We analyzed our two shared controllers during physical human-robot interaction, mimicking a physiotherapy session. In both cases, the human subject moved their arm, and the robot behavior was dictated alternatively by one of the two algorithms presented in Sections II-C.1, II-C.2. As the movement started from a safe region, initially both modules guaranteed minimal interaction force. On the contrary, the behavior was different as the unsafe zone was approached. The lower authority module (Figure 4) damped the human movement as the subject entered the damped zone, generating a dragging force opposing human velocities pointing towards the unsafe zone. The subject continued their movement and entered the unsafe zone, triggering the algorithm to pull them toward the closest point on the zone contour. Finally, the subject left the unsafe zone and moved away from it, receiving no further robot intervention in virtue of the safe direction of movement.

Regarding the higher authority module (Figure 5), the subject could move undisturbed closer to the unsafe zone until their predicted future trajectory was no longer safe. At this stage, the algorithm proposed a minimal deflection of the original trajectory, triggering the robot to lead the human subject toward a position where they could move safely again. For both cases, we analyzed the magnitude of the Cartesian forces that were commanded to the human subject and found that the first control method led to a peak interaction force of about 8 N, while a maximum force of about 6 N was reached with the second control method.

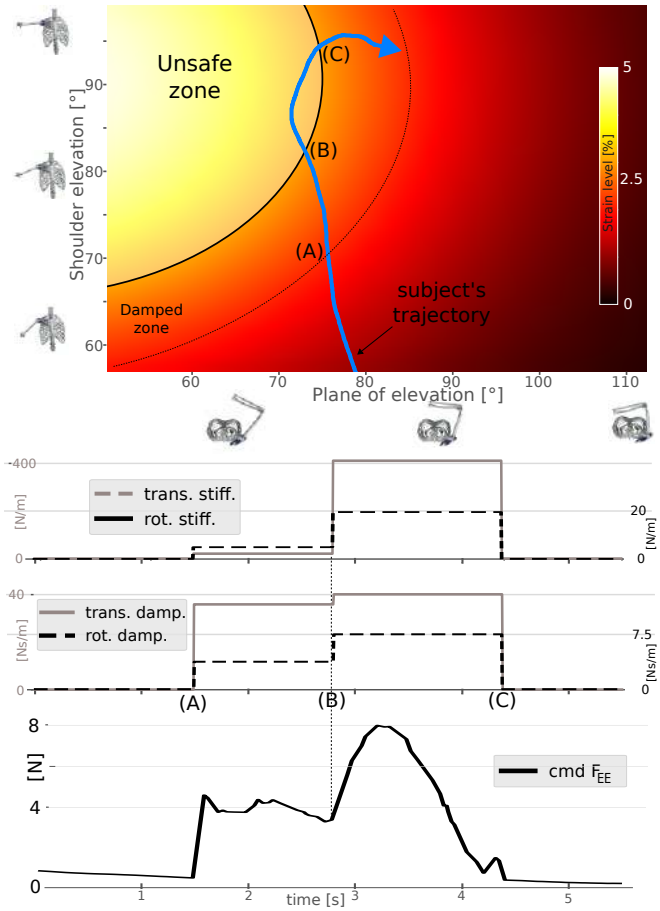

Fig. 4. Low-authority shared control module behavior, during physical human-robot interaction. Top: strain map in which the subject moved, with skeletal poses detailing the axes. The subject approached the unsafe zone: (A) first, the "damped zone" was encountered, then (B) they entered the "unsafe zone" and experienced higher robot correction before leaving the zone and continuing with their free movement (C). Evolution of the controller's stiffness and damping and resulting interaction force are highlighted.

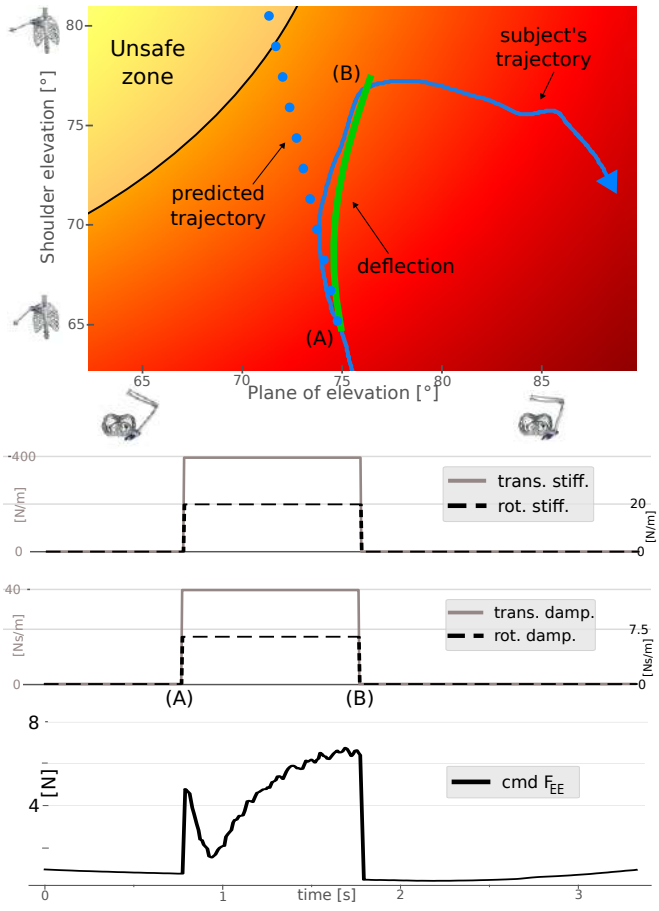

Fig. 5. High-authority shared control module behavior, during physical human-robot interaction. Top: strain map in which the subject moved, with skeletal poses detailing the axes. The subject approached the unsafe zone, triggering the system to impose a short deflection on their movement (A). After that (B), control was given back to the human, who could independently continue their free motion. The evolution of the controller's stiffness and damping and the resulting interaction force are highlighted.

IV. Discussion and Conclusions

We have presented two shared control modalities that allow a robot to limit unsafe human movement during robotic-assisted shoulder rehabilitation, using information from a high-fidelity biomechanical model. Both modules permit human-led movements to maximize patients' independent exploration of their shoulder range of motion, safeguarding their users against reaching shoulder configurations that could generate unsafe levels of strain in injured/healing tendons. When the current human action is deemed unsafe, our controller intervenes with different degrees of authority to shape the resulting human movement. The use of the shared control paradigm expands our previous contributions, in which the robotic therapist unilaterally dictated the therapeutic motion [16] and did not anticipate human intentions [15].

In the present work, the low-authority control modality, designed to allow the human subject to retain greater agency over the resulting movement, was capable of providing state-dependent haptic feedback during human motion. The system produced a force field that can allow the user to avoid unsafe zones autonomously (Figure 4). While entering such zones is still possible, the maximum robot-commanded force was smaller than what was observed when no predictive damping was provided to the user for similar movements, since higher unsafe velocities were limited. The high-authority control modality, on the other hand, is expected to reduce the autonomy of the human subject, as it temporarily takes over the movement, to reposition the human in a pose where they can safely continue their therapy. This approach allowed the system to avoid our experimental unsafe zone better, with lower force produced by the robot, by guaranteeing initial alignment between the human intention and the robot's deflection. Moreover, our real-robot results validated the initial simulation findings reported in Figure 3, showing that the subject can be smoothly deflected without accounting for the specific human skeletal dynamics, for the type of rehabilitation movements considered.

Simplifying human inertia also allows for reduced computational costs. Comparing the optimal deflections obtained with and without accounting for the human skeletal dynamics highlighted minor differences in our simulation results (see Figure 3), likely due to different relative weighting of

the torque terms in the cost function. Indeed, the inertial parameters of virtual point mass navigating across the strain map were not tuned to our participant since only the human kinematics was employed by the robot's impedance controller. Identifying the human-arm inertia at the robot's end-effector and using these parameters in the point mass approximation could enhance the alignment between the two methods under low accelerations, as in our case. This approach could also enable integrating optimized generalized torques from the human model into the robot controller, such as for personalized gravity compensation [16].

While our findings demonstrate the potential of the proposed shared control modalities, there are limitations that warrant consideration and open avenues for interesting research. In this work, we considered a stationary exemplary strain map, purely dependent on the human shoulder pose, which simplified the demonstration of our control modalities. However, the effects of tendon fiber velocity and muscle activation on the resulting strain are currently ignored, and their inclusion will be necessary in the future, as was demonstrated previously [26]. Including rapid estimation of the muscle activation through dedicated solvers such as [27] is an interesting future direction, as it would improve the quality of the strain estimations by accounting directly for the effect of the interaction wrenches that are exchanged between the human and the robot during their physical interaction.

We are also planning to further explore the control modality that potential users/stakeholders (both patients and therapists) might prefer, allowing us to better define the most effective way to share control of therapy between human and robotic agents. As noted in the methodology, to gather feedback on the system during development, we have conducted a preliminary interactive session with one of the leading experts in orthopedic physiotherapy in the Netherlands. The response was generally very positive, and the main takeaway was to make the shared control system slightly less aggressive. We accounted for this feedback prior to doing experiments for this paper, but our future work will need to focus on testing the method on multiple healthy participants first, to further explore the user experience before moving to tests in more clinical settings.

***Abstract*—Brain-Computer Interface (BCI) technology promotes neuroplasticity mechanisms which favor the functional motor recovery in stroke survivors. Patients' residual motor abilities determine the intention, which, once detected by the BCI is fed back via an effector. The majority of studies aimed at optimizing the feedback branch, but not enough attention has been posed to supporting patient in the movement intention that should be detected by the BCI system. The inclusion of a visual motor priming (observed action before a task) in a BCI could promote the retrieval of movements from the patient's own impaired motor repertoire. None of the motor priming proposed until so far have been tailored to the patients' residual motor ability, although it is well known that the human brain recognizes movements closer from a kinematic perspective to its own repertoire more easily. The aim of this study was to investigate how individual motor style in an action observation task would affect the observer's cortical excitability. EEG signals were recorded from 10 individuals during an action observation task where different levels of motor distance between the observer and the agent were modulated. EEG-based group spectral activations shown an involvement of bilateral parietal areas in beta band in case of more unpredictable kinematics. The results would open the way for the design of a kinematic-based visual motor priming to be embedded in a BCI system for post-stroke rehabilitation.**

I. Introduction

Brain computer Interfaces (BCIs) are one of several technology-based approaches used to restore upper limb motor function after stroke [1]. BCIs establish a real-time bi-directional coupling between central and peripherical nervous systems which enhances recovery by driving the brain reorganization towards improved motor function [2], [3]. In fact, BCI systems collect and process in real-time the physical correlates of brain activity (e.g. recorded by electroencephalography-EEG or electrocorticography-ECoG) to provide feedback to the user regarding the modulation of their brain activity. The feedback most often consists of a sensory stimulus, e.g. visual, auditory, tactile, or could be translated in a more complex design that allows the patient to complete/execute the movement through the BCI-based activation of an external device such as a robotic prosthesis or a functional electrical stimulator (FES) [4]. In the context of motor rehabilitation, the BCI task is usually based on motor imagery (MI) or motor execution (ME) depending on the patient's residual motor abilities. Both BCI tasks involve the primary motor cortex and when the patients' mental activity produces event-related desynchronization (ERD) of the sensorimotor rhythm, they receive specific feedback that, by closing the loop, induces neuroplasticity's mechanisms crucial for functional recovery [5]. As a result, most of research efforts were focused on the optimization of the BCI feedback to maximize plasticity phenomena [6], [7]. However, little or no attention was devoted to supporting the patient in the execution of the task required by the BCI, being it MI or ME.

Providing structured support for these processes could represent an effective method of enhancing neural excitability within the patient's brain, which in turn may strengthen the closed-loop effect. This approach could simultaneously promote the retrieval and reactivation of motor patterns from the patient's own impaired motor repertoire, fostering a more effective neurorehabilitation process. In fact, stroke survivors often experience a phenomenon known as "learned non-use," in which the prolonged inactivity of the affected limb leads to a gradual decline in motor function. This not only results in the deterioration of upper extremity motor skills but may also contribute to a weakening or even loss of cognitive motor control schemes specifically related to the movement of the impaired side. Over time, the neural representations associated with voluntary movement may become less accessible, making it even more challenging for patients to regain functional use of the affected limb. Therefore, integrating strategies that actively engage patients in MI or ME tasks while providing appropriate guidance and reinforcement could help counteract these negative effects [8].

Such support to the patients could be provided by integrating the BCI system with a visual motor priming, where the motor response is facilitated by an observed action (i.e. representing an action before a task [9])) that it has been shown to increase corticospinal excitability [10], [11], leading to

improved motor outcomes. However, none of the motor priming proposed until now have been tailored to the patients' residual motor ability as assessed by kinematics and thus selected according to the specific patient's motor repertoire. Indeed, it has been shown how the human brain is better at recognizing the kinematics of a movement when it falls within their own range of expertise [12], [13], [14] . In this context, we conducted a preliminary study to investigate how individual motor and perceptual characteristics (i.e. individual motor style [15]) would affect the cortical excitability, expressed in terms of ERD, induced by observing an action performed by an agent with a dissimilar or similar motor style to that of the observer. This would help the design of a kinematic-based visual motor priming to be embedded in a BCI system for post-stroke rehabilitation. Specifically, we leveraged on the metric of motor distance to quantify motor (dis)similarities between agents and observer, in an action observation paradigm [16]. We hypothesize that the kinematic characteristics of the observed movement influence the ERD patterns. To this end, ten individuals without motor impairment were subjected to an action observation paradigm where motor distance factor was manipulated while their EEG signals were recorded.

II. MATERIAL AND METHODS

A. Visual stimuli creation

We employed a dataset of 2093 movements obtained by recording naïve participants grasping either a light (150g) or a heavy (510g) bottle. From the reach-to-grasp phase of each action we extracted the following kinematic parameters: wrist velocity (mm/s), wrist acceleration (mm/s2), wrist jerk (mm/s3), grip aperture (mm) and wrist height (mm) and used them to quantify the motor distance by using a novel technique proposed by [16], that leverages on the Procrustes transformation to compare couples of movements. Notably, this approach allowed to jointly operate on the 5 selected kinematic features, rather than on one variable at a time, so that the computed motor distance reflects a global representation of the movement.

B. Participants

Ten subjects (6 M, aged 22-34 years; mean age = 26,7; SD = 2,53) who had previously taken part in a reach-to-grasp action execution task (section II.A), were recruited in an action observation study. All participants were right-handed, with normal or corrected-to-normal vision, with no history of either psychiatric or neurological disorders, with no motor impairment and with no current medications. Handedness was assessed in all participants by means of the short form the Edinburgh Handedness Inventory (EHI) [17] and they had to score at least 61 to be considered as right handers and being enrolled. The dataset used for the purposes of this study was obtained within a research project approved by the bioethics committee of the University of Turin (approval number: 0260704). All the participants signed an informed consent.

C. Experimental design

Participants were presented with video-clips of reach-to-grasp movements described in section A. With the intent of manipulating the motor distance between the participant (i.e. observer) and the agent performing the action in the video clips, we classified the experimental pool videos in four

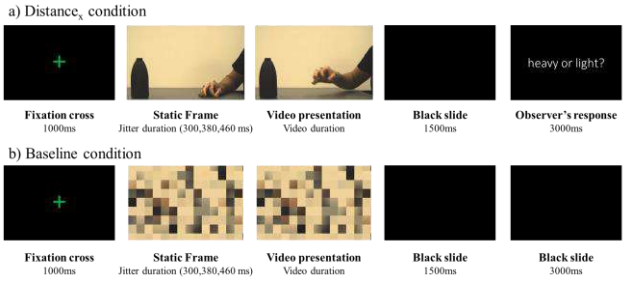

Fig.1 Frames' sequence of a trial during Distance$_x$ condition (a) and a trial during baseline condition (b).

classes depending on the motor similarity, expressed in kinematic terms, in the execution of the reach-to-grasp movement. Specifically, for each observer we selected: i) 10 videos of movements falling within the first quartile of the motor distance distribution (Distance 1; i.e., highly similar kinematics between the observer and the agent); ii) 10 videos of movements falling between the first and the second quartile of the motor distance distribution (Distance 2); iii) 10 videos of movements falling between the second and the third quartile of the motor distance distribution (Distance 3); iii) 10 videos of movements falling above the third quartile of the motor distance distribution (Distance 4; i.e., highly different kinematics between the observer and the agent). 10 additional stimuli were created by randomly selecting 10 videoclips within the experimental stimuli pool and by scrambling the pixels' position at each frame of the video. In this way, these baseline stimuli were no kinematically informative, but of duration and pixels colour comparable to those of the videos of other conditions.

Participants were seated in a comfortable chair in front of a monitor at a distance of 50cm, in which were presented the videos, and a response keyboard was placed at a distance of 15cm from their body midline. Additionally, black panels were placed around the experimental setting to create an isolated and quiet environment for the observers. Before the start of the action observation paradigm, participants were requested to execute 10 reach-to-grasp movements, 5 directed toward a light object and 5 toward a heavy object, to familiarize again with the objects that they manipulated during the action execution task. During the action observation paradigm, participants were presented with the reach-to-grasp video clips extracted by the custom selection based on their motor distances. The experiment was administered according to a block design approach including 6 blocks of 50 trials each, with a break among them. In each block, were administered 10 videos for each motor distance (Distance 1, Distance 2, Distance 3, Distance 4) and 10 baseline videos. The presentation's order of the stimuli was randomized within blocks and each video was shown once per block. Each trial began with the presentation of a green cross fixation with duration of 1000ms, followed by the videoclip of the movement. To avoid anticipation and to keep subjects focused, a static frame of pseudo-random duration was added at the beginning of each clip. Possible duration values were: 300ms, 380ms and 460ms. After the video presentation there was an interstimulus interval with duration of 1500ms and, after this, participants were asked to indicate accurately if

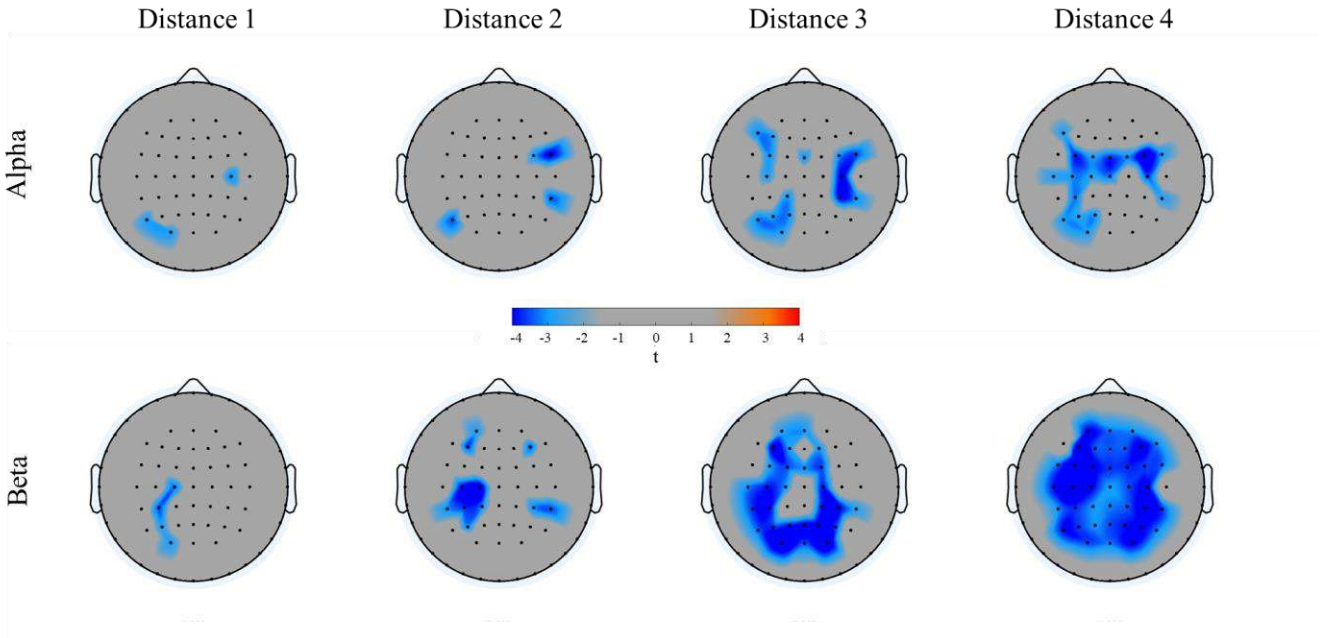

Fig. 2 Topographical scalp maps in alpha and beta bands obtained performing a paired t-test ($\alpha = 0.05$, False Discovery Rate correction), comparing the PSD values obtained in each of the four experimental condition (i.e. Distance 1, Distance 2, Distance 3, Distance 4) vs those obtained for Baseline condition. Results are mapped over a 2D scalp model with the nose pointing the upper part of the page. Pixels color codes for t-values obtained for the different channels. T-values below statistical threshold were represented in gray. Red pixels codes for significant synchronizations (t-values when condition$_x$ > baseline) while blue colobar for desynchronizations (t-value when condition$_x$ < baseline).

the grasped object was heavy or light by using the keyboard. Participants were instructed to respond within a maximum of 3000ms, during the response slide. In baseline condition, this frame was replaced by a black slide with a duration of 3000 ms. After the response an inter-trial interval, represented by a black slide, was shown for 500ms. The sequence of frames of a trial during the presentation of a video falling in Distance$_x$ condition and in baseline condition is depicted in Fig.1. No feedback about the correctness of their responses was provided to participants. The entire experimental session lasted approximately 40 minutes and was managed using E-prime V3.0 software (Psychology Software Tools, Inc, Sharpsburg, PA, USA).

D. EEG data collection

EEG data were acquired during the paradigm administration and sampled at 500Hz. EEG signals were recorded from the scalp by means of a 61-channel active electrodes system (LiveAmp, Brain Products GmbH, Germany) positioned according to an extension of the 10-20 International System. The ground and reference were placed on the right and left mastoid respectively. Markers related to the different experimental conditions were delivered to the EEG amplifier through the BrainVision TriggerBox (Brain Products GmbH, Germany).

E. EEG data analysis

An ad-hoc EEG pre-processing pipeline was implemented to maximize the signal information extrapolated from the noise. First of all, EEG signals were down-sampled to 250 Hz using a spline interpolation to minimize data manipulation. Sequentially, the data were band-pass filtered [1- 45] Hz by means of an 8th order zero-phase shift Butterworth IIR filter and also a 50 Hz notch filter was applied to remove power line interference. The noisy channels were identified and excluded from further analysis. Eye artefacts (i.e. blinks and saccades) were removed using the independent component analysis (ICA). EEG data of each subject were re-referenced to the Common Average Reference and segmented according to the different experimental conditions (i.e. Distance 1, Distance 2, Distance 3, Distance 4 and Baseline). Only the video-related trials with a duration between 500 and 1100 ms were selected. Channels located at the scalp edge were excluded from further analyses being mostly subjected to the presence of artifacts. A voltage semi-automatic threshold criterion (±100 μV) was applied to highlight residual artefacts. In particular, if we found more than five channels which exceeded the threshold in a trial, we removed it, otherwise we interpolated the bad channels by means of a spherical interpolation including all the other channels. Only artefact-free epochs were considered for further analyses.

F. Grand Average Spectral Maps

The power spectral density (PSD) was computed by means of Welch periodogram (Hann's window of 1100ms duration and with 0% overlap) for each electrode, experimental condition (i.e. Distance 1, Distance 2, Distance 3, Distance 4 and Baseline) and participant. We applied the decibel (db) transformation of PSD values, and we averaged them in the two frequency bands more related to motor tasks: Alpha [8-12] Hz and Beta [13-30] Hz.

In order to identify the spectral activations solely associated with the observation of motor actions and thus discard all that could be associated to confounding factors such as the environment or the use of a monitor to administer the stimuli, we designed a statistical test in which PSD values,

obtained during the observation of videos labelled by different motor distances, were compared with those obtained in the baseline condition. Such condition was in fact planned as reference since it contains all the brain activations related to the context of the experiment except for the motor content. In particular, we compared the PSD values for each motor distance level with the baseline by performing a paired t-test ($\alpha = 0.05$, False Discovery Rate correction) across the participants (N=10) for each electrode. The t-values resulting from the statistical test were then filtered using statistical thresholds derived from the theoretical t-student distribution ($\alpha = 0.05$), thereby yielding grand-average statistical spectral maps at the scalp level between each condition and the baseline. These results are illustrated in Fig. 2.

G. Assessing the effect of motor distance on ERD

In order to confirm what was qualitatively noticed at the group level by means of statistical mapping and thus to evaluate how the motor distance would affect the level of desynchronization of specific brain areas, we computed at single subject level the ERD for each experimental condition (Distance 1, Distance 2, Distance 3, Distance 4) in alpha and beta frequency bands and for each channel, as follows:

$$\frac{PSD_{condition}\text{-}PSD_{baseline}}{PSD_{baseline}} \quad (1)$$

Since we hypothesized that motor distance in the observed videos could modulate the level of desynchronizations of specific brain areas of the observer mainly in the beta band, we designed a statistical test comparing ERD values between the two experimental conditions associated to the extreme values of motor distance (1 and 4) where we expected the higher size of the effect. We then compared the ERD values computed in Distance 4 and Distance 1 conditions by performing a paired t-test ($\alpha = 0.05$) for each band and each channel.

III. RESULTS

A. Grand Average spectral maps

In Figure 2 we reported the grand-average statistical spectral maps obtained for alpha and beta bands obtained by comparing the PSD values for each experimental condition with those related to baseline. The effect of the motor distance manipulation is evident on spectral activations in both frequency bands. Specifically, as for alpha band, in case of high motor distance (Distance 3 and 4) spectral desynchronizations are located over the bilateral sensorimotor areas and in left parietal area. When the observer was exposed to motor actions kinematically closer to them (Distance 1 and 2) the desynchronizations are more focal over the right central area. As for beta band, we obtained the activation of bilateral sensori-motor areas more spread in left hemisphere (that is contralateral to the side used to perform the motor action shown in the videos) independently on the applied motor distance manipulation. Moreover, observations of videos exhibiting kinematic movement dissimilar between the agent and observer (i.e. Distance 3 and Distance 4 conditions) revealed the activation of bilateral parietal areas.

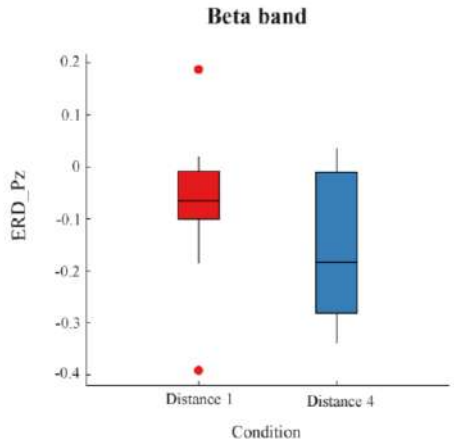

Fig. 3 Boxplot reporting the result of paired t-test ($\alpha = 0.05$) comparing the distribution of ERD values between Distance 4 and Distance 1 condition computed in beta band for Pz channel

B. Assessing the effect of motor distance on ERD

As for the comparison of ERD values between Distance 4 and Distance 1 conditions, we obtained a statistically significant difference for the Pz channel in the beta band, as shown in the Fig.3. In particular, the degree of desynchronization is significantly greater at maximum motor distance (Distance 4) than to at minimum motor distance (Distance 1). This result confirms quantitatively what we have described from grand average spectral maps.

IV. DISCUSSION AND CONCLUSION

In this preliminary study, we proposed to evaluate the effect of kinematic-based motor distance on neural activity in a group of subjects without motor impairment and neurological disorders during an action observation paradigm in order to design a kinematic-based visual motor priming to be embedded in a BCI system for post-stroke rehabilitation.

The grand-average statistical spectral maps reveal different neural activations depending on the frequency band considered. In both alpha and beta bands we found significant desynchronizations over the bilateral sensorimotor areas (centro-parietal electrodes), even if more lateralized over the left hemisphere, when the kinematic-based motor distance computed between the observer and the actor in the video is low (Fig. 1). This result is in line with what is already known about the role of such areas in motor tasks. In fact, motor and pre-motor areas are active not only when an individual performs a movement but also when such movement is imagined or observed, even if with a reduced level of desynchronization [18]. The lateralization over the left hemisphere is explained by the fact that the videos shown to the participants were played by individuals performing motor actions with right limb, thus an activation localized over the contralateral hemisphere is expected [5]. The effect of motor distance handling in action observation task was more evident in beta band. In particular, when participants observed videos characterized by a motor content kinematically unexpected (Distance 3 and Distance 4 conditions) activations over the bilateral parietal areas resulted. This is also confirmed by the

result of the paired t-test performed on the ERD scores, in which a higher desynchronization in Pz was found when observing movement with kinematics far from their internal mental motor representation with respect to the closer one (Fig.3). These results are consistent with previous studies that have shown how the kinematic characteristics and biological plausibility of observed movement has an influence on the brain activations [19]. In fact, an fMRI study shown how sensorimotor parietal regions are modulated when observing a movement with kinematics different from what is considered plausible [20].

In conclusion, this preliminary study demonstrates how the manipulation of kinematics-based motor distance in an action observation task influences observer's neural activation highlighting how the motor action shown to the observer should be closer to their motor repertoire otherwise it is perceived as unexpected and unpredictable. This is a key information to be taken into account if we are interested in the design of a motor priming for BCI systems, that supports patients in accomplishing the request to attempt/execute a motor action [11], [21]. The use of a kinematic-based motor priming preceding the request to the patients to attempt a movement supported by BCI would increase corticospinal excitability thus facilitating the recognition of the motor pattern ultimately promoting plasticity phenomena related to the use of a closed-loop rehabilitation approach. Priming presupposes, in fact, that enhanced neural activity before training could facilitate the activation of long-term potentiation-like mechanisms supporting synaptic plasticity [22]. To the best of our knowledge, none of the motor priming included in the available BCI systems has been tailored to the residual motor ability of the patient as assessed by kinematics. Adapting the motor priming to the specific patient's kinematics would allow to bring them to a level of corticospinal excitability where they would benefit the most from BCI intervention. In addition, such tailored priming would support the patient in movement attempt/execution helping them in the recall of movements from their own impaired motor repertoire and not from a general repertoire which could be perceived as unrelated.

***Abstract*—Robot-Enhanced Therapies (RET) are gaining recognition in autism interventions, though limited empirical evaluations of their effectiveness exist. This study introduces a novel RET focused on imitation training to promote social skills, incorporating gestures from children's songs to enhance engagement. This work presents preliminary findings from eight autistic children who underwent a 12-week intervention, assessing improvements in adaptive abilities using the Adaptive Behavioral Assessment Scale (ABAS-II) and *Primo Vocabolario del Bambino* (PVB), with the Social Adaptive Domain (SAD) of ABAS-II as the primary outcome. Treatment adherence is measured as the proportion of correctly imitated gestures, which is also quantified by leveraging a CNN-based gesture recognition algorithm. While results show overall trends of improvement, the primary outcome does not reach statistically significant. However, adherence was significantly higher in subjects with improved social skills, underscoring the importance of active participation The gesture recognition algorithm achieved an F1-score of 0.57. While findings are promising, the comparison with a control group will permit differentiating the outcomes of the therapy protocol and the developmental trajectory. Future efforts should focus on improving the gesture-imitation algorithm and refining adherence assessment tools.**

***Index Terms*—Robot-Enhanced Therapy, Autism, Social skills**

I. Introduction

Autism Spectrum Disorder (ASD) is a neurodevelopmental condition characterized by restricted and repetitive behaviors as well as social and communication deficits [1]. The prevalence of autism is increasing, with an estimated 1 in 36 children diagnosed with ASD in the U.S. [2]. Existing interventions are designed to promote the development of socio-communicative skills, addressing the core symptoms and their influence on child's development and easing inclusion in a neurotypical society [3]. Advancements in Artificial Intelligence (AI) and robotics have fostered a growing interest towards their applications for autism [4]. Specifically, HRI research on autism primarily follows a medical model, highlighting robots' role in ASD interventions [5]. The rationale underpinning robots' use in ASD therapy is rooted in their predictability, which can reduce discomfort elements for autistic children compared to human-human interaction [6]–[8]. Several robot-mediated approaches have been explored in ASD intervention. For instance, Marino and colleagues proposed the use of robots to improve emotion recognition skills [9]; Javed et al, utilized a humanoid robot to address sensory processing difficulties in ASD children [10]; Cao et al, developed a Robot-Enhanced Therapies (RET) for joint attention training [6]. Additionally, some studies have investigated the use of robots for imitation training [11], [12], given that gesture imitation plays a crucial role in empathy development [13] and serves as a social function by facilitating engagement in social and emotional contexts. Moreover, gesture imitation has been found to positively correlate with joint attention [14].

In all forms of intervention, active involvement of the child is essential to achieve therapeutic outcomes [15]. The measurement of adherence to the protocol is thus crucial to determine whether the observed changes can be imputable to the proposed intervention. In this direction, Rakhymbayeva et al. proposed quantifying adherence using a 1-5 Likert scale [16] based on the number of prompts needed to complete the task. However, this method is prone to inter-operator variabil-

ity and lacks sensitivity to subtle changes. Alternatively, van den Berk-Smeekens and colleagues assessed adherence as the percentage of therapy sessions in which participants accepted the use of the NAO robot, reflecting sufficient motivation to complete the interaction [17]. Nonetheless, their approach did not account for the child's effective participation in the therapy protocol.

