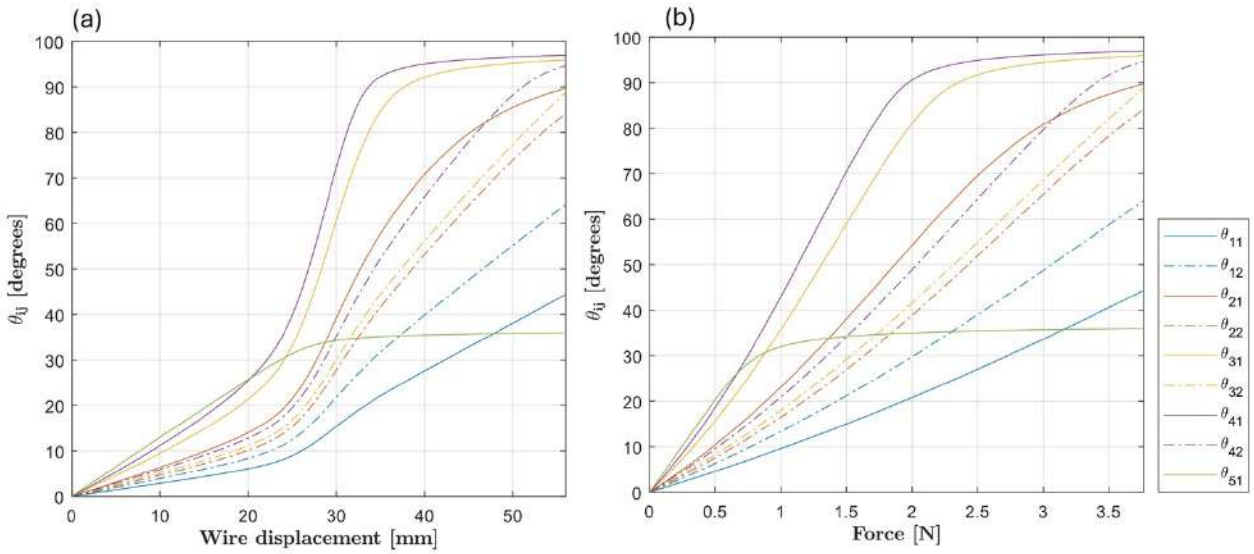

Fig. 5: The variation of the joint angles based on: (a) length of wire pulled by the actuator, and (b) force applied by the actuator

Recall that:

$$F_1 = F_2 = \frac{F_{L_1}}{2} \quad \text{and} \quad F_3 = F_4 = \frac{F_{L_2}}{2}.$$

Hence, F_{L_3} can be expressed as:

$$F_{L_3} = 4F_1 = 4F_2 = 4F_3 = 4F_4.$$

Following a similar analysis for Link 4:

$$F_{L_4} = 2F_5 = 8F_i, \quad \text{for } i = 1, 2, 3, 4. \tag{Eq.8}$$

where F_{L_4} is the magnitude of actuation force produced by the single servo motor. Eq.8 also describes the relationship between the force applied to the thumb (Finger 5) relative to the rest of the fingers. With this, we can create a system of equations that relate the forces applied to each joint, as follows:

$$f_{ij} = \begin{cases} f_{ij}, & \text{if } i = 1, 2, 3, 4 \text{ and } j = 1, 2 \\ \frac{1}{4} f_{ij}, & \text{if } i = 5 \text{ and } j = 1, 2 \end{cases} \tag{Eq.9}$$

where:

$$f_{ij} = \frac{k_{ij}\theta_{ij}\sqrt{a_{ij}^2 + b_{ij}^2 - 2a_{ij}b_{ij}\cos(\phi_{ij}^0 - \theta_{ij})}}{a_{ij}b_{ij}\sin(\phi_{ij}^0 - \theta_{ij})}.$$

Moreover, the relationship between the tendon displacement at the actuator, Δl, and at the fingers, Δl_i, can be expressed using a similar method of analysis used to derive Eq.7 as:

$$\Delta l = \min(\Delta l_5, \Delta l_{L_3}) + \frac{|\Delta l_{L_3} - \Delta l_5|}{2}, \tag{Eq.10}$$

where:

$$\Delta l_{L_3} = \min(\Delta l_{L_1}, \Delta l_{L_2}) + \frac{|\Delta l_{L_2} - \Delta l_{L_1}|}{2}.$$

Thus, Eq.9 and Eq.10 form a system of ten equations that make it possible to obtain all the joint angles θ_{ij} for $i = 1, 2, 3, 4, 5$ and $j = 1, 2$ for a given length for wire displacement at the actuator Δl.

III. Inverse Design for Encoding Desired Synergy of Fingers

The objective of the inverse design is to produce the required joint stiffness values, k_{ij}, for all joints for a given desired synergy of the fingers and the tendon displacement at the actuator, Δl. This inverse design aims to obtain the stiffness values that minimise the constituent joint angular discrepancy between the finger synergy produced and the desired synergy. A finger synergy refers to the coordinated set of joint angles that achieves a desired hand motion trajectory. However, this preliminary study will solely focus on a single desired pose. In future works, the inverse design is to be implemented such that it finds the most suitable stiffness values for each joint that yield the closest joint motion to the desired finger synergy. Thus, the inverse design becomes an optimisation problem, which is defined as:

$$\min_{k_{ij}} \sum_{i=1}^{5}\sum_{j=1}^{2} || \ \theta_{ij} - \theta_{ij}^* \ ||^2,$$
$$\text{s.t.} \quad \text{Eq.9}$$

where θ_{ij}^* denotes the target joint angles required to produce the desired finger synergy. If we are interested in implementing specific constraints on the joints, they can be included in the optimisation formulation above.

IV. Simulation Results

In this section, we analyse an example finger synergy to determine the required stiffness of each finger joint to achieve the intended coordination. Since the goal is to design a robotic hand with multi-articulation capabilities that can perform more than one grasp type for manipulating a variety of objects, we focus on a synergy that enables both power and pinch grasps. Together, these two grasp types account for over 70% of the grasping actions required for activities of

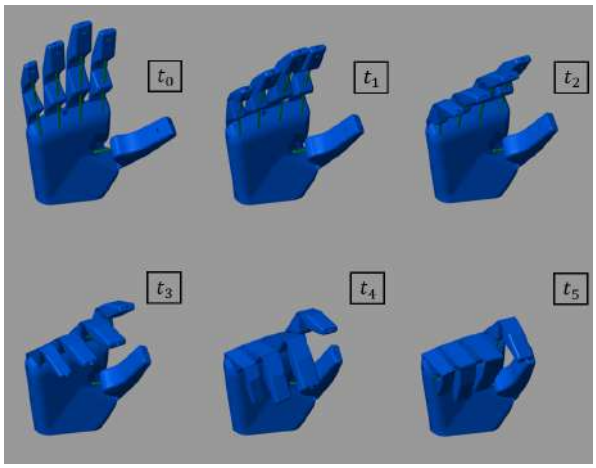

Fig. 6: Visual illustration of the obtained finger synergy.

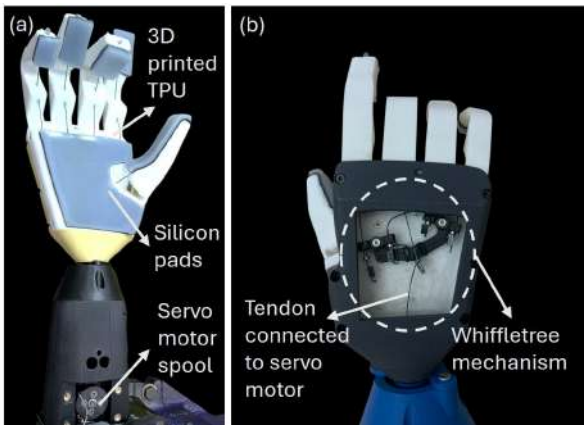

Fig. 7: Overall design of the single-actuator, tendon-driven soft robotic prosthetic hand with flexure joints: (a) front view; (b) back view with force transmission mechanism

daily living by prosthetic hand users [16]. Achieving multiple grasp types with a single actuator ensures that the prosthetic hand remains lightweight and compact while providing the functionality needed for a wide range of applications.

The described finger synergy enables both types of grasp by allowing the user to perform a power grasp initially, followed by a pinch grasp as the angular displacement of the joints increases. To approximate this finger synergy as closely as possible, the final joint angles listed in Table I are used as input parameters for the inverse analysis. While the general analysis was conducted for ten joints (two per digit), the simulation was simplified to nine joints: two per finger and one for the thumb, the latter ensuring a stable pinch grip as it will limit further movement of the thumb after a certain stage of tendon actuation, so the user can focus on controlling the index finger.

For this demonstration, the joints' geometrical parameters are provided in Table II. The tendon displacement is assumed to be $\Delta l = 57$ mm. The joint stiffness values, k_{ij}, generated by the inverse design are shown in Table III.

Using the calculated joint stiffness values, Fig. 5 illustrates

TABLE I: Desired joint angles to produce two grasp type finger synergy

Desired Joint Angles (degrees)

θ^0_{ij} (deg)	0 (all zeros)								

the variation in joint angles for each finger as a function of the displacement of the tendon cable driven by the actuator, as well as the force exerted on the tendon by the actuator.