In order to sustain engagement, researchers have explored integrating music and dance to stimulate spontaneous communication [18]. Music, in particular, is widely acknowledged as an effective tool for promoting communication within therapeutic settings [19].

Various quantitative approaches have been proposed to measure engagement during therapy. Gaze direction has been identified as a biomarker for detecting engagement [20], while Joint Attention Behaviors have been used to estimate the level of child involvement [21]. Additionally, more advanced multi-modal methods combining gaze features with emotion recognition have been explored [22].

In this work, we propose a Robot-Enhanced Therapy (RET) centered on gesture imitation and empowered by the introduction of songs in the imitation activities, with the aim of permitting the engagement of children with moderate or high levels of autism. The primary research question of this study is to evaluate the effectiveness of the proposed intervention in terms of adaptive abilities with a particular focus on social skills. A secondary research question examines whether differences in outcome measures are associated with children's adherence to the intervention protocol. The final research question explores whether an automatic quantitative algorithm can assess adherence to the therapy.

II. Materials and Methods

A. Study Design

This study presents preliminary results from a Randomized Controlled Trial (RCT) currently underway at IRCCS Fondazione Don Carlo Gnocchi, Milan, Italy. Specifically, a subset of participants from the experimental group has been analyzed. Eligibility criteria include a confirmed autism diagnosis via the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2) [23] and an age of under six years at recruitment. Participants completed 12 weekly sessions of Robot-Enhanced Therapy, each lasting approximately 20 minutes, as detailed in Section II-C. The study protocol was approved by the Ethical Committees of Politecnico di Milano (approval number 34/2022, dated 16/09/2022) and Fondazione Don Gnocchi (approval number 07/2023, dated 29/03/2023). All parents provided written informed consent before the intervention, and participants were free to withdraw at any time.

B. Setup

The therapy setup includes a NAO (6th version) humanoid robot, developed by Aldebaran Robotics, integrated with a Microsoft Azure Kinect camera to track participants' movements. A serial communication protocol is established between the robot and the camera through a dedicated computer. A tablet-based Graphical User Interface (GUI) enables the therapist to control the robot.

Fig. 1. Gestures included in the current protocol for each song [26].

C. Therapy protocol

The therapy protocol is based on a triadic interaction involving the therapist, the child, and the NAO robot, which serves as a mediator to promote socio-communicative skills between the two human partners. Sessions begin with a familiarization phase, during which the robot interacts with the child with sensory stimuli such as lights, sounds, and simple movements. Once the child feels comfortable with NAO, the therapist transitions to the core phase, which centers on gesture imitation. Body movements and gesture imitation are believed to help establish an effective communication channel between the child and the therapist [24]. A previous pilot study included only semantic gestures related to daily living activities [25]. However, as children with severe autism often struggled to engage with these tasks, the protocol was expanded to incorporate gestures from popular children's songs. Specifically, *Noah's Song* (*L'arca di Noè*), *Baby Shark*, and *Crocodile Song* (*Il coccodrillo come fa?*) were introduced, with corresponding gestures selected based on the lyrics, as illustrated in Figure 1.

The imitation interaction begins with the therapist selecting a song through the GUI, considering the child's verbal and non-verbal preferences and requests. The robot starts singing the song and it demonstrates the gestures related to the lyrics when the specific part associated with that gesture is sung. After the demonstration, the robot repeats the same segment without showing the gesture anymore. In this phase, the therapist structures the triadic interaction by encouraging imitation but does not provide additional prompts beyond those given by the robot. This pattern continues till the end of the song. Besides gesture training, this protocol is aimed to exercise the turn-taking skills of the children and to enhance their social interaction with the therapist. Although parents are allowed to be present during therapy, children typically participate independently.

D. Outcome measurements

The Griffiths Mental Development Scales III (GMDS-III) [27] are administered at the baseline to evaluate each child's Global Developmental Quotient (GDQ), which ranges between 20 and 150. To evaluate the effectiveness of the therapy protocol, two assessment scales are employed: The Adaptive Behavior Assessment Scale - Second Edition (ABAS-II) [28] and the Italian adaptation of the MacArthur-Bates Communicative Development Inventories, *Primo Vocabolario Del Bambino* (PVB) [29]. The ABAS-II is a parent-reported questionnaire that measures the adaptive abilities by assessing the presence and frequency of specific behaviors. The scale provides a Global Adaptive Composite Score (GAC), ranging from 37 to 170, along with three subdomain scores. The Conceptual Adaptive Domain (CAD), ranging from 41 to 150, assesses communication skills and self-regulation. The Social Adaptive Domain (SAD), with a range of 49 to 148, measures socialization abilities, including interactions with peers and adults. Lastly, the Practical Adaptive Domain (PAD), spanning 44 to 149, evaluates self-care and school-related skills. In all cases, higher scores indicate better adaptive skills. Given that the therapy protocol primarily targets socio-relational development, the SAD subdomain was selected as the primary outcome measure. The PVB scale is a questionnaire aimed to assess children's communication skills. Specifically, its *Gestures and Words* subtest quantifies the words and phrases understood and pronounced, as well as the gestures observed and acquired, providing insights about the development of their receptive and expressive abilities. The scale ranges between 0 and 63. Both questionnaires are administered at T0, before the beginning of the intervention, and at T1, the week after its conclusion.

E. Adherence Assessment

Although the therapy protocol is designed to offer standardized interaction possibilities, with the inclusion of the robot further enhancing the consistency of the intervention, each session differs from the others by the number of stimuli provided. These variations primarily depend on the child's willingness to engage during the session. Therefore, adherence to the conceived therapeutic protocol can be quantified by the proportion of gestures imitated by the child compared to the total amount of stimuli presented. Specifically, the number of gestures imitated during each therapy session is recorded and divided by the total number of stimuli provided along the whole session. This latter is defined as the sum of the gestures presented in each song multiplied by the number of times each song was played during the session.

F. Automatic Method for Adherence Assessment

Despite the robustness of the proposed metric for assessing the impact of child adherence on therapy outcomes, the manual annotation of all sessions is highly time demanding. To overcome this limitation, an automatic gesture recognition algorithm was implemented. The algorithm builds upon our previous work [26], processing kinematic data acquired via the Azure Kinect camera. This data is fed into a set of binary classifiers — one per gesture — based on Convolutional Neural Networks (CNNs), which determine whether the child performed the expected gesture or not. In our previous study, gestures were precisely segmented via manual video observation, achieving high classification accuracy. However, to enable a fully automatic computation, in this work manual segmentation was avoided and an automated alternative was implemented [30].

Only sessions in which at least one gesture was proposed have been included in the automatic analysis. Indeed, during some sessions, no imitation activities were proposed due to technical issues (e.g. Kinect cable disconnections or Wi-Fi instability affecting the Graphical User Interface) or to child's complete refusal to interact with NAO.

G. Data analysis

To answer the first research question, the General Composite Score of the ABAS-II scale, as well as all its subdomains and the PVB were assessed both before and after the intervention for all children. The Wilcoxon test with a significance of 0.05 was used to assess the statistical significance of the differences found at the two time points. A deeper analysis was performed by dividing the cohort into two subpopulations depending on the variations in the SAD subdomain score: a first one defined as *Respondent Group* which encompasses those children presenting a positive change in the SAD scale and a second one, named *Non-Respondent Group*, that comprehends those subjects with no change in the SAD subdomain. To answer the second research question, the Mann-Whitney U test was applied to compare the mean percentage of imitated gestures between the *Respondent* and *Non-Respondent* subjects. The performance of the automatic method for adherence assessment was evaluated using the F1-score, considering class imbalances. Moreover, in order to better investigate the performances of each classifier, each gesture's dataset was artificially balanced by sourcing the additional false samples from the true representations of the other classes and the accuracy for the specific dataset is considered [26].

III. Results

A. Participants

Eight participants (3 females and 5 males; mean age 52.1 ± 12.9 months) completed the Robot Enhanced Therapy protocol and underwent the assessment phases. Table I summarizes their demographic and clinical characteristics. Since the minimum value of the GDQ as reported by the GMDS-III score is 20, children who scored below this threshold are reported as < 20. ADOS-2 comparison scores assess the level of symptoms related to Autism Spectrum Disorders, with values between 5 and 7 indicating a moderate evidence of autism-related symptoms and between 8 and 10 indicating a high level of symptoms.

Patient ID	Sex	Age (months)	GDQ	ADOS
DG01	F	52	56	9
DG02	M	42	<20	10
DG03	M	38	63	9
DG04	F	55	42	6
DG08	M	61	<20	7
DG10	F	63	<20	7
DG12	M	71	<20	6
DG13	M	35	73	9

TABLE I

DEMOGRAPHIC AND CLINIC CHARACTERISTICS OF CHILDREN INCLUDED IN THE STUDY. THE AGE IS REPORTED AT THE TIME OF T0 ASSESSMENT. GLOBAL DEVELOPMENTAL QUOTIENT (GDQ) IS ASSESSED THROUGH THE GMDS-III. ADOS-II COMPARISON SCORE IS REPORTED TO ACCOUNT FOR AUTISM SEVERITY (5-7 MODERATE; 8-10 HIGH LEVEL OF SYMPTOMS).

Scale	T0	T1	p-value
GAC	41 [37-51]	49 [39-68]	**0.04**
CAD	45.5 [41-60]	56 41-78]	0.3
SAD	49 [49-61]	56 [49-66]	0.3
PAD	46 [44-61]	57.5 [49-68]	**0.04**
PVB	38.5 [34-35]	42.5 [37-54]	0.1

TABLE II

MEDIAN [INTER-QUARTILE RANGE] RESULTS OF THE ABAS-II SCALE GENERAL ADAPTIVE COMPOSITE (GAC) AND ITS SUBDOMAINS, NAMELY THE CONCEPTUAL ADAPTIVE DOMAIN (CAD), THE SOCIAL ADAPTIVE DOMAIN (SAD) AND THE PRACTICAL ADAPTIVE DOMAIN (PAD) AND OF THE *Primo Vocabolario del Bambino* (PVB). THE LAST COLUMN REPORTS THE P-VALUE OBTAINED AT THE WILCOXON TEST AND SIGNIFICANT RESULTS ARE HIGHLIGHTED IN BOLD

B. Clinical Scales

Table II presents the median and interquartile ranges for the scores obtained across these scales and their respective subdomains. The results indicate that while the median values of all considered metrics improved, statistical significance was found only for the General Adaptive Composite score ($p = 0.04$) and for the Practical Adaptive Domain ($p = 0.04$).

Since the proposed treatment primarily targets social aspects, individual changes in the SAD subdomain were further analyzed, with the results depicted in Figure 2. The population can be distinctly clustered into two subgroups: a *respondent* one, consisting of individuals who exhibit an improvement in the SAD score during the intervention, and a *non-respondent* group, comprising children who do not present any pre to post-treatment change.

C. Adherence Assessment

Our second research question investigates whether active engagement by the child during therapy positively impacts treatment effectiveness. We hypothesize that the proportion of gestures imitated by the child could serve as a meaningful parameter to assess adherence to the proposed therapeutic approach.

The percentage of gestures imitated by the child during each session computed by manual annotation is illustrated in Figure 3. The distinction between *respondent* and *non-respondent* groups presented in Section III-B is maintained to highlight behavioral differences between the two groups. Specifically, the left panel depicts the *respondent* group, while the right one

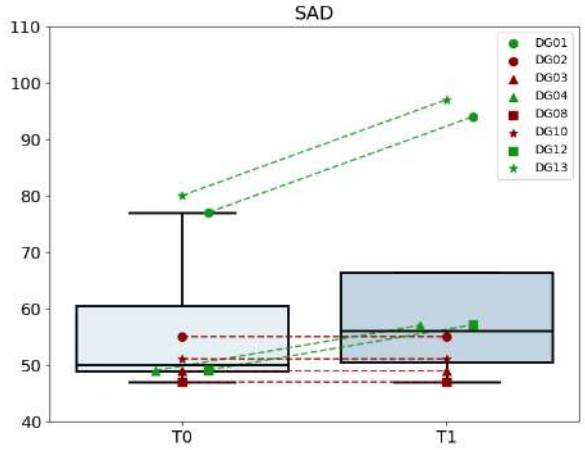

Fig. 2. Results in the Social Adaptive Domain (SAD) of the ABAS-II scale at T0 and T1. Each points represents a specific subject. Green points represent *respondent* subjects while red ones indicate *non-respondent* children.

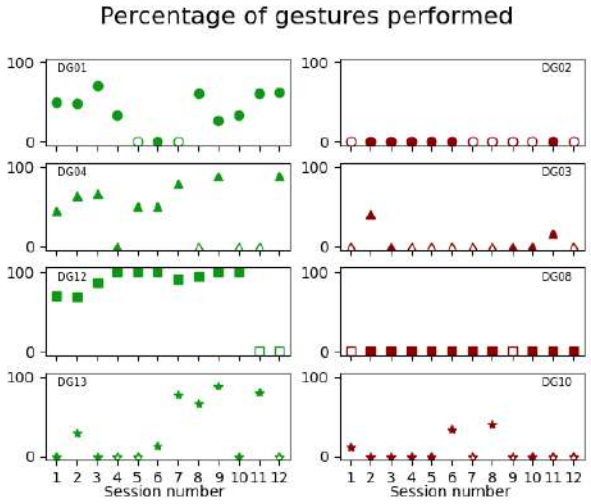

Fig. 3. Percentage of gestures imitated by each child. Green symbols represent children in the *respondent* group while red symbols represent the *non-respondent* group. Empty symbols indicate the sessions excluded from the analysis, i.e. when no gestures were proposed.

represents the *non-respondent* group. Notably, only respondents actively engaged in the imitation task, while the non-responders demonstrated a marked absence of participation in imitation activities throughout all sessions. The difference in the average number of imitated gestures between the two groups was statistically significant, as confirmed by the Mann-Whitney U test ($p = 0.02$).

D. Automatic Method for Adherence Assessment

Of the 96 sessions conducted in this study, 67 (70%) were included in the analysis. The dataset consists of 316 stimuli, defined as instances when the child was expected to replicate a gesture demonstrated by the robot. The dataset is imbalanced, with 216 gestures manually labeled as correct imitations and 100 classified as incorrect imitations. Given this imbalance,

the F1-score was used to evaluate the method's performance, yielding a result of 0.57, with a precision of 0.66 and a recall of 0.55. To further analyze classifiers' performances, each gesture's dataset was artificially balanced by adding true representations pertaining to the other classes, and the accuracy of the algorithm was computed separately for each gesture, as detailed in Table III.

Gesture	True samples	False samples	Total samples balanced	Accuracy
baby	18	11	36	0.64
boh	8	6	16	0.5
bye	19	12	38	0.45
daddy	24	4	48	0.67
drink	8	5	16	0.38
eagle	19	4	38	0.71
eat	9	5	18	0.5
elephant	14	9	28	0.57
mommy	24	7	48	0.58
no	24	12	48	0.54
orangutan	16	8	32	0.69
sad	10	4	20	0.5
swim	18	12	36	0.47
walk	4	1	10	0.6
Total	**216**	**100**	**432**	

TABLE III
TRUE AND FALSE SAMPLES INDICATE THE ORIGINAL DATASET DISTRIBUTION. ACCURACY WAS COMPUTED AFTER BALANCING EACH GESTURE'S DATASET.

IV. DISCUSSION

The primary research question of this study investigates the effectiveness of the proposed Robot Enhanced Therapy, based on gesture imitation. To assess this, we analyzed the General Adaptive Composite (GAC) score of the ABAS-II scale and its subdomains, along with the *Primo Vocabolario del Bambino*. While all metrics indicated a median improvement from T0 to T1, only the GAC and PAD subdomains reached statistical significance. Since the intervention primarily targets social skills, the Social Adaptive Domain (SAD) of the ABAS-II scale was selected as the primary outcome. Four children (DG01, DG04, DG12, DG13) showed improvement, forming the *respondent group*, while the remaining four exhibited no pre-post variation and were categorized as *non-respondents*. Notably, the two children with the highest SAD scores at T0 are also the ones who showed a more marked improvement. The other two respondents displayed better interaction skills at the baseline, although they did not stand out in clinical scales. Conversely, three of the non-respondents had a GDQ below the minimum threshold. These findings may suggest that this RET could be more effective for children with a minimum level of social skills at baseline.

To explore the impact of adherence on therapy outcomes, we computed the percentage of imitated gestures. Only children who actively engaged in imitation tasks showed improvement in the SAD score, indicating that participation is crucial for achieving therapeutic benefits. Interestingly, DG13, the youngest participant, initially exhibited low adherence, which gradually increased from session 7 onward. This might suggest that younger children may require a longer adaptation period. Conversely, the severity of ASD symptoms, appears to have no correlation with either therapy effectiveness or adherence level.

Given the time-intensive nature of manual adherence assessment, we propose the use of an automatic gesture recognition algorithm. Results reveal the challenges of applying this method with autistic children data, as reflected in the low F1-score. This is probably due to the fact that ASD children move a lot during the acquisition without maintaining the expected standing pose. In fact, the training set of the Gesture Recognition Algorithm was composed of neurotypical individuals, both adults and children, without including any autistic child. Moreover, these results are lower than the ones reported in [26] probably because in the present work the algorithm has been applied following an online approach in order to avoid the need for manual segmentation, which was in turn done when the algorithm was tested in the previous work. To gain further information on this result, each gesture dataset was balanced, and the corresponding recognition accuracies were computed. Gestures involving broader movements (*daddy*) and those primarily occurring in the frontal plane (*orangutan*, *eagle*) achieved higher recognition rates. This aligns with previous research indicating that the Azure Kinect performs well under these conditions but struggles with sagittal-plane movements and gestures with limited amplitude [31].

V. CONCLUSION

In this study, we proposed a new Robot-Enhanced Therapy protocol based on imitation training of gestures derived from children's songs, with the objective of enhancing participant engagement. While a general trend of improvement across all metrics suggests potential benefits of the proposed treatment, the primary outcome measure, the Social Adaptive Domain (SAD) of the ABAS-II scales, did not demonstrate statistical significance between pre- and post treatment. The subsequent analysis of the data involved the establishment of two distinct subgroups: those who exhibited a positive response to the intervention and those who did not, based on the primary outcome. To address the second research question, the adherence to treatment was quantified using the percentage of gestures imitated by the child. The obtained results indicate that only those children who actively engaged in the imitation activity demonstrated a performance improvement in the main outcome metric. In conclusion, given the significant time investment required for manual computation of the percentage of imitated gestures, we implemented of an automatic algorithm, which yielded an F1-score performance of 0.57, underscoring the necessity for further research in this domain.

Although the results of this study are encouraging, several limitations must be acknowledged. Firstly, the RET was evaluated on a small sample of eight children from the experimental group. A larger dataset and a control group will permit drawing more robust conclusions about the effectiveness of the proposed intervention. Secondly, adherence was assessed solely based on the percentage of gestures imitated by the children, without considering other aspects of engagement not directly tied to the therapy protocol. Future studies should

incorporate additional measures, such as motor abilities, eye gaze, and emotion recognition, to provide a more comprehensive understanding of the child's engagement. Lastly, gesture recognition was used to automate adherence assessment. While this approach demonstrated feasibility, further refinements are needed to enable full automation, facilitating adherence assessment in larger cohorts.

ACKNOWLEDGMENT

We would like to acknowledge the therapists Arianna Caglio and Eleonora Santini who carried out the interventions.

***Abstract*—Sensory feedback enhances the intuitive operation of upper limb prostheses. However, most modern commercial prosthetic devices lack sensory feedback mechanisms due to the difficulty of integration and added complexity. Mechanotactile haptic feedback provides a non-invasive and low-cost alternative to traditional electromechanical haptic feedback modalities. While mechanotactile haptic feedback systems have been studied for their mechanical behaviour, their practical integration in prosthetic devices and associated human factors still remain to be investigated. Therefore, in this paper, we perform a psychophysics study to investigate the perceptual thresholds associated with a mechanotactile feedback system. We use a mechanotactile sensory system and feedback device to provide force feedback on the forearm of healthy volunteers. We systematically assess the optimal placement of the feedback devices and the minimum perceptible forces at each position. We found that the minimum perceptible force that a user can perceive range lies in the range of 0.39 N to 1.36 N at various points on the forearm. The distal forearm was found to have higher perception sensitivity compared to the proximal forearm. Our results shed light on the perception thresholds achievable with mechanotactile haptic elements. Results also indicate that proper placement and site selection of the mechanotactile feedback elements are crucial to enhance force perception accuracy.**

***Index Terms*—Mechano-tactile feedback, psychophysical measurement**

I. Introduction

The human hand is one of the most complex structures in nature, showcasing remarkable flexibility, dexterity, and sensory capabilities. It operates within a closed-loop sensory feedback system that is essential for maintaining precise control over its movements and interactions with the environment [1]. The sense of touch in the human hand is achieved by different types of mechanoreceptors present in the skin [2]. However, individuals with upper-extremity amputation who utilize upper limb prosthetic devices lack the ability to perceive sensory information related to touch. Therefore, crucial information required to execute simple tasks, grasping and holding objects without slipping or crushing them often exhibits poor force modulation and high failure rates [3], [4]. As a result, a vast majority of prosthetic users end up abandoning their devices and often cite the lack of sensory feedback as a key determinant [5], [6].

Several techniques have been adopted to sense distal tactile interactions and to provide haptic feedback to users to restore the sense of touch in prosthetic devices [7]. Several groups have reported resistive, capacitive and optical systems to sense the interaction forces on the fingertips of prosthetic devices and robotic grippers. BioTac, employed a conductive fluid enclosed in an elastomeric chamber to measure changes in electrical impedance due to tactile interactions [8].

On the other hand, sensory feedback can also be delivered through multiple modalities, including vibration, compressive and shear forces (skin stretch) and electrotactile feedback [9]. Invasive methods involving the implantation of neural interfaces have been successful in eliciting illusory sensory percepts in phantom limbs, providing highly realistic feedback to individuals with amputation [10]. However, the high risk of surgery and coupled with poor long-term stability of neural interfaces, has led to limited adoption [11].

Shi et al. developed a purely mechanical haptic feedback and sensing system [12], [13]. Briefly, the system utilizes a fluid-filled mechanotactile system, which has three main components: a fingertip sensor, an actuator, and a tube. This system senses the force on the fingertip sensor and transfers the force through the fluid to the actuator to produce modality-matched tactile stimuli. Unlike traditional approaches, the sensing element and the haptic feedback element are purely mechanical in nature, obviating the need for electrical connections or signal processing. Therefore, mechanotactile haptic systems are uniquely suited for integration into passive prosthetic devices and devices with limited electrical and electronic hardware resources. However, a systematic psychophysical measurement is required to understand the relationship between sensory input and perceived stimuli, i.e. the perception thresholds for mechanotactile haptic systems [14], [15].

Therefore, in this paper, we perform a thorough psychophysical evaluation of the mechanotactile systems reported by Shi et. al [12], [13]. First, we conducted an experiment to identify

This work is funded in part by a grant from the Department of Biotechnology, Government of India- BT/PR50638/MED/32/951/2023 (PI: Biswarup Mukherjee) and by IIT Delhi-University College London MFIRP grant - MI02264G (PIs: Biswarup Mukherjee and Helge A. Wurdemann.)

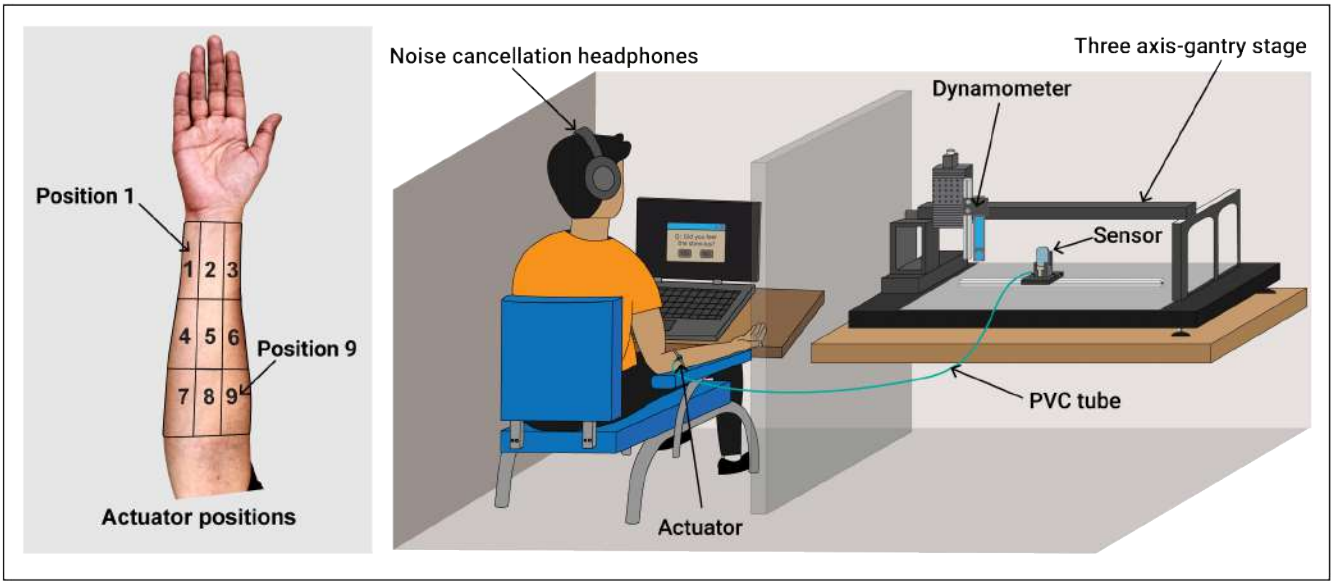

Fig. 1. The experimental setup for the psychophysical evaluation of mechano-tactile haptic device. The feedback actuator was placed on the Participant's forearm, and the fingertip sensor was fixed on the gantry. A curtain was placed between the gantry setup and the subject, and noise-cancellation headphones were used to avoid visual and audio bias.

the most suitable position for placing the mechanotactile actuator on the forearm. In a follow-up experiment we also assess the smallest perceptible force.

II. Methods

A. Participants

We recruited six non-disabled participants for this study. The mean age of all participants was 27$\pm$6. All the participants self-reported being right-hand dominant with no history of injury to the dominant arm. All procedures reported here were approved by the Institute's ethics committee (IEC) at the Indian Institute of Technology, Delhi, New Delhi. Participants provided written consent prior to participating in the study.

B. Experimental setup

The main components of the experimental setup include a three-axis-gantry stage (by Holmarc), dynamometer (Go Direct by Vernier), mechanotactile haptic system [12], Laptop with intel i7 processor 32 GB RAM Windows 11 64-bit, one external monitor, noise cancellation headphones. The mechanotactile sensing system was filled with water and assembled. The fingertip sensor was fixed on the gantry platform with the help of the custom-designed 3D printed holder, as shown in Fig. 2. The use of the gantry in the experiment ensures precise control and repeatably for every trial and across the subjects. The dynamometer was attached to the moving arm of the gantry such that it could be pressed against the sensing element with a pre-calibrated force. The actuator of the mechanotactile system was placed on the forearm of the participant at various locations (discussed in the next section).The outer diameter of the actuator is 20 mm, and the membrane diameter is 12 mm, the thickness of the actuator is 8mm. From the palmer side of the fingertip sensor, the width of the sensor is around 12mm, height is around 32 mm, and the thickness of the sensor is around 20 to 25 mm. The sensor and actuator are connected via a water-filled 3mm diameter PVC pipe, which transfers the force. The three-axis-gantry stage and dynamometer are connected to the Laptop using USB. The experiment was run on a custom-developed MATLAB script (The MathWorks, Inc., Natick, MA).

C. Experiment Procedure

Experiment one was conducted to obtain the minimum perceptible forces at each position and identify the most suitable position for placing the mechanotactile actuator on the forearm. One mechanotactile actuator element is placed in nine different positions on the glabrous side of the forearm (palmar aspect). The feedback actuators were placed on the forearm by measuring the length of the forearm and dividing it into three equal portions from distal to proximal with a 2 cm margin from wrist and elbow joints.

A noise-cancellation headphones (Bose Quiet Comfort 15, Bose Corporation, USA) with brown noise sound was used to avoid any external disturbance. Additionally, an opaque curtain was used between the subject and the gantry to remove any effect of direct visual feedback.

The experiment sequence used in this experiment was as follows: the actuator was placed at one of the positions on the forearm and secured using a velcro strap. The random sequence of the six different force levels (0, 0.4, 1, 1.2, 2, 2.2) N, including sham, are presented one by one. All these forces are pre-measured by indentation of the fingertip sensors from 1 mm to 3.5 mm displacement with a difference of 0.5 mm by moving the dynamometer with the speed of 16 mm/s. The range of displacement for this experiment was restricted to

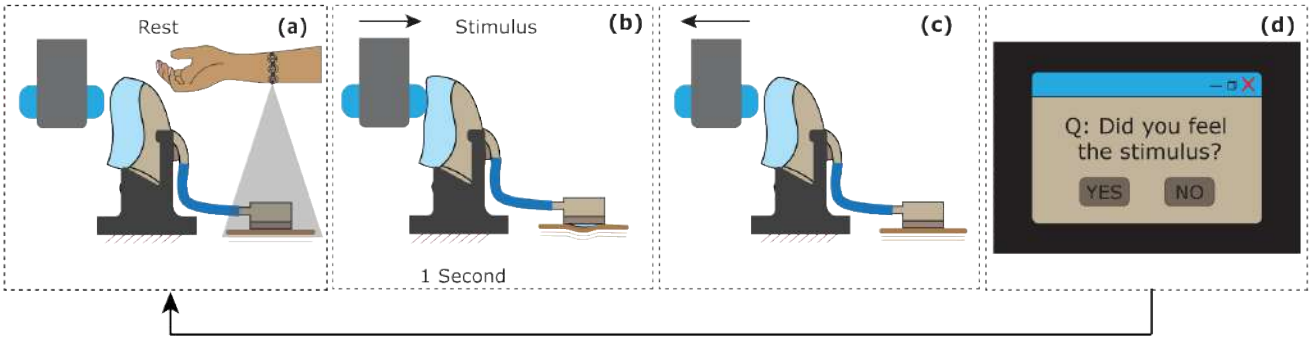

Fig. 2. Experiment sequence. (a) The dynamometer is in rest condition (no tactile feedback on the forearm). (b) The dynamometer moves and applies force on the fingertip sensor, holding it for one second. (c) The dynamometer returns to its resting condition. (d) A pop-up window appears on the screen with the question, "Did you feel the stimulus? Yes/ No".

3.5 mm to prevent the fingertip sensor from any physical damage.

As shown in Fig. 2(a), the dynamometer is on rest condition (no stimulus is applied); after 2 s, the dynamometer is translated by the gantry and exerted the pre-determined force on the actuator and was held for a period of 1 s as shown in Fig. 2(b). The gantry was then moved back to its original position to release the force stimulus, as shown in Fig. 1(c). Immediately following the release of the stimulus, the MATLAB control interface was programmed to pose the following question to the user: "Did you feel the stimulus?". The user was allowed to verbally respond - 'Yes' or 'No', as shown in Fig. 2 (d). the verbal response was recorded by the experimenter. After entering the response, the next force stimulus in the random sequence was presented, and the process was repeated till all force values had been presented. A total of ten trials were conducted at each position on the forearm.

The experiment two is the follow-up experiment of the first study. This study only includes the proximal position on the forearm. The mechanotectile actuator was placed in the best suitable position that was found in experiment one. The criteria for choosing the most suitable position on the proximal side was based on the minimum absolute force value on the forearm out of three positions from medial to lateral. In this study, another force value, 1.6 N, was introduced between 1.2 N and 2 N to improve the resolution of the psychometric curve above the 90% of the proportion of perceived stimuli. The experiment setup of this experiment is shown in Fig. 1. The noise-cancellation headphones and the opaque curtain were used the same as the previous experiment, as shown in Fig. 1. The sequence used in this experiment was as follows: the mechanotactile actuator was placed on position 8 (between medial and lateral on the proximal side) shown in the Fig. 1. The random sequence of the six different force levels (0, 0.4, 1, 1.2, 1.6, 2) N, including sham, are presented one by one. As illustrated in Fig. 2 (a), the dynamometer is on rest condition (no stimulus is applied); after 2 s, the dynamometer is translated by the gantry and exerted the pre-determined force on the actuator and was held for a period of 1 s as shown in Fig. 2(b). The gantry was then moved back to its original position to release the force stimulus, as shown in Fig. 1(c). Immediately following the release of the stimulus, the MATLAB control interface was programmed to pose the following question to the user: "Did you feel the stimulus?". The user was allowed to verbally respond - 'Yes' or 'No', as shown in Fig. 2 (d). the verbal response was recorded by the experimenter. After entering the response, the next force stimulus in the random sequence was presented, and the process was repeated till all force values had been presented. A total of ten trials were conducted on signal position.

III. Result

The recorded response data for all the positions were processed through a custom MATLAB script by taking the mean and standard deviation of all ten trials for each force level. The sigmoidal model with the logistic fit function was used to fit the psychometric curve. The psychometric curve was generated with 95% confidence interval for each position. The logistic fit function is mentioned in the Equation (1) [16].

$$y = \frac{A_1 - A_2}{1 + \left(\frac{x}{x_0}\right)^p} + A_2 \tag{1}$$

Where y is the proportion of perceived stimuli, x is the force in Newton (N) , A_1 and A_2 represent the initial and final values of the proportion of perceived stimuli, x_o is the centre or midpoint between minimum and maximum values of response, and p is the power it determines slope of the curve. The absolute force thresholds were calculated by taking the force value at 50% of the proportion of perceived stimuli. The equation for calculating absolute force thresholds is given in Eq (2) by rearranging Eq (1)

$$x = x_0 \cdot \left[\frac{A_1 - A_2}{y - A_2} - 1\right]^{1/p} \tag{2}$$

where: $y = (A_1 + A_2)/2$ for 50% of the proportion of perceived stimuli.

The absolute force distribution for all nine positions on

the forearm is shown in Fig. 3. The results show that the minimum and maximum absolute force thresholds on the forearm are 0.39 N (0.14 N, 0.43 N: 95% CI) and 1.36 N (0.99 N, 1.46 N: 95% CI) at positions 2 and 5 respectively (see Fig. 1).

However, considering our target population of individuals with amputation, distal placement of actuators may not be possible depending on the length of the residuum. At the proximal end, position 8, demonstrated the lowest absolute force perception threshold of 0.51 N (0.43 N, 0.63 N: 95% CI). Therefore, we conducted experiment 2, at position 8, by repeating the psychophysical evaluation with 5 additional participants.

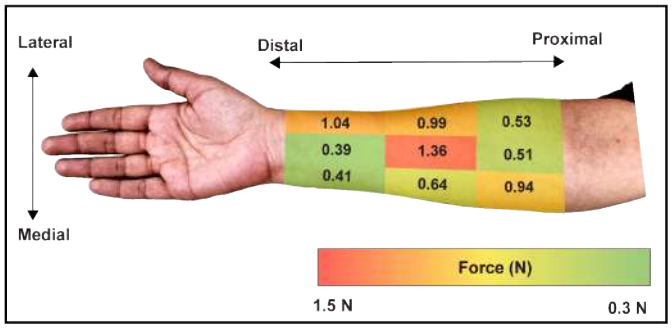

Fig. 3. Absolute force discrimination threshold obtained with the mechanotactile haptic feedback unit across the volar aspect of the forearm .

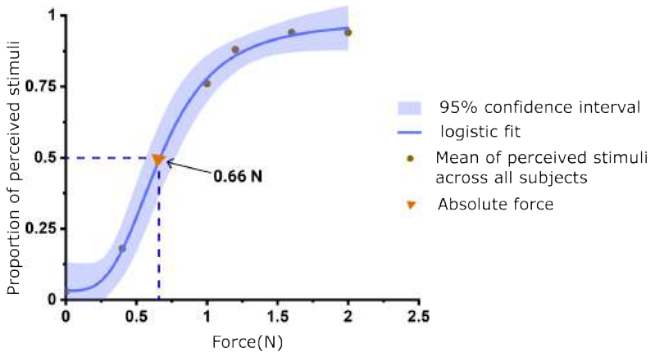

Fig. 4. Psychometric curve showing responses to the absolute force discrimination task of Experiment 2.

For Experiment 2, all five subject responses were processed through a custom MATLAB script, and the mean and standard deviation across all ten trials for each subject were calculated individually. A psychometric curve was plotted using the sigmoidal model with a logistic fit function as mentioned in Eq 1. The psychometric curve with 95% of CI for position eight is shown in Fig. 4. The absolute force threshold was calculated by taking the force at 50% of the proportion of perceived stimuli. As mentioned in the Fig. 4 the calculated absolute force threshold is 0.66 N (0.56 N, 0.77 N: 95% CI).

IV. Discussion and Future Work

In this study, we conducted two experiments. In the first experiment, a pilot study was conducted to determine the distribution of the absolute force perception threshold of the mechanotactile haptic unit for the volar aspect of the forearm. Our findings indicate that while the distal regions of the forearm exhibit perception thresholds as low as 0.39 N, the proximal portion of the forearm may be more appropriate for individuals with an upper limb amputation. In the follow-up experiment, we also investigated the minimum perceptible force values that the user could perceive at a single position with five subjects. For experiment 2, we found that at the proximal forearm, the minimum force perceptible was approximately 0.66 N.

This study has a few critical limitations. The study was conducted with a sample size of six, one for the initial and five for the follow-up experiment. Further, we used only one mechanotactile device for this study, requiring repositioning of the feedback actuator at each step possibly leading to minor errors in placement over repeated trials. In future work, more mechanotactile devices will be used to reduce the duration of the experiment. In a follow-up study, we also intend to determine the discriminability of two closely matched forces exerted through the mechanotactile units. This experiment will further shed light on the minimum achievable and perceptible force resolution with the mechanotactile haptic units.

V. Conclusion

In this paper, we performed a psychophysical evaluation to investigate the relationship between physical force and perceived force in mechanotactile haptic devices. First, we placed feedback actuators at various positions along the forearm and applied different force stimuli randomly. Based on the participants' responses, we determined the perceptible minimum force values at each position and found that the distal sensitivity was as low as 0.39 N while the perceptibility was 0.51 N at the proximal forearm.

3 University of Szeged, Department of Rehabilitation Medicine, Szeged, Hungary

***Abstract* — Mass-produced industrial and service robots have been used to build therapeutic rehabilitation robots since the 1990s. REHAROB 1.0, the dual-arm upper limb rehabilitation robot prototype, was among the pioneers. The industrial collaborative robot is a new type of robot in terms of safety, appearance, performance, and cost, thanks to which it is proving itself in more and more applications. To take advantage of these benefits, the REHAROB 3.0 Robotic Trainer for Activities of Daily Living, also updated in its name, was designed and built using two industrial collaborative robots and two uniquely developed robotic fingers. The goal of our study was to introduce an iterative design and simulation process in which digital human modeling is intertwined with digital robot modeling, leading to an upper limb rehabilitation robot system targeting outstanding performance features such as synchronous exercising of every upper limb anatomical joint and training reaching and grasping Activities of Daily Living with real objects in a real environment.**

I. Introduction

It was an epoch-making milestone in the era of robotics when an international standards body, the International Organization for Standardization defined the term "industrial robot" in the standard ISO 9283:1990 Manipulating industrial robots - Performance criteria and related test methods. The second milestone of similar significance is related to the 2016 standard defining collaborative industrial robots [1]. Due to their versatility, reliability, accuracy, and cost, ordinary and collaborative industrial robots have gained an essential presence in the construction of non-industrial robot applications.

For a long time, our goal has been to see if industrial robots can be used effectively for upper limb movement rehabilitation. The aim of the research presented in this article was to design an upper limb movement rehabilitation system built from industrial collaborative robots. The innovation lies in the design method, where the system model is subjected to iterative simulation and assessment in an integrated digital human and robot simulation software environment.

* This work was done in the confines of Project no. K_125263/125357 and 2017-2.3.7-TÉT-IN-2017-00048 supported by the National Research, Development and Innovation Fund of Hungary.

II. Review of industrial robots and Collaborative Robots Used in Medical Applications

This chapter reviews commercial and experimental industrial robot- and cobot-based medical robot systems, first in a broader spectrum and second, those that comply with the RACA [2] or the surgical robot [3] safety standards. Two pioneering medical robotic systems were developed using industrial robots in the late 20th century. The CASPAR (Computer Assisted Surgical Planning and Robotics) system used a Stäubli RX90CR industrial robot for the autonomous implantation of knee prostheses [4]. The upper limb rehabilitation robot MIME (Mirror-Image Motion Enabler) was based on a Westinghouse PUMA 560 industrial robot [5].

Currently, nine commercial and eight laboratory medical robotic systems demonstrate the use of industrial robots. The CyberKnife® System [6], is a robot-driven alternative to conventional radiotherapy, where the radiation unit is mounted on a KUKA KR 240 industrial robot. Various ROSA™ systems [7] support robot-assisted Total Knee Arthroplasty: cranial and spinal surgery. ROSA™ uses the Stäubli TX2-60 industrial robot. The actuator of the YOMI® dental robotic system [8] holds the tool, and later, the implant is a SCHUNK POWERBALL LWA 4P lightweight industrial robot arm. ARTAS iX™[9] is a robotic hair restoration system with a KUKA LBR MED medically certified cobot. The Sculptura™[10] integrated with a KUKA LBR Med cobot is a mobile platform focusing on robot-assisted intraoperative radiation therapy. The CARLO® system [11] incorporates a KUKA LBR Med cobot to perform orthopaedic surgical operations with cold ablation robot-guided laser osteotome. The TMS-Cobot [12] is a robot-assisted Transcranial Magnetic Stimulation system that integrates a UR5 cobot of Universal Robots Inc. Modus V™[13] uses a UR5 cobot to precisely move and keep in pose the digital microscope during neurosurgical operations. The iYU Pro [14] uses a KUKA LBR MED cobot to massage the neck and back by moving and pressing the massaging pad on the client's body part. EMMA[15] is a robotic massaging system developed to provide Traditional Chinese Massage assessment and professional therapeutic massage services. EMMA integrates

* The research reported in this paper and carried out at BME has been supported by the NRDI Fund (TKP2022 EGA, Grant No. BME-EGA-BIO) based on the charter of bolster issued by the NRDI Office under the auspices of the Ministry for Innovation and Technology.

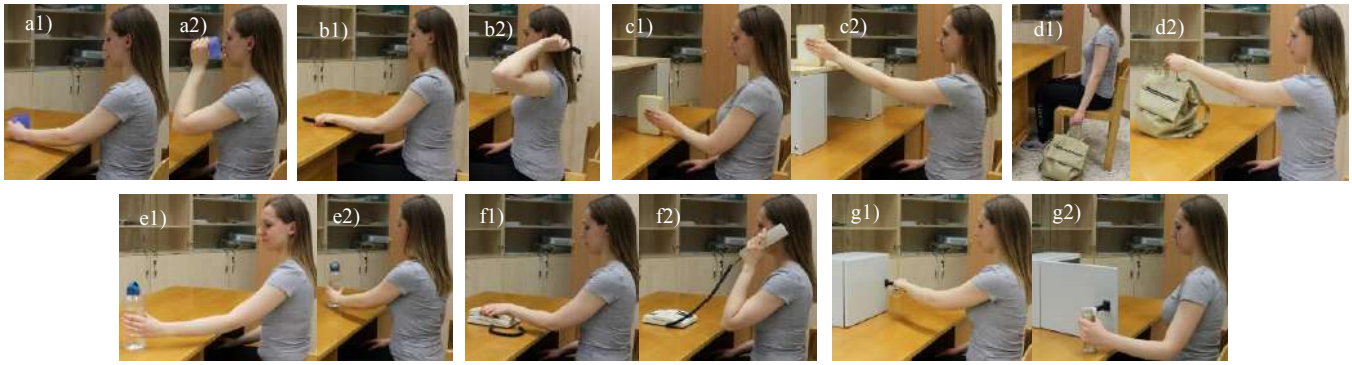

Figure 1. Seven reach-and-grasp type Activity of Daily Living exercises defined for REHAROB 3.0 (1-grasping, 2-target of motion): a) drinking from a glass, b) combing with a hairbrush, c) putting a book on the shelf, d) lifting a bag, e) moving a bottle to the side, f) picking up a phone, g) opening a door

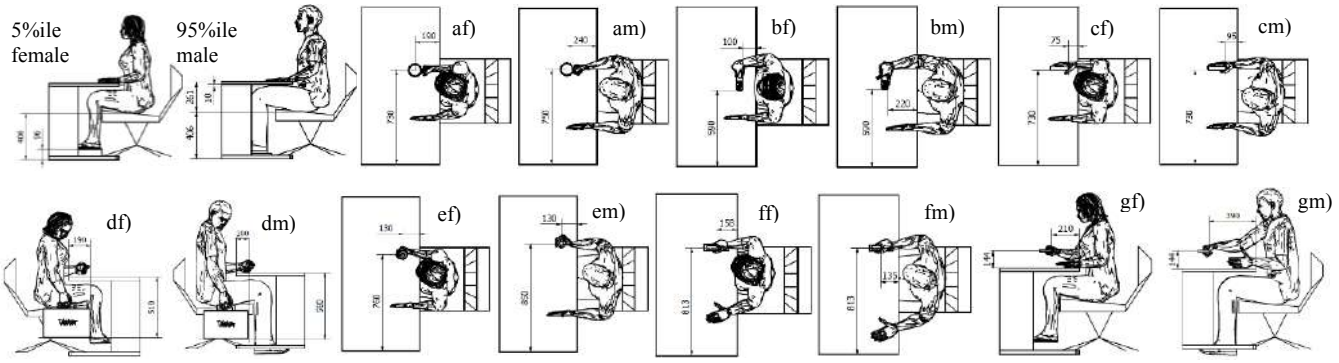

Figure 2. Reach-and-grasp type Activities of Daily Living exercises and setup modeled and simulated for 5%ile female (f) and 95%ile male (m): a) drinking from a glass, b) combing with a hairbrush, c) putting a book on the shelf, d) lifting a bag, e) moving a bottle, f) picking up a phone, g) opening a door

a UR5 cobot to precisely move and press multiple massaging rollers and pads on the client's body. The ROBERT®[16] movement rehabilitation robot assists health professionals with numerous tasks, including lower limb motion therapy. ROBERT®, in its early prototype, used the UR10 cobot, but the current version applies a KUKA LBR MED cobot. ALEX [17] is a dual-arm robotic massaging system with two UR10 cobots to deliver safe full-body massage therapy. RAINER (Universal RoboTrainer) [18] with a UR10 cobot is designed to help patients with repetitive functional movements as part of their rehabilitation process. The Cobot with Prismatic Compliant Joint Intended for Doppler Sonography [19] is a master-slave robotic diagnostic system, which integrates the 7 DoF cobot Panda of Franka Emika AG. BROCA [20] uses three UR5 cobots to assist surgeons with laparoscopy procedures. The Chinese robot dentist [21] with a UR5 cobot fits implants in the patient's mouth without any human involvement. The inRehaRob [22] uses a KUKA LBR MED cobot to guide the stroke patient's forearm in repetitive exercise scenarios. The VELYS™ Active Robotic-Assisted System [23] applies a KUKA LBR MED cobot for use in planning and instrumenting spinal fusion procedures in the cervical, thoracolumbar and sacroiliac spine. The NaoTrac [24] applies a UR5 cobot for neurosurgical navigation. The REHAROB Therapeutic System is a dual-arm robot-assisted movement therapy system that integrated IRB140 and IRB400H industrial robots of ABB in its version 1.0 [25,26] and IRB140 and IRB1600 robots in its version 2.0 [27].

III. Functional Task Definition and Digital Human Modeling

The REHAROB motion therapy process focused on the application of functional tasks with real objects already in version 2.0 [27]. To radically reduce size and weight and improve functionality, we decided to replace industrial robots with industrial cobots in the new REHAROB 3.0 Robotic Trainer for Activities of Daily Living. We have transitioned to a fully digital design and testing process, leveraging the latest developments in Digital Human Modeling (DHM) and offline robot programming (OLP) technologies. For the first time in the history of developing a movement rehabilitation system, we applied the Siemens® Tecnomatix Process Simulate software platform [28].

The set of five REHAROB 2.0 reach-and-grasp type Activitiy of Daily Living (ADL) exercises [27] has been increased to seven with movements of greater difficulty levels at the side of the body and at the head (Figure 1). Then, we designed and modeled the exercises with the extreme size 5%ile female and 95%ile male mannequins in the Process Simulate Human environment (Figure 2). Using the semi-automatic toolsets of Process Simulate: Task Simulation Builder and Human Control Panel, the ADL exercises, including grasping and manipulating of objects were modeled with validated human ergonomics (Figure 3). The ADL exercises were made uniform in terms of their anatomical joint trajectory, so that each patient moved along a standard anatomical reference trajectory, regardless of size.

Figure 3. ADL exercise design in Process Simulate Human environment

IV. Robot Selection and 3D Layout Design

A. Selection of the Industrial Collaborative Robots for Dual-Arm Upper Limb Therapy

Unlike at REHAROB 1.0 and 2.0 systems, an industrial collaborative robot arm A) with at least 6DOF, load capacity of at least 10 kg, and a reach of approximately 1400 mm to move the hand therapy module [29] and the human hand; and B) with at least 6DOF, load capacity of at least 5 kg, and reach of approximately 800 mm to move the human elbow were sought. In addition to structural requirements, eligible cobots must have built-in force/torque sensors and a controller that allows continuous streaming of the trajectory by an external device. Only Universal Robot Inc. has met the stringent requirements listed with its UR10e and UR5e cobots and the ability to stream 500 Hz externally. Like us, Cai et al. chose Universal Robot cobots, but unlike us, they used two identical UR5e industrial collaborative robots in their unilateral upper limb rehabilitation robotic system [30]. One of their UR5e cobots moves the patient's lower arm, and the other UR5e cobot moves the upper arm. Although the patient's upper limb can be connected to two UR5e robots, its anatomical Range of Motion is severely limited when using two identical robots. REHAROB, on the contrary, insists on its structural hypothesis that the size of the robotic arms used in two-arm end-effector-type rehabilitation robots should be two to three times the distance between the actuated body point and the shoulder.

B. Definition of the Tool Center Point Frame trajectories

The unsurpassed advantage of the Siemens® Tecnomatix Process Simulate software is that it integrates full-fledged Digital Human Modeling and offline robot programming toolsets in a shared environment. This allowed for simultaneous simulation of the movements of the human mannequin, the UR5e/UR10e cobots, and the robot fingers of the hand module. First, the UR5e and UR10e cobots were placed in temporary locations. To emulate the offset between the Tool Center Point Frame (TCPF) and the actuated body point, suitably sized boxes were attached to the hand and elbow (Figure 4). The digital human simulator was then started and stopped to create a green frame of the virtual box. In our case, an ADL trajectory contains approximately 200-300

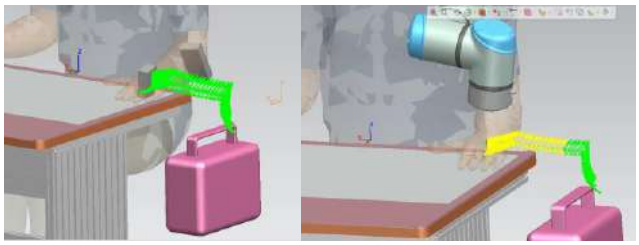

Figure 4. Trajectory generation of ADL tasks (series of green frames) and of robot TCPFs (series of yellow frames)

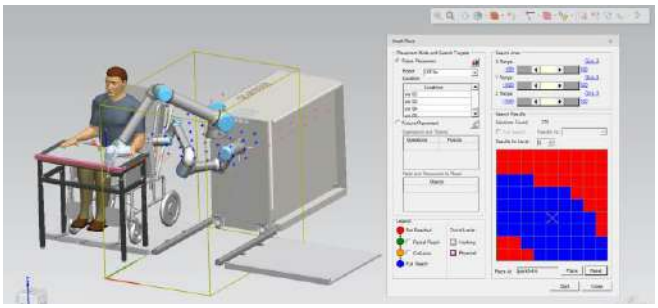

Figure 5. Use of the Smart Place function to find the suitable placement locations of the UR10e cobot at the lifting a bag ADL exercise

frames. The robot simulator also started, and the yellow TCPF of the selected cobot was aligned automatically to the last created green frame (right side of Figure 4). If the alignment failed due to workspace, collision, singularity, or configuration issues, the affected cobot had to be relocated, and the layout planning procedure restarted. The success of this procedure depends on the skills of the simulation engineer.

C. Determining the Ideal Location for the Two Cobots

The advantage of the applied digital human-robot intertwined modeling method becomes apparent when we need to locate the UR5e and UR10e cobots relative to the patient without compromising the ADL environment described in Figure 2. The challenge is that in the ideal layout, both cobots simultaneously avoid collisions, joint range, velocity, acceleration limits, and singularities, and neither cobot changes configuration. Process Simulate can help solve this challenge with Smart Place service. This tool can classify robot placement grids distributed in a box-shaped spatial domain. Figure 5 shows entirely suitable cobot placement locations in blue, collisions in orange, misorientation in green, and unusable robot placement locations with a red cursor.

We further filtered the suitable placement locations according to robot configurations. On the left panel of Figure 6, all eight possible inverse kinematics solution configurations are listed for the UR10e cobot at a given target location. The highlighted elbow-down configuration is unacceptable. The right elbow-up configuration is also available in this case (right side of Figure 7). Only those suitable placement locations where all seven ADL exercises can be performed in fixed UR5e and UR10e inverse kinematics solution configurations are acceptable.

Finally, simulation diagnostic reports were obtained from Process Simulate Robot Viewer for all remaining suitable placement locations. The software logs and visualizes information such as the joint range of motions, the joint

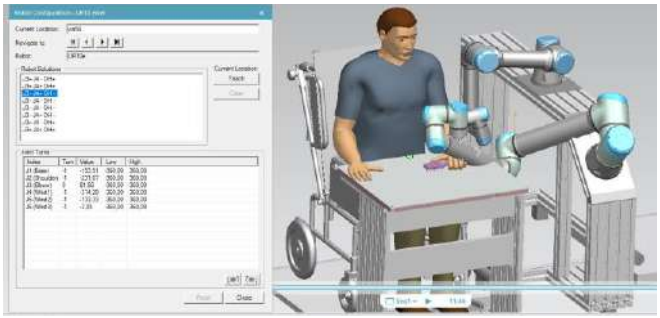

Figure 6. An unacceptable elbow-down configuration of the UR10e cobot

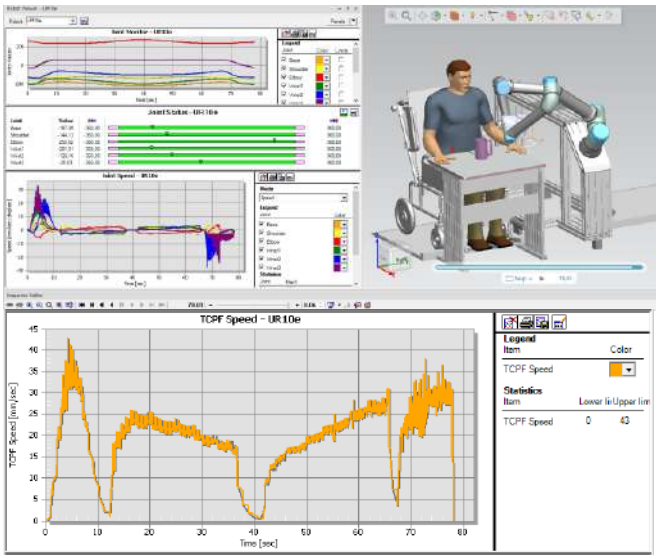

Figure 7. Robot diagnostic report about the simulation of the drinking ADL with UR5e cobot

speeds, joint accelerations, and the speed of the tool-center point. Figure 7 shows the diagnostic report of the UR10e robot about the simulation of the drinking ADL.

V. Industrial and Mechanical Design of the REHAROB 3.0 Robot System

We also started the industrial and mechanical design process in parallel with the digital human and robot modeling.

The design requirements focused on elements derived from the critical review of the REHAROB 1.0 and 2.0 systems. The dimensions and weight of the system must be reduced to such an extent that the REHAROB 3.0 rehabilitation robot can be easily moved manually from one ward to another. Two wheelchair docking platforms allow for unilateral therapies. These docking platforms should be foldable platforms that, when folded down, ensure the mechanical stability of the system during treatment and, when folded up, do not make the system unstable during manual transport. The central cabinet holds the two industrial collaborative robots, the two wheelchair docking platforms and includes all electrical and control components. Depending on the treatment side, the ADL desk connects to the left or right docking platform.

The images in Figure 8 a)-d) show some initial design concepts. Images e)-f) show the detailed design of the central cabinet and wheelchair docking platforms, which was later discarded. The final industrial design of the REHAROB 3.0 system is shown in image g). The free-body diagrams show the centers of mass in the transport (image h) and handling (image i) conditions. Mechanical stability is achieved in all use cases, but the calculations themselves are not disclosed.

The mechanical, electrical, electronic and control designs have been prepared following the RACA standard [2] and the Medical Device Regulation (MDR) of the European Union. Python, polyscope, microcontroller and PLC codes have been completed for the high-level control PC, UR robot controllers, hand module controller and SICK safety PLC.

Various concepts for a)-b)-c) left-right symmetry, d) wheelchair docking platform, e) ready for transfer, f) platforms folded down, g) ADL desk, h) static stability during transfer when the docking platforms are folded-up, i) static stability during therapy when the docking platforms are folded-down

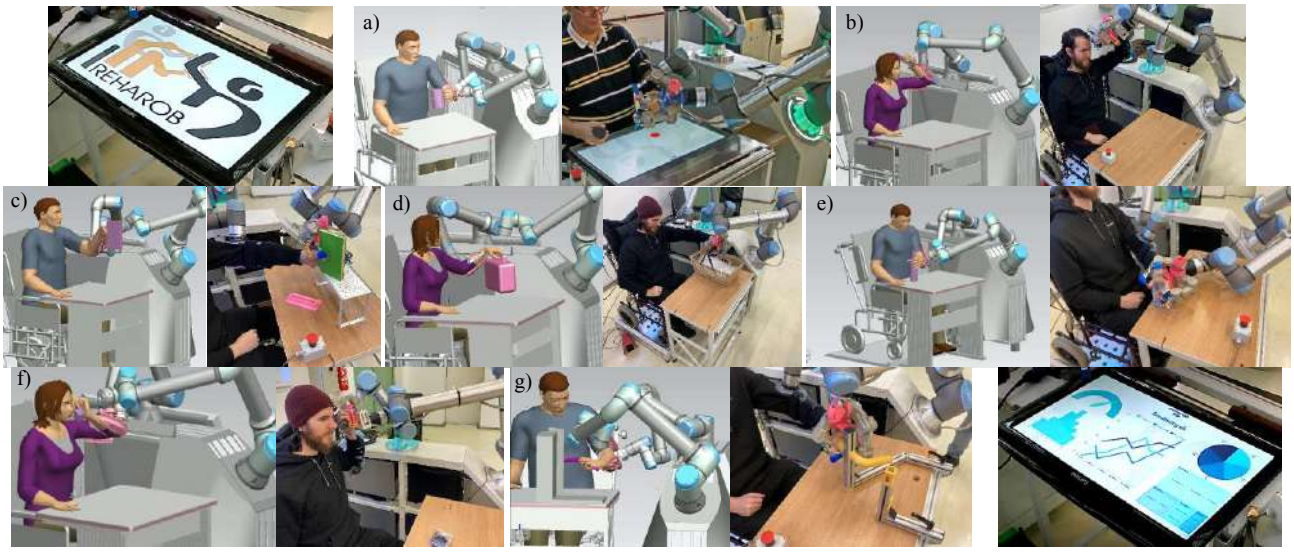

Figure 9. The REHAROB 3.0 reach-and-grasp type Activities of Daily Living exercises simulated in Process Simulate® environment for 5%ile female/95%ile male and tested with 95%ile male healthy volunteers: a) drinking from a glass, b) combing with a hairbrush, c) putting a book on the shelf, d) lifting a bag, e) moving a bottle, f) picking up a phone, g) opening a door

VI. Acceptance and Usability Testing

The development of the REHAROB 3.0 rehabilitation robot took five years from compiling the requirements list to completing the prototype. The acceptance testing of the REHAROB 3.0 prototype began with a sensorized dummy upper limb we developed for this purpose [31]. In the next step, physiotherapists tested the system by having one of them play the role of the patient and the other the physiotherapist, and then they switched roles. Finally, we tested all seven ADL exercises with a 95%ile male volunteer who had better control over the geometric operating extremes of the system than a 5%ile female (Figure 9). One suggestion was to transform the ordinary desktop board into a digital Human Machine Interface dashboard for both the patient and the physiotherapist (first and third images in the first row, last image in the third row of Figure 9). While the REHAROB 3.0 system performed excellently in all three test batteries (see also Video Appendix), with the exception of the digital dashboard, the invaluable experience gained can be utilized in future product development.

In the reach-and-grasp type movement therapy with real objects, the REHAROB 3.0 hand module, which contains two robotic fingers and moves human fingers, plays an equally important role as the two robotic arms that move the hand and elbow. Although we have previously reported on the development of the REHAROB 3.0 robotic fingers [29], the hand module with the robotic fingers, the tool changer, the finger and hand orthoses shown in Figure 9 is a brand-new achievement.

Similar to the clinical testing of the REHAROB 1.0 and 2.0 systems, we are also planning a clinical trial of the 3.0 system.

Conclusions

The presented iterative design approach, in which digital human modeling is intertwined with offline robot programming, has proven to be extremely effective in overcoming geometric and kinematic deficiencies, anthropometric scaling, layout planning and collision avoidance in an upper limb rehabilitation robotic system. The key is to use a professional simulation environment, in our case, the Siemens Tecnomatix Process Simulate®, which integrates a validated human and robot modeling toolset in the same scene. The simulation engineering skill-driven process (Figure 10) radically shifts design iterations from the physical to the digital world. As a result, the REHAROB 3.0 Robotic Trainer for Activities of Daily Living has the following technical data:

- Intended for adult patients from 5%ile female to 95%ile male (ANSUR II),
- Anatomical joints simultaneously treated in the upper limb: shoulder complex, elbow, wrist, all joints of the thumb, MCP and PIP joints of the index/middle/ring fingers, altogether 19 DOFs,
- Free exercises: 3D continuous passive,
- Active exercises: Seven reach-and-grasp ADL exercises with real objects: passive, active assisted-guided-resisted,
- Two wheelchair docking platforms at the sides of the cabinet for the left and right side treatments,

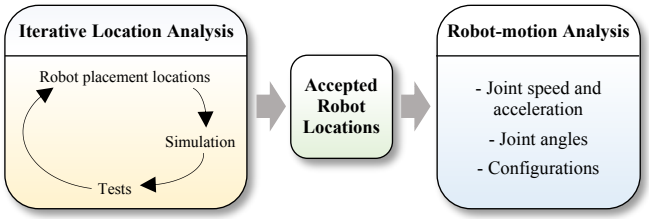

Figure 10. The process of 3D robot placement optimization

- Actuator A connected to the elbow: min 6 active DOFs, min reach 850 mm, axis 1 aligned by Y axis, base placed 830 mm (-X) from the sagittal YZ plane of the wheelchair, 754 mm (+Y) from the wheelchair seat, 405 mm (+Z) from the wheelchair backrest,

- Actuator B connected to the hand: min 6 active DOFs, min reach 1300 mm, axis 1 tilted 45 around axis X, base placed 0 mm (X), 206 mm (-Y), 644.5 mm (+Z) from the base of actuator A,
- Actuator C mounted on Actuator B and connected to the index/middle/ring fingers: min 3 active DOFs,
- Actuator D mounted on Actuator B and connected to the thumb: min 2 active DOFs and min 3 passive DOFs,
- Real objects for ADL exercises: glass, hairbrush, bag or basket, book, bottle, phone, door mockup with handle

Based on the REHAROB 1.0, 2.0 and 3.0 upper limb rehabilitation robot systems, we develop the geometric law of two-arm end-effector type rehabilitation robots, i.e. the length of each actuator must be proportional to the distance between the actuated body point and the shoulder.

UTILITY MODEL

The examination of the Utility Model application number U 25 000xx, entitled *End-effector type quad-arm robotic system for unilateral upper limb movement rehabilitation*, submitted on 21 February 2025 to the Hungarian Intellectual Property Office, is in progress.

ACKNOWLEDGMENT

A. Tóth, T. Pilissy, and M. O. Bauer thank Nándor Bánvölgyi for his contribution to ADL object and exercise design, and László Péter Sándor for his contribution to concepting and industrial design of the frame structure. G. Fazekas thanks Zsófia Markó for her contribution to ADL definition and presentation.

FES-induced and voluntary-induced fatigue in a rehabilitation-like task

Lucille Cazenave[1, 2], Nuria Peña-Pérez[3], Aaron Yurkewich[4], and Etienne Burdet[1]

Abstract— **In the context of FES-based rehabilitation and assistance tasks, there is a growing interest in managing the induced fatigue, which is an obvious limiting factor in training duration. However, it is unclear whether and how fatigue may develop in tasks commonly used in stroke rehabilitation. This work explored the effect of FES- or volition- induced movements on EMG-based effort and M-wave metrics that characterise fatigue, during a continuous wrist target-tracking task completed by 22 unimpaired participants. We found no significant changes in the mechanical and electrical responses of the muscles during the Volition-only, FES-only, and Volition-FES conditions, suggesting that during this task, FES did not induce muscular fatigue, while both mental and physical demands were reported as low. Our results thus suggest that it may not be necessary to consider FES-induced fatigue during such continuous FES-assisted tasks, that can be used in post-stroke motor rehabilitation training.**

I. Introduction

Functional electrical stimulation (FES) training often leads to rapid muscle fatigue due to the constant motor unit recruitment, unlike the naturally varying recruitment pattern seen in voluntary movements [1]–[5]. This fatigue is evident in tasks like the Cybathlon cycling race [6], where pilots with spinal cord injuries experience a decline in pedal power over time. Physical rehabilitation after stroke commonly uses FES and might thus be affected by muscle fatigue, however it is usually applied as an assistive device, in conjunction with voluntary movement, and involves frequent breaks [7]. To explore how fatigue develops during such activities, we investigated the effects of FES-induced and voluntary motion in a simple target-tracking task designed to simulate motor rehabilitation training [8], [9].