Fig. 6 visualises the finger synergy from t_0 to t_5, corresponding to different stages of tendon cable displacement. The results demonstrate that the encoded finger synergy in the robotic hand enables both power and pinch grasps. From t_0 to t_3, the hand performs a power grasp suitable for holding larger objects. Subsequently, from t_3 to t_5, the hand transitions to performing a pinch grasp or a power grasp for objects with smaller diameters.

V. Experimental Demonstration

To demonstrate the applicability of the proposed method in a real-world soft bionic arm, we developed a flexure joint-based soft robotic prosthetic hand, using the designs proposed in [5] and [17]. Fig. 7 illustrates the overall design of the bionic hand. The hand was 3D-printed in a single process using a benchtop 3D printer (Bambu P1S) with Thermoplastic Polyurethane (TPU) of Shore hardness 85A.

The fingers are actuated via a fishing line connected to a whiffletree mechanism, which is driven by a digital servo

TABLE III: Result of inverse analysis of feasible joint stiffness values.

motor with a spool to pull the tendon cable attached to the final link of the mechanism. The servo motor is included in the forearm of the bionic arm close to the wrist. The postural synergies of the fingers are depicted in Fig. 8.

To validate the functionality of the hand in grasping objects of various shapes, sizes, and weights, we conducted experiments involving ten objects that required power and pinch grasps. The grasping results are shown in Fig. 9. A supplementary video (Video-S1.mp4) demonstrating these experiments is included with the paper.

VI. Conclusion and Future Work

This paper presented the design, modeling, and experimental validation of a single-actuator soft robotic prosthetic hand that encodes desired postural synergies through the use of flexure joints with varying geometrical parameters. The results demonstrated that a simple tendon-driven mechanism, combined with tailored stiffness in the flexure joints, can effectively produce postural synergies, enabling multiple grip types for grasping a wide range of objects with different shapes and sizes. Future work will focus on conducting clinical trials to assess the practical utility, adaptability, and user experience of the proposed prosthetic hand design.

A Novel Approach to Trunk Rehabilitation: Designing an Upper Body Robotic Mobilizer for Neurological Disorders

Giulia Bodo[1,2], Gianluca Capitta[2], Mattia Modenese[1,2], Luca De Guglielmo[2], Eleonora Guanziroli[3] and Matteo Laffranchi[2]

***Abstract*— After a neurological adverse event, restoring trunk functionality is essential for regaining balance, proprioception, and strength, all of which are critical for performing activities of daily living and enabling rehabilitation for impaired upper and lower limbs. Traditional therapy focuses on enhancing core strength, stability, and proprioceptive capabilities. Recent advancements in the field propose robotic solutions that utilize platforms to induce specific movements, stimulating muscular activation and prompting patients to respond to guided motions. These solutions often employ robotic seats that mimic traditional clinical tools, such as cushions or physiotherapy balls, to assist in mobilizing patients.**

In this work, we introduce a novel approach to trunk rehabilitation through a robotic system: a Series Elastic Actuator (SEA)-based trunk robotic mobilizer. This device is paired with a suite of control strategies designed to address various neurological conditions, including spinal cord injury, post-stroke impairments, and pusher syndrome.

I. INTRODUCTION

In the last decades, a growing demand for advanced technologies that facilitate neuromotor and functional rehabilitation of the upper body has emerged. The complexity of the rehabilitation scenario increases when neurological disorders cause the disability: in such cases, impairments such as spasticity, synkinesias, and cognitive or sensory deficits compound the existing limitations [1], making the treatment even more challenging. Effective and lasting rehabilitation in these cases requires active patient involvement [2]. Patients must be encouraged to voluntarily perform movements to stimulate natural processes of neural reorganization and regeneration [3]. Robotic-mediated rehabilitation is emerging as a promising solution to address the challenges faced in traditional therapy. This approach caters to neurological rehabilitation needs, offering the potential for more effective and efficient treatment outcomes. These technologies aim to provide repetitive, precise, and intensive training [4] across different stages of rehabilitation, transitioning from fully supported modes to scenarios where the patient is increasingly active and engaged. After a neurological event, the trunk often remains an impaired area, significantly impacting both balance and activities of daily living (ADLs) [5].

The trunk is essential for stabilizing the upper body, and when its function is compromised, it can lead to challenges in maintaining balance and performing routine tasks. In stroke patients, trunk muscle contractions, both isometric and isokinetic, are typically weaker than those in healthy individuals [6], several studies have demonstrated strong correlations between trunk impairment, functional performance, and muscle activity [7]. Similarly, individuals with Spinal Cord Injury (SCI) who experience paralysis of the trunk muscles [8] often have diminished control over trunk movements and struggle to maintain a stable posture [9]. Another clinical condition that significantly disrupts trunk motor activity is Pusher Syndrome (or lateropulsion) [10], a specific variation of stroke characterized by a loss of proprioception related to one's posture. Individuals with this syndrome tend to apply a strong, constant push toward their hemiplegic side, regardless of their position [11]. This behaviour actively resists any attempts to correct their posture passively, such as shifting their weight toward the body's midline or, through it, to the unaffected side. Pusher Syndrome presents various neuropsychological symptoms that affect motor function in distinct ways. Specifically, individuals often struggle in antigravity situations, showing an inability to recognize and process proprioceptive feedback. This leads to unbalanced postures misaligned with the body's midline [12]. Patients with pusher syndrome and those in the post-acute phase are typically treated in a seated position to regain control of imbalance-related falls [13] [10].

The authors explored a different concept of upper body robotic mediated rehabilitation, going outside the state-of-the-art concept that mostly proposes the adoption of motorized seats and platforms. Instead, a robotic mobilizer meant to provide robust and stable rehabilitation of the core muscles is directly interfaced with the trunk of the subject, aiming at improving its mobility and stability. This work will present the developed prototype and the different control strategies that have been implemented and tested using a real-time Rapid Control Prototyping (RCP) approach.

II. DEVICE DESIGN

The ideation of the proposed design stemmed from close collaboration between researchers, engineers, and clinicians, following a user-centered design approach. The mechanical and control design requirements were gathered from feedback during interactions with clinicians. The primary goal was to enable patient rehabilitation using a robotic device from the early acute phases, when trunk proprioception and balance have yet to be restored, providing clinicians with a

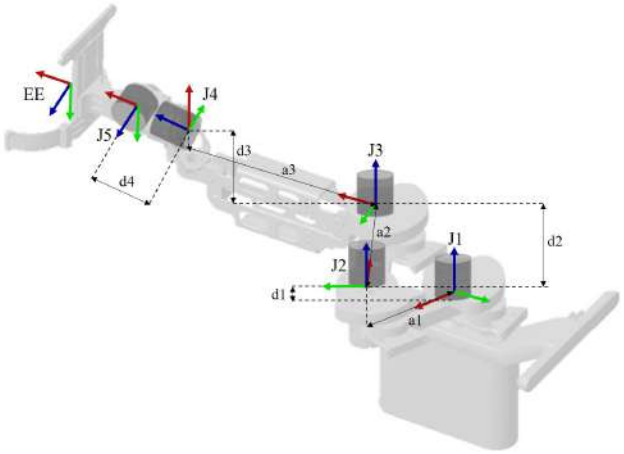

Fig. 1: Graphical representation of the Denavit-Hartenberg convention parameters, as defined in Table I. The parameters *a* and *d* correspond to translations along the x and z-axes of the current frame, respectively. The depicted configuration represents the zero-rotation reference for each joint. Consequently, the range of motion (ROM) values in Table II should be considered relative to this reference.

valuable tool to mobilize the trunk and stimulate the recovery of upper body control.

A. Kinematics

The device is inspired by the passive multi-jointed arm supporting the Float exoskeleton [14]. Compared to the Float multi-jointed arm, the new design incorporates actuation via Series Elastic Actuators (SEAs) for the planar kinematics. Additionally, two more SEA joints are added at the end of the kinematic chain to enable frontal and lateral trunk flexion, and a corset has been designed to support and interface with the patient's trunk. Unlike in the Float system, where the central part of the arm (regarding Figure 1, the link connecting J3 to J4) was adjustable in height, it is now a fixed connection link. The proposed system is designed with five actuated degrees of freedom, as shown in Figure 1. Joints J1, J2, and J3 enable planar movement, which is particularly active during trunk rotation. These joints also work in synergy with J4, primarily involved in lateral flexion, and J5, responsible for trunk flexion in the frontal plane.

The kinematic of the system follows the Denavit-Hartenberg convention and can be described as reported in Table I; the parameters have been identified as shown in Figure 1. The joints' ranges of motion are reported in Table II; those are defined with respect to the zero-configuration shown in Figure 1.

TABLE I: Trunk robotic device Denavit-Hartenberg kinematic parameters.

$Link_{id}$	a $[m]$	α $[rad]$	d $[m]$	θ_i
l_1	0.240	0	0.075	θ_1
l_2	0.240	0	0.033	θ_2
l_3	0.533	$\pi/2$	0.082	θ_3
l_4	0	$\pi/2$	0.101	θ_4

TABLE II: Ranges of motion for each joint, constrained by its mechanical end of travel. These angles are measured relative to the robot's zero-configuration, shown in Figure 1.