Various metrics have been employed to characterise muscle fatigue during specific volitional or FES-induced contractions. Traditionally, EMG-based effort and fatigue metrics include time-domain measures such as EMG envelope amplitude, reciprocal activation, and cocontraction. In the frequency domain, metrics such as mean and median frequency are commonly used to assess muscle fatigue [10], [11]. On the other hand, the muscle's response to electrical stimulation can be used to estimate muscle fatigue. This so-called M-wave represents the total electrical activity of all motor units depolarized within the stimulation electrodes' range [12], where its amplitude, duration, and area can be used as fatigue measures [12]–[15]. However, the literature presents discrepancies regarding which M-wave parameters best quantify muscle fatigue, as the underlying mechanisms are not fully understood. Some studies report a decrease in M-wave peak-to-peak amplitude with fatigue [13], [14], [16], and the extent of this change may be influenced by stimulation parameters and muscle type [15], [17]. Conversely, other research highlights an increase in M-wave duration (or a decrease in frequency) or area with fatigue [13], [18]–[20].

In light of these inconsistent findings, some researchers have focused on the biphasic characteristic of the M-wave, extracting parameters from each of the two phases separately. It is believed that these phases are differently affected by the physiological processes of fatigue [12], [19], [21], [22]. Studies suggest that the second phase of the M-wave may be influenced by changes in muscle architecture, such as shortening muscle length or relative positional changes between the muscle and recording electrodes, making it less suitable for fatigue analysis [12], [21]. However, recent findings indicate that the first phase of the M-wave may remain unaffected by such structural changes and may reflect more accurately fatigue-related mechanisms [22]. Thus, separate analysis of the two M-wave phases is recommended [12].

However, most studies using fatiguing protocols have focused on isometric contractions induced by voluntary or FES input [12]. These are not typically used in a stroke rehabilitation scenario where continuous movements, through the patient's range of motion, are often preferred. To investigate how fatigue develops in such a task, we investigated these EMG-based effort and M-wave metrics during FES and/or volitionally induced muscle contractions, both in an isometric and dynamic (target-tracking) scenario. We recorded kinematic data to assess tracking performance, EMG data to extract effort and fatigue metrics, and NASA-TLX questionnaire responses, with a focus on mental and physical demand. We hypothesised that muscle fatigue would be more prominent in the presence of FES compared to the volition-only condition.

II. Methods

A. Experimental design

Twenty-two unimpaired individuals (11 female, 3 left-handed), aged 21-30 years old, participated in this experiment, approved by the Research Ethics Committee of Imperial College London (approval number: 21IC6935). Participants completed three block conditions of 25 trials of target-tracking task (Fig. 1 B). In each 30 s-trial they tracked a target moving pseudo-randomly along the horizontal axis with their right wrist flexion/exte?ZXx'nsion motions [23]. The

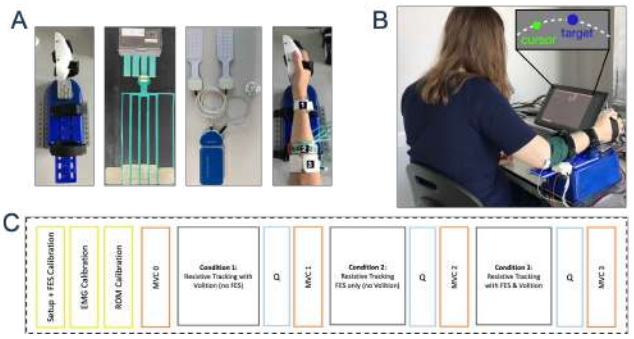

Fig. 1: Experiment description. **A.** Wrist robot-FES interface (left to right): HRX-1 wrist robotic device; FES device with 16-electrode array; EMG recording device with ground electrode and two high-density 32-channel electrode arrays; Device set-up, where the FES anode electrode (1), was placed on the dorsal side of the wrist near the ulnar head and the cathode electrodes array (2), were around the arm inline with the wrist flexor and extensor muscle belly with the EMG electrodes placed distally (3). **B.** Unimpaired individuals track a randomly moving target on-screen with wrist flexion/extension. **C.** Experimental protocol for the study on fatigue with unimpaired participants. The three conditions were presented in random order for each participant and consisted of 25 trials of a 30-second wrist target-tracking task. MVC refers to three repetitions of maximum voluntary wrist flexion and extension, followed by three repetitions of maximum flexor and extensor stimulation while participants were instructed to relax.

conditions, presented in a random order, required participants to: (i) track the target as accurately as possible, (ii) remain relaxed while FES was applied to their wrist flexor/extensor muscles to track the target, and (iii) track the target as accurately as possible while they received the same FES assistance as in (ii). The randomisation was designed to ensure that all six possible sequences of experimental conditions were presented, with each sequence carried out by at least three participants to maintain balanced exposure across conditions. The general difficulty of the task was increased by adding damping to the robot ($D = 0.0068\,Nm\,s/^\circ$).

The FES assistance was implemented with stimulation intensity proportional to the difference between the target position and the participant's wrist position $e(t)$. Prior to carrying out these experimental conditions, an FES calibration was conducted to determine the optimal location for the stimulation electrodes and the maximum comfortable amplitude for the flexor (s_f^{max}) and extensor (s_e^{max}) muscle stimulation, and the sensory thresholds s_f^{min} and s_e^{min}, which altogether provided the stimulation range to use throughout the experiment. This was followed by a range of motion (ROM) calibration, used to determine the amplitude range of the target, set to 85% of the participants' ROM.

The amplitudes of the stimulation provided to the wrist flexor $s_f(t)$ and extensor $s_e(t)$ muscles were computed as:

$$\begin{cases} s_e(t) = -\kappa\, e(t) \;+\; s_e^{min} & e(t) < 0 \\ s_f(t) = \kappa\, e(t) \;+\; s_f^{min} & e(t) \geq 0 \end{cases} \tag{1}$$

Here, κ is the FES control stiffness (in mA/°) for the flexor and extensor stimulation and (after calibration) is equivalent to a robot control stiffness $K = 0.0097\,Nm/^\circ$ [24].

After completion of each condition, participants filled the NASA-TLX questionnaire and performed a maximum voluntary contraction (MVC) exercise, where they were asked to flex and extend their wrist for 3.5 s as forcefully as possible three times on each side. Following this, they were instructed to relax while the maximum calibrated FES was applied for 3.5 s to their wrist flexor (s_f^{max}), followed by their wrist extensor (s_e^{max}), three times as well. For this step, the same calibrated FES intensity was used throughout the experiment.

B. FES and robotic device

The electrical stimulation device used was a 16-electrode array (Tecnalia Research & Innovation, Spain), where the anode was placed on the dorsal side of the wrist near the ulnar head and the cathode on the wrist flexor and extensor muscle belly to ensure comfortable and effective muscle contraction (Fig. 1 A). The frequency of the stimulation was set to 35 Hz, the pulse width to 300 μs and the amplitude of the stimulation varied during the experiment (with 1 mA resolution) (see Eq. 1). The robotic interface used was the HRX-1 one degree-of-freedom wrist robotic interface (HumanRobotiX, UK), which is actuated by a brushless low-friction motor and contains an embedded optical encoder (0.01 ° resolution) recorded the wrist angle (Fig. 1 A). Muscle activity was recorded using two 32-channel EMG electrode arrays (GR10MM0804, OT Bioelettronica, Italy) with a Sessantaquattro amplifier (OT Bioelettronica, Italy).

C. Data analysis

To analyse whether the target-tracking task induced fatigue, either with or without FES, we focused on five key aspects: i) the perceived mental and physical demand, ii) changes in EMG envelope amplitude during MVC, iii) changes in FES-induced torque and M-wave characteristics during continuous maximum stimulation, iv) tracking error, and v) cocontraction, and reciprocal activation of the flexor and extensor muscles during the condition trials. For evaluating metrics within each condition block, the first three trials used for familiarisation were excluded from the analysis, hence the remaining 22 trials were considered.

EMG pre-processing: EMG was recorded from the participants' wrist flexor and extensor muscles at a frequency of 2000 Hz. Mains noise was attenuated using a notch filter (Matlab function *iirnotch* with a notch at 50 Hz). A band-pass second order Butterworth filters (cut-off frequencies of 10 Hz and 500 Hz) were applied in the forward and reverse directions, so without inducing delay. An adaptive filter designed for EMG-based torque estimation under stimulation of wrist flexor and extensor with the same setup as here [25] was used to filter out the FES artifact and M-wave contribution for the in-trial EMG. The EMG signal was then rectified, and the envelope was obtained using a low-pass second-order Butterworth filter with a cut-off frequency of 5 Hz. The amplitude of the EMG envelope was normalised by the mean EMG envelope during the first MVC in flexion/extension (MVC0 condition in Fig. 1 C), so muscle activity is reported as a ratio of this maximum MVC amplitude. For subsequent analyses, the channel on the extensor and flexor arrays with the highest envelope amplitude during the EMG calibration

was selected. EMG metrics are reported for N = 21, as the EMG data for one participant were corrupted.

Metrics computation: Perceived effort was assessed based on the mental and physical demand items from the TLX-NASA questionnaire. To evaluate a potential decrease in MVC, we calculated the difference in muscle activity during the MVC performed before and after each condition. The average EMG value over the peak 1 s window of the 3.5 s MVC was used to characterize the MVC and the normalization value [26]–[28].

Similarly, to assess changes in FES-induced torque and M-wave characteristics, we computed the difference in mean torque and M-wave metrics during 3 s of continuous stimulation performed before and after each condition. The first 0.5 s of stimulation were excluded from the analysis to account for the delay between stimulation onset and muscle contraction. For M-wave analysis, the 3 s EMG signal was divided into pulse windows, each containing a stimulus artifact that marked the start of the window, followed by the corresponding M-wave. Within each window, we extracted the amplitude, area, and duration of each M-wave phase, averaging these metrics across the 3 s stimulation period for each M-wave phase separately [22]. Since this task is dynamic and can thus induce changes in muscle length and in the relative position of the recording and stimulating electrodes, the two M-wave phases were analysed separately (as previous work found that the first M-wave phase may be less affected by these structural changes [22]). We also analysed these metrics for the full M-wave by summing the parameters extracted from each phase to obtain the overall M-wave amplitude, duration, and area, as these are also commonly used to assess muscular fatigue [12]–[15].

We evaluated effort within trials using the cocontraction and the reciprocal activation of the wrist flexor and extensor normalised EMG envelope as described above, where co-contraction was defined as the minimum envelope amplitude between the flexor and extensor and the reciprocal activation as their difference. The tracking performance in each trial was evaluated using the Root Mean Square Error (RMSE) between the participant's and target trajectories.

Statistics: To compare perceived mental and physical demands, MVC levels, FES-induced torque, M-wave parameters, performance metrics, and EMG-based metrics during conditions, we used a one-way repeated measures ANOVA, or a non-parametric Friedman test when data were not normally distributed. Normality was assessed using the Shapiro-Wilk test. For pairwise comparisons of these metrics between conditions, we used paired sample t-tests or paired Wilcoxon signed-rank tests, controlling for the family-wise error rate using the Bonferroni-Holm correction. To determine whether differences in MVC torque, FES-induced torque, and M-wave parameters before and after each condition differed from a distribution with a mean of zero, we applied one-sample t-tests or Wilcoxon signed-rank tests for each condition individually. Moreover, for these differences, we performed this statistical analysis on the metrics distributions based on the chronological order in which the conditions were presented, regardless of their types, to identify any temporal changes in the metrics. We also conducted the same analysis after categorising the data by condition labels (FES, Volition, Volition-FES) to investigate differences associated with the specific condition types.

To explore whether tracking performance and EMG changed over time, we (i) explored trends within conditions using a linear mixed-effects model (LME) with restricted maximum likelihood, with the trial number as a fixed effect (slope) and a random intercept for each participant; and (ii) examined differences between the first and last three trials of each condition (excluding familiarisation trials), both across and within conditions. We used a one-way ANOVA or Friedman test and corresponding post-hoc tests to compare across conditions, and we used a one-sample t-test or Wilcoxon signed-rank test to compare the distribution of the metric within one condition, to one with a zero mean.

III. Results

A. Perceived mental and physical demand

We observed a significant effect of the condition on the NASA-TLX responses for the questions: "How physically demanding was this task?" ($\chi^2(2)$ = 26.66, $p < 0.001$) and "How mentally demanding was this task?" ($\chi^2(2)$ = 30.34, $p < 0.001$), where the mean for the Volition and Volition-FES conditions is below 6/10, and for the FES condition below 3/10, for both items. When participants were asked to relax while FES was applied, the task was perceived as the least demanding. In contrast, no differences were observed between the Volition and Volition-FES conditions in physical ($p = 0.73$) or mental demand ratings ($p = 0.45$).

B. MVC differences

Changes in MVC during the condition (a negative difference indicates a decrease in MVC) are reported in Fig. 2. No significant differences in MVC change across conditions were observed (MVC EMG flexor: $\chi^2(2)$ = 1.52, $p = 0.467$; MVC EMG extensor: $\chi^2(2)$ = 0.10, $p = 0.954$). Additionally, none of the conditions induced a significant change in MVC compared to zero (all $p > 0.1924$). We also investigated the chronological evolution of the MVC throughout the experiment by computing the difference between the current MVC and the previous one, independently of the condition order, and found a significant effect of the condition for the flexor MVC ($\chi^2(2)$ = 9.09, $p = 0.0106$), but no significant pairwise comparisons between conditions (all $p > 0.276$). There was no effect of the condition on the extensor MVC ($\chi^2(2)$ = 0.09, $p = 0.956$).

C. FES-induced torque differences

Similarly, we explored changes in the torque generated under maximum comfortable stimulation intensity (calibrated at the start of the experiment) while participants were at rest, across conditions. Fig. 2 shows the difference between FES-induced torque before and after each condition to assess potential decreases in this induced torque (where a negative difference indicates a decrease). No significant differences

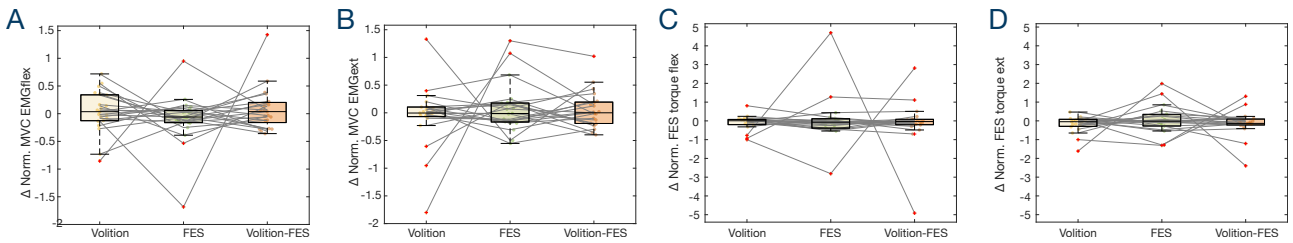

Fig. 2: Difference in mean normalised EMG during MVC trials for the flexor MVC (A) and extensor MVC (B), and in mean normalised FES-induced torque for the flexor stimulation (C) and extensor stimulation (D), for each condition. A negative difference indicates a decrease in MVC or FES-induced torque after the condition compared to before the condition.

in FES-induced torque changes across conditions were observed (FES torque flexor: $\chi^2(2)$ = 4.11, $p = 0.1284$; FES torque extensor: $\chi^2(2)$ = 0.42, $p = 0.8102$). Additionally, there were no significant changes (different from zero) in FES-induced torque within any condition (all $p > 0.1842$). When investigating chronological evolution of this metric, where conditions are considered in the order they were presented to the participants, we did not find an effect of the condition either (FES torque flexor: $\chi^2(2)$ = 3.26, $p = 0.1956$; FES torque extensor: $\chi^2(2)$ = 0.74, $p = 0.6918$).

D. M-wave parameters differences

Additionally, we evaluated the changes of various parameters characterising the M-wave recorded during maximum comfortable stimulation intensity while participants were at rest. We explored differences between the current M-wave peak-to-peak amplitude, duration and area, before and after each condition to assess potential changes in these metrics. There was no significant effect of the condition type on these metrics (MW amplitude flexor: $\chi^2(2)$ = 0.4, $p = 0.8187$; MW amplitude extensor: $\chi^2(2)$ = 0.11, $p = 0.9487$; MW duration flexor: $\chi^2(2)$ = 0.7, $p = 0.7047$; MW duration extensor: $\chi^2(2)$ = 5.05, $p = 0.08$; MW area flexor: $\chi^2(2)$ = 0.7, $p = 0.7047$; MW area extensor: $\chi^2(2)$ = 2.63, $p = 0.2683$). We also examined changes in parameters for each phase of the M-wave separately but found no significant effect of the condition (all $p > 0.0648$). When assessing whether changes within each condition differed from zero, no significant results were found for any full M-wave parameters across conditions (all $p > 0.062$). However, in the Volition-FES condition, significant changes were observed in the MW2 amplitude ($p = 0.0442$) and MW2 area ($p = 0.0329$) during extensor stimulation. Similarly when considering the data chronologically, regardless of the condition type, no effect of the condition was observed (MW amplitude flexor: $\chi^2(2)$ = 0.3, $p = 0.8607$; MW amplitude extensor: $\chi^2(2)$ = 2.63, $p = 0.2683$; MW duration flexor: $F(2)$ = 1.94, $p = 0.1536$; MW duration extensor: $\chi^2(2)$ = 0.95, $p = 0.6227$; MW area flexor: $\chi^2(2)$ = 1.3, $p = 0.5220$; MW area extensor: $F(2)$ = 0.15, $p = 0.8648$).

E. Changes in performance metrics across conditions

Fig. 3 A shows the changes in RMSE across trials for each condition. In the Volition and FES conditions, we observed a significant effect of trial number on RMSE, with a positive slope indicating a slight decrease in tracking performance (Volition: slope = 0.0275, $t(461) = 2.282$, $p = 0.023$; FES: slope = 0.0278, $t(461) = 5.171$, $p < 0.001$). In contrast, the Volition-FES condition showed no significant slope (slope = 0.0027, $t(461) = 0.245$, $p = 0.806$). When investigating the difference in RMSE between the last three trials and the first three trials for each condition, we found no significant effect of condition ($\chi^2(2)$ = 0.27, $p = 0.87$). We also considered each condition individually and evaluated whether the change in RMSE across each condition is significantly different from zero. There, we found that RMSE change during the FES condition is significantly different from zero ($p = 0.0112$), with a positive median, indicating a decrease in tracking performance throughout the condition.

F. Changes in effort across conditions

We examined how the mean cocontraction (CC) and reciprocal activation (RA) of the wrist flexor and extensor varied over trials in each condition, to measure voluntary effort (Fig. 3 B, C). For the CC, we observed a significant negative effect of the trial number on the FES (slope = -0.0004, $t(437) = -2.125$, $p = 0.0341$) and Volition-FES (slope = -0.0016, $t(437) = -4.344$, $p < 0.001$) conditions, suggesting adaptation and learning. However, the slope was not significant in the Volition condition (slope = -0.0003, $t(440) = -0.991$, $p = 0.322$). For RA, a significant positive slope was observed in the Volition-FES condition (slope = 0.0004, $t(437) = 2.811$, $p < 0.0052$), while non-significant effects were found in the other two conditions (Volition: slope = -0.0005, $t(440) = -1.491$, $p = 0.137$; FES: slope = 0.0002, $t(437) = 1.931$, $p = 0.0541$). Additionally, in the (relaxed) FES condition, the median of the normalised RA and CC was lower compared to the other two conditions, where participants actively followed the target (Fig. 3 B, C). We also investigated whether changes in mean CC and RA, over trials differed across conditions by computing the difference between the last three and first three trials and did not find a significant effect of condition type (CC: $\chi^2(2)$ = 2.67, $p = 0.264$; RA: $\chi^2(2)$ = 0.38, $p = 0.827$).

IV. Discussion

The aim of this study was to determine whether FES-assisted tasks, similar to those used in rehabilitation, induce muscular fatigue, and how this should inform the design of FES-based motor rehabilitation systems. We explored the effects of FES-induced and voluntary motion on perceived and muscular fatigue, performance, and effort during a continuous target-tracking task.

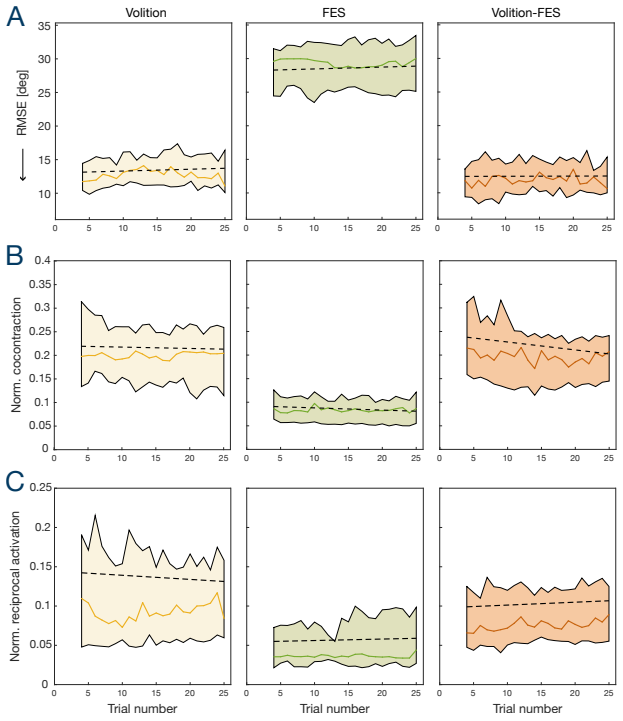

Fig. 3: Evolution of performance metrics across trials for each condition: RMSE between the participant's and target positions (A), cocontraction of the wrist flexor and extensor (B), reciprocal activation of the wrist flexor and extensor (C). The lines represent the median of each metric computed over all participants and the shaded areas represents the data from the first to third quartile of the metric. The first three trials are excluded as they were used as familiarisation trials.

A. Subjective, mechanical and electrical responses after condition

We did not observe significant changes in mechanical responses following each training block involving FES-induced and/or voluntary wrist motion aimed at tracking a continuously moving target, as was indicated by consistent MVC torque output across all conditions (Fig. 2 A, B). Similarly, no significant changes were detected in the electrical response, as assessed by the M-wave response to maximum stimulation and the constant FES-induced torque across conditions (Fig. 2 C, D). Since fatigue is typically characterised by a reduction in maximal power or force output [29], the absence of changes in MVC before and after each condition suggests that fatigue did not develop over time in this study. The M-wave parameters measured under maximum comfortable stimulation after each condition also remained stable, indicating that the muscle's electrical response was unaffected by the tracking task conditions. Even when separating the M-wave phases to compute these parameters—which has been found to be more suitable for fatigue estimation during tasks involving changes in muscle architecture—we did not find any changes across conditions [12], [21]. These findings contradict our initial hypothesis that the Volition-FES condition would result in greater fatigue compared to the Volition condition.

Indeed, previous research has shown that fatigue tends to be greater in conditions involving electrical stimulation, potentially due to the unnatural recruitment patterns and the early recruitment of fast and fatigable muscle fibres under FES [3]. However, despite the task being designed to simulate an FES-assisted rehabilitation scenario, and involving continuous stimulation for 25 trials of 30 seconds each, it did not induce noticeable muscular fatigue. This may be attributed to the task not being sufficiently challenging or tiring for participants. The mean questionnaire ratings indeed suggest that the task was not physically demanding, with ratings consistently lower than or equal to 6/10 across conditions. Literature on fatiguing protocols typically involves more intense conditions, such as 1-5 minutes of MVC or 1-3 minutes of tetanic stimulations [12]. This may also be related to the electrode configuration used for stimulation in this experiment, which may not have been optimal for extracting parameters from the M-wave, as a monopolar (belly-tendon) configuration is typically recommended. In this study, we used the FES electrode placement recommended by our clinical collaborators and employed in our clinical studies [23]. This choice may have made the recordings more susceptible to crosstalk and positional shifts, particularly since the wrist flexor and extensor muscles of interest are relatively small [12]. On the other hand, the aim of this study was to explore whether FES-assisted motor training, relevant for post-stroke rehabilitation, induces fatigue, and while muscle fatigue might manifest differently in stroke patients, it was not observed in the unimpaired participants in this scenario. The mechanical and electrical response of stroke patients' muscles following FES-based rehabilitation exercise should be further investigated to confirm whether these findings translate to the target clinical population.

B. Performance and effort across conditions

We also investigated the evolution of metrics potentially associated with muscle fatigue over time, including tracking performance, cocontraction, and reciprocal activation (Fig. 3). Tracking performance decreased over trials in both the Volition and FES conditions (Fig. 3 A). This was also confirmed by the increase in tracking error between the first three and last three trials in the FES condition. This suggests that, over time, the stimulation became less effective at contracting the muscles to follow the target trajectory, consistent with previous studies on FES during continuous tasks [30]. It is also possible that the decrease in tracking performance is related to variations in the electromechanical delay between stimulation and motion onset [31], resulting in a delayed motion response relative to the target. This decrease in performance may thus be in part due to fatigue and could be used as a marker of fatigue in a closed-loop control system.

In contrast, the EMG metrics did not show significant performance degradation. A decrease in cocontraction over trials was found in the Volition-FES and FES conditions, together with an increase in reciprocal activation in the Volition-FES condition (Fig. 3). This decrease in cocontraction suggests learning and adaptation, where participants reduce their muscle activation over time and learn to interact

with FES assistance [32], [33]. The increased reciprocal activation could suggest that muscle usage became more efficient and movement directionality more pronounced. On the other hand, although no significant decrease in performance and MVC was observed in the Volition-FES condition, the slight increase in reciprocal activation could constitute an early sign of muscle fatigue or a fatigue management mechanism [34].

When further examining the effect of condition on changes in tracking performance and effort from the first to the last trials, we found no significant differences across conditions. This suggests that no single condition led to greater performance reduction or effort alteration compared to others. This outcome was unexpected given the differing physiological processes underlying voluntary and FES-induced muscle contractions [3]. Despite observing higher tracking error and lower muscle activity in the relaxed FES condition, no significant difference in performance or effort changes was found across conditions. This discrepancy may be due to the experimental task design, which did not involve long-duration MVCs or tetanic stimulations as seen in studies reporting fatigue [3], [12]. Overall, these results suggest that continuous FES-assisted tasks, which could be used in post-stroke motor rehabilitation, may be suitable and may not induce significant muscular fatigue.

V. Conclusion

We investigated the impact of FES-induced and/or voluntary movement during a continuous target-tracking task on perceived fatigue, performance, effort, and muscular fatigue in unimpaired participants. Our findings revealed no significant changes in the mechanical and electrical responses of the muscles across any of the three conditions, suggesting that the task did not induce muscular fatigue, although we observed a larger decline in tracking performance in the FES condition, which may indicate that the movement resulting from stimulation could be altered over time without necessarily leading to fatigue. Together, these findings suggest that for this type of continuous FES-assisted task, that can be used in post-stroke rehabilitation, FES-induced fatigue may not be a major factor to be considered.

Towards Unsupervised Incremental and Proportional Myocontrol based on Higher-Density Surface Electromyography

Alisa Schulz[1], Fabio Egle[1], Marius Osswald[2], Alessandro Del Vecchio[2] and Claudio Castellini[1,3]

***Abstract*— Upper limb differences present tremendous challenges for autonomy in daily living, and current prostheses often face high abandonment rates due to complexity and lack of functionality. This study investigates fully unsupervised incremental myocontrol using higher-density surface EMG. Utilizing incremental sparse non-negative matrix factorization (ISNMF), we employed two 32-channel sEMG bracelets to incrementally extract muscle synergies from EMG signals in real-time. Eight able-bodied participants underwent this unsupervised training paradigm with an increasing number of target synergies and were evaluated with a virtual target achievement control (TAC) test. Participants demonstrated up to six independently controllable synergies in full-intensity tasks, exceeding the current state of the art. However, proportional control remained challenging, reflected in a median success rate of 10% for half-intensity targets. Subjective feedback across the number of synergies showed only small variations in cognitive and physical workload despite increased complexity. This approach shows promise for enabling fully unsupervised myocontrol, but further refinement of training protocol and hyperparameters, as well as testing on users with limb differences, are necessary to validate and improve this approach.**

I. INTRODUCTION

Congenital anomalies of the upper limb affect approximately one in 500 births [1]. Italy and the UK report 3500 and 5200 upper limb amputations per year, respectively [2]. Furthermore, due to an aging population and increasing prevalence of diabetes and cardiovascular disease, the number of people with upper limb amputation in the US is expected to double by 2050 [3]. Individuals with limb difference (LD) face challenges in autonomy and daily functioning as well as a heightened risk to their psychological well-being, including anxiety and depression [4].

Despite the considerable advances in the field of upper limb prosthesis (ULP) in the last decades, prosthesis abandonment is still very high [5]. The reasons for this include comfort, lack of functionality, and complex control systems [6]. Methods based on pattern recognition (PR) have been developed in the last decades to approach the latter two reasons [7], [8]. One of the main issues with the developed prosthesis control methods is the non-stationarity of surface electromyography (sEMG) signals due to sweat, muscle fatigue, sensor shift, and user adaptation [9]. To overcome this problem and to foster the co-adaptation process between the user and system, incremental learning approaches providing regression or classification have been developed and tested in recent years [10]–[12]. While these methods empower the user to voluntarily update their model, they are still limited by the requirement for the user to provide accurate labels. These labels can be provided either by a contralateral data acquisition [13], by following a visual reference [14], or by training on a steady-state, e.g., a certain percentage of the maximum contraction. Providing these labels can be especially challenging for people with LD, as this requires dedicated pre-prosthetic user training and data acquisition protocols [15]. Unsupervised myocontrol (UM) allows continuous adaptation without labels, thus potentially solving this problem. Furthermore, instead of only using small portions of labeled data, it allows a stream of (interaction) data to update the model continuously.

In 2009, Jiang et al. [16] applied the non-negative matrix factorization (NMF) as a myocontrol algorithm to achieve both proportional and simultaneous control of multiple degrees of freedom (DOFs). Building on this, Lin et al. proposed a NMF algorithm with additional sparsity constraints for the control signal, thereby simplifying the training and even allowing arbitrary movements during the training phase [17]. Yeung et al. [18] designed an incremental NMF that can adapt to changes and counteract performance degradation. Gigli et al. [19] developed this approach further by adding an arbitrary motor mapping, which eliminates the necessity for labeled data. Finally, [20] adapted the method to add muscle synergies progressively during the training process.

This work investigates the feasibility and potential of combining incremental unsupervised learning with higher-density sEMG as previously used in such unsupervised myocontrol paradigms. For this, we implemented the incremental sparse NMF (ISNMF) approach described by Gigli et al. [19] in combination with two 32-channel sEMG dry electrode bracelets. Although sEMG setups with higher number of electrodes, in many cases high-density (interelectrode distance <= 10 mm) electrode grids have previously been used for real-time myocontrol in experimental conditions [14], [21]–[23], most of these works rely either on supervised approaches, the use of computationally demanding neural networks, adhesive electrode grids applied to the skin with conductive paste limiting their usefulness in real-world settings, or a combination of the above.

*This work was partially supported by the European Commission's Horizon Europe Framework Program with the project IntelliMan (AI-Powered Manipulation System for Advanced Robotic Service, Manufacturing and Prosthetics) under Grant Agreement 101070136.

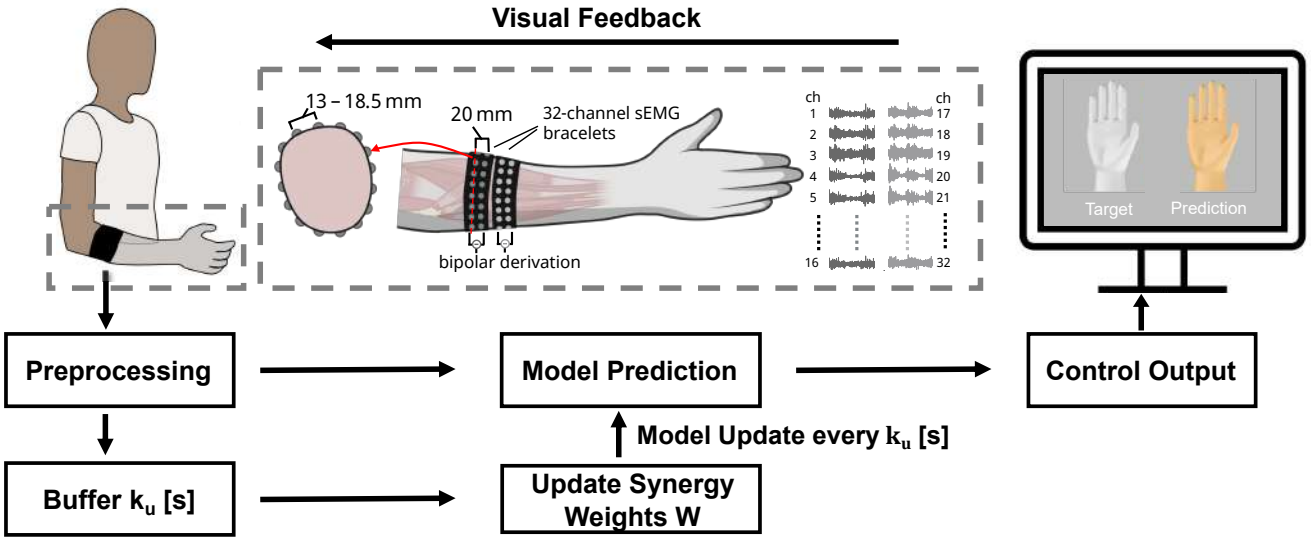

Fig. 1. *Experimental setup of the online myocontrol experiment.* Two 32-channel dry electrode bracelets were placed around the participant's forearm. Each electrode bracelet consisted of two rows of 16 electrodes. The bipolar configuration of the monopolar signals was derived for each pair of electrodes in the longitudinal direction of the arm, resulting in an output of 16 EMG signals per bracelet. Interelectrode distance in the transversal and longitudinal direction is shown in the bottom panel. Signals were preprocessed (see Methods) and then simultaneously fed into a buffer and the latest prediction NMF model. The collected data in the buffer was used to update the currently extracted weights W at defined intervals k_u. The model's prediction controlled a virtual hand on a monitor, that gave the user feedback on the model´s current prediction.

We tested our developed system in an online myocontrol experiment with eight able-bodied (AB) participants. During the experimental sessions, the subjects had to train a number of muscle synergies incrementally, increasing the number of synergies by one each round. After each round, the participants performed a target achievement control (TAC) test as an objective and filled in the NASA-TLX questionnaire as a subjective measure of perceived workload. To the author's knowledge, no dry electrode setup with such an electrode density as used in this work has been used for fully unsupervised and incremental online myocontrol to this date.

II. METHODS

A. Processing and Incremental Unsupervised Myocontrol

In order to extract the participants' movement intention from their sEMG signals, the ISNMF algorithm proposed by Gigli et al. [19] was implemented. The standard NMF algorithm aims to minimize the difference between the input EMG $V \in \mathbb{R}_+^{s\times n}$ consisting of s n-dimensional samples and WH. Where $W \in \mathbb{R}_+^{r\times n}$ contains r extracted synergies and $H \in \mathbb{R}_+^{r\times s}$ holds the activation coefficients. The ISNMF model uses iterative multiplicative updates on input batches of V based on Formula 1 and 2 to extract and refine muscle synergies in the m-th update. The matrices A and B are history matrices and eliminate the necessity of storing the entire training data set. While the forgetting factor μ reduces the contribution of the previous training batches. [19].

$$W^m \leftarrow W^m \circ \frac{\mu A^{m-1} + V_m H_m^{mT}}{\mu W^m B^{m-1} + W^m H_m^m H_m^{mT} + \frac{\mu(1-\mu^m)}{(1-\mu)}\beta W^m} \quad (1)$$

To compute the activation coefficients, H is optimized based on Formula 2.

$$H_m^m \leftarrow H_m^m \circ \frac{W^{mT} V_m}{W^{mT} W^m H_m^m + \gamma (H_m^m)^{-0.5}} \quad (2)$$

To improve the sparsity of the predictions, H is regularised with an $L_0.5$ norm weighted by γ, while W is regularised with an L_2 norm weighted by β.

For the online application, two ISNMF models were run in parallel, one for computing the predictions and one performing the updates, to guarantee that predictions were computed in real-time without disruptions through model updates, as shown in Figure 1. Each muscle synergy in W is arbitrarily mapped to a predefined myocontrol action of the hand model. The activation coefficients are normalized to a range of [0, 1] based on the historical 95th percentile of previous activations [19].

B. Hardware

For sEMG acquisition, two 32-channel sEMG bracelets (HD20MM1602B, OT Bioelettronica, Turin, Italy) were placed around the forearm of the participants. The electrodes of the sEMG bracelets are arranged in two columns of 16 electrodes each, with a longitudinal interelectrode distance (IED) of 20 mm between the columns and 13-18.5 mm IED in transversal direction, depending on the participants´ forearm circumference (20.8 - 29.5 cm in this study) (Fig. 1). Signals were sampled at 2000 Hz by a commercially available, wireless amplification system (MUOVI, OT Bioelettronica, Turin, Italy).

C. sEMG Preprocessing

To improve signal stability, the bipolar derivation of each pair of electrodes in the longitudinal direction of the arm was computed and used for further processing, resulting in 16 sEMG signals per bracelet. Then, the EMG was amplified by a factor of 100 and filtered with a bandpass filter over a frequency range of 20 Hz to 90 Hz and a bandstop filter over a frequency range of 45 Hz to 55 Hz. Finally, the root mean square (RMS) was calculated over a sliding window of 500 ms with a step size of 50 ms.

D. Online Myocontrol Experiment

1) Participants: The study was conducted with eight AB subjects (sex: $2f$, $6m$; age: 26.6 ± 3.0, range $[20, 30]$). Participants 1 and 5 had prior experience in myocontrol-based study designs.

2) Experimental Setup: As visualized in Figure 1, two sEMG bracelets, as described in II-B, were placed around the participants' forearm, targeting all superficial extrinsic hand and wrist muscles. The recorded sEMG was preprocessed as described in II-C. Due to limited space available, the wrist, hand, and fingers were not fixed with an orthosis. The participants were placed in front of a monitor that displayed a target hand, and the control hand. The target hand displayed the desired hand postures during the TAC test. While the control hand performed the hand movements according to the currently detected synergy activation and arbitrary motor mapping.

3) ISNMF: The value of the forget factor μ, was fixed at 0.9 throughout the course of the online trials. The tolerance ε was set to 10^{-5}, and the maximum number of iterations per update and prediction was limited to 200. In each trial, the number of extracted synergies, r, was increased from the initial value of $r = 3$ to a maximum of $r = 7$. The training batch size k_u was set to $10s$ for $r = [3,4]$, $15s$ for $r = [5,6]$, and $20s$ for $r = 7$. The initial values of the regularization terms β and γ were set to 10, although these could be modified by the experimenter if, for example, extracted synergies diminished repeatedly.

4) Study protocol: Each participant trains multiple ISNMF models with an increasing number of synergies, starting with three synergies. Each model is trained for a maximum time of ten minutes. Afterward, the ISNMF model was no longer updated, and a TAC test was performed, which requested the participant to reach a specific target position and hold them for 2 seconds with a maximal myocontrol error of 0.2. Thereby the myocontrol error is defined as the maximum component of the elementwise absolute difference between the target and the predicted pose [20]. The target poses require the activation of single synergies at *half-* and *full-intensity* to assess proportional control. Between the training and test phases of the models controlling more than three synergies, the NASA-TLX questionnaire (p. 1) is filled out by the participant. If a new synergy (four or later) could not be correctly activated at all, the experiment was terminated. The study was conducted following the WMA Declaration of Helsinki, participants provided informed consent, and the experiment was approved by the Ethics Committee of FAU Erlangen-Nürnberg (No. 22-275-S) before the experiments were carried out.

5) Data Analysis: The objective evaluation of the myocontrol of the participants was conducted through the analysis of the TAC test results, i.e. the success rate and task completion time. Each participant's success rate was calculated as the number of successfully reached and held target poses divided by the total number of target poses. In the case of a successful trial, the task completion time was calculated. Furthermore, both metrics are again provided for *half-intensity tasks* and *full-intensity tasks* separately (see II-D.4). For further use, the metrics from single-task trials are aggregated as a mean on a TAC level per participant. Missing values due to early termination (see II-D.4) were filled with the success rate of the last synergy minus the tasks corresponding to the new synergy. This approach assumes that the participant would have successfully achieved the same number of synergies again but would not have been able to control the subsequent synergy. The workload, assessed by the NASA-TLX part 1, was evaluated as a mean of the single categories [24] Due to a data loss during the acquisition of the participant, $S5$ was excluded from the study.

III. RESULTS

A. Objective Measurements

Figure 2 shows the success rate during the TAC tests for the increasing number of synergies across all targets. Missing values (see II-D.5) were anticipated for $S2(7)$, $S7(6,7)$, $S8(7)$, $S9(7)$. A downward trend of the success rate with an increasing number of synergies is visible, except for S3. It is also visible that all participants performed equally or better in TAC 4 than in TAC 3. The success rates of target poses with *half-* and *full-intensity* clearly show that the *full-intensity* poses were performed much better in comparison to the *half-intensity* targets. Furthermore, while the *half-intensity* targets commonly decrease for all participants except for S3, the *full-intensity* targets heavily differ between participants. There, it is particularly noteworthy that three of the participants achieved test results of 100% for $r = 5$ and two reached $\geq 80\%$. For $r = 6$ still, one participant reached 100% success, and three other subjects reached scores $\geq 80\%$.

TABLE I
TASK COMPLETION TIME OF SUCCESSFUL TASKS PER NUMBER OF SYNERGIES r IN [S] (MEAN AND STANDARD DEVIATION)

r	Target intensity		
	all	*full*	*half*
3	6.70 ± 1.62	5.96 ± 2.07	7.36 ± 2.34
4	6.14 ± 0.69	5.72 ± 0.93	7.53 ± 1.34
5	6.69 ± 1.70	6.21 ± 1.42	10.95 ± 4.66
6	7.44 ± 2.64	6.85 ± 2.61	10.96 ± 4.28
7	6.79 ± 1.24	6.58 ± 1.32	7.66 ± 1.50

Also, the time to task completion of successful tasks shown in Tab. I shows substantially longer task completion times for *half-* compared to *full-intensity targets* across all

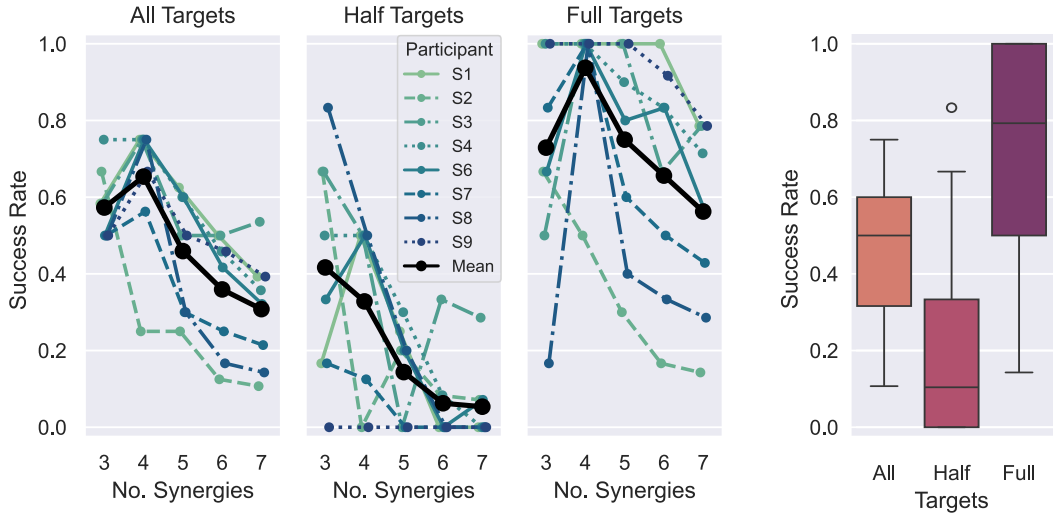

Fig. 2. *TAC test performance.* Left: Mean success rate (black) and each participant's success rate across the number of synergies r and targets (*all targets*, *only half-intensity targets*, and *only full-intensity* targets). Right: Box plot shows the success rates across target categories with median and IQR across all participants. Absent values for $S2(7)$, $S7(6,7)$, $S8(7)$, $S9(7)$ were filled as described in II-D.5

synergies. An overall increasing trend in completion time is visible from $r = 3$ to $r = 6$.

B. Subjective Measurement

The results of the NASA-TLX are shown in Fig. 3. Of all TLX dimensions combined, $r = 6$ received the highest scores and thus the highest perceived workload. Amongst the individual dimensions, Temporal Demand (TD) and Frustration (F) received, with the exception of 7 synergies (only $n = 4$), the lowest scores. Mental demand (MD), Effort (E), and Performance (P) were scored higher across most synergies. Physical Demand (PD) stayed relatively consistent across synergies.

IV. DISCUSSION AND CONCLUSION

A. Objective Measurements:

The main goal of this work was to improve current state-of-the-art results on incremental unsupervised online myocontrol by leveraging higher-density electrode setups as previously used. In comparison, Gigli et al. achieved success rates of 80% with a maximum of 4 separately controllable synergies [20]. We were able to reach similar success rates with 5-6 independently controllable synergies as shown in Figure 2. At four synergies, near-perfect *full-intensity* target scores were reached in all but one participant. Multiple participants even reached rates of ˜80% with seven controllable synergies (*S1*, *S3*, *S4*, *S9*). The significantly lower success rates at 3 active synergies compared to 4, 5, 6, and 7 synergies suggest a strong need for familiarisation and customization of the participants with the protocol and the interaction with the prediction model. The decrease in success rate in *full-intensity* target control at 5, 6, and 7 synergies can be attributed to the increased model complexity and the model's difficulty in identifying and separating new muscle synergies that were independent of the existing ones. Prominently, the high success rates in full-intensity target control could not be replicated in *half-intensity* target control, where success rates of less than 50% were achieved even at 3 and 4 synergies by all participants. One potential explanation for this might have been a too strong regularization of the activation coefficients by the ISNMF, or issues in the scaling of the coefficients. A hyperparameter optimization optimized towards the TAC test's demands could have also improved proportional control. A further possibility is that, in order to activate a myofunction with a half-intensity, the EMG amplitude must be maintained within a specific amplitude range. Conversely, for a full activation, the EMG amplitude merely needs to reach a certain threshold value. Notably, in two participants (*S6, S7*), significant model degradation was observed between the model training phase and the TAC tests in higher synergies numbers, suggesting a shift in electrode placement during the completion of the NASA-TLX questionnaire.

Given the much higher number of electrodes used in this study compared to previous work and the high number of controllable synergies in multiple participants, we hypothesize a high possible number of reliably and independently controllable synergies given further optimized hyperparameters and experimental protocol, including longer familiarization with the prediction model and setup, and increased duration of model training before the TAC tests.

B. Subjective Measurements

Similar to Gigli et al. [20], the results of the NASA-TLX scores presented in Figure 3 suggest no consistent decrease or increase of physical demand, mental demand, or frustration with increasing number of synergies despite decreasing success rates towards higher synergy numbers. This suggests that the higher familiarity with the system might be counteracted by the increased difficulty of controlling more myocontrol actions.

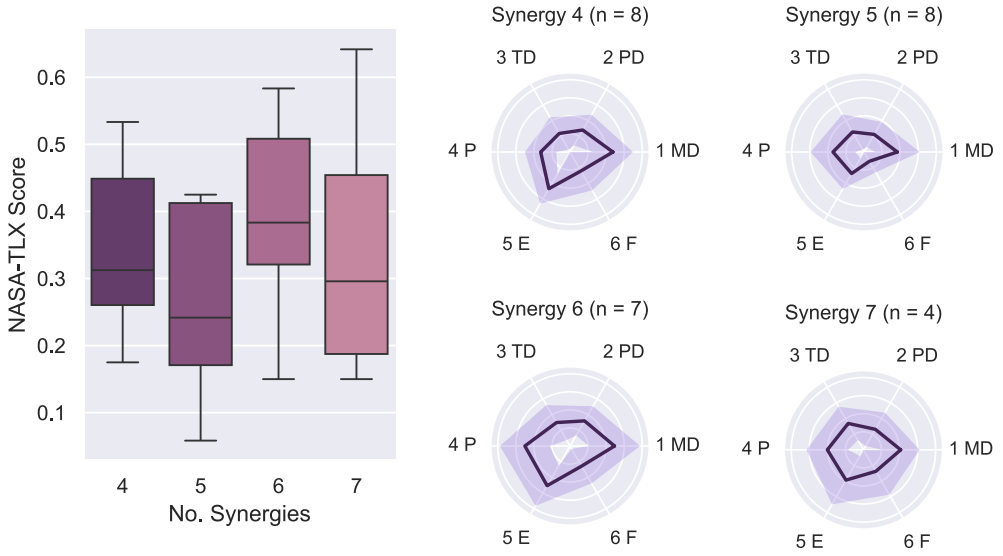

Fig. 3. *Results of the NASA-TLX questionnaire.* Left: NASA-TLX score for the number of synergies. Right: Each questionnaire subcategory result averaged across participants for synergies 4 to 7 with circular ticks from 0 to 0.8, with 0.8 corresponding to a high perceived workload. Subcategories: Temporal Demand (TD), Physical Demand (PD), Mental demand (MD), Frustration (F) Effort (E), and Performance (P). Only the number of participants n who successfully performed the previous synergy TAC test completed the respective NASA-TLX questionnaire.

C. Limitations

All participants in this study were non-disabled individuals. Furthermore, the wrist, hand, and fingers were not constrained with an orthosis. Both factors limit the generalizability to individuals with LD. Since it has been shown that limiting non-disabled subjects to isometric muscle contractions makes them more comparable with individuals with LD [25]. In Addition, this study was conducted in a controlled laboratory setting, which may not fully replicate the complexities and variabilities of daily life scenarios. Furthermore, the TAC-tests did not include simultaneous actions, therefore not evaluating combined control. The gradual increase in controllable Myocontrol functions influenced the results due to familiarisation. However, future users will also start with limited functions and increase the complexity over time. The sequential method therefore models the real use cases.

D. Outlook

Increasing the number of sEMG channels and, therefore, input dimensions not only increases the information density and possibly achievable prediction accuracy but also increases computational demand and model complexity, especially when dealing with the processing of raw EMG signals at high sampling frequencies.

We show that an unsupervised NMF-based control system, such as the one used in this work, can extract a considerable number of muscle synergies from higher-density dry electrode grids. Such a control system could also be used to extract movement intents in an unsupervised fashion from motor unit activation patterns. Motor unit activity extraction was recently shown to be possible in real-time scenarios [26]–[28]. Research suggests, that specific motor unit recruitment patterns encode distinct DoFs that could pose as lightweight but reliable input signals to the NMF model [29]–[31].

The optimal values for the hyperparameters β and γ, which are used to regulate W and H, directly affect myocontrol quality and vary between individuals. Standardized methods to determine the best hyper-parameters for proportional control for each individual are essential to ensure optimal user satisfaction.

The ISNMF algorithm has the capability to counteract model degradation from sEMG non-stationarities, such as user adaptation, without requiring stored training data or calibration procedures [18]. Moreover, it enables closed-loop co-adaptive learning, thereby enhancing its usability for individuals with congenital LD [32]. Additionally, the progressive and incremental NMF proposed by Gigli et al., allows an increase in the number of extracted synergies, thus enabling the integration of newly learned motor skills [20]. This study confirmed that muscle synergies extracted by ISNMF have the potential to control multiple myocontrol actions (which can be mapped to DOFs) without labeling and calibration procedures. Therefore, it could be used as a myocontrol algorithm for upper limb prosthesis control for individuals with a LD, especially a congenital LD. Furthermore, it allows the identification of distinct muscle synergies with minimal supervision, making it a suitable method for periprosthetic training.

E. Conclusion

This study investigated the feasibility of transferring unsupervised incremental myocontrol to HD-EMG. While preliminary studies based on sEMG and unsupervised incremental

learning demonstrated control over four actions, we showed that it is possible to archive more controllable actions by increasing the number of electrodes.

Nevertheless, the study has certain limitations. It was conducted in a controlled environment and was tested with non-disabled participants. These factors may affect the generalizability of the results for individuals with LDs. Future research should aim to validate these findings with a representative target group and increase the number and density of electrodes even further.

***Abstract*— Stiff-Knee gait (SKG) is a common post-stroke impairment, marked by insufficient knee flexion during the swing phase, which reduces toe clearance, increases fall risk, and requires compensatory movements that can have adverse biomechanical effects. To address muscle weakness and paresis in SKG, assistive technologies, such as functional electrical stimulation (FES) and robotic exoskeletons, have been introduced. However, robotic assistance may inadvertently increase spinal reflex excitability by activating muscle stretch receptors, potentially worsening SKG. Previous studies suggest that SKG may stem from quadriceps hyperreflexia, particularly in the rectus femoris (RF) muscle. As such, assistive interventions could exacerbate, rather than alleviate, this condition via artificial activation of stretch receptors. In this study, we examined the impact of two FES modalities, plantarflexor and knee flexor assistance, on RF reflex excitability at rest and during gait in six post-stroke individuals with SKG. Results showed that, at rest, plantarflexor FES facilitated the RF reflex excitability, while knee flexor FES led to a slight inhibition. During gait, we observed that some individuals exhibited changes in reflex excitability during FES, but this effect was not as consistent as during rest. These preliminary results suggest that assistive technology such as FES modulates reflex excitability dependent on context.**

Keywords—H-reflex, stroke, gait, functional electrical stimulation, reflex excitability, exoskeleton

I. INTRODUCTION

Approximately 80% of stroke survivors experience gait impairments (Duncan, 2005), with 25–75% of these individuals developing Stiff-Knee gait (SKG)[1], [2]. Characterized by reduced peak knee flexion during swing phase, SKG limits foot clearance, raising fall risk[3] and leading to asymmetric gait patterns that impact joint loading and energy efficiency [4]. These consequences often translate to more sedentary lifestyles, reduced community engagement, social isolation, depression, and heightened fear of falls among stroke survivors.

Mechanical assistance devices, such as exoskeletons, and functional electrical stimulation (FES) can potentially compensate for weakness, offering insights into SKG mechanisms. Our prior research applied a lightweight exoskeleton to assist knee flexion during pre-swing in individuals with chronic SKG[5]. Contrary to our expectations, this assistance increased quadriceps reflex excitability, potentially due to elevated RF fiber stretch velocity and subsequent Ia afferent activation[6]. Notably, RF hyperreflexia, measured as evoked H-reflex potentials [7], [8], correlated strongly with reduced peak knee flexion angle ($R = -0.92$)[9]. This finding aligns with prior hypotheses linking quadriceps hyperreflexia to SKG [10], [11], supported by studies demonstrating reduced quadriceps reflex excitability following fatigue [12], [13].

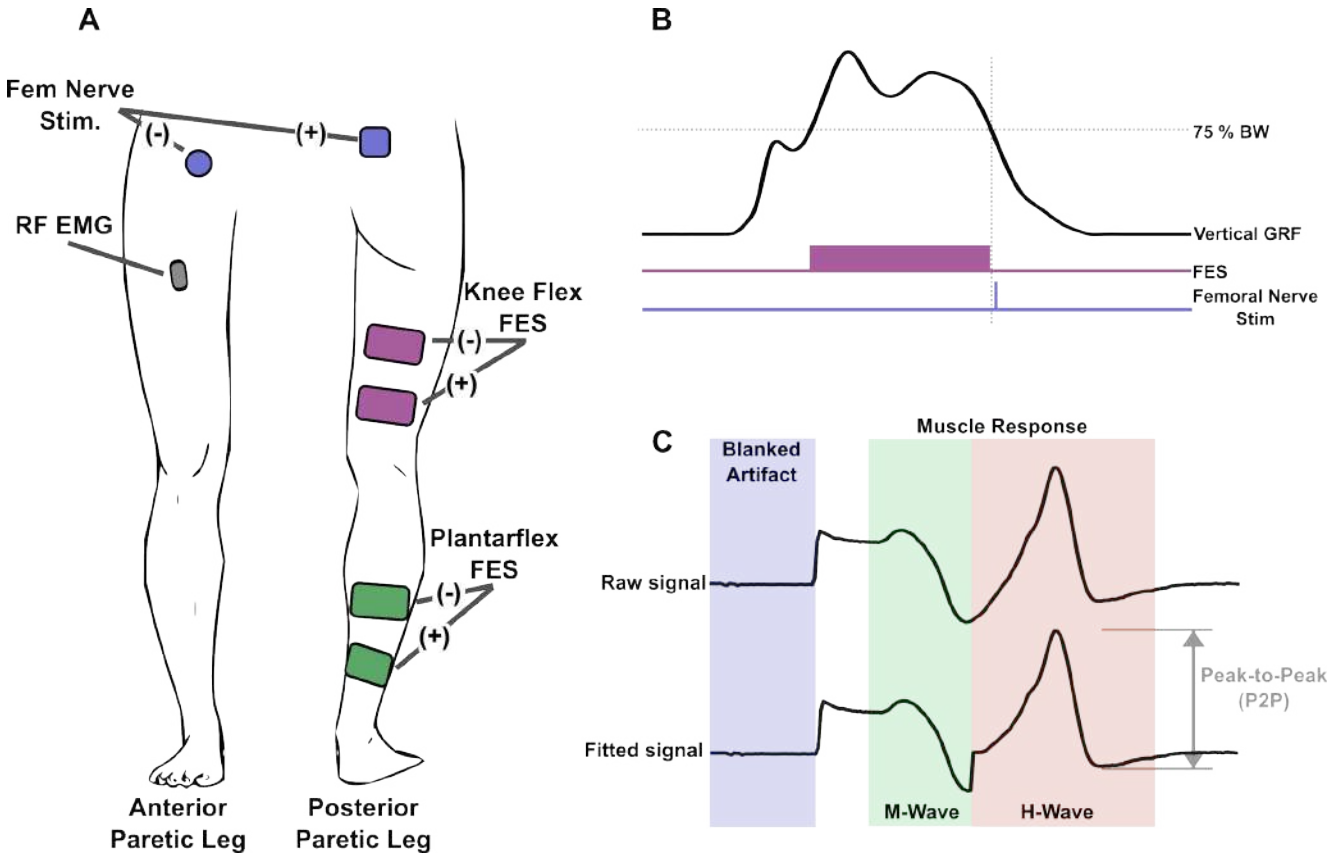

Fig. 1. Experimental setup for assessing spinal reflexes during FES-assisted gait in post-stroke survivors. (A) FES electrodes were placed on the posterior aspect of the paretic limb to evoke functional contractions of the plantarflexors and knee flexors. An EMG electrode positioned on the RF muscle recorded the H-reflex, elicited by transcutaneous stimulation of the femoral nerve. (B) FES activation and H-reflex probing pulses were synchronized with gait phases using ground reaction force data collected from an instrumented treadmill. The probing pulse was delivered during the pre-swing phase, corresponding to 25% body weight unloading. (C) EMG responses were processed to isolate the H-wave by subtracting residual depolarization from the overlapping M-wave using a fitted exponential decay function. The peak-to-peak amplitude of the processed H-wave was used as a measure of reflex excitability.

While interventions like FES have shown promise, they can have complex effects on the spinal reflex system, particularly in SKG. For example, Tenniglo et al. (2018)[14] applied FES to the hamstrings of post-stroke individuals with SKG, achieving modest yet significant improvements in knee flexion range following five weeks of training, although responsiveness varied. Unlike exoskeletons, which primarily stretch antagonist muscle spindles, FES induces excitation of Ia afferents, impacting both homonymous and heteronymous pathways [15] and creating complex excitatory and inhibitory effects across the lower limbs[16], [17]. Beyond Ia pathways, FES can stimulate Golgi tendon organ (Ib) afferents and Renshaw cells, introducing further inhibitory influences across quadriceps and soleus muscles [18], [19]. Task context, muscle state, and other afferent inputs also modulate reflex excitability, with stroke leading to distinctive alterations in both heteronymous and monosynaptic pathways [20], [21]. Given these intricate spinal adaptations, understanding FES and exoskeleton interactions with spinal reflexes is essential for optimizing therapeutic efficacy.

To address this gap, we investigated RF H-reflex behavior in response to FES-assisted gait in post-stroke SKG survivors, applying plantarflexor or knee flexor FES during gait pre-swing and at rest. By probing these reflex circuits, we aim to refine FES protocols that leverage heteronymous pathways to enhance locomotor outcomes and provide mechanistic insights for improving FES-based therapies and optimized integration with hybrid exoskeleton systems.

II. Methods

Six post-stroke survivors with chronic hemiparetic locomotor impairments presenting with SKG were recruited for this study. A licensed physical therapist confirmed the presence of SKG in all participants. Written informed consent was obtained following procedures approved by the local Institutional Review Board. The presence of the RF H-reflex was verified prior to beginning FES testing. Participants' level of quadriceps spasticity was clinically assessed using the Modified Ashworth Scale (MAS). Additionally, two functional measures were used: the peak knee flexion angle difference between the paretic and nonparetic limb [22], where a larger difference indicates more pronounced SKG, and the quadriceps reflex threshold angle (QRTA) from the quadriceps pendulum test, where a lower first inflection angle reflects greater quadriceps spasticity [23]. Table 1 shows

Table 1. Participant information showing sex, time since stroke incident, Modified Ashworth Scale (MAS) score for the quadricep muscles, treadmill speed used during gait assessments, the difference between peak knee angles between the paretic and nonparetic side, the quadriceps reflex threshold angle during a pendulum test, and the average percent change (%Δ) from control trials for each tested condition. The MAS, peak knee flexion angle difference, and quadriceps reflex threshold angle can serve as indicators of quadriceps hyperreflexia severity.

Participant	Sex	Time post-stroke (yrs)	Treadmill Speed (m/s)	MAS Score (Knee Extensors)	Peak Knee Flexion Angle Difference (Δ°)	Quadriceps Reflex Threshold Angle (°)	Rest PF FES (%Δ)	Rest KF FES (%Δ)	Gait PF FES (%Δ)	Gait KF FES (%Δ)
P1	M	0.5	0.6	2	27.33 ± 3.74	26.6 ± 12.3	-3.8	-21.2	+29.5	+44.2
P2	M	4.5	0.6	1	3.10 ± 1.50	57.3 ± 14	+3.4	-7.9	+2.1	-21.9

participant demographics as well as a summary of their results.

A recording electrode was positioned on the RF muscle to capture responses from femoral nerve stimulation. An EMG amplifier (CED 1408, Cambridge Electronics Design Ltd, Cambridge, UK) with blanking capabilities was used to eliminate stimulation artifacts and prevent amplifier saturation. Ground reaction force (GRF) data were collected via an instrumented treadmill (FIT 5 Instrumented Treadmill, Bertec Inc, Columbus, OH). EMG and GRF data were sampled at 5 kHz using custom MATLAB software, and MATLAB Simulink Desktop Real-Time was utilized to achieve real-time stimulation during gait.

For femoral nerve stimulation, a cathode electrode (1", Axelgaard Valutrode, Axelgaard Manufacturing Co Ltd, Fallbrook, CA) was placed on the skin above the femoral nerve, while an anode electrode (2"x2", Axelgaard Valutrode) was positioned over the ipsilateral sacrum (Figure 1A). For plantarflexor FES, cathode electrodes (2x3.5", Axelgaard Valutrode) were placed on the distal gastrocnemius, with an anode positioned above the malleolus. Knee flexor FES involved placing cathode electrodes on the biceps femoris muscle mid-thigh, with the distal cathode approximately 2" above the knee crease. Femoral nerve stimulation pulses were biphasic (cathodic first) square pulses with 500 μs phase duration and a 50 μs interphase interval. FES stimulation followed similar pulse parameters, adjusted only in amplitude, and was delivered at 40 Hz. Both femoral nerve stimulation and FES were administered via an external stimulator (DS8R, Digitimer Ltd, Welwyn Garden City, UK) connected to a switchbox for multichannel stimulation with precise temporal control.

The femoral nerve stimulation amplitude was determined by generating a recruitment curve and selecting a level that evoked 50% of the maximum H-reflex along the ascending phase. For FES, amplitude was set at twice the motor threshold to ensure functional muscle contraction; if this level was uncomfortable, it was reduced to a level the participant found tolerable.

At rest, six responses were collected for each condition: control (no FES), plantarflexor FES, and knee flexor FES. During gait trials, where variability was higher, ten responses were collected per condition. The femoral nerve stimulation interval was set to at least 10 seconds to reduce potential homosynaptic depression effects [24]. For at rest FES trials, femoral nerve stimulation was delivered 1.5 seconds after initiating FES, at which point the FES was deactivated. During walking assessments, femoral nerve stimulation was triggered based on ground reaction forces measured by the instrumented treadmill described above. Participants were asked to walk for up to 3 minutes at a time with the option of a seated rest between trials. Stimulation occurred during the pre-swing phase, defined as the downward phase of the vertical GRF reaching 75% of the participants body weight (BW). FES was active throughout stance for both modalities, where stance was defined as vertical GRF exceeding 75% of the standing vertical GRF (Figure 1B).

The primary outcome measure was the percent change in the peak-to-peak RF H-reflex response. The peak-to-peak value was determined as the difference between the maximum and minimum amplitudes within a visually selected window, starting approximately 20 ms after stimulation onset and lasting approximately 30 ms. Given the RF muscle's close proximity to the spinal cord, the M-wave and H-wave responses occasionally overlapped. To address this, an exponential decay function was fitted from the end of the M-wave to the end of the H-wave (Figure 1C). This fitted decay curve was subtracted from the original signal, isolating the H-wave and removing any M-wave artifacts [9]. An arbitrary threshold of 10% was used to qualitatively determine if modulation was present within each condition for each participant.