$Joint_{id}$	θ_{min} $[deg]$	θ_{max} $[deg]$
$J1$	-67	30
$J2$	-20	65
$J3$	-82	41
$J4$	-20	20
$J5$	-10	30

Following clinicians' requests, the links connecting the different joints and the actuation system have been dimensioned to guarantee the frontal and lateral flexion ranges of motion reported in Table II (J4, J5). Specifically, the system allows for ± 20 deg of lateral flexion in the frontal plane, -10 deg of extension and 30 deg of flexion in the sagittal plane.

B. Actuation

All the joints are equipped with torque sensors. Series Elastic Actuators (SEAs) have been adopted in the design to implement control strategies that account for human interaction in the loop.

The joints are actuated using EC45 Maxon brushless motor for J1-J2-J3 and EC60 for J4-J5. They are combined with a Harmonic drive with a reduction ratio of 1:100 and 1:120, respectively. The SEAs' characteristic element is a custom torsional spring; two different spring designs have been incorporated into the joints: a titanium spiral spring (SPTF1P) for J1-J2-J3 and a steel spiral (SPS1P) spring for J4-J5. They have been characterized and presented in a previous work by Bodo et al. in [15]. The torque estimation can be obtained by exploiting Hooke's law (Equation 6). The values of the spring stiffness k and the linear model intercept $\Delta_{\tau_{lm}}$ obtained from bench characterization of the joints are reported in Table III. Aksim-2 absolute position encoders are adopted to measure the spring displacement and translate it into a torque measurement. Since 19-bit encoders are adopted, the sensor torque resolution ranges from 0.011 Nm to 0.018 Nm, depending on the stiffness of the compliant element.

TABLE III: SEAs spring linear model: stiffness k and linear intercept $\Delta_{\tau_{lm}}$.

	J1	J2	J3	J4	J5
Spring type	SPTF1P	SPTF1P	SPTF1P	SPS1P	SPS1P
k $[Nm/rad]$	878	1017	920	1528	1517
$\Delta\tau_{lm}$ [Nm]	0.056	0.451	0.047	0.306	2.594

C. Design Specifications

Aligning with traditional therapeutic approaches, the device has been designed to mobilize a seated patient. The system has been dimensioned to accommodate a 95th-percentile male to guarantee upper body weight support.

The device configurations corresponding to the maximum joint loads were analyzed using the Mechanism tool provided by CREO PTC CAD software. These configurations

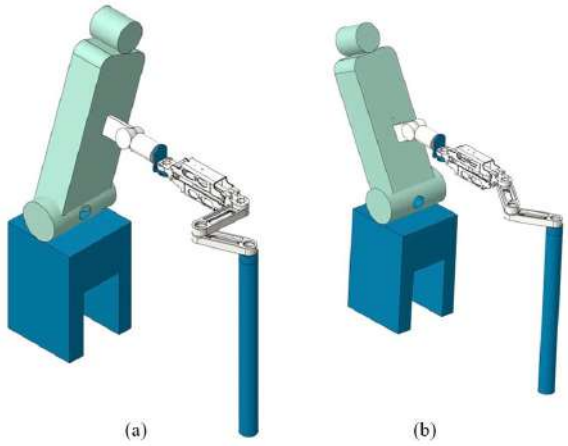

Fig. 2: Device configurations adopted for the load static analysis performed in the CREO PTC CAD software. The manikin represents the 95th percentile in 20 deg lateral flexion and 30 deg frontal flexion positions.

maximize leverage relative to the joints' rotational axes, specifically during full frontal flexion (30 deg) and full lateral flexion (20 deg), as shown in Figure 2.

The load analysis was conducted using the following settings: the simulation was performed for a 95th percentile male (body weight: 96.78 kg, upper body weight: 48.39 kg). All joint rotations were restricted, and only the effects of gravitational force were considered. The obtained system specifications, including the maximum torques required to be supported by the joints, are summarized in Table IV.

TABLE IV: Torque values, simulated in CREO PTC Mechanism analysis, for maximum lateral and frontal flexion across joints.

	τ_{J1}	τ_{J2}	τ_{J3}	τ_{J4}	τ_{J5}
τ Lateral Flex. [Nm]	-15.56	15.93	**-18.25**	0.00	0.00
τ Frontal Flex. [Nm]	-8.82	**25.25**	8.06	-0.08	0.00

To achieve these maximum target torques, specifically with the joints of the planar complex actuated with EC45 motors, an additional reduction stage with a ratio of 1:2.88 was implemented for the joints composing the planar complex. This design choice was guided by the following considerations: movement simulations were performed in CREO PTC in agreement with clinicians' suggestions, and the maximum desired speed for exercise performance was set to 6.66 rad/s (40 deg/s). The SEAs used in the joints embed a harmonic drive with a 1:100 reduction ratio, resulting in a fast shaft speed of:

$$\omega_{\text{fast}} = rr \cdot \omega_{\text{slow}} = 100 \cdot 6.66 = 666 \text{ rpm} \quad (1)$$

From the harmonic drive data sheet, the maximum average input speed is given as $\omega_{HD_{\text{avgMax}}} = 3500$ rpm. To meet this limitation, the maximum allowable second-stage reduction ratio can be computed as follows:

$$rr_{\text{secondStage}} = \frac{\omega_{HD_{\text{avgMax}}}}{\omega_{\text{fast}}} = \frac{3500}{666} = 5.25 \quad (2)$$

The maximum slow shaft torque deliverable by the SEA is the product of the motor's nominal torque and the harmonic drive reduction ratio:

$$\tau_{SEA_{\text{max}}} = \tau_{nomEC45} \cdot rr = 0.167 \cdot 100 = 16.7 \text{ Nm} \quad (3)$$

This respects the datasheet limit of 27 Nm for the harmonic drive output torque. Finally, considering space constraints and assembly requirements, a new reduction stage was implemented using a geared mechanism with two gears (18 and 52 teeth, respectively), resulting in:

$$rr_{\text{secondStage}} = \frac{52}{18} = 2.88 \quad (4)$$

This design allows for the delivery of a maximum output torque of:

$$\tau_{\text{max}} = \tau_{SEA_{\text{max}}} \cdot rr_{\text{secondStage}} = 16.7 \cdot 2.88 = 48.09 \text{ Nm} \quad (5)$$

which is sufficient to support the computed maximum loads presented in Table IV, also ensuring a safety coefficient of 1.9.

D. Electronic setup

The prototype has been connected to a Speedgoat baseline real-time target machine [16]. Five EPOS boards were programmed to control the motors, and custom logic boards were used for each motor to read data from the Aksim-2 encoders on both sides of the SEA torsional spring. Both the boards communicated with the target machine via CAN. A 36 V line supplied EPOS and logic boards, while a 12 V line powered the CAN.

E. Human-Robotic device interface

An orthopaedic corset was incorporated to maintain the patient in the correct position and to support their weight. A custom interface was designed to secure the corset and attach it to the device's end effector (Figure 3, Figure 4). This interface is adjustable in width and height to accommodate different body sizes. It offers a height adjustment range from 20 mm to 100 mm, measured from the centre of the corset, and a side width adjustment range from 285 mm to 375 mm, ensuring compatibility with various body percentiles.

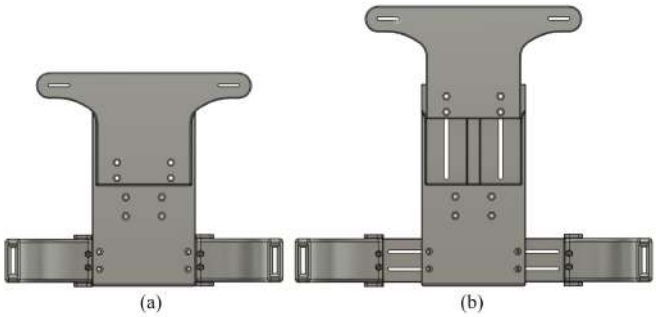

Fig. 3: Custom adaptable interface: (a) completely closed configuration to accommodate lower anthropometric percentiles, (b) fully extended corset configuration.

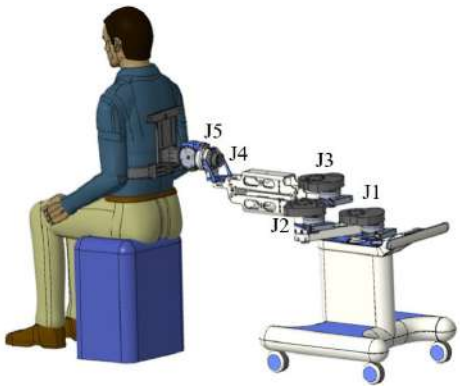

Fig. 4: Example of user positioning during device usage. The user is seated in front of the robotic device and secured to it using a custom corset.

III. CONTROL DESIGN

The control system adopts the RCP model proposed in [17], which architecture has been modified and adapted for the trunk device by developing control strategies for the following use cases: (i) Post-Stroke use case: retraining of elementary movements. (ii) Pusher Syndrome use case: fixed target impedance control to restore posture proprioception. (iii) Spinal Cord Injury use case: resistive control to train muscle strength.