Statistical analysis was not conducted due to the small sample size and significant inter-individual variability observed among participants. With only six participants, the study lacked the statistical power needed to detect meaningful differences between conditions. Additionally, the high variability in responses, both within and across participants, highlighted the heterogeneity of neurological impairments and their effects on reflex modulation. As a result, descriptive

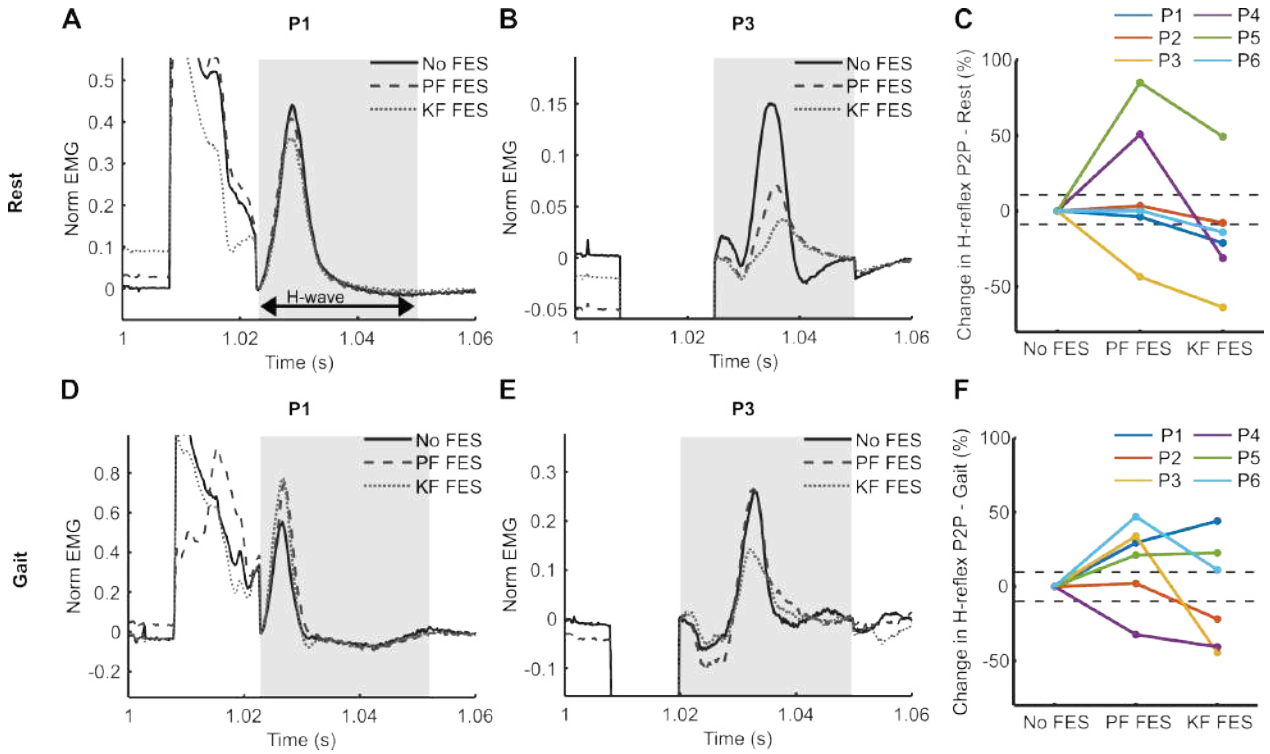

Fig. 2. Modulation of RF H-reflex by heteronymous muscle group stimulation at rest and during gait in post-stroke survivors with stiff-knee gait. (A, B) Reflex responses from two participants (P1 and P3) at rest without FES (solid), with PF FES (dashed), and with KF FES (dotted). Shaded region depicts the H-wave analysis window. P1 exhibited minimal changes across conditions, while P3 showed substantial inhibition with both PF FES and KF FES, with greater inhibition during KF FES. (C) Percent change in peak-to-peak H-reflex amplitude relative to No FES for all participants at rest highlights inter-individual variability. Dashed line at 10% represents modulation threshold. (D, E) Reflex responses during gait for P1 and P3 under the same conditions. P1 showed facilitation with both FES modalities, whereas P3 exhibited significant inhibition with KF FES and minimal facilitation with PF FES. (F) Percent change in H-reflex amplitude during gait demonstrates considerable variability in responses across participants.

analyses were prioritized to qualitatively examine trends and patterns, providing preliminary insights to guide future studies with larger, more homogeneous samples. Nonetheless, a preliminary Spearman's rank correlation analysis was performed to explore potential relationships between participants' level of spasticity, measured by the reflex threshold angle, and the percent change in RF H-reflex amplitude across tested conditions.

III. Results

At rest, the effects of FES on the RF H-reflex varied across participants, as shown in representative responses in Figures 2A and 2B. In Participant 1 (P1), PF FES had no discernible effect on the H-reflex (-4%), while KF FES led to slight inhibition (-21%). In contrast, Participant 3 (P3) demonstrated substantial modulation of the H-reflex amplitude by both FES modalities, with KF FES producing greater inhibition (-63%) than PF FES (-43%). Figure 2C summarizes the percent change in peak-to-peak H-reflex amplitude across all participants during rest. PF FES facilitated the H-reflex in two of six participants (P4, 51%; P5, 85%), caused minimal changes (<10%) in three (P1, -4%; P2, 4%, P6, 0.3%), and inhibited the response in one (P3, 44%). KF FES, on the other hand, consistently either inhibited or resulted in minimal changes in all (P1, -21%; P2, -8%; P3, -64%; P4, -31%, P6, -14%) but 1 participant (P5, 49%). These findings highlight notable inter-individual variability, as indicated by the wide distribution of data points across conditions, but show a trend towards inhibition during KF FES.

During gait, the effects of FES on RF H-reflex modulation were even more variable between participants. Figures 2D and 2E depict responses from P1 and P3, respectively. In P1, both PF FES and KF FES increased H-reflex amplitude compared to the no-FES condition, suggesting an overall facilitatory effect of FES during walking. Conversely, in P3, PF FES produced slight facilitation, whereas KF FES caused approximately 45% inhibition relative to the no-FES baseline. The aggregated percent changes in H-reflex amplitude across participants during gait are shown in Figure 2F. Three participants exhibited facilitation with both PF FES (P1, 30%; P5, 21%, P6, 47%) and KF FES (P1, 44%; P5, 23%, P6, 11%), one showed facilitation with PF FES (P3, 34%) and inhibition with KF FES (P3, -45%), one demonstrated inhibition with both PF FES (P4, 32%) and KF FES (P4, 41%), and one showed less than 10% change with PF FES (2%) and inhibition with KF FES (P2, 22%). Similar to the rest condition, large inter-individual variability was evident. Overall, no consistent pattern of facilitation or inhibition

emerged across the cohort, underscoring the participant-specific nature of FES effects during gait.

Preliminary correlation analysis using Spearman's rank method revealed varying relationships between the QRTA and the percent change in RF H-reflex amplitude across different conditions. During rest, a weak positive correlation was observed with PF FES (r_s = 0.31), suggesting a limited association between spasticity and reflex facilitation. In contrast, KF FES at rest showed no meaningful relationship (r_s = -0.03). During gait, PF FES exhibited a moderate negative correlation (r_s = -0.66), indicating that higher spasticity levels may correspond to greater reflex inhibition. Similarly, KF FES during gait showed a strong negative correlation (r_s = -0.71), suggesting a more pronounced inhibitory effect with increased spasticity. These findings suggest that spasticity, as measured by reflex threshold angle, may differentially influence H-reflex modulation depending on the condition and stimulation modality.

IV. Discussion

This preliminary study investigated the effects of functional electrical stimulation (FES) on the modulation of the rectus femoris (RF) H-reflex at rest and during gait in post-stroke individuals with Stiff-Knee gait (SKG). These preliminary findings revealed substantial inter-individual variability in H-reflex responses, both at rest and during gait, suggesting that FES effects are highly participant-specific and may depend on individual characteristics, including severity of spasticity and sensorimotor capabilities.

At rest, PF FES predominantly facilitated the RF H-reflex in a subset of participants, likely due to heteronymous facilitation, a spinal mechanism where anatomically distinct muscles activate synergistically to enhance motor functionality [15]. In contrast, KF FES exhibited predominantly inhibitory or negligible effects, potentially mediated by reciprocal inhibition, where antagonistic muscle activation reduces excitability in the quadriceps motor pool [25]. During gait, these patterns became less consistent, with some participants exhibiting facilitation and others showing inhibition or variable responses across conditions. This variability underscores the dynamic and task-dependent nature of spinal reflex modulation during locomotion, driven by interactions between central pattern generators, descending motor control, and sensory feedback [26], [27]. These findings highlight the complexity of generalizing FES effects across a heterogeneous population of post-stroke individuals with SKG, as gait-specific mechanisms likely override reflex responses elicited during rest.

The correlations between reflex threshold angle and H-reflex percent change further emphasize the influence of spasticity on reflex modulation. While PF FES at rest showed a weak positive correlation, suggesting a limited role of spasticity under static conditions, the strong negative correlations observed during gait, particularly with KF FES, highlight the impact of spasticity in dynamic contexts. Spasticity-related reflex excitability may amplify during functional tasks like walking, reducing the efficacy of therapeutic interventions [9], [28]. These results underscore the importance of tailoring FES parameters to individual spasticity profiles, as well as the need to develop approaches that adaptively account for spasticity-driven reflex changes.

Robotic exoskeletal assistance presents a promising strategy to address these challenges. By offering precise control over joint movement and muscle activation, exoskeletons equipped with advanced sensors and real-time feedback systems could coordinate adaptively with FES to enhance reflex modulation while mitigating excessive facilitation or inhibition. Future studies should investigate whether the facilitatory and inhibitory mechanisms observed here interact with those seen during robotic-assisted gait in individuals with SKG [5], and explore their potential to improve gait biomechanics through personalized, context-specific interventions.

While these findings provide valuable insights, several limitations must be addressed in future studies. The small sample size in this preliminary trial and lack of an age-matched control group limits generalizability and introduces potential bias, particularly for such a heterogeneous population. A larger randomized clinical study would allow for a more comprehensive evaluation of FES effects and account for inter-individual variability. Additionally, future research should explore key factors not addressed in this study, including the relationship of RF H-reflex modulation with other measures of spasticity, the dose-response relationship of FES on reflex modulation, the long-term rehabilitative effects of repeated FES sessions, and the impact of FES on reflex modulation during walking on non-level surfaces, better reflecting real-world mobility challenges.

In conclusion, this study underscores the highly participant-specific nature of FES effects on RF H-reflex modulation, reflecting the complexity of spinal reflex dynamics in post-stroke individuals with SKG. These preliminary findings highlight the need for tailored stimulation protocols that account for individual neuromuscular profiles and the interplay between reflex mechanisms and functional tasks. Future research should prioritize the refinement of FES parameters, the integration of multimodal assistive technologies such as robotic exoskeletons, and the identification of reliable biomarkers to predict FES responsiveness. These efforts will be essential for advancing personalized therapeutic strategies aimed at optimizing locomotor outcomes and enhancing quality of life in individuals with SKG.

Acknowledgment

The authors would like to thank Shreya Ramani for assistance during data collection, Sebastian Correa for insightful feedback during the conceptualization process, and Kristine Hansen for participant selection, recruitment, and coordination.

Enhancing Human Walking Economy Through a Biomimetic Cable-Driven Ankle Exoskeleton*

Xianyu Zhang, Kotaro Hinuma, Zhengguang Wang, Zhenzhi Ying, Naohiko Sugita, Shihao Li

Abstract— **Enhancing the walking economy is a primary goal in the application of exoskeletons for gait assistance. However, traditional exoskeletons often face challenges due to rigid designs and the additional distal mass they introduce, limiting their effectiveness. In this study, inspired by the muscle-tendon complex of the human calf, we present a cable-driven ankle exoskeleton designed to provide targeted assistance during plantarflexion movements at the ankle joint. The proposed exoskeleton integrates a compact, lightweight actuation unit with a flexible fabric shank sleeve, ensuring efficient torque transmission from the motor to the ankle joint. A feedback-based cascaded repetitive control system, combined with a multi-sensor fusion communication framework, was developed to achieve precise force control. The system's actuation performance was evaluated through benchtop experiments, demonstrating a bandwidth of approximately 13.5 Hz and a force tracking error of 5% under position disturbances. Treadmill experiments further validated the effectiveness of the exoskeleton, showing a 7.53% improvement in walking economy compared to no-assistance conditions. These findings highlight the potential of the proposed design to advance the development of cable-driven exoskeletons for improved gait assistance.**

I. Introduction

Through millions of years of evolution, humans have refined bipedal locomotion, achieving remarkable efficiency in walking. This evolution has optimized energy-efficient gaits by fine-tuning factors such as cadence and stride length, supported by biomechanical strategies like arm swinging [1]. Despite these advancements, walking remains a metabolically demanding activity. For a typical adult, walking consumes approximately 2.5 J/kg/m at a speed of 4.5 km/h, with energy expenditure increasing at higher speeds [2]. Given that daily life involves thousands of steps, walking becomes one of the most energy-intensive activities. While this metabolic cost is manageable for healthy individuals, it poses challenges for those with mobility impairments or in contexts requiring sustained walking, where reducing energy expenditure is critical for improving performance and quality of life [3]. As a result, recent research has increasingly focused on developing assistive technologies to assist human walking and enhance walking efficiency.

A promising approach for enhancing walking efficiency involves the use of lower limb exoskeletons (LLEs), which are wearable devices designed to deliver targeted assistance to specific joints [4]. Over the past decade, the diversity of LLEs has grown substantially. Among these, passive LLEs, which emulate the function of biological muscle tendons through the use of springs and clutches for energy storage and release, have gained attention for their simplicity and cost-effectiveness [5]. Despite these advantages, passive LLEs are limited by their static assistance, which is dictated by the inherent properties of their elastic components and lacks dynamical adaptability. To overcome these limitations, active LLEs equipped with sensing and control systems have been developed to regulate the provided assistance [6]. Active LLEs typically employ electric motors to drive joint movements., with notable examples including the Berkeley Lower Extremity Exoskeleton [7] and the Hybrid Assistive Limb exoskeleton [8]. Traditional active LLEs often rely on rigid frames to transmit actuator forces to the target joints. This design not only restricts the wearer's natural movements but also introduces challenges related to misalignment. Additionally, the non-ignorable distal mass of these systems diminishes some of the benefits provided by the exoskeleton, ultimately hindering improvements in the gait economy.

In recent years, there has been an increasing trend toward designing soft LLEs that merge the advantages of being lightweight and structurally simple with the capability for adjustable assistance [9]. These soft LLEs primarily adopt cable-driven mechanisms, specifically designed for joints including the hip [10], knee [11], and ankle [12][13]. In these configurations, heavy components like actuators and batteries are strategically placed in more proximal body regions to minimize the impact of distal mass. Assistance is transmitted through cables connected to anchors embedded in functional textiles attached to the limbs. By adjusting the distance between adjacent anchors, the mechanism mimics muscle contraction and delivers support. However, challenges persist with cable-driven LLEs, particularly in the magnitude and precision of the torque delivered. This issue arises mainly from the inherent elasticity of the cables and friction losses within the transmission system [14]. Furthermore, despite cable-driven LLEs holding promise, comprehensive evidence demonstrating their effectiveness in enhancing the walking economy remains limited.

During walking, the ankle and hip joint are the primary contributors to mechanical work, ranking first and second, respectively [15]. In the push-off phase, the ankle joint generates the largest forward propulsion through plantar flexion driven by calf muscle contraction [16]. Inspired by this, we propose a cable-driven exoskeleton aligned with the posterior calf's muscle-tendon units to reduce muscle efforts

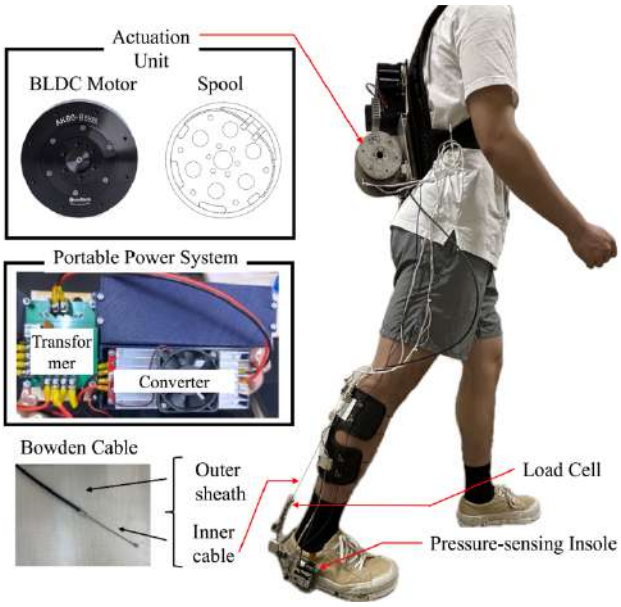

Figure 1. The proposed cable-driven ankle exoskeleton and its components.

and enhance walking economy. The contributions of this study are as follows. A compact, lightweight actuation unit was developed, reducing the system weight to 4.2 kg while delivering high pulling forces and effectively managing cable tension and slack through a self-aligning spool design. A feedback-based cascaded repetitive control system was implemented, achieving precise tension control (± 5%) without additional mechanisms. The exoskeleton's ability to improve walking economy was validated through treadmill experiments, demonstrating significant performance gains (7.53%). The remainder of this paper is organized as follows. Section II details the design of the exoskeleton. Section III describes the treadmill experiment setup, results, and analysis. Section IV discusses the advantages and limitations, and Section V concludes this study.

II. Exoskeleton Design and Characterization

This section presents a detailed description of the structure design of the proposed cable-driven ankle exoskeleton, along with its integrated sensing and control system. Additionally, benchtop experiments were conducted to evaluate and characterize the performance of the actuator unit.

A. Mechanical Design

The proposed cable-driven exoskeleton mimics the contraction of the soleus muscle-Achilles tendon complex by aiding during the ankle's plantarflexion movement in the propulsion phase of walking (50–65% of the gait cycle). During this phase, the motor activates, winding the inner cable around the spool to emulate the contraction of the soleus muscle. This reduces the workload on the user's calf muscles and improves walking economy. Designed for lightweight portability and sufficient force output, the system comprises a compact actuation unit and a fabric-based wearable interface, as illustrated in Fig. 1.

The actuation unit generates mechanical power through a brushless DC motor equipped with an 8:1 planetary gearhead (AK80-8, CubeMars, China), featuring a weight of 0.57 kg, a rated torque of 10 Nm, a peak torque of 25 Nm, and a rated speed of 243 rpm. To minimize distal mass, the heavier components, including the actuation unit, are strategically positioned on the user's back. To transmit the actuator's torque to the ankle joint, a Bowden cable (XA507100, Nippon Flex Controls, Japan) is employed as the force transmission medium. It comprises an inner steel cable (diameter: 1.2 mm, load capacity: 390 N) and an outer resin sheath (external diameter: 4.2 mm, inner diameter: 2.3 mm). The output shaft of the gearhead is directly coupled to a custom-designed spool made of aluminum alloy, with an effective radius r of 40 mm and a weight of 0.16 kg. The spool is specifically designed for winding the inner cable and features smooth grooves and strategically placed anchor points to facilitate cable installation and prevent derailment. The distal end of the inner cable is anchored to a metal rod extending from the heel, with an effective length l of approximately 120 mm. The force applied to the ankle joint is related to the gearhead's output torque through the following equation:

$$F_{applied} = \frac{\eta \tau_{gear}}{r} \quad (1)$$

Here, η denotes the transmission efficiency, which accounts for losses such as friction within the Bowden cable. Its value was determined to be 0.8 based on experimental verification.

The fabric-based wearable interface includes a customized shank sleeve and a backpack. The shank sleeve is specifically designed to securely fix the distal end of the Bowden cable sheath to the user's calf, preventing sliding while ensuring comfort and ease of wear. Constructed from soft materials such as OK fabric and cow leather, it features a rubber inner layer to enhance friction with the skin, thereby improving stability. Sponge padding is added at key areas with thinner subcutaneous fat to reduce shear forces and distribute pressure evenly. The outer leather surface incorporates metal fixtures attached with stitching and bolts. Additionally, a lacing system (L7-1, Fitgo, China) enables quick donning and doffing with a dial rotation, allowing precise tension adjustment for an optimal fit. The final design weighs less than 0.1 kg per leg.

The backpack houses heavy components such as the actuation units, controller, and power supply system. Adapted from a commercially available motorcycle protective backplate, it includes extensive padding for cushioning and prolonged comfort. The backpack is securely mounted on the user's back using shoulder and waist straps for stability and ergonomic support. Weighting 4.04 kg in total, it comprises two actuation units (0.73 kg each), a lithium battery (1.65 kg), a Raspberry Pi-based control circuit (0.08 kg), and a harness system (0.85 kg), offering a lightweight and practical solution.

B. Sensing and Control System

An appropriate sensing and control system is essential for achieving improved human-robot interaction. As shown in Fig. 2(a), a Raspberry Pi is chosen as the upper-level controller, with the main loop operating at 100 Hz. A load cell (MCDW-50L, Toyo Sokki, Japan) is mounted on the posterior side of the heel to measure cable tension. The measured signal is then sent to the amplifier (LA-1024A-2-EXC5V-500Hz, Toyo Sokki, Japan) and converted into a digital signal via an A/D converter (MCP3208-CI/P, Microchip Technology, USA), which is subsequently received by the Raspberry Pi. Additionally, the built-in controller within the motor performs lower-level closed-loop control while also monitoring motor states such as angle and current. To enhance the perception of the wearer's motion state, two IMU sensors (LSM9DS0, STMicroelectronics, Switzerland) are placed on the shank sleeve and shoes. The global link angles are calculated using the Extended Kalman Filter algorithm [17]. A pressure sensing insole (RPPS-45, LEGACT Technology, China), positioned beneath the wearer's foot inside the shoes, is used to approximate the ground reaction force and segment the gait cycle based on the right heel strike event. Communication between the motor, sensors, and the Raspberry Pi is established through the CAN protocol. Considering portability, a 24V lithium-ion battery is chosen as the power supply module. It is coupled with both a boost and buck converter to provide output voltages of 48V, 24V, and 5V, which power the motor, amplifier, and sensors, respectively.

To achieve precise tension control, we designed a dual-layer cascaded closed-loop control system based on sensor feedback, as illustrated in Fig. 2(b). Given that the Bowden cable is designed to mimic the contraction of the muscle-tendon complex and apply a desired force profile throughout the gait cycle, the outer layer implements force control, while the inner layer employs current control. In the outer layer, the desired force, derived from our previous research [18], serves as the input. The error between this desired force and the actual tension measured by the load cell is processed by a proportional-integral-derivative (PID) controller. Then, a feedforward term of the desired force is incorporated before transmitting the command to the inner layer. To further enhance force tracking performance, a delay-based repetitive control (RC) mechanism is introduced, leveraging the cyclic nature of walking. In this delay term, T corresponds to the duration of the gait cycle, which is estimated from the preceding three consecutive gait cycles. The outer layer operates at a frequency of 100 Hz, generating the current command for the inner layer. The inner layer, running at 500 Hz, precisely adjusts the motor's actual current to meet the command requirements.

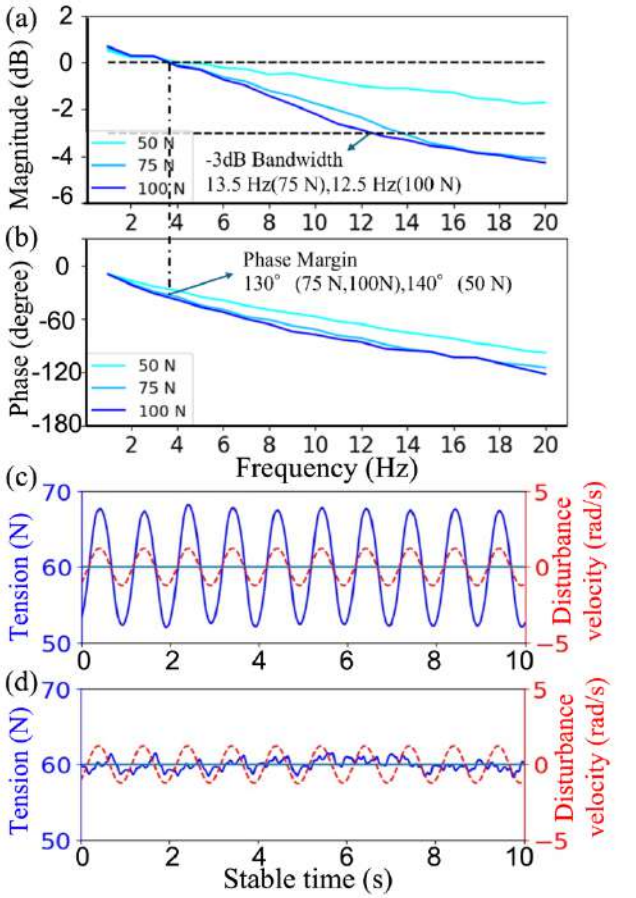

Figure 3. Benchtop experiment results. (a) and (b) Bandwidth test results of the system, (c) and (d) Dynamic disturbance experiment results. (c) shows the result of the traditional PID controller, while (d) presents the result of the repetitive controller.

C. Actuation Performance Characterization

To evaluate the performance of the proposed exoskeleton, a dedicated test platform was constructed, and a series of characterization experiments were performed. To assess active force tracking capability, a bandwidth test was conducted. In this experiment, the load cell was fixed, and sinusoidal force signals with amplitudes of 50 N (peak-to-peak 100 N), 75 N, and 100 N were applied, with frequencies sweeping from 1 Hz to 20 Hz. These force amplitudes were chosen based on practical application requirements. Each amplitude test was repeated three times, with each trial maintaining over 20 seconds at each frequency, ensuring at least 20 complete cycles were available for analysis. The experimental results are presented in Fig. 3(a) and 3(b). The -3 dB bandwidth was undetectable at 50 N, approximately 13.5 Hz at 75 N, and 12.5 Hz at 100 N. The phase margin was measured at approximately 140° for 50 N and 130° for both 75 N and 100 N. These results confirm that the device's is significantly higher than the typical frequency spectrum of human motion.

To assess the impact of disturbances caused by human motion on force control accuracy, dynamic experiments were conducted. An additional identical actuation unit was employed as a towing system to drive the distal end of the Bowden cable in a sinusoidal, periodic reciprocating motion.

This motion simulated the ankle joint's behavior during a gait cycle, operating at a frequency of 1 Hz, approximately corresponding to the natural walking frequency. During this experiment, the desired force was maintained at a constant value of 60 N. The force control performance of a traditional PID controller was compared with that of a RC controller, PID parameters are the same for both controllers. The results, showing the steady-state control performance of both controllers, are presented in Fig. 3(c) and Fig. 3(d). The measured tension exhibited periodic variations around the target value. Potential causes for these fluctuations include backlash in the Bowden cable and gearbox, as well as the stiffness and friction of the cable. Initially, the fluctuation range was 60 ± 8 N, with the period of variation aligning with the disturbance motion. However, when repetitive control was implemented, the amplitude of the fluctuations gradually decreased over time, ultimately stabilizing at a reduced range of 60 ± 3 N (±5%).

III. Walking Experiment and Results

The exoskeleton aims to assist walking and enhance the walking economy. For safety considerations, an off-board version of the exoskeleton was used during the treadmill experiments. The power supply and actuation unit were placed beside the treadmill, and participants only wore the shank sleeve. This setup ensured that the added mass was negligible and did not interfere with metabolic cost measurements. This section summarizes the experimental protocol, apparatus, and results of the human walking assistance tests.

A. Experimental Protocol

To evaluate the device's walking assistance (unilateral) performance, treadmill experiments were conducted with approval from the University of Tokyo's Research Ethics Committee (No. KE24-129). Two healthy young participants (details in Table 1), without movement disabilities were recruited. Written informed consent was obtained before participation. Each participant completed a two-day protocol: a two-hour familiarization session on day one and a formal testing session on day two. Three conditions were evaluated—no assistance, low assistance (peak force of 30 N), and high assistance (peak force of 50 N). The desired torque profiles, derived from previous studies [18][19], and shown in Fig. 4(b), were adjusted based on safety considerations and feedback from the familiarization session. Timing parameters for each participant were derived from our previous research [18] and further refined during the familiarization session.

For each assistance condition, participants were instructed to stand still on the treadmill for 90 seconds before the treadmill was started at a speed of 4 km/h, a typical walking speed. Participants then walked for 6 minutes under each condition. After completing one condition, participants rested for 12 minutes to minimize the effects of fatigue before proceeding to the next condition. The order of the three conditions was randomized in each trial. Upon completing all conditions in a trial, participants rested for one hour before repeating the trial. Each trial was repeated three times in total.

B. Apparatus and Data Process

During the treadmill experiments, in addition to the sensors embedded in the exoskeleton, additional wearable sensors

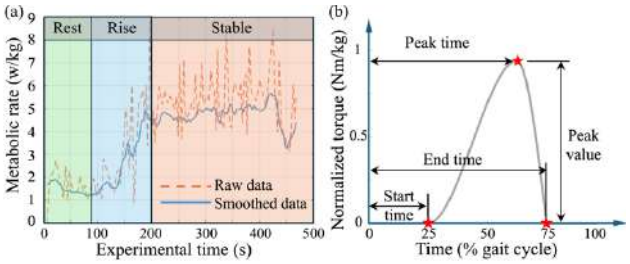

Figure 4. (a) Example of the test results from the respiratory mask in the treadmill experiment, (b) Torque profile applied during the experiment.

TABLE I. Subject Specific Information

Subject	Gender	Age(yrs)	Weight(Kg)	Height(m)
01	Male	22	84	1.83
02	Male	26	73	1.75

were utilized to assess the participants' walking performance. A respiratory mask (PNOE metabolic analysis system, PNOE, USA) was employed to measure the oxygen uptake (*VO2*) and carbon dioxide production (*VCO2*) rates. The metabolic consumption rate was indirectly estimated using an empirical model from [20], expressed by the following equation:

$$r = 16.58\,VO_2 + 4.51VCO_2 - 5.90N \qquad (2)$$

where *VO2* is the oxygen uptake in L/s; *VCO2* is the carbon dioxide production in L/s; *N* is the nitrogen in g; *r* is the metabolic rate in *W*. However, respiratory measurements often exhibit instability due to low sampling rates and delayed responses. As shown in Fig. 4(a), it typically takes 1–2 minutes for changes in physical activity to appear in respiratory gas readings, consistent with previous studies [19]. To address this, the sensor mask was calibrated before each experiment, and a moving average filter with a 20-sample window was applied to the collected data.

Two 64-channel high-density surface electromyography (HDsEMG) sensors (GR08MM1305, OT Bioelettronica, Italy) were placed on the lateral and medial gastrocnemius muscles, which are pivotal for ankle plantarflexion and easily accessible for activation monitoring. Before placement, the skin was shaved and cleaned to enhance signal quality. In accordance with SENIAM recommendations [21], each sensor grid was centered on the muscle belly with its long axis parallel to the fibers. Electrolyte paste was applied, and the grid was secured with double-sided tape and an elastic bandage for added stability during walking. EMG signals were recorded at 2 kHz and initially processed with a comb filter to remove 50 Hz power line noise and its six harmonics. The data were then band-pass filtered within a frequency range of 20–500 Hz. The envelope of each channel was computed using a Hilbert transform. For refinement, the envelope from the center channel and its eight neighbors were averaged. Finally, the resulting signal was smoothed with a 200-millisecond moving average filter.

C. Experimental Results

Metabolic cost is widely recognized as the gold standard

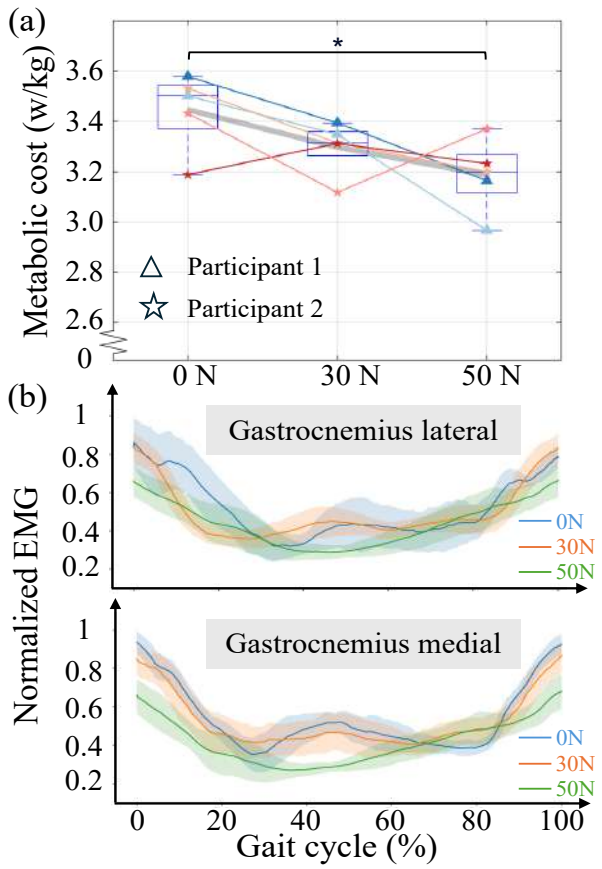

Figure 5. Treadmill experiment results under different assistance conditions: (a) metabolic consumption, (b) EMG intensity of the lateral and medial gastrocnemius muscles.

TABLE II. PEAK AND MEAN EMG VALUES OF LATERAL AND MEDIAL GASTROCNEMIUS MUSCLES UNDER DIFFERENT ASSISTANCE CONDITIONS

	Lateral		Medial	
	Peak	Mean	Peak	Mean
0N	1	0.5132	1	0.5357
30N	0.9189	0.4902	0.9529	0.5202
50N	0.7562	0.4361	0.7771	0.4153

for evaluating walking economy [22]. The metabolic cost under different assistance conditions is presented in Fig. 5(a), representing the increase in metabolic cost during walking relative to baseline standing. The resting metabolic rate was averaged over the first 60 seconds, while the active metabolic rate during walking was calculated over 250–400 seconds. Values were normalized to each participant's weight for comparison. Triangles and stars in Fig. 5(a) indicate data for different participants, with one trial for Participant 2 excluded due to equipment issues, leaving two valid data sets. The measured metabolic cost was 3.45 ± 0.15 W/kg for no assistance, 3.30 ± 0.11 W/kg for 30 N assistance, and 3.19 ± 0.15 W/kg for 50 N assistance. Compared to no assistance, the metabolic cost decreased by 0.15 W/kg (4.35%) under 30 N assistance and by 0.26 W/kg (7.53%) under 50 N assistance. The reduction in metabolic cost became more pronounced with increasing assistance levels. An ordinary one-way analysis of variance analysis showed a statistically significant difference ($p < 0.1$) only between the 0 N and 50 N conditions, with no significant differences observed between other conditions.