The control model was developed in the MATLAB 2022b Simulink environment. A state-machine logic was implemented to manage the various tasks involved in device control, including receiving signals from sensors and from a graphical user interface (designed using MATLAB App Designer), processing these signals, and computing the target control signals (position or torque targets).

The processing unit is responsible for computing the torques sensed by the series elastic actuators (SEAs) and estimating gravity torques (τ_{g_i}) using MATLAB's *gravityTorque* function from the Robotics Toolbox. This function calculates the gravity torques that must be compensated at each joint based on the robot's dynamic and kinematic parameters. Additionally, a state-machine logic for friction compensation (τ_{f_i}) has been implemented as described in [17].

The model also includes a trajectory generation module, enabling the selection of different exercises with adjustable parameters such as the number of repetitions, amplitude, and duration. The model and a custom Graphic User Interface (GUI) operate in real-time at a frequency of 500 Hz. The architecture allows users to select exercise types (movement type, number of repetitions, amplitude, and duration) and control modes (kinematic, assistive, posture-holding, or resistive) directly from the GUI.

A. SEA torque estimation

Thanks to incorporating SEAs, designing closed-loop control systems that account for human-robot interaction becomes feasible. Specifically, the torque sensed by the SEAs can be computed as:

$$\tau_{SEA} = ((\theta_{AkOut} - \theta_{AkIn}) - \Delta\theta_{AkOffset}) \cdot k + \Delta\tau_{lm} \quad (6)$$

Here, θ_{AkOut}, θ_{AkIn}, and $\Delta\theta_{AkOffset}$ represent, respectively, the angular displacement measured after the spring, the angular displacement measured before the spring, and the encoder offset of the assembly. Additionally, $\Delta\tau_{lm}$ denotes the intercept of the linear model, while k corresponds to the stiffness of the spring (see Table III).

B. Control Modes

The following control modes have been implemented:

a) Passive kinematic exercises: In position control mode, the device rigidly mobilizes the user, guiding them through standard rehabilitative movements, such as frontal and lateral flexions. For this control mode, a trajectory generation algorithm has been implemented for the real-time generation of target positions. The exercise trajectories have been designed by simulating the movements in the CAD software, constraining the end effector position on the desired planes. These trajectories, which could be modelled as straight lines or cosine functions, were then implemented in the Simulink model. To allow customization of the movement range (q_{rng}) and duration (Δt), the trajectories were integrated into the control framework using the following general formula:

$$q_{t_i} = \frac{q_{rng_i}}{\Delta t} \cdot (\Delta t_{el}) + q_{start_i} \quad (7)$$

where Δt_{el} is the elapsed time from the beginning of the movement, and q_{start} is the joint exercise starting position.

b) Assistive Control and Posture-Holding mode: In torque control mode, the same movements proposed in the passive kinematic mode can be performed gradually, actively involving the user in the movement. Three levels of assistance have been empirically tuned by modulating the impedance control's virtual stiffness and damping coefficients (parameters are reported in Table V).

TABLE V: Virtual impedance stiffness (k_v) and damper (β_v) parameters set for the different assistance levels.

	High	Medium	Low
$k_v[Nm/rad]$	250	125	31
$\beta_v[Nm \cdot s/rad]$	35	25	15

The lower the level of assistance, the greater the involvement required from the user. The impedance contribution can be computed as:

$$\tau_{i_i} = (q_{t_i} - q_i) \cdot k_v + \dot{q_i} \cdot \beta_v, \quad i = 1 \dots N \quad (8)$$

The resulting torque control signal for each joint can be written as:

$$\tau_{ctrl_i} = \tau_{g_i} + \tau_{f_i} + \tau_{i_i}, \quad i = 1 \dots N \quad (9)$$

Suppose the *Posture-Holding* mode is selected from the GUI. In that case, impedance control is applied with the springs' equilibrium points centred on the resting position (Figure

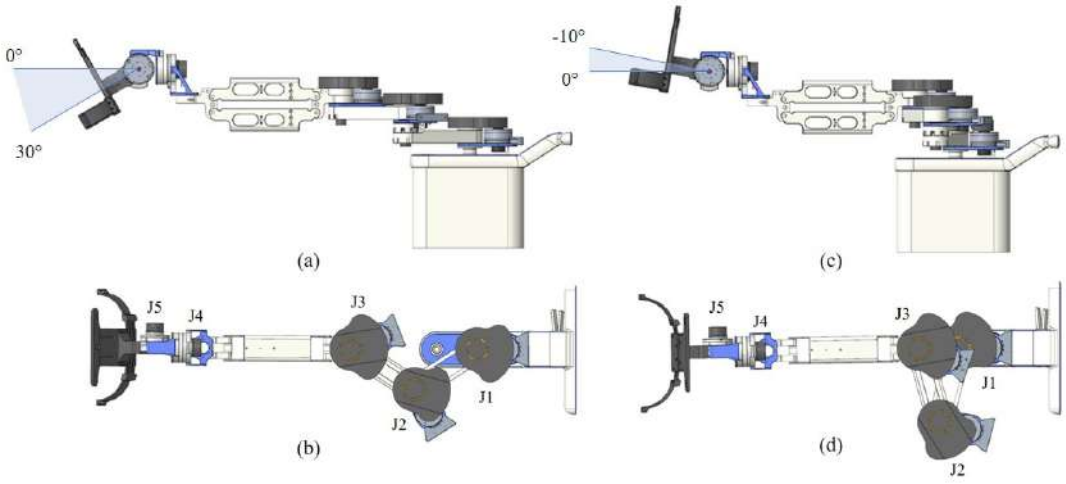

Fig. 5: Trunk device kinematic configurations at the frontal flexion maximum range of motion: (a, b) 30 deg flexion and (c, d) -10 deg extension

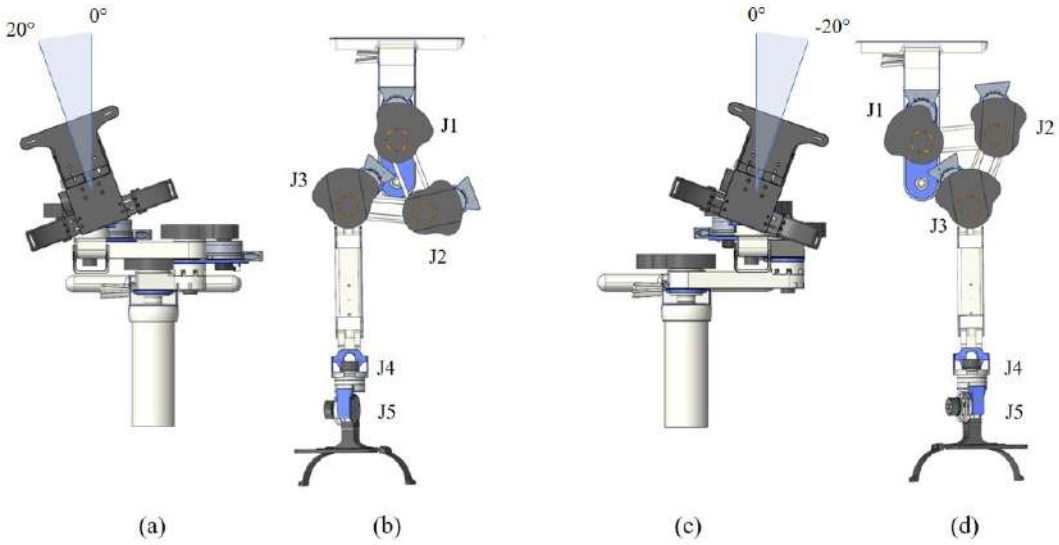

Fig. 6: Trunk device kinematic configurations at the lateral flexion maximum range of motion: (a, b) 20 deg lateral flexion and (c, d) -20 deg lateral flexion.

1 configuration), thus the target positions $q_{t_i} = const$. This control strategy uses a virtual spring-damper effect to correct deviations from the correct posture, guiding the subject back to the proper position through the resulting virtual forces (Figure 7). The levels of assistance featuring the parameters described in Table V are also available for this control mode.

c) Resistive Control Mode: In this mode, a constant resistive contribution is provided along with an impedance contribution (τ_{i_i}) exploited to guarantee a compliant and safe interaction with the machine. The resistance opposing the user's motion can be selected from the GUI for each SEA joint ranging from 1 Nm to 15 Nm ($\tau_{res} = const$), allowing to customize the training, targeting a specific movement and selecting the exercise intensity.

d) Against Interaction Mode: Exploiting the SEA reading, it is possible to compute the interaction torque as:

$$\tau_{int_i} = \tau_{SEA_i} - \tau_{g_i} \tag{10}$$

Interaction-based resistive contributions can be implemented as:

$$\tau_{res_i} = \%_{res_i} \cdot \tau_{int_i} \tag{11}$$

The resistance is expressed as a percentage ($\%_{res}$) of the user's driving force. The gain factor can be selected for each joint, allowing customization of the delivered resistive therapy. For example, if 50% resistance is selected, the system opposes half of the force transmitted via human-machine interaction. If 100% resistance is selected, the user should not be able to move the system. To avoid excessively rigid behaviour, also, in this case, a low impedance term (τ_i) is applied to the joints so that the device remains partially

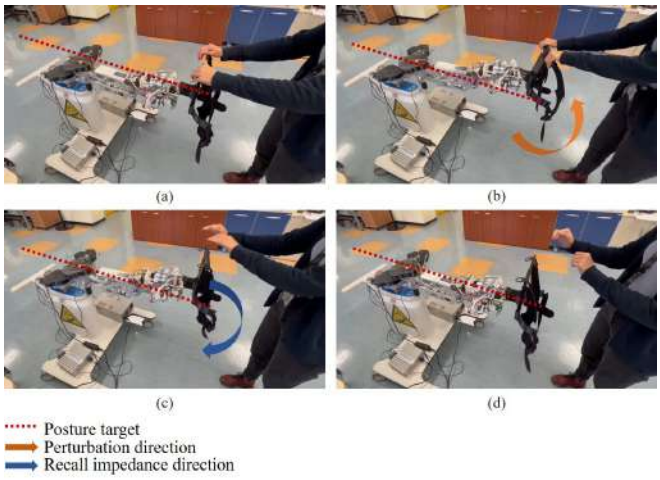

Fig. 7: Experimental testing of Posture-Holding mode: (a) the device operates in torque control, maintaining a fixed target position. (b) An operator manually perturbs the device to simulate posture deviations. (c) In response, the device applies a recall force until (d) it returns to the target position.

compliant with human interaction even when an opposing force is generated.

The torque control signals for the aforementioned resistive control strategies can be computed as:

$$\tau_{ctrl_i} = \tau_{g_i} + \tau_{f_i} + \tau_{i_i} + \tau_{res_i}, \quad i = 1 \dots N \tag{12}$$

In torque control modes, the computed control signal is processed through a PI closed-loop torque controller, where τ_{ctrl} is compared with the SEA torque estimation (τ_{SEA}). This signal is then converted into a current signal using the motor's torque-to-current constant and regulated by the PID controller of the EPOS driver boards. In contrast, the position targets generated by the kinematic mode are directly handled by the EPOS position controller.

IV. DISCUSSION AND CONCLUSION

In this work, we proposed a novel approach meant specifically to target trunk core rehabilitation, showcasing the mechanics and control design of an upper body robotic mobilizer. The device was developed with input and suggestions from clinical partners, ensuring its suitability for addressing various neurological pathologies. The control strategies were implemented using a Rapid Control Prototyping approach and validated through bench testing, confirming the functionality of different control modes. Future work will focus on obtaining hardware and software certification to enable testing on healthy subjects, followed by trials with patients. Additionally, the integration of EMG signal acquisition is planned to fine-tune the assistive and resistive controllers. This will enhance the machine's support capabilities (assistive mode) and optimize muscle activation to promote strengthening and recovery (resistive mode).

***Abstract*—Spasticity is a common movement disorder symptom in individuals with cerebral palsy, hereditary spastic paraplegia, spinal cord injury and stroke, being one of the most disabling features in the progression of these diseases. Despite the potential benefit of using wearable robots to treat spasticity, their use is not currently recommended to subjects with a level of spasticity above 1^+ in the Modified Ashworth Scale. The varying dynamics of this velocity-dependent tonic stretch reflexes makes difficult to deploy safe personalized controllers. Here, we describe a novel adaptive torque controller via deep reinforcement learning (RL) for a knee exoskeleton under joint spasticity conditions, which accounts for task performance and interaction forces reduction. To train the RL agent, we developed a digital twin, including a musculoskeletal-exoskeleton system with joint misalignment and a differentiable spastic reflexes model for the muscles activation. Results for a simulated knee extension movement showed that the agent learns to control the exoskeleton for individuals with different levels of spasticity. The proposed controller was able to reduce maximum torques applied to the human joint under spastic conditions by an average of 10.6% and decreases the root mean square until the settling time by 8.9% compared to a conventional compliant controller.**

***Index Terms*—Wearable Robotics, Spasticity, Movement disorders, Reinforcement Learning, Musculoskeletal systems.**

I. Introduction

Spasticity is a neurological impairment consequence of an upper motor neuron syndrome commonly seen in neurodegenerative movement disorders associated with damage to the brain, spinal cord and motor nerves. It often manifests as one of the initial motor symptons in conditions such as cerebral palsy, hereditary spastic paraplegia, spinal cord injury or stroke, and is one of the most disabling features as these diseases progress [1]–[3]. This phenomenon was defined by James Lance in 1980 as "a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex" [4]. Users with joint spasticity often experience posture and movement abnormalities due to increased muscle tone and persistent primitive reflexes, leading to limitations in walking speed, balance, and specific movements. Within these mobility restrictions, the knee joint presents particular complications due to its crucial role in gait mechanics and weight-bearing [5].

Wearable robots (WRs), such as robotic exoskeletons, have proven to be valuable tools for therapists in rehabilitation and assistive applications. Under spasticity conditions, the use of WRs has shown that intensive early rehabilitation can potentially prevent the later onset of spasticity, revealing intra-session changes in muscle resistance to passive extension in elbows [6] and limb joint [7]. In addition, it has been shown that the use of exoskeletons in spastic patients during gait has an important influence on the distribution of plantar pressure [8]. Despite the potential benefit on using WRs to treat spasticity, their use is not currently recommended to subjects with a level of spasticity above 1^+ in the Modified Ashworth Scale (MAS) [9], from a maximum level of four, due to safety restrictions. Indeed, the use of WRs under spastic conditions presents several challenges. Conversely to assistance in healthy subjects [10], the primary goal of WRs in movement disorders is not performance (e.g., to speed-up the movement) but to ensure safety (e.g., reducing undesired interaction forces) during the recovery or assistance period. Hence, adaptive control of WRs is an essential feature to ensure safety under different users and scenarios.

A. Related works in WRs control

While there is wide research in WR control, most current market-available solutions are primarily open-loop driven by PID low-level controllers. In essence, these approaches force the leg to follow a specific trajectory without adapting to user or pathology-specific needs. Thus, these usually need to be calibrated for each subject, implying the need for technicians and experts during rehabilitation, and do not adhere to any complex safety restrictions and physical interactions between the robot, the human musculo-skeletal (MS) system and the environment [11]. Model-based controllers are also investigated [12], e.g., model predictive control for prosthetics [13], but require complex dynamic models that are prone to changes due to user-dependent characteristics and errors due to unknown and changing environmental conditions.

A.C.S. and D.R.C. are funded by the RL-EXO project and 2nd Body project, MOMENTUM program, Spanish National Research Council.

B. Learning to control exoskeletons under movement disorders

Particularly in the WRs field, where the exoskeleton needs to adapt to both human interactions and the environment, the use of learning-based control algorithms could be greatly beneficial. Among these, RL [14]—learning to interact with the environment by maximizing the expected future reward—appears as one of the most promising approaches given the recent results in assisting healthy users to reduce energy consumption during walking [10]. Still, the use of RL in WRs, particularly in neurorehabilitation is currently in an early research stay—see [15] for a review. Few works focused on enhancing gait rehabilitation but oversimplified the MS-exo system (e.g., joint misalignments) and only addressed muscles weakness pathologies. Besides, RL has been also used for optimizing the parameters of compliant controllers [16]. RL control under movement disorders, such as spasticity, has not been properly investigated, while being a potential solution due to the challenging nature of the MS changing dynamics, its heterogeneity and safety requirements.

C. Contribution

This work presents a novel adaptive torque controller via Reinforcement Learning (RL) for a knee exoskeleton (Exo) under joint spasticity conditions. This is, learning to control exoskeletons when the dynamics of the human MS system change depending on its velocity and position, while reducing undesired interaction forces to promote user's safety. This is challenging as the controller should be adjusted for each spasticity level and subject. This work contributes with: i) a digital twin of the Human-Exo system that accounts for joint misalignments and relative human-exoskeleton displacements due to soft tissues; ii) A differentiable model of different levels of spasticity; iii) an adaptive WR torque controller, providing improved compliant control for different levels of spasticity compared to a standard PID torque controller.

II. Methods

We developed musculoskeletal spasticity models within a digital human-exoskeleton environment and implemented a Deep RL architecture for training and testing an end-to-end torque controller for a knee exoskeleton in the presence of different levels of knee spasticity—Fig. 1. The digital twin includes: the human MS coupled with a knee exoskeleton, incorporating realistic MS-Exo coupling able to account for the presence of joint misalignments (Sec. II-A), and spastic reflexes model, with a characterization of several pathological spasticity levels (Sec. II-B). We also describe the Deep RL architecture, explaining the reward function design and the implemented policy improvement algorithm (Sec. II-C). Finally, we introduce the experimental setup and the simulation framework (Sec. II-D).