The average EMG curves of the lateral and medial gastrocnemius muscles over one gait cycle under different assistance conditions are illustrated in Fig. 5(b). The gait cycle was segmented based on the peak EMG signals of the respective muscles, rather than the conventional heel strike events. Solid lines represent the mean EMG signals recorded from the two participants during a 1-minute interval (340-400 seconds), while shaded regions indicate standard deviations. EMG signals were normalized to the peak values under the no-assistance condition. As summarized in Table 2, both the lateral and medial gastrocnemius muscles exhibited reduced peak and mean EMG values with assistance when compared to the no-assistance condition. For the lateral gastrocnemius, EMG peak values decreased by 8.11% and 24.38%, and mean values by 4.48% and 15.02%, respectively. Similarly, for the medial gastrocnemius, peak values decreased by 4.71% and 22.29%, and mean values by 2.89% and 22.47%, respectively. These results indicate that higher assistance levels lead to greater reductions in muscle activation, demonstrating the enhanced effect of assistance.

IV. DISCUSSION

In this study, we present a biomimetic cable-driven ankle exoskeleton designed to provide plantarflexion assistance to the ankle joint. Through a series of benchtop tests and treadmill experiments, we validated both the actuation performance of the exoskeleton and its effectiveness in enhancing walking economy. Compared to existing designs [13][23], the proposed exoskeleton features a compact, lightweight structure, with each actuation unit weighing approximately 0.7 kg and a total weight (including the battery) of 4 kg. Powered by a BLDC motor coupled with a gearbox and lever mechanism, it can deliver a maximum assistive force of 500 N, achieving a high torque-to-weight ratio. The cascaded repetitive control system enables precise force control with an error margin of ±5%, eliminating the need for additional components such as clutch in [13]. Benchtop tests confirmed a force control bandwidth of 13.5 Hz under a 50 N load, far exceeding the 1~2 Hz typically required for human walking. To prevent cable derailment and slack, the spool groove was designed with a self-aligning cross-section, ensuring the cable automatically centers upon entry. Anti-slip flanges at the groove edges further enhance stability. To avoid slack without complex tensioning mechanisms [12][13], the controller applies a small tensioning force when the target torque is zero, maintaining consistent cable tension. Additionally, an integrated communication and sensing system improves motion perception, enhancing practicality in real-world applications.

To assess the exoskeleton's effectiveness in enhancing the walking economy, treadmill experiments were conducted using a respiratory mask and HDsEMG sensors for

quantitative analysis. Unilateral assistance was employed due to the availability of single-leg hardware, with plans for bilateral assistance. The results showed significant improvement in the walking economy, with higher assistance levels providing greater benefits. Remarkably, a 50 N assistance level achieved a 7.53% improvement in the economy with unilateral assistance. In comparison, a previous study [24] reported a 6.2 kg cable-driven ankle exoskeleton that achieved a 5.6% improvement under bilateral assistance. Our exoskeleton, weighing 4.2 kg, achieved a comparable 7.53% improvement with unilateral assistance. IMU data analysis confirmed that unilateral assistance preserved gait symmetry, as joint angle patterns remained consistent with no-assistance conditions. Combined with EMG results, these findings suggest that the metabolic cost reduction primarily stems from decreased muscle activation in the assisted leg. Given the inherent symmetry of walking, it can be inferred that bilateral assistance could potentially improve the economy by over 15%.

However, this study has several limitations. In the treadmill experiments, the maximum assistance level was limited to 50 N to ensure safety, which is considerably below the exoskeleton's designed maximum capacity. In future work, we plan to reinforce mechanical structures and components to safely explore higher assistance levels. Additionally, the treadmill experiments involved only two participants and were conducted at a fixed walking speed of 4 km/h. This small sample size and single walking condition may introduce variability and limit the generalizability of the findings. To address these, future studies will recruit more participants, explore a broader range of walking conditions, and incorporate overground walking experiments to improve the reliability and applicability of the findings. Although this study did not include EMG measurements of the non-assisted leg, we recognize the potential value of such data in understanding compensatory mechanisms and will consider incorporating these measurements in future research. While the current exoskeleton is relatively lightweight, future iterations will aim to further reduce its weight through structural optimization and the use of lighter materials. Additionally, expanding the exoskeleton to assist multiple joint movements simultaneously will be considered in future work.

V. Conclusion

In conclusion, we present a biomimetic cable-driven ankle exoskeleton designed to provide plantarflexion assistance to the ankle joint. Experimental results demonstrated that even with unilateral assistance, the device effectively improved walking economy by 7.53%.

A Qualitative Exploration of EMG Visual Feedback for Spinal Cord Injury Rehabilitation*

Janelle Aikens, Aaron Tabor, Kevin Englehart, *Fellow, IEEE*, Erik Scheme, *Senior Member, IEEE*

***Abstract*—Sustaining motivation during hand function rehabilitation after a Spinal cord injury (SCI) can be challenging, particularly when natural movement feedback is impaired. Augmented feedback, such as through visual feedback of electromyography (EMG) muscle activity, may support motor (re-) learning and user motivation, but its impact on SCI rehabilitation remains underexplored. This study involved the design of an EMG-based visual feedback tool and an exploration of its suitability in rehabilitation and potential impact on user motivation. Using a qualitative approach informed by Self-Determination Theory (SDT) and a custom-developed EMG visualization interface, data were collected through semi-structured interviews with five quadriplegic participants and a focus group with seven occupational therapists (OT). Findings revealed that EMG visual feedback functions as an extrinsic motivator, providing tangible progress indicators, and has the potential to enhance intrinsic motivation by fostering enjoyment and aligning with personal interests. Themes highlight EMG feedback's potential in various rehabilitation contexts, from pre-functional muscle awareness to improved patient-therapist communication, offering a promising tool for advancing SCI rehabilitation.**

***Keywords*—EMG, electromyography biofeedback, visual feedback, spinal cord injury, rehabilitation, motivation**

I. Introduction

Spinal cord injuries (SCI) can result in significant impairments in movement, sensation, and visceral functions below the level of injury. Rehabilitation aims to re-learn muscle control and enhance mobility and independence but requires substantial effort and motivation [1], [2], [3], [4]. Because of the nature of these injuries, natural movement feedback—like visual coordination and proprioception (the sense of body position)—is often impaired.

Due to this impaired ability to receive natural feedback during movement, individuals with SCI may benefit from augmented feedback mechanisms that provide external sensory cues, such as visual or auditory signals, to compensate for this loss. By allowing individuals to "see" or "hear" their movement efforts in real-time, augmented feedback can help restore part of this essential feedback loop [5]. This not only plays a role in motor learning and the underlying mechanisms of neuroplasticity but also plays an integral role in driving and sustaining the learner's motivation [6].

Among augmented feedback modalities, visual feedback of muscle activity is widely recognized [7], [8]. In this type of feedback, electromyography (EMG) signals produced by muscle contractions are recorded and used, translating even subtle movement intentions into visual data.

Existing research, however, has predominantly focused on post-stroke patients, employing traditional methods that rely on muscle signals from single muscles or pairs, which presents challenges when working with populations with limited voluntary muscle activation. Although post-stroke studies have shown positive outcomes, such as improved hand function [9], enhanced EMG signals [10], and reduced spasticity [11], similar studies in SCI remain inconclusive [12], [13], [14]. Therefore, this study investigates how diverse forms of EMG-based visual feedback could influence motivation and support hand-function rehabilitation in individuals with SCI.

II. Methods

A. Study Design and Setting

This qualitative descriptive study was conducted in New Brunswick, Canada, involving participants recruited from a local rehabilitation center. The EMG feedback tool was developed through an iterative process, incorporating clinician input to refine its functionality and usability. After a pilot session with a patient participant, a focus group and individual interviews were conducted to explore user experiences. All participants provided informed consent as approved by the research ethics boards of the rehabilitation center (#2023-3284) and the University of New Brunswick (#2023-139).

B. Study Tool

The EMG Visualizer App is a Python-based desktop application that leveraged early features of the now open-source library LibEMG [15]. It was designed to enable the real-time exploration of EMG signals streamed from the Myo Armband (Thalmic Labs) in various formats. Its core functionality includes multiple visualization options such as time-series graphs, signal amplitude bars, and multi-channel muscle activity indicators for the forearm. Users can also record trials representing different motion classes (e.g. wrist flexion or hand open) to enable more pattern-based explorations of contractions and muscle synergies. Fig 1. illustrates some of the available screens. Key features include real-time signal smoothing, a snapshot of activation history from the most recent repetition ("max bar"), and adjustable y-axis scaling for enhanced focus on smaller signals.

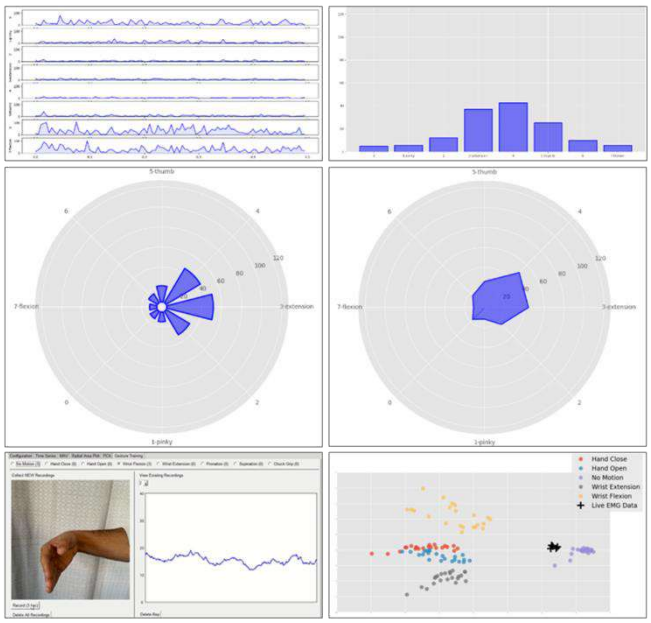

Fig. 1 Examples of the EMG data representations explored (from left to right, top to bottom): EMG time-series; Signal amplitude (MAV) bars; MAV radial bars; Radial area; Self-paced screen-guided training; and PCA-projected feature space.

C. Data Collection

1) Focus Group

Seven occupational therapists (OT) from a local rehabilitation center participated in a 1.5-hour focus group. The group included six females and one male (ages 22–56) with 2–20 years of experience. Four had no prior exposure to visual feedback, and three had limited experience. The discussion, guided by pre-determined questions, focused on motor learning, feedback interpretability, and potential use cases. Participants viewed a brief presentation featuring pilot EMG session excerpts before the discussion, which was audio-recorded and facilitated by the principal investigator (PI) with research team support.

2) Semi-Structured Interviews

Five male participants with quadriplegia (Table 1) were recruited through the participating OTs. Sessions included a guided exploration of EMG visualizations and a flexible interview and the audio, video, and screen were recorded. Interviews explored how EMG visual feedback could influence motivation, along with usability and general user feedback. Example questions included: *What motivates you in rehabilitation and how has it changed over time? What is challenging about understanding what's happening in your muscles since your injury? What were your thoughts on the amount of information on the screen? How would you describe your experience with the visualization—did you feel in control of it, or did it feel more like passively watching a screen? How do you feel about the idea of using visual feedback independently at home? What would make it useful or challenging for you? In what ways do you think a tool like this could impact your communication with your therapist? Can you think of any specific scenarios where it would be helpful?* The patient sessions were conducted with the PI and an OT present.

a) Patient Session Protocol

The Myo Armband was placed around the participants' upper forearm of their choice. Participants were prompted through verbal and visual cues to perform various forearm muscle contractions and hand movements while interacting with different EMG visualizations displayed on a monitor. Each EMG session lasted approximately 1.5 to 2 hours.

D. Data Analysis

Audio recordings were transcribed using Whisper [16], an AI-based audio-to-text software, run on a local server and manually deidentified. Transcripts were checked against the recordings for accuracy and coded by a single researcher. Thematic analysis was conducted following the six phases outlined by Braun and Clarke [17], employing both inductive and deductive approaches. Video and screen recordings were included in the analysis. NVivo software version 14 was used to manage data.

1) Establishing Trustworthiness

To ensure trustworthiness in this qualitative study, we applied the criteria outlined in [18]: credibility, dependability, confirmability, and transferability. Credibility was achieved through pilot interviews, expert-reviewed interview guides, verbatim quotes, and data triangulation. Dependability was ensured by providing a detailed study protocol and following the six phases of thematic analysis. Confirmability was supported by a rich description of methods and data triangulation. Transferability was addressed by collecting demographic information, offering a detailed context description, and using purposive and convenience sampling.

2) Theoretical Framework

This study is grounded in the Self-Determination Theory of Motivation (SDT) [19], a framework well-suited for exploring various behaviors in individuals with SCI, including participation in daily and social activities [20], engagement in physical activity [21], goal setting during rehabilitation [22], and health-related motivational processes [23]. SDT posits a continuum of motivation, ranging from amotivation (absence of intent), through extrinsic motivation (driven by external factors), to intrinsic motivation (driven by inherent satisfaction and enjoyment), with distinct regulatory styles influencing behavior along this continuum [19].

III. Findings

Our analysis identified multiple themes, organized into two broad categories: A) Motivation Along a Continuum, and B) Use Cases and Considerations.

A. Motivation Along a Continuum

In our study, EMG visual feedback functioned as an extrinsic motivator by providing tangible evidence of progress and clear benchmarks to work toward. At the same time, it demonstrated the potential to enhance intrinsic motivation by fostering enjoyment and aligning with personal interests.

1) Tangible Evidence as a Source of Hope

EMG visual feedback has the potential to provide participants with emotional reassurance by offering tangible

evidence of muscle activity, which could instill hope and encourage continued effort in rehabilitation. For some, it could be a powerful source of hope. P2 shared: "*If I could see [the visual feedback] moving a little bit, I could see [my muscles are] firing [...] [and they have the] possibility to improve*." Similarly, P1 noted that seeing a signal on the screen, even when physical sensation was absent, could provide reassurance: "*If I'm contracting and didn't feel my arm, seeing that there is a signal would be super positive*." A clinician in the focus group emphasized the value of objective data in sustaining motivation:

> *Something cool about this is you have concrete data... You may not see the difference looking at your hand [or it may not] feel like a huge difference, but objectively you have progressed.*

Conversely, the absence of feedback has made it harder to stay hopeful. P5 shared, "*When you don't know you have it, it makes it difficult [...] I'm not getting any feedback. I'm not getting encouragement*."

These insights suggest that real-time EMG feedback could serve as a powerful tool to validate patient efforts, rekindle hope, and support emotional resilience, which may enhance engagement in rehabilitation activities.

2) Thresholds, Numerical Markers, and Personal Bests

EMG visual feedback could also offer motivational benefits by enabling patients to track concrete, measurable progress. P3 explained that visualizing improvements, such as increased signal amplitude, could motivate patients more effectively than vague encouragement: "*It's a tool that therapists could use to motivate people to work [...] harder than just saying, 'if we do this, something may happen*.'"

Thresholds and numerical markers in EMG feedback can be powerful motivators by providing clear, measurable targets, and fostering both extrinsic and intrinsic motivation. These features turn rehabilitation exercises into structured tasks with defined goals, promoting focus and engagement. Before the max bar threshold feature was introduced, participants recognized its potential. A focus group member suggested, "*Even having a threshold of where they should achieve [...] if they had a threshold or a goal that you could change and vary*." P1 found the max bar threshold meaningful, saying, "*There's something for me to get at. For those lines to mean something to me*." Similarly, P3 stated, "*I like working towards an achievable, visual goal*." By offering adjustable goals and visual benchmarks, EMG feedback provides extrinsic motivation, helping users stay focused on incremental progress and surpass established targets.

Incorporating personal challenges, such as surpassing previous results or achieving personal bests, further enhanced motivation. P5 found excitement in outperforming his own results, sharing, *"It motivated me to try to beat what I was seeing on the screen."* He went on to say:

Similarly, P2 enjoyed the aspect of self-competition, stating, *"I like storing your high score. And beating your high score."* P3 echoed these sentiments, appreciating how visual goals made the exercises more satisfying. These insights suggest that EMG feedback systems designed with thresholds, numerical markers, and self-competition features can inspire both extrinsic motivation through structured goals and intrinsic motivation by fostering personal mastery and enjoyment.

> *When you told me there were numbers, I was way more motivated, like, 'Oh, so I'm only at a 50? Well, give me a week, and I'll show you—I'll be at 60.'* (P5)

3) Enjoyment

A key aspect of intrinsic motivation is the enjoyment derived from the activity itself. In this study, P4 expressed excitement when engaging with the real-time visual feedback: "*Just to see that play out in front of me, like see all the waves in real time, that's exciting enough for me*" (P4). The real-time nature of the feedback provided a tangible connection to his efforts, making the activity enjoyable.

Similarly, P3 contrasted exercises with and without visual feedback, describing the latter as tedious and unengaging while the former made him enthusiastic about participation: "*It's black and white. You know, it's 180 degrees. I hate doing that. I like doing this*." Even repetitive tasks sometimes led to states of flow. For instance, P3 completed 20 repetitions of an exercise while exclaiming, "*Yeah, that's incredible*," as the research team noted his sustained energy and motivation throughout the task.

4) Aligning with Personal Interests

Intrinsic motivation is closely tied to personal interests and values. When rehabilitation tools aligned with participants' interests, they found greater motivation to engage. For example, P2, a sports enthusiast, likened the EMG feedback system to sports data analytics, describing how it resembled baseball pitching trends and provided a similar sense of feedback and progress. He explained, "*It kind of gives you that feedback of what spot you're hitting and how you're getting there.*" These personal connections underscored how tailoring rehabilitation tools to individual preferences can enhance engagement.

A. Use Cases and Considerations

In our exploration, we identified several use cases where this tool shows promise and important factors to consider.

1) Pre-Functional Muscle Awareness

EMG visual feedback has the potential to be used in helping patients recognize sub-functional muscle activity and fostering muscle awareness, particularly in the early stages of rehabilitation.

TABLE 1. SCI PARTICIPANT DEMOGRAPHICS

ID	Age	Sex	Lesion Level	Lesion Classification	Years since injury	Hand used	Experience with VF (1-5)[a]
P1 (pilot)	46	M	C4	Incomplete[b]	10	R	1
P2	51	M	C2	Motor Incomplete	2	R	1
P3	50	M	C5	Complete	17	R	1
P4	58	M	C4	Motor Incomplete	2	L	1
P5	46	M	C5	Motor Incomplete	27	R	2

a. Level of experience with visual feedback (VF) of EMG activity on a scale of 1 to 5. 1 = no experience and 5 = highly experienced. b. Lesion classification undetermined

A clinician highlighted how visual feedback could support patients when functional tasks are still unattainable:

> *I can picture it being helpful [during] that hard time when someone first comes in [and] can't do anything functional yet, just trying to [build] awareness of when they're activating what and they're frustrated.*

By providing real-time insights into muscle activation, EMG feedback may motivate patients by making even minimal progress visible, reinforcing the value of small achievements in their rehabilitation journey.

2) Muscle Isolation

Visual feedback demonstrated potential in helping participants isolate specific muscle groups during exercises, addressing a common challenge in traditional rehabilitation. A clinician described the difficulty of isolating muscles during therapy:

> *Getting them to see if they're activating the wrong thing and fighting themselves, I find really challenging... I don't think I ever found a way to get some visual feedback on that besides looking at their hand.*

P1 struggled with co-contraction of opposing forearm muscles during wrist extension, limiting his movement. The study team asked him to extend his wrist while monitoring the visual display of muscle activity. The Study OT instructed, "*Look at the flexion bar and try to extend your wrist while keeping it low*." This feedback helped P1 relax his flexors during wrist extension. Reflecting on the experience, he shared: *"There's feedback. I had no idea that [points to forearm] this was a thing."* For participants like P1, real-time feedback highlighted unintended co-contractions, allowing them to make corrective adjustments and refine their muscle control. As P1 explained:

> *I liked the isolation [pointing to the MAV bars] to work on what you want me to work on and relax when I'm supposed to relax. Otherwise, I'd probably still do the same bad habit... using both my muscle groups instead of what I'm supposed to use. (P1)*

3) Spasticity Management

Spasticity management is a significant challenge for individuals with SCI, and visual feedback of muscle activity could be a valuable tool for both patients and therapists. The study OT noted, "*The thing about muscles firing at the same time, especially with spasticity, [it] is such an incredibly difficult concept to understand*." A clinician added, "*Spasticity [management]... we spend a lot of time doing that [...] It's [that] they're over-recruiting*." A visual feedback tool could help identify where spasticity persists and guide interventions.

Patients often struggle to determine if they are successfully relaxing their muscles. For example, P1 expressed frustration, saying, "*Yes, [I'm asked to relax] all the time, but my muscles don't relax. At least I don't think [they] do*." Seeing the feedback gave P1 clarity, reinforcing that muscle relaxation is achievable and measurable: *"So seeing that feedback happen is definitely a lot more helpful than me guessing whether this is relaxed or not*." EMG feedback could help address spasticity-related challenges in identifying muscle activation, leading to more effective strategies for relaxation.

4) Informing Clinical Decisions: Breaking Tenodesis Grip

Deciding when to break the tenodesis grip in SCI rehabilitation is a critical and nuanced decision for therapists. Tenodesis grasp is a technique used to create a passive grip by extending the wrist, causing the fingers to bend towards the palm. This grasp is essential for patients with certain levels of SCI who lack the muscle strength for an active grip. In these cases, avoiding overstretching of the fingers is important. However, if muscle strength returns, there may come a point in the rehabilitation process when patients could grasp naturally, prompting a discussion about whether to break the tenodesis grasp:

> *We often have talks about when clients need to break their tenodesis or not. So, I wondered if we had visual feedback to know, 'okay, there's a muscle group waking up, but because they're using their tenodesis, we are not breaking it'.*

This tool could offer a more precise understanding of whether a patient's muscle activity is strong enough to shift from a passive grip to an active one, potentially allowing them to make more informed decisions.

5) Focused Rehabilitation and Remote Monitoring

In rehabilitation, particularly when patients are sent home with exercises, compliance and oversight become crucial elements of ensuring progress. Visual feedback tools could enhance rehabilitation by providing structured protocols and enabling oversight during home exercises. A therapist emphasized its potential:

> *If they have visual feedback, we could coach them and say, 'This is exactly what we want the screen to look like when you're trying to activate your wrist.'*

Participants also appreciated the potential to track progress and connect with their OT remotely. P5 envisioned:

> *Say we weren't together, but somehow you could connect [through the EMG feedback system] like, 'Hey, can I check in on your strength? How have you been doing?' (P5)*

This remote monitoring could reduce in-person visits while maintaining engagement. By setting thresholds for home exercises, therapists could ensure patients adhere to proper techniques, even outside the clinic. The benefits extend beyond compliance. Visual feedback offers insights into patient performance that verbal reporting cannot capture. One therapist noted:

> *You could look at this as a therapist and say, 'You did your homework, but this really didn't go well,' which that's not the insight you always get.*

6) Improved Patient-Clinician Communication

Some participants recognized that visual feedback tools could improve communication with therapists. P3 noted that such tools would help articulate bodily sensations during rehabilitation, enabling more precise discussions about progress and challenges. He explained:

> *Yeah, I could explain what's happening... '[sensor] number 5 is working more than number 4, and that's not the way I want it' [...] you could articulate more what the problem was and what your goals were. (P3)*

P1 echoed similar sentiments, describing how visual aids could make it easier to communicate his experiences to healthcare professionals. He said:

> *It would be much easier because instead of me trying to figure things out on my own and trying to convey that information to the doctor or to physio. (P1)*

These insights suggest that visual feedback could help bridge communication gaps and strengthen therapeutic relationships by fostering a shared understanding between patients and therapists.

7) Feedback Modalities and Focus Strategies

In SCI rehabilitation, various feedback modalities, including visual, tactile, and auditory, offer distinct benefits depending on the patient's condition and task. Visual feedback, such as real-time muscle activity on a screen, is useful but may not always be ideal, especially for patients with functional movement. As a focus group member noted, patients who had functional control of their limb may prefer focusing on their limb rather than a screen: "*If someone is functional or they're expecting some functional [movement], their focus is gonna be here [on their limb], not on the screen.*" Similarly, P1 found actual limb movement more effective than screen-based feedback: "*Seeing the actual action happen... would probably be better feedback than seeing the numbers [on a screen].*"

Tactile feedback plays a critical role in helping patients locate and activate specific muscles. P5 shared that physical touch greatly improves his ability to fire muscles that are harder to engage:

> *I get way better reaction. You rubbed your finger over the inside of my arm [and] as soon as someone triggers that my brain's like, 'ohh' there's where it is. (P5)*

Tactile feedback serves as a reminder, helping patients identify the correct muscle pathways and improve activation. P5 described this as "pathfinding," where physical touch aids in locating and firing the intended muscle. Similarly, P3 found it helpful when the experimenter placed a finger on the back of his wrist during an exercise, saying, *"It gave me a focus."* This subtle input helped him direct his attention more precisely, improving control.

Auditory feedback can complement visual focus, providing simultaneous guidance, especially for patients who struggle with movement awareness. As one therapist explained, *"Some people do not have great insight into what their movement is like... [with] auditory feedback, they can do both at once."*

For some patients, visual feedback can hinder relaxation, particularly when they need to engage internal sensations for muscle activation. P5 found closing his eyes helped him focus on muscle recruitment without visual distractions: *"If I shut my eyes, it's mostly pathway finding... it helps me channel to silence everything else and completely focus."* P5 also found visual feedback frustrating when it interfered with relaxation: *"Watching it made me intently focus on trying to calm it down, which is probably the opposite of what [my muscles] needed."* Similarly, P3 preferred closing his eyes, saying, *"Each time you do it, you can kind of hone in on it a little more precisely."* Too much feedback, whether visual or otherwise, can overwhelm patients and detract from the rehabilitation goal. P3 noted:

> *With just the two [channels of feedback], I was less prone to close my eyes because I wasn't being overwhelmed with all of the information. (P3)*

8) Functional Movements in Occupational Therapy

In discussions with OTs, it was reiterated that functional movements are a primary focus in occupational therapy, with the goal of helping patients regain the ability to perform daily tasks. In contrast, during our sessions with EMG feedback, participants were often directed to focus on specific muscle groups, such as their wrist "flexors", rather than engaging in functional tasks like reaching for a bottle. P1 reflected, "*I've never been told to focus on a specific muscle group if I'm doing an [exercise]. It's always been like 'pick the blocks up.*'" This highlights a potential gap between what clinicians focus on and what the current EMG visual feedback system may be able to reinforce. As seen in our findings, our tool has the potential to support functional recovery by targeting subtasks such as muscle isolation and improved synergies—key elements essential for most functional movements. However, aligning the protocol gestures more closely with everyday tasks could further enhance outcomes. There may be opportunities for more targeted interventions that connect functional tasks with the muscle activity required.

9) Importance of Clinician's Guidance

The study highlights the essential role of clinicians in the rehabilitation process, particularly in coaching patients using visual feedback systems for muscle activity. While technology can offer some independence, the clinician's presence is crucial for effective learning and muscle control. For example, during a session with P3, the OT used verbal cues and physical guidance, such as visualizing flexor muscles as a "loose rubber band" and extensor muscles as a "tight rubber band." This coaching technique helped P3 better understand muscle dynamics and improve his wrist extension. The therapist's tailored approach, based on the patient's needs, was key in enhancing muscle engagement and relaxation.

IV. Discussion

This study examined the impact of visual feedback of EMG activity on motivation and its role in supporting hand function goals in SCI rehabilitation. Our findings, in conjunction with literature from stroke rehabilitation, sports psychology, and gaming, provide deeper insights into the potential of EMG visual feedback in enhancing SCI rehabilitation outcomes.

A. Motivation Along a Continuum

Extrinsic motivation, driven by external rewards or feedback, plays a crucial role in SCI rehabilitation, particularly in the early stages when progress may be slow or difficult to perceive [24]. Our findings suggest that visual feedback has the potential to provide participants with tangible markers of muscle activity and progress. This form

of objective validation may help foster hope and reduce the risk of hopelessness and demotivation often associated with slow recovery [4]. Furthermore, our findings align with previous observations [4], emphasizing participants' preference for objective reinforcement over verbal positive feedback from clinicians. By offering concrete metrics of effort and improvement, feedback systems address the doubts and frustrations that may arise when verbal reinforcement is the sole source of encouragement.

Visual feedback systems can incorporate game-like features, such as progress markers and goal setting, to further enhance motivation—an approach supported by findings in both rehabilitation and gaming research [25], [26], [27]. For example, numerical feedback, like EMG signal amplitude, enabled participants in our study to set personalized goals akin to game mechanics, promoting engagement and fostering a sense of achievement.

Self-competition emerged as a particularly effective motivator. Participants were driven to surpass their personal benchmarks, demonstrating a strong desire for self-directed improvement. This aligns with sports psychology literature, which highlights the role of personal records in boosting self-efficacy, a critical factor for sustained effort [22], [28]. In our study, participants' enthusiasm for improving their scores underscored the importance of incorporating self-directed challenges into rehabilitation to maintain motivation and foster a growth mindset.

Research further suggests that optimal challenges—goals that are achievable but not overly easy—enhance feelings of competence, a central element of intrinsic motivation [19]. The visual feedback system introduced concrete challenges, such as regulating muscle activity and meeting strength thresholds, which maintained participants' engagement. By tailoring rehabilitation activities to the right level of challenge, the system not only has the potential to boost competence but also support long-term adherence to rehabilitation efforts [29].

Intrinsic motivation, driven by inherent enjoyment or interest, plays a critical role in long-term SCI rehabilitation. Studies emphasize its importance in healthcare, where intrinsically motivated behaviors contribute to better adherence and outcomes [19], particularly when visible progress plateaus and extrinsic rewards lose their impact [4]. While extrinsic motivation is crucial during the early stages of recovery, sustaining motivation in later rehabilitation stages requires individuals to find personal value in the process.

Our study found that visual feedback tools could enhance participant engagement and enjoyment, even during repetitive tasks. Although it is uncommon for individuals to inherently enjoy rehabilitation [4], these tools appear to bridge the gap between extrinsic rewards and intrinsic motivation by making the process more interactive and intrinsically rewarding. Participants noted that they were more motivated when rehabilitation activities aligned with their interests, reinforcing the idea that intrinsic motivation is heightened when activities hold personal significance [19], [30].

B. Use Cases and Considerations in SCI Rehabilitation

Rehabilitation following an SCI focuses on restoring muscle control to enhance mobility, with hand function playing a key role in quality of life [31], [32], [33], [34].

Participants in this study reported that visual feedback enhanced their muscle awareness by highlighting sub-functional muscle activity, such as minor wrist extensions. This type of feedback could foster motivation during early rehabilitation and support motor learning [6], [26], [35]. For individuals with impaired proprioception, visual feedback could compensate as a form of "sensory substitution," reinforcing the brain-body connection and anchoring neuroplastic processes through the "use it or lose it" principle to prevent functional decline [36].

The tool showed potential to aid in muscle isolation, addressing challenges in traditional rehabilitation. Minimizing co-activation has been shown to enhance motor function [37], [38], and participants in our study successfully reduced co-activation that hindered movement. Additionally, visual feedback could help manage spasticity by improving awareness of over-activation, enabling patients to adjust and work with therapists to refine muscle relaxation strategies. Research supports the effectiveness of EMG feedback in improving spasticity management and motor function in persons living with stroke [11].

The tool could also inform decisions about tenodesis grip, a technique enabling passive grip in SCI rehabilitation. EMG visual feedback provides insights into whether muscle activity is sufficient to transition from passive to active grip, aiding clinicians in modifying rehabilitation strategies [39].

Participants noted that EMG visual feedback could improve rehabilitation by enabling real-time progress tracking and exercise adjustments, promoting error correction and goal calibration. Our EMG feedback system uses abstract visualizations, such as lines or bars, that are effective for motor learning [7]. Participants also expressed interest in remote therapist check-ins, underscoring the value of tools that extend rehabilitation beyond clinical settings. Research demonstrates a positive correlation between therapy duration and clinical outcomes, with more sessions yielding greater recovery in stroke survivors [40]. Aligned with Activity-Based Therapy (ABT) principles—repetition, intensity, and task specificity—the EMG feedback tool supports neuroplasticity-driven rehabilitation and promotes habit formation and flexibility for home use [41], [42].

Furthermore, participants emphasized that visual feedback strengthens communication with therapists by enabling clearer articulation of challenges and progress, which fosters a therapeutic alliance associated with improved outcomes [43].

While EMG visual feedback shows promise in SCI rehabilitation, its integration requires consideration of individual preferences. None of our participants had prior experience with EMG feedback, emphasizing the need for a personalized introduction. Some may benefit from focusing directly on limb movements, while others may prefer visual, auditory (e.g., tones), or tactile (e.g., vibrations) feedback, or combinations of these modalities [7]. Tailoring feedback to individual needs could optimize outcomes.