A. Human MS system with Exo coupling

We modeled an adult of 1,75 m and 70 Kg with a leg exoskeleton (Fig. 2), using the Myosuite conversion of Rajagopal's gait model [17] as a close reference. The model

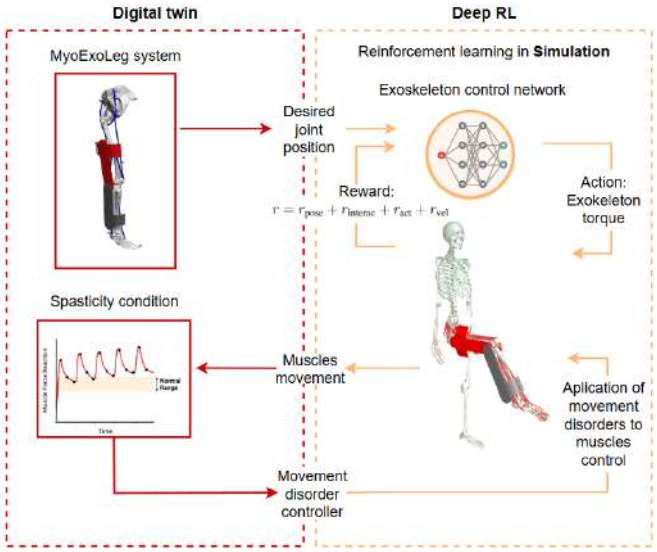

Fig. 1. RL Exo Pipeline. Digital twin development with MyoexoLeg system and spastic model in a red box at left. Deep RL architecture in simulation with RL algorithm and environment in orange box at rigth. The interactions between the digital twin and Deep RL architecture are presented at the middle.

is a unique stand up body with a fixed 90º right hip flexion, allowing freedom of the knee and ankle joints that includes 40 Hill-based muscles with tendon compliance [18]. Human knee joint has a special feature, it rotation axis varying under the sagittal plane during the flexo-extension movement, which implies significant challenges in achieving effective coupling with the Exo. To solve these delineations, this MS-Exo union was designed with 4 DOF, 1 DOF for Exo knee joint and 3 DOF simulating a soft coupling with straps.

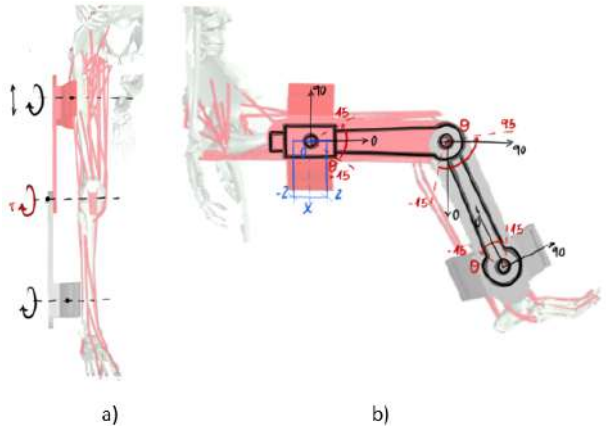

Fig. 2. Knee-Exo coupling model with the upper Exo in red and lower Exo in grey. a) Front view of the Human-Exo attachment, including passive joints in black and actuated joints in red. b) Lateral view of the Slider-Crank mechanism designed to simulate a soft knee-Exo coupling, with angular joints ranges for thigh's and shank's cranks in red and thigh's slider range in blue.

The MS-Exo coupling (Fig. 2) was modeled by means of a slider-crank mechanism with two attachment points; i) the first, on the upper part of the thigh, with two joints, a linear joint with a slide range of $x_{\text{slider}} \in [-0.02m, 0.02m]$ and a

linear friction coefficient of $\eta = 0.97$, and a pin joint with a rotation range of $\theta = \pm 15°$, and ii) the second, on the lower limit of the shank with a pin joint and a rotation range of $\theta = \pm 15°$, in order to simulate the relative movement of the exoskeleton due to human soft tissue compliance. The Exo included one active pin joint at the union of the upper Exo (attached on thigh) and the lower Exo (on the shank) to drive the knee joint that included an actuator with a maximum torque of 100 Nm and a joint range of $\theta_{\text{Torque}} \in [-15°, 95°]$.

B. Spastic reflex model

Joint spasticity is defined as a velocity-dependent muscle tone increase and a muscular activation according to the level of intensity of the muscular reflex and the joint range in the MAS. Here, we provide a spasticity model for muscular activation with a angular velocity parameter [19] and a joint range dependency. The parameter of the four spasticity levels are described in Table: I following the sign convention presented in Fig. 2. We merged level 1 with level 1+ due to their close similarities [20] and left out the most severe level (level 4) due to the inability of these subjects to perform any movement without a potentially harmful increase in muscle tone.

TABLE I
SPASTICITY LEVELS AND CORRESPONDING PARAMETERS

Lv	Muscular activation range limits	Activation coefficient
0	Knee joint range (θ): [-45, 95]° Velocity limit (v): [-10, 10] rad/s	Angular Spasticity s_θ: 0 Velocity Spasticity s_v: 0
1	Knee joint range: (θ): [-35, 80]° Velocity limit (v): [-1, 1] rad/s	Angular Spasticity s_θ: 0.2 Velocity Spasticity s_v: 0.2
2	Knee joint range (θ): [-30, 75]° Velocity limit (v): [-0.5, 0.5] rad/s	Angular Spasticity s_θ: 0.3 Velocity Spasticity s_v: 0.3
3	Knee joint range (θ): [-15, 60]° Velocity limit (v): [-0.25, 0.25] rad/s	Angular Spasticity s_θ: 0.3 Velocity Spasticity s_v: 0.5
4	Not Implemented	

1) Spasticity coefficient to model muscle activation: Muscular activation was implemented as a spasticity coefficient (SC), adjusting muscular tone based on angular and velocity readings at the knee joint following Eq. 1. The SC is composed by an angular and velocity coefficient as follows:

$$SC_{\text{total}} = sc_{\text{angular}}(\theta) + sc_{\text{velocity}}(v) \quad (1)$$

Both coefficient functions are defined using sigmoid equations across thresholds (differentiable model) to avoid non-linear transitions and creating spastic reflexes that increase or decrease around specified angle and velocity limits (See table. I and Fig. 3). The appearance and the intensity of spasticity for each individual was modeled by a transition slope k [0, 0.5, 0.2, 0.1] depending on the spasticity level. This slope allows modelling the appearance of spasticity by a muscular activation value in the last part of the joint range for the level 1 and the progressive and maintained behaviour of the upper levels 2 and 3 (Fig. 3). The SC equation given the sigmoid adjustable slope k and β, β_0 the joint position and velocity range limits results in:

$$\phi(k, \beta, \beta_0) = \frac{1}{1 + e^{k(\beta - \beta_0)}} \quad (2)$$

We define:

a) Angle-based spasticity coefficient: To account for the angle-dependent nature of spasticity, we added a term that considers both flexion and extension limits for the appearance of spasticity depending on the severity level sc_{a}:

$$sc_{\text{a}}(\theta) = s_{\theta\text{Max}} \left[1 - (\phi(k_{\text{ang}}, \theta, \theta_{\text{flex}}) - \phi(k_{\text{ang}}, \theta, \theta_{\text{ext}}))\right] \quad (3)$$

where $s_{\theta\text{Max}}$ is the maximum SC, k_{ang} the slope of the sigmoid transition depending spasticity level muscular activation, θ_{flex} and θ_{ext} the angle threshold for flexion and extension respectively.

b) Velocity-based spasticity: Analogously, lower v_{lower} and upper v_{upper} velocity limits are used in sc_{v} as a function of the velocity v:

$$sc_{\text{v}}(v) = s_{\text{vMax}} \left[1 - (\phi(k_{\text{vel}}, v, v_{\text{lower}}) - \phi(k_{\text{vel}}, v, v_{\text{upper}}))\right] \quad (4)$$

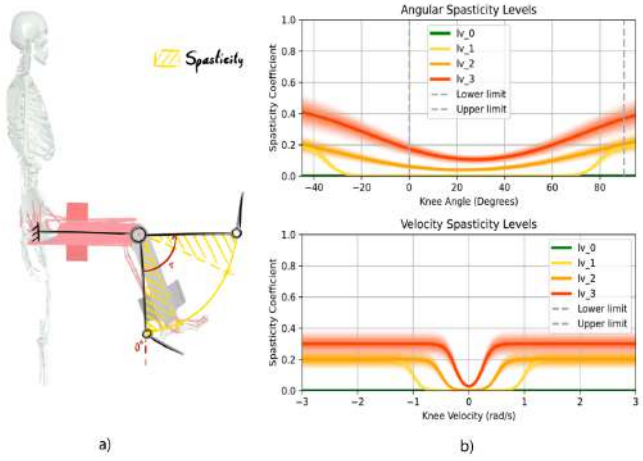

Fig. 3. Knee flexion-extension and spasticity model. (a) Spastic regions (yellow), knee joint extension movement (red). (b) Spasticity coefficients as a function of the knee angle (top) and velocity (bottom) for each spasticity level including individual variance to account for inter-subject variability. Level 0 (green), level 1 (yellow), level 2 (orange) and level 3 (red).

2) Using the spasticity coefficient in the MS model: SC_{total} represents a normalized measure of the percentage of maximum isometric force generated by each muscle. Consequently, when spastic reflexes are incorporated into the simulation, each muscle produces a spastic force proportional to its maximum isometric capacity. Spastic reflexes were implemented in 11 muscles involved in knee joint flexion-extension movement grouped into two categories, based on the literature [21]: i) Flexion-related muscles, including Gastrocnemius Lateral and Gastrocnemius Medial on the Calf, and Semimembranosus, Semitendinosus, Biceps Sural Long and Biceps Sural Short on the Hamstrings; and ii) Extension-related muscles, comprising Gracillis on rectus, and Vastus Medialis, Vastus Lateralis, Vastus Intermedius, and Rectus Femoris on the cuadriceps.

3) Generating individual subjects: To account for inter-subject variability and ensure the robustness of the model, the parameters for the different levels of table I, necessary for eq.3 and eq.4, were generated by introducing Gaussian noise η with a standard deviation of 10% of the absolute parameter value. This approach enables the simulation to capture natural variations observed across individuals, providing a more realistic representation of subject-specific dynamics.

C. Deep Reinforcement Learning Architecture

To address the challenges of adaptive exoskeleton control in the presence of spasticity, we designed and trained a deep reinforcement learning architecture able to provide torque control commands to the exoskeleton that fulfill the following objectives:

- Learning to reach a specific angular joint position.
- Reducing undesired Human-Exo interaction forces.
- Minimizing joint velocity.
- Ensuring smooth Exo actuation to guarantee user comfort.

These control objectives were translated into a reward function with four main terms:

$$r = r_{\text{pose}} + r_{\text{interac}} + r_{\text{vel}} + r_{\text{act}} \tag{5}$$

Pose reward (r_{pose}) is based on the position error (e_{pose}), using a exponential equation with σ^2 as a growth factor and penalized by a linear term.

$$r_{\text{pose}} = \exp\left(-\frac{e_{\text{pose}}}{2 \cdot \sigma^2}\right) - \|e_{\text{pose}}\| \tag{6}$$

Additionally, a cumulative reward of 0.01 is added to r_{pose} when these 2 conditions are satisfied: i) $r_{\text{pose}} < 0.05$ rads and ii) $knee_{\text{vel}} < 0.05$ rads/s.

$\tau_{\text{exo_torque}}$ represent the sum of torques applied (exo and spastic reflexes) on the MS knee joint obtained as an output from Myosuite physics simulator. r_{interact} modulates the maximum torque applied to the human knee joint with a linear normalization penalty of $\nabla_{\text{exo_torque}}$ and a quadratic penalty based on $\tau_{\text{threshold}}$ of 75Nm.

$$r_{\text{inter}} = \begin{cases} \|\nabla_{\text{exo_torque}}\|^2, & \text{if } \tau_{\text{exo_torque}} \leq \tau_{\text{threshold}}, \\ \|\nabla_{\text{exo_torque}}\|^2 + \tau^2_{\text{exo_torque}}, & \text{if } \tau_{\text{exo_torque}} > \tau_{\text{threshold}}. \end{cases} \tag{7}$$

r_{act} and r_{vel} use a linear normalization penalty of the gradients $[\nabla_{\text{exo_control}}, \nabla_{\text{knee_vel}}]$ to reduce undesired motor current spikes and promote a smooth control signal:

$$r_{\text{act}} = \|\nabla_{\text{exo_control}}\|^2 \quad ; \quad r_{\text{vel}} = \|\nabla_{\text{knee_vel}}\| \tag{8}$$

Solving the current continuous control problem using RL requires finding the policy that optimizes the maximum expected reward. From the policy optimizers already tested in WRs [15] we selected the Soft Actor Critic Algorithm (SAC) [22] due to the changing dynamics of the environment and its exploratory properties. SAC is a policy improvement method with an additional policy entropy parameter for data-expensive and complex environments where the agent has to interact and explore a real-world. The SAC model implemented is summarized in table II

TABLE II
NEURAL NETWORK ARCHITECTURE FOR SAC

Component	**Layer Type**	**Input Dim**	**Output Dim**
Actor Network (Policy)			
Input	Observation (state)	93	93
Layer 1	Fully Connected (Dense)	93	64
Layer 2	Fully Connected (Dense)	64	64

Parameters	**Value**	**Parameters**	**Value**
Memory buffer	$5e^6$	Steps	$5e^7$
Adam lr	10^{-4}	Tau	0.05
Batch size	4096	Gamma	0.99

D. Simulation setup and training

The experiment was designed for a point to point trajectory, simulating an almost complete extension of the knee joint (Fig. 3.a). The movement begins at a 90º knee flexion position up until a total knee extension rotation of 83º to avoid the risk of knee hyperextension. The policy was derived from the best-performing model after training for 50 million steps, corresponding to approximately 10,000 full knee joint extension cycles. Spasticity levels were uniformly randomized to ensure a balanced number of interactions across all four implemented levels. Additionally, at the start of each iteration, spastic reflex parameters were generated according to the level of spasticity using the methodology described earlier, simulating individual-specific conditions. The results from the SAC controller were compared to those of a baseline PID-based compliant torque controller to assess its improvement over a classical control method. It produced torque control commands based on angular position deviations from the target position using a PID controller tunned to a spasticity level of 1 following the Ziegler-Nichols method with $K_{\text{p}} = 7$, $K_{\text{i}} = 40$ and $K_{\text{d}} = 0.05$. This comparison aims to demonstrate the adaptive capability of the SAC controller, which employs a single agent, compared to a classical control method optimized for a single spasticity level.

III. RESULTS

The dynamic behavior of control strategies is crucial in managing spasticity during motor tasks, particularly as spasticity severity increases. Hence, we evaluated our developed RL-based controller with respect to the PID-based torque controller over 1000 trials in generated subjects with and without spasticity. We studied the evolution of the following metrics: i) leg extension performance, using the angular position error; ii) smooth behavior, using the control input signal and iii) interaction torques, expressed as the sum of the total torque applied at the knee joint, including the Exo actuation and the spastic reflexes.

A. SAC learned behaviours over spasticity levels

Figure 4 shows the behavior of the SAC controller for different levels of spasticity, grouped by color. In the upper graph, the angular position error during knee extension, where differences are observed in terms of the evolution and settling time within 2% of the final value corresponding to 0.26 s, 0.78 s, 3.77 s, 7.94 s for levels 0, 1, 2, and 3, respectively.

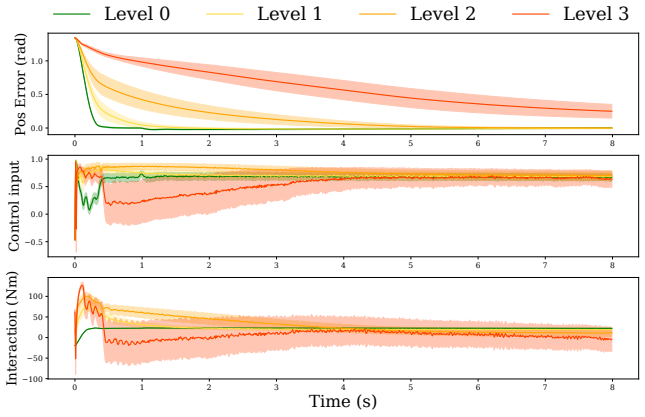

Fig. 4. Simulation results of the SAC algorithm for the implemented spasticity levels. In green, yellow, orange and red for level 0 to 3. The upper graph shows the joint position error, the middle graph, the control signal and the lower graphs shows the interaction torques, during 8s of simulation.

As observed, at level 3 the controller is unable to achieve full knee extension, reaching a steady-state angular error of 11.45º. The middle graph corresponds to the exoskeleton control signal, normalized within a control range of [-1, 1] corresponding to [-100, 100] Nm. Its behavior has a closely relation with the observed in the depicting graph, the summary of torques exerted on the knee joint. The results reveals an increase in the exerted torque proportionally to the severity of the spasticity for levels 0, 1 and 2.

B. Comparison with a PID torque controller baseline

Figure 5 presents a graphical comparison of the RL trained single agent SAC controller over a classical PID torque controller, optimized for a single spasticity level (level 1), for the three metrics discussed earlier (angular position error, control input, and interaction torques), organizing the data by columns corresponding to the four implemented levels of spasticity, with level 0 comparison being the first column. Analysis of these data for the angular position error reveals an overshoot in the PID controller's performance at levels 0 and 1. At levels 2 and 3, where spastic reflexes are more pronounced, the PID controller achieves full extension with a final error of 6.3º at level 2 and 9.3º at level 3. In contrast, the SAC controller achieves position errors of less than 1º for levels below and equal to level 2 but encounters a superior error of 11.45º at level 3.

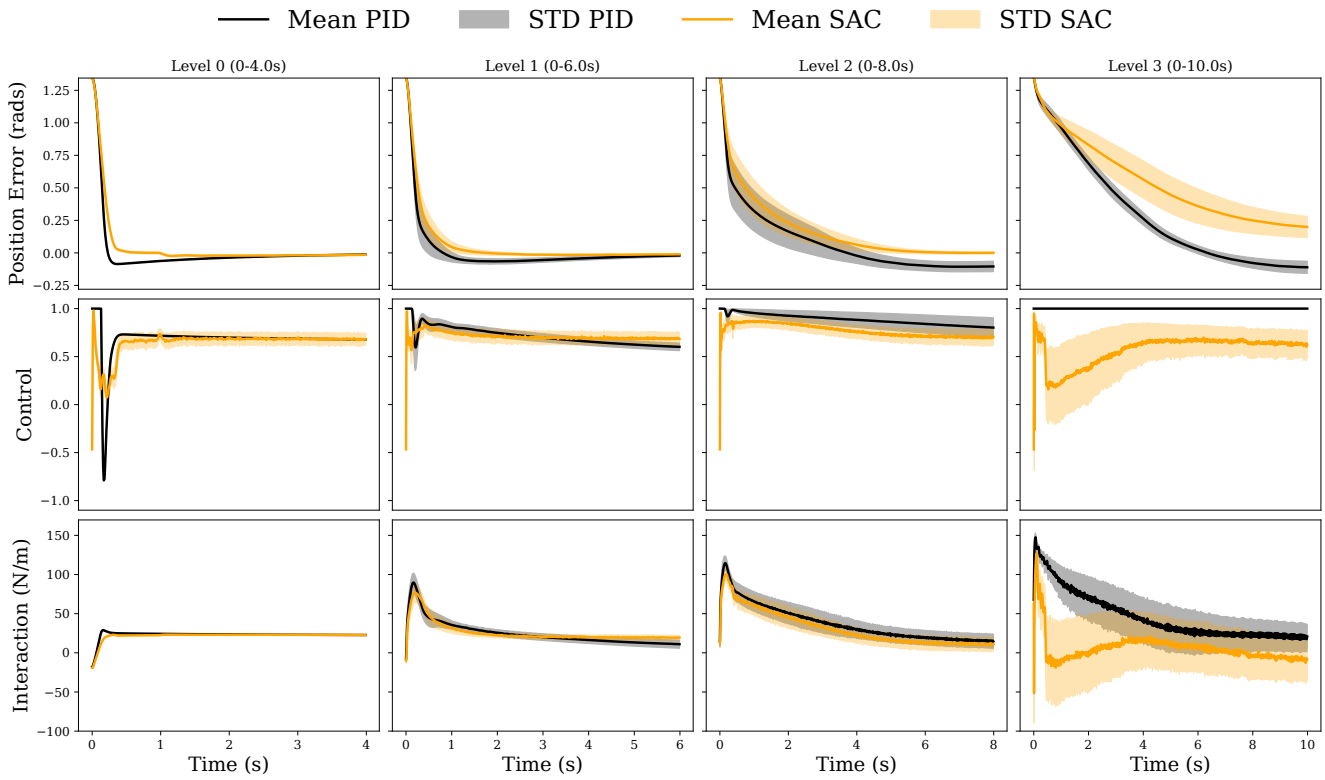

Fig. 5. Comparison of PID and SAC algorithms for different levels of spasticity, grouped in columns. In black, PID; in yellow, SAC, representing their mean and standard deviation values. From left to right in columns, the levels of spasticity implemented from a) Level 0 b) Level 1 c) Level 2 d) Level 3. From top to bottom the comparison of a) Position error b) Control signal c) Interaction torque summary exerted by the exoskeleton and spastic reflexes.

The final row of graphs compares the interaction torques between the exoskeleton and the knee joint. A trend similar to the control signal (middle row graphs) is observed, with lower interaction torques values achieved by the SAC controller throughout the simulation period. The difference is more pronounced at spasticity level 3 compared to the other levels. The subsequent results section delves deeper into these interaction torques, analyzing the most representative parameters.

C. Interaction torques analysis

The aim of the present work was to reduce the MS-Exo interaction forces, thus increasing the safety of the system in spastic conditions.

1) Reduction of undesired interaction torques during the settling interval: The evolution of the torque exerted by the exoskeleton is analyzed through the Root Mean Square (RMS) value of the interaction torques over the settling time obtained at each level within 2% of the final value (Fig. 6) for 1000 simulations . The graph demonstrates an increase in settling time corresponding to the severity of spasticity, as well as higher RMS values. However, the SAC controller achieves lower RMS values across all four levels, reducing RMS by 35.3%, 9.7%, and 8.1% in levels 0, 1, and 2, respectively, where full knee extension is achieved.

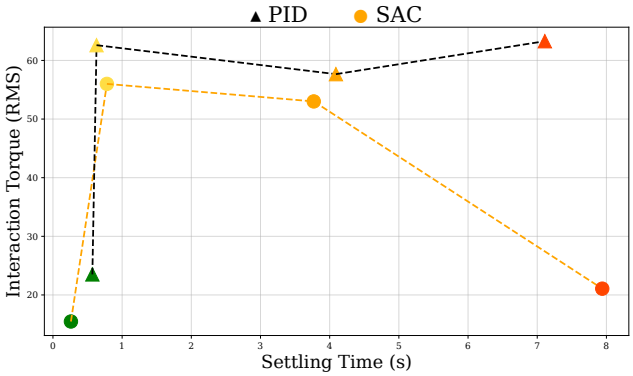

Fig. 6. Mean RMS of interaction torques up to the settling time for the implemented spasticity levels. Spasticity levels are color-coded as follows: Level 0 (green), Level 1 (yellow), Level 2 (orange), and Level 3 (red). The control strategies are represented by distinct markers, with circles for the SAC controller and triangles for the PID controller.

2) Reduction of the maximum torque applied at the knee joint: Figure 7 compares the maximum torques achieved by the SAC and PID controller for different spasticity levels. The SAC controller demonstrates a mean peak torque reduction of 10.8±3.4 Nm, corresponding to decreases of 23.6% at level 0, 12.5% at level 1, 8.8% at level 2, and 11.3% at level 3.

Level 1 exhibits the highest variability in both controllers, with fluctuations in maximum torque reaching a mean of 48 Nm within the Interquartile Range (IQR). Variations of 27.5 Nm and 13 Nm are observed for levels 2 and 3, respectively.

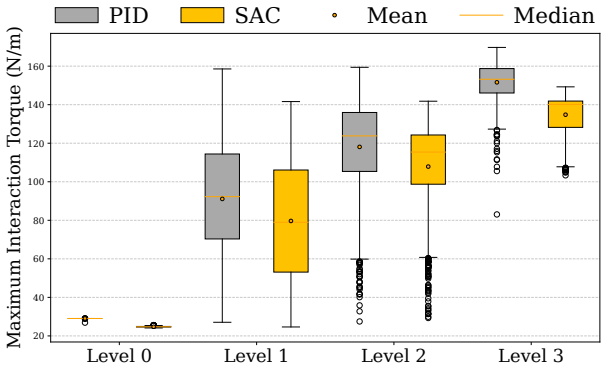

Fig. 7. Peak interaction torque for the SAC and PID controllers across the implemented spasticity levels. The results are presented for spasticity levels 0, 1, 2, and 3, with SAC represented in orange and PID in grey. The box plots show the mean (dot), median (line), interquartile range (IQR) (box), and data spread (outliers).

IV. Discussion and Conclusions

This paper presented an adaptive torque controller for a knee exoskeleton under joint spasticity conditions using RL, offering a suitable approach for wearable robotics for subjects with motor disorders that present muscle position-velocity changing dynamics. The main goal of the approach was to ensure safety (e.g., reducing the amount of undesired interaction forces to complete the task) and provide individualized behavior.

The results of the proposed method demonstrated the effectiveness of the SAC controller to perform the task and reduce maximum torques applied to the human knee joint under spastic conditions by an average of 10.6% (Fig. 7) and decreasing the root mean square (RMS) of the torque until the settling time by 8.9% (Fig. 6) compared to a conventional PID torque controller. Most importantly, the settling time in these cases shows improved results, with reductions at levels 0 and 2 and similar values at level 1. This indicates that the SAC controller is capable of performing knee extension in less time and with reduced effort. These improvements could translate into enhanced safety during repetitive exercises aimed at spasticity treatment.

The reduced steady-state interaction torque at the final joint position in high levels of spasticity for the SAC controller avoids the application of high torques over prolonged periods, highlighting the controller priority of user safety (reduced interaction forces) over task performance. This was particularly noticeable at level 3 (Fig. 5), where the SAC controller prioritized not achieving the target position when the torque required was excessive. Regarding the control input graphs a difference in signal smoothness between the PID and SAC controllers is observed. The SAC controller, driven by the RL algorithm, demonstrates more reactive behavior with a less stable control signal. However, this instability does not propagate to the position response, as the system filters the over-adjustments effectively. Notably, the SAC controller, despite achieving better final position results, maintains a lower control signal than the optimal PID control method

across all cases, maintaining a maximum standard deviation below 5% across randomized spasticity parameters for levels 1 and 2.

Although the evaluation was conducted in a simulated environment, the digital twin model incorporated critical biomechanical characteristics, including joint misalignments and relative displacements of the human exoskeleton due to soft tissue interactions. These considerations enhance the potential for future deployment in physical exoskeleton systems and eventual application in human trials. This physical implementation falls within the scope of the research framework, encompassing the methodologies employed such as domain randomization and physical or non-physical retraining, as well future work aims to extend this approach to address a broader spectrum of motor disorders, such as ataxia and tremor, with the ultimate goal of developing a reinforcement learning-based controller capable of ensuring comprehensive safety and efficacy for individuals with neurodegenerative conditions involving complex and multifaceted movement impairments.

Environment code availability

The Myosuite environment used in this study is available at a repository of NAIR Group Github page: https://github.com/neuro-ai-robotics/RL_Exo.

Acknowledgment

We thank Abián Torres, member of NAIR Group, for his insightful help at the algorithmic and data implementation and Pierre Schumacher for technical details with the Myosuite environment.