In SCI, where sensory and motor impairments limit proprioceptive feedback, visually observing the limb becomes crucial. Internal Focus of Attention (IFA), where individuals focus on their movements and sensations, can enhance muscle awareness, but excessive reliance on IFA may hinder performance [44]. While IFA can be beneficial in certain contexts, such as increasing awareness of muscle activation, excessive reliance on this focus may hinder motor performance and learning [44]. Van Vliet & Wulf [44] suggest that an External Focus of Attention (EFA), concentrating on the effects of one's movements on the environment, improves task performance, highlighting its relevance in SCI rehabilitation. In our study, participants with more functional movement preferred observing their limbs directly, while those with greater motor impairment found EMG feedback more useful, suggesting that feedback should match individual impairments and preferences.

Auditory feedback, such as tones, can help patients track muscle activity without solely relying on visual cues, though it may be distracting for some [45]. Tactile feedback, such as vibration, has also been reported to enhance muscle recruitment and focus, supporting its potential as a complementary modality alongside visual and auditory feedback.

Functional recovery, particularly in gripping and dexterity, is a core goal of SCI rehabilitation [46]. While our EMG feedback tool focused on basic movements, such as wrist flexion, extension, and hand opening, these movements are vital for restoring function. A strength of the tool was its ability to visualize antagonistic muscle pairs, helping participants refine control and isolate muscles. Aligning the gestures more closely with everyday tasks could further improve outcomes. Future versions could allow customization, enabling clinicians to tailor exercises to functional goals.

Clinicians are crucial in helping patients use visual feedback systems effectively. While these tools promote independence, prescriptive feedback in the early stages is essential for progress [7]. In this study, the lack of prescriptive capabilities in the EMG feedback system required participants to rely on guidance from the research team, highlighting the importance of clinician support in maximizing the tool's effectiveness in SCI rehabilitation.

C. *Beyond Visualizations – Games and Device Control*

As an extension of visual feedback of EMG activity, EMG amplitude and patterns of activation can be leveraged to control a curser in a game environment or serve as input to assistive devices. Pattern-recognition techniques have shown promise in detecting and decoding movement intent from subfunctional muscle contractions, with successful applications in individuals with SCI [47][48]. Over the past decade, rehabilitation games targeting post-stroke populations have gained significant research attention due to their potential to boost patient motivation, enhance motor skills, and provide effective pain management through positive distraction [49][50].

V. Conclusion

This exploratory study highlights the significant potential of EMG visual feedback in enhancing motivation and supporting the rehabilitation of hand function in individuals with SCI. By expanding access to remote and cost-effective care, this technology has the potential to improve patient outcomes and provide essential early, intensive, and consistent rehabilitation.

Biplanar Ankle Assistance for Dropfoot Gait Post-Stroke with Multi-objective Human-in-the-Loop Optimization: A Case Study

Xiaochen Zhang[1], Axel Fredriksen[2], Susanne Palmcrantz[2], and *Elena M. Gutierrez-Farewik[1,3]

***Abstract*— Exoskeletons are frequently explored for their efficacy in rehabilitation and in assisting in daily activities in people with motor disorders, yet relatively few have convincing evidence for use, nor do many aim to personalize assistance for maximum benefit of each user. Here, we describe a cable-driven ankle exoskeleton that assists persons with dropfoot and excessive inversion after stroke. We propose a multi-objective human-in-the-loop optimization that simultaneously adjusts exoskeleton assistive profiles to minimize two independent gait quality indices: foot kinematics deviation and step length asymmetry. This optimization proposes, rather than a single solution, a group of solutions that minimize both indices. We present experimental findings from one participant with chronic stroke, specifically the feasibility of the device in assisting ankle motion in two anatomical planes, the resulting gait pattern and individualized optimal assistive profiles. Following the design goals, the exoskeleton improved the dropfoot and excessive inversion gait pattern; with the exoskeleton, the participant's foot inclination angle at initial contact increased from -2° to 10°, ankle inversion angle decreased from 2° to 0°, foot clearance during swing increased from 31 mm to 44 mm, and step length asymmetry decreased from 12% to 6%. The optimal solutions are an inventory of profiles from which the user can choose based on priorities. We believe the device and approach have a large potential in achieving individualized assistance.**

I. INTRODUCTION

Exoskeletons and exosuits for gait are developed with increasing frequency, with objectives often focusing on a single, albeit complex, criterion [1], e.g. strength augmentation, reduced target muscle activation [2], normalized joint kinematics, or reduced metabolic cost of transport [3]. Outcome and compliance, however, often depend on the user's perception and subjective experience [4]. Goals to improve gait quality, furthermore, often rely on an individualized approach [5] and on gait metrics that are of a more holistic nature [6], such as walking speed or symmetry. An approach that considers several gait metrics simultaneously may have to strike an optimal balance between different metrics.

The gait pathology in focus in this study is dropfoot, or the inability to dorsiflex the foot during swing and to position the foot for heel contact [7]. Dropfoot is a common secondary gait disorder after a stroke or other neurological injury that affects motor control. It is often accompanied by excessive subtalar inversion due to spasticity of the tibialis posterior [8]. Together, these symptoms can affect stability in stance and risk of falling [9]. Addressing these can vastly improve the quality of life and promote independence [10], [11] in the large post-stroke population. While exoskeletons have shown promise in improving mobility after stroke [11], existing devices largely focus on sagittal plane assistance, neglecting frontal plane malalignments that are also crucial for stability.

Thanks to approaches such as human-in-the-loop (HIL) optimization, significant progress has been made in recent years in customizing exoskeleton control [4], [12]. To date, these efforts have predominantly targeted non-disabled individuals; few attempts have been made to optimize exoskeleton control for individuals with motor disorders, leaving a critical gap in addressing the unique needs of this population. Furthermore, metabolic cost or muscle activity reduction has typically been the pre-defined physiological objective [13]–[15], whereas for people with motor disorders, performance metrics related to gait quality can be more relevant [16]. Evaluation of gait quality generally involves multiple, rather than single, outcome measures, including but not limited to temporospatial symmetry and kinematics of specific joints or segments.

We recently proposed a cable-driven ankle exoskeleton that can simultaneously guide the foot in the sagittal and frontal planes, and thereby increase foot clearance height and stabilize the foot and ankle in initial contact [17]. We also recently proposed a multi-objective HIL optimization to improve foot segment kinematics in swing and initial contact as well as step length symmetry and pilot-tested it on a group of nondisabled adults [18].

This paper presents a case study of one woman with chronic stroke and a dropfoot gait pattern, with aims to evaluate the exoskeleton's feasibility and effectiveness in two criteria: minimizing step length asymmetry and foot kinematic deviations in swing and initial contact. The key contributions presented in this study are as follows: 1) In a participant in the chronic phase after stroke and a dropfoot gait pattern, we demonstrated performance enhancements in two gait quality indices simultaneously, achieved through an ankle exoskeleton and multi-objective HIL protocol. 2) We introduce a flexible decision-making individualization framework that can tailor assistive solutions to individual goals and abilities.

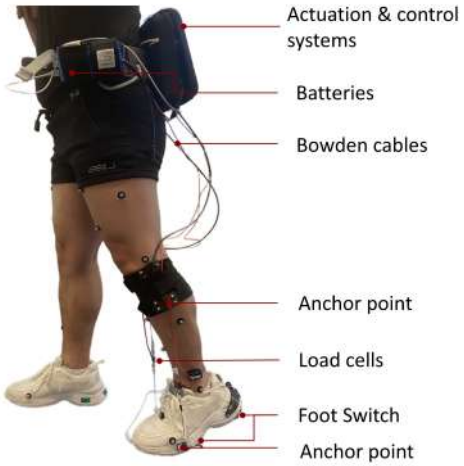

Fig. 1. The cable-driven ankle exoskeleton. The exoskeleton, designed to dorsiflex and evert the foot, consists of an actuation and control system, two Bowden cables that span to anchor points on the medial and lateral forefoot, textile components, and sensors.

II. MATERIALS AND METHODS

A. Device design and control

Our active soft ankle exoskeleton (Fig. 1) consisted of a waist unit, a calf wrap, a pair of shoes, cables, and sensors, with a total mass of 3.1 kg. The waist unit houses the actuation module, which consists of two brushless DC motors (Maxon, max torque 5.54 Nm), 3D printed pulleys, and Bowden cables with a maximum retraction force of 396 N. A microcomputer (Raspberry Pi 4B) controls the actuators by sending control signals to motor drivers, and can be monitored and controlled remotely. Encoders mounted on the motors monitor motor positions. Each Bowden cable is aligned in series with a load cell (Futek) and amplifier, which measure cable tension and transmit values to the controller. The two Bowden cables span distally to the shoe via anchors on the medial and lateral sides of the calf wrap, to hooks in the medial and lateral shoe forefoot. A set of foot switches (Cometa), with 4 force sensitive resisters under each foot detect foot-floor contact. Movement information is extracted from sensors, the microcomputer sends control signals to the motor drivers, and the actuators are driven to follow the control profiles.

In the high-level controller, the foot switch information is used to identify the stance and swing phases. In the mid-level controller, assistance profiles are generated as two parameters – t_p: the combined torque generated by two motors, and r_{lm}: the torque ratio between lateral and medial motors, wherein a larger ratio results in more cable tension on the lateral than the medial side. Ramp ascent and descent timing of the current profiles were based on swing phase duration and were the same for both motors. The low-level controller drives the motors to follow the assistive profiles defined by the mid-level controller precisely.

B. Multi-objective HIL optimization protocol

We integrated a multi-objective optimization algorithm into the HIL protocol to identify exoskeleton assistive profiles, defined by [t_p, r_{lm}], with two objectives: improving segment kinematics and enhancing overall performance.

1) Variable and constraints: Two variables, the sum of the torque magnitude of the two motors t_p and the torque ratio between lateral and medial motors r_{lm}, determined the assistive profile, and were set to 57 ± 12 Nmm/kg and 1.15 ± 0.1, respectively.

2) Multiple objective functions: Two independent gait quality metrics were minimized in the optimization approach; 1) deviation of paretic side foot segment kinematics compared to nonparetic side, characterized by two parameters: foot inclination angle in the sagittal plane at initial contact and foot clearance height during swing, as per Eq. 1, and 2) minimal step length asymmetry, as per Eq. 2.

$$\mathrm{Dev}_{\mathrm{foot}} = \left(\left|\frac{\alpha_{\mathrm{p}} - \alpha_{\mathrm{np}}}{\alpha_{\mathrm{np}}}\right| + \left|\frac{H_{\mathrm{p}} - H_{\mathrm{np}}}{H_{\mathrm{np}}}\right|\right) \times 100\% \quad (1)$$

$$\mathrm{ASI}_{\mathrm{SL}} = \left|\frac{L_{\mathrm{step,p}} - L_{\mathrm{step,np}}}{0.5 \cdot (L_{\mathrm{step,p}} + L_{\mathrm{step,np}})}\right| \times 100\% \quad (2)$$

where $\mathrm{Dev}_{\mathrm{foot}}$ is the deviation index of the foot's kinematics of the paretic side compared to the non-paretic side, α_{p} and α_{np} are the foot inclination angle at initial contact for paretic and non-paretic sides, respectively, in the sagittal plane, H_{p} and H_{np} are the clearance height of the paretic and non-paretic feet during swing, $\mathrm{ASI}_{\mathrm{SL}}$ is the step length asymmetry index, $L_{\mathrm{step,\,p}}$ and $L_{\mathrm{step,\,np}}$ are step length of paretic and non-paretic sides [16], [19], defined as the distance between the ipsilateral and contralateral heel marker at initial contact in the direction of walking.

3) Optimization algorithm: A non-dominated sorting genetic algorithm II (NSGA-II) was used for multi-objective optimization in the HIL framework. Three generations, each comprising 10 assistive profiles constrained by t_p and r_{lm}, were tested, with crossover and mutation rates set to 0.7 and 0.3, respectively.

C. Participant

One participant with chronic stroke, a 47-year-old woman, 159 cm, 73 kg, participated in this study. Her left side was affected following a stroke nearly 5 years previously. She habitually used an AFO but could walk without it. Her Fugl-Meyer Lower Extremity scores were 25 (out of 34) for motor function and 9 (out of 12) for sensory function. She presented with spasticity according to the Modified Ashworth Scale of 2 in the rectus femoris, 2 in the soleus, and 0 in the gastrocnemius. Her dorsiflexion passive range of motion was -2 degrees, with the knee extended. The Swedish Ethical Review Authority granted approval for this experiment (Dnr. 2023-02891-01). The participant provided informed written consent before the experiment.

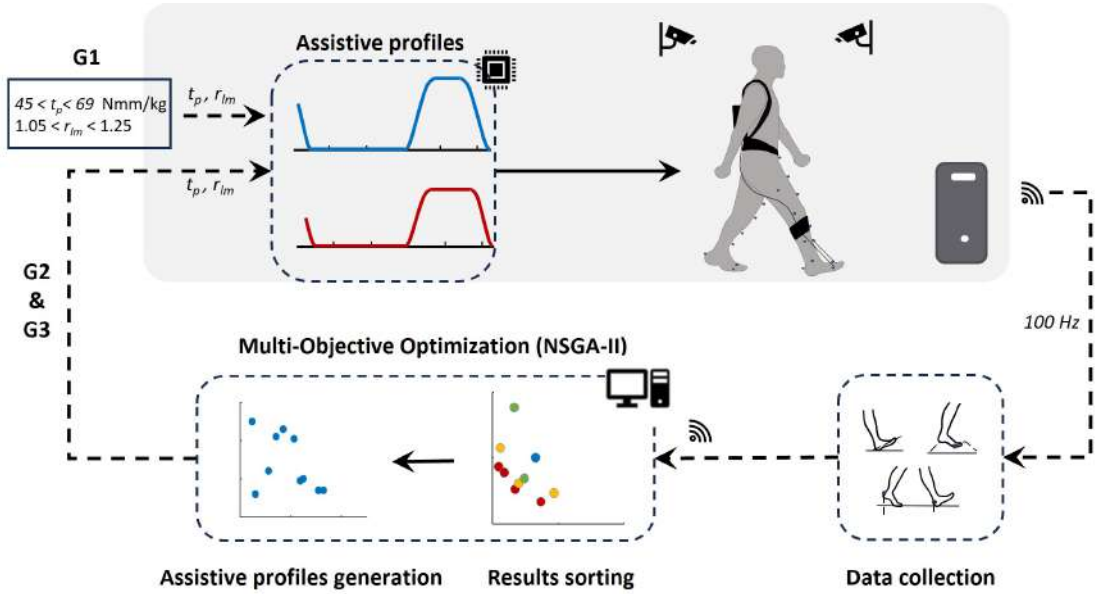

Fig. 2. The experimental setup for multi-objective HIL optimization. The participant underwent three generations of assistance trials, each consisting of two 10-meter trials. Kinematic and spatiotemporal parameters were collected by the motion capture system, and the two optimization functions were computed - deviation of foot segment kinematics and step length asymmetry. NSGA-II was used to sort the assistive profiles after each generation, and new assistive profiles were generated for the subsequent generation.

D. Experiments

The experiment was conducted in the Promobilia Move-Ability Lab, in overground walking along a 10-meter walkway. Markers were placed on the lower extremity and trunk according to a common model (CGM 2.4) and their trajectories were captured with a 10-camera motion capture system (Vicon V16, UK) at 100 Hz.

Equipped with markers, the participant walked at her preferred speed in the following conditions:

- NoExo: walking with regular shoes, e.g. no exoskeleton or AFO, to establish the participant's baseline gait.
- Familiarization: The participant donned the exoskeleton and walked with it for 20-30 minutes, during which several different assistive profiles were randomized. No specific instructions about modifying the walking strategy were given, so that the participant could respond naturally to the device.
- UnpowExo: The participant wore the exoskeleton unpowered and with the cables detached, to evaluate the effect of donning the exoskeleton but independent of active assistance or passive device resistance.
- PowExoHIL: The participant walked with the powered exoskeleton, through 3 generations of ten assistive profiles each and HIL optimization.

For Generation 1 of PowerExo, the range of assistance profiles was constrained to: $45<t_p<69$ Nmm/kg as per suggestion [10] and $1.05<r_{lm}<1.25$, with a uniform distribution. A 1-minute interval for rest was provided between different profiles. Immediately after Generation 1 experiments, the two objective functions (Eq. 1 and Eq. 2) were computed from all solutions in the generation. The NSGA-II algorithm sorted the objective function results into multiple fronts, wherein the Pareto front represents the optimal solutions for this generation. It then generated a new set of assistive profiles, subject to the same constraints for t_p and r_{lm}, which formed Generation 2. This process was iterated again, and the experiment concluded after Generation 3.

After the experiment, the participant answered the Quebec User Evaluation of Satisfaction with Assistive Technology 2.0 (QUEST 2.0) [20] pertaining to the device's dimensions, weight, stability and security, comfort, and effectiveness. The answers were given on a 5-point scale, with 5 indicating "very satisfied," and 1 indicating "not satisfied at all," so that a grade of 1-2 can be defined as negative, 3 as neutral, and 4-5 as positive.

III. Results

During the HIL optimization, the solutions progressed towards better gait quality metrics, specifically lower foot segment deviation and step length asymmetry. (Fig. 3), wherein both indices converged towards 0. The solutions from Generation 3 on the Pareto front can be seen as the optimal solutions for this participant and these two defined optimization criteria.

Compared to NoExo, with the PowExoHIL optimal solutions, the ankle joint kinematics were normalized; a first/heel rocker occurred after initial contact, and the ankle was in dorsiflexion throughout the stance. The key gait metrics improved; at initial contact, the foot inclination angle increased from -2° to 11°, and the ankle inversion angle decreased slightly from 2° to around 0°. Foot clearance height in swing increased from 31 mm to 43 mm, and step length asymmetry reduced from 12% to 6%.

We also observed slight differences between the NoExo and UnpowExo conditions, indicating that the structure itself

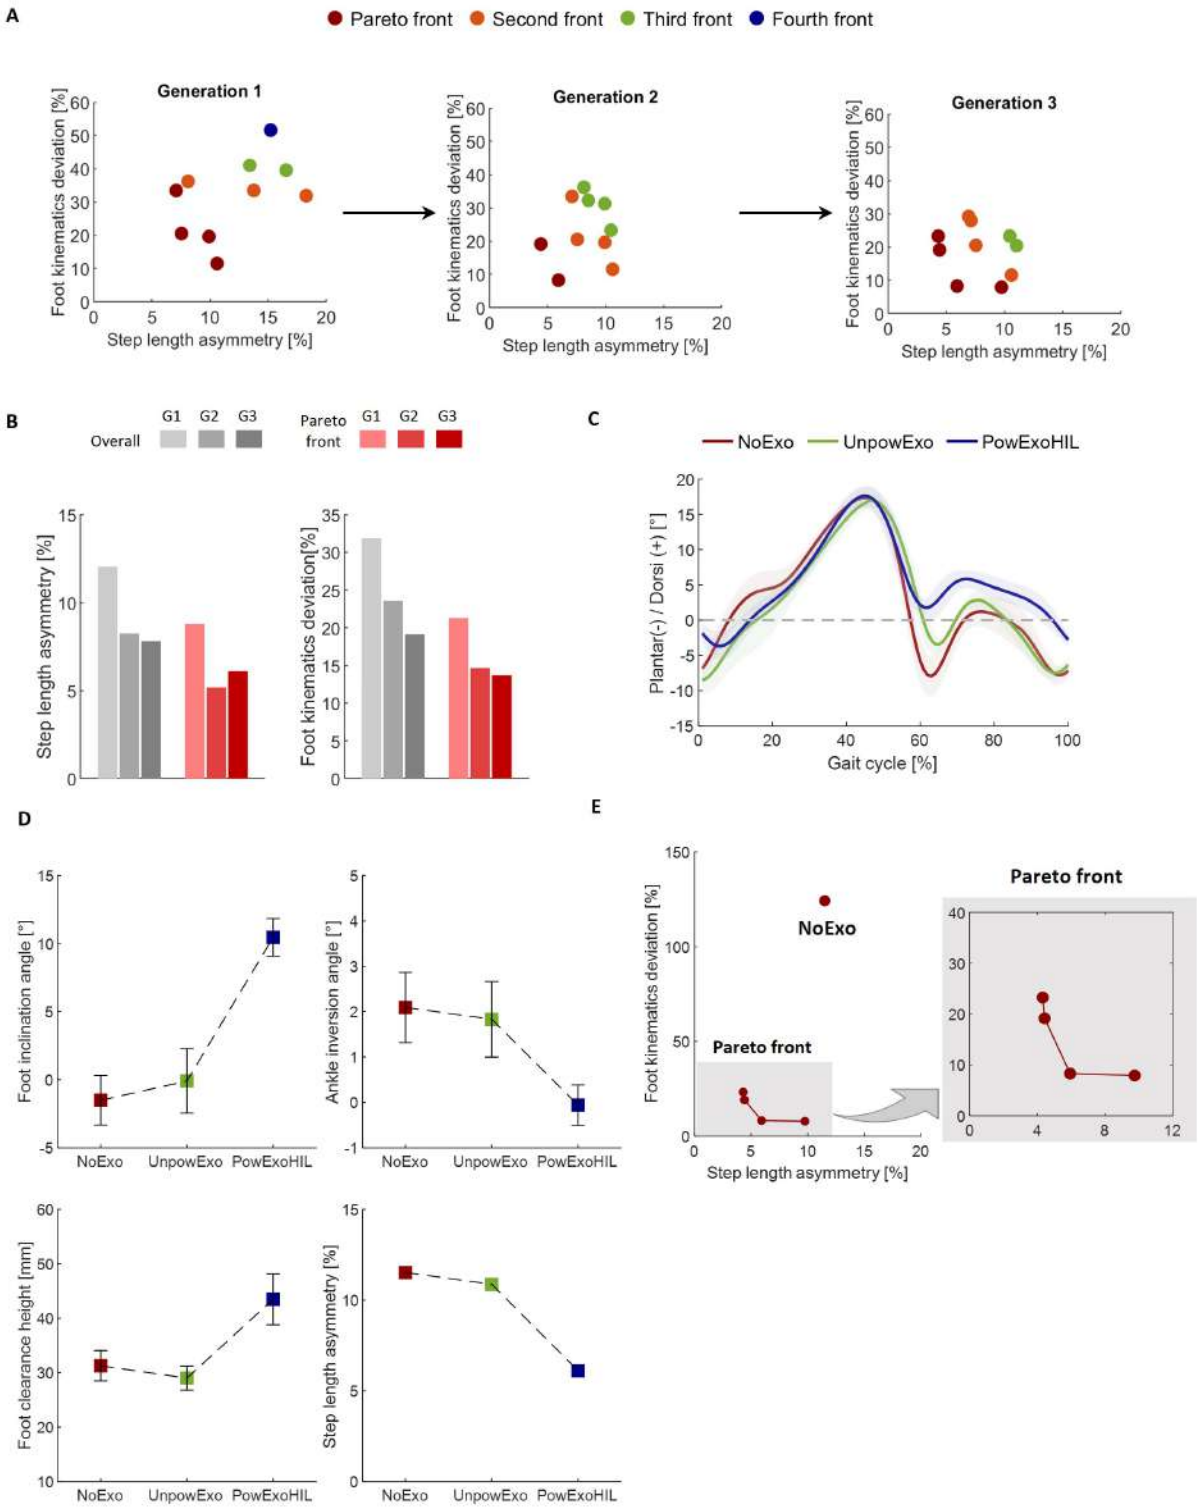

Fig. 3. A. Resulting gait quality metrics during the multi-objective HIL optimization process for the participant across three generations. B. Mean gait quality metrics of the overall solutions and the solutions on the Pareto front across three generations. C. The participant's ankle joint kinematics without the exoskeleton (NoExo), with the exoskeleton but no cables or power (UnpowExo), and with the exoskeleton and optimal assistance (PowExoHIL). D. The participant's gait metrics in NoExo, UnpowExo, and PowExoHIL conditions. Four metrics are listed: Foot inclination angle at initial contact, Ankle inversion angle at initial contact, Foot clearance height during swing, and step length asymmetry. E. Subject-specific Pareto front illustrates the trade-off between gait deviation and step length asymmetry for the participant. The metrics in the NoExo condition are shown in the inset at the top left for comparison.

has some effect, but this difference was small compared to the improvements observed with optimal assistance (PowExoHIL).

The gait metrics with solutions on the Pareto front illustrate the improvements in both metrics with assistance. These solutions can all be seen as optimal, even though trade-offs among them can be observed. No single solution minimized both gait quality metrics; the solution that minimizes step length symmetry resulted in a much lower foot kinematics deviation than the baseline NoExo, but was not minimum, and vice versa. The optimal assistive profiles that correspond to the gait quality indices on the Pareto front in Fig. 3E from left to right are [64.4, 1.07], [62.9, 1.10], [68.1, 1.17], and [60.8, 1.11] (Nmm/kg, /).

The participant was satisfied with the device's weight (5/5), stability and security (4/5), and effectiveness (4/5), neutral to the dimension (3/5), and not satisfied with the device's comfort (2/5).

IV. Discussions

In this study, we evaluated the feasibility and potential efficacy of a cable-driven ankle exoskeleton and a multi-objective HIL framework, which were designed to improve gait quality in persons with dropfoot and excessive inversion following a stroke. This evaluation included both objective biomechanical metrics and subjective perception of the user. The simultaneous improvements in multiple gait quality metrics, namely foot kinematics deviation and step length asymmetry, were achieved with the exoskeleton and the HIL framework. The generated Pareto front represents, instead of one optimal solution, a diverse set of optimal solutions that all improve the gait quality metrics in the optimization algorithm. These findings highlight the exoskeleton's ability to effectively address pathological gait patterns while demonstrating the effectiveness of the individualized control framework. This approach offers versatile solutions to accommodate varying individual needs, suggesting a new perspective to personalize the assistance.

The improvements in both gait quality metrics support the effectiveness of the multi-objective HIL optimization introduced in our previous study [18], which was previously only tested on non-disabled subjects with simulated impairments. This study, therefore, addresses three key gaps in the state-of-the-art: individualizing assistance for people with motor disorders, using gait quality kinematic metrics as optimization objectives, and incorporating multiple objectives in the optimization process.

Foot clearance in swing, appropriate pre-positioning of the foot for initial contact, stability in stance, and adequate step length are 4 of the 5 prerequisites of normal and efficient gait, as defined by Gage [21]. Perry has described the importance of the heel rocker mechanism in early stance [9] for stable and efficient gait. Swing phase gait deviations and a forefoot initial contact, with or without excessive ankle inversion, are commonly observed in persons with a dropfoot gait following stroke [8]. They disrupt an efficient gait pattern, commonly requiring compensatory movements to achieve clearance and weight acceptance, and can lead to instability and fall risk [6], and are thus a common target for orthotic treatment [22]. Our exoskeleton and the optimal control solutions improved these features in the participant, as illustrated by the more dorsiflexed ankle position during swing, the greater ankle dorsiflexion and foot segment inclination at initial contact, the presence of a heel rocker in early stance, i.e. the short phase of plantarflexion movement immediately following initial contact, the increased foot clearance height during swing, and the correction of ankle inversion at initial contact. These results are encouraging for the exoskeleton's potential effectiveness in the biplanar assistance required to improve swing phase quality and stability in stance in a post-stroke population, despite its relatively simple design and control concepts.

Gait asymmetry is commonly observed in hemiplegic gait following a stroke [23], [24], and was thus also targetted in this study, here specifically as step length asymmetry. This metric was chosen since its improvement would suggest a positive effect on whole-body kinematics, promoting a more balanced and efficient walking pattern [19], and would also demonstrate that ankle joint assistance can potentially contribute to holistic enhancements in gait quality.

The optimal solutions that make up the Pareto front served as a foundation for individualization of assistance. Each solution can be considered beneficial and unique in that they demonstrated substantial improvements in both gait quality indices compared to without the exoskeleton and presumably contributed to increased stability and efficiency. The multiple, rather than singular, nature of the Pareto front solutions enables each individual to prioritize among the predefined objectives according to goal, preference, and subjective experience; it is conceivable that one solution can be preferable in some walking situations, or that one of the objectives is perceived as more important than the other. This adaptability provides greater flexibility and supports dynamic decision-making during the post-processing stage, making a multi-objective protocol more flexible than traditional single-objective approaches, even those in which the single objective function consists of a weighted sum of different objectives [25].

Thanks to the HIL approach, the solutions identified in this participant are personalized. It can be expected that variations exist in a larger population with dropfoot gait following stroke, as the extent of inability to dorsiflex the ankle and evert the foot will vary. Numerous interesting questions arise regarding how much individual optimal solutions would vary in a larger population, and whether the exoskeleton with this HIL approach can further personalize assistive exoskeleton control.

It can furthermore be expected that the optimization approach would produce entirely different solutions if tasked with optimizing other gait quality and/or performance metrics; the objectives in this study were carefully selected for the targetted gait problem and patient population, and can be constructed instead with different objectives, as deemed appropriate for a specific gait pathology or performance goal.

The participant's overall feedback from the questionnaire was relatively positive and comparable with the subjective feedback reported from other studies [26], [27], indicating that the device largely met their expectations. The only reported point of dissatisfaction was related to comfort, which was attributed to the placement of the EMG transmitter under the relatively tight calf wrap. An interesting point to explore in the future is whether the user's subjective assessment of each assistance profile corresponds to its efficacy in improving gait quality, and whether it can further personalize the device's assistance.

There are, of course, some limitations in this study. The UnpowExo condition was designed to isolate the effects of assistance and assess the impact of the exoskeleton hardware itself on the participant. While slight effects were observed in some metrics, they were not considered to be of a substantial impact, indicating minimal interference from the device. In the HIL framework, three generations comprising 30 assistive profiles in total were tested, which is fewer compared to the four generations used in our previous study [18]. The main reason for this adjustment was practical; the participant reported being tired after 1–2 hours of testing. Drastically reduced walking endurance can be expected in a population post-stroke [28], so the experimental protocol should be kept as short as possible. However, the convergence of mean values for the Pareto front between the second and third generations, along with participant endurance status, suggest that three generations was sufficient for this participant and may be sufficient for a post-stroke population. Furthermore, in this study, we only evaluated the exoskeleton's efficacy in short-term use and in a controlled laboratory setting; its efficacy to improve gait in real-world environments over a long time should be addressed in future studies, as should the clinical significance of improving these gait quality metrics. This is an ongoing study; we only present the findings of one participant in this study and will be able to make firmer conclusions after more participants have been included.

V. Conclusions

To the best of our knowledge, this is the first active exoskeleton device to successfully provide assistance for individuals with dropfoot gait in two anatomical planes with a relatively simple, lightweight, and largely soft design, using an individualized human-in-the-loop approach that seeks the optimality of two objectives simultaneously. The generated family of optimal solutions represents possible choices for an individualized plan for a specific person. Future work will explore additional objectives, including participants' subjective assessments of different assistance profiles.

Organizing and prioritizing user needs for upper limb prostheses

Palma Borracci, Robinson Guachi, Linda Paternò, *Member, IEEE,* Irene Mannari, Flavio Napoleoni and Marco Controzzi, *Member, IEEE*

***Abstract*—Upper limb amputation leads to severe restrictions in daily activities and psychosocial difficulties, which can dramatically reduce the quality of life of affected people. Despite the significant scientific and engineering effort in building advanced robotic prostheses, their abandonment rates suggest a discrepancy between user needs and device performance. To address this gap, we present an initial step in identifying, harmonizing, and prioritizing the needs of people with limb loss. Using the PRISMA methodology, we analysed 73 papers on the topic. Using a bottom-up approach, we clustered the needs identified in different surveys into categories and macro-categories based on a taxonomy derived from the terms identified in the literature. We then prioritized the needs after a normalization of the major surveys. We believe that this work will provide both a high-level and low-level understanding of the needs of people with limb loss, thereby helping to guide the design of more user-friendly prostheses. In the future, combining these results with the definition of technical specifications will enable the identification of needs that can be satisfied through personalized design, particularly considering recent advances in manufacturing processes.**

I. Introduction

Hands are our primary elements of interaction with the world, enabling us to perform a wide range of tasks, from daily essentials like opening a bottle of water to more complex activities such as self-feeding [1]. In addition to their functional role, hands also play a key part in expressing identity, second only to the face in their ability to convey emotions for most individuals [2]. Thus, hand amputation represents a devastating event that limits one's ability to carry out daily activities and hinders social participation. Globally, approximately 5 million people live with upper limb amputations [3], with trauma being the leading cause. The prevalence of amputations varies by region, with trauma accounting for more than 80% of cases in areas affected by conflict, while vascular diseases, including diabetes, are more common causes in other regions. Cancer also contributes, although less frequently [3]. Given these causes, the number of people living with upper limb amputations is expected to rise due to ongoing conflicts, the increasing prevalence of vascular diseases, and the global rise in diabetes [3]. Post-amputation rehabilitation is a complex process that involves a multidisciplinary team. From an engineering perspective, prostheses aim to restore both functionality and aesthetics, improving patients' quality of life and enabling reintegration into social and work life [4]. Upper limb prostheses can be classified into two categories: passive and active. Passive prostheses include cosmetic devices, which replicate the limb's appearance, and functional devices, which feature interchangeable tools for specific tasks. Active prostheses are

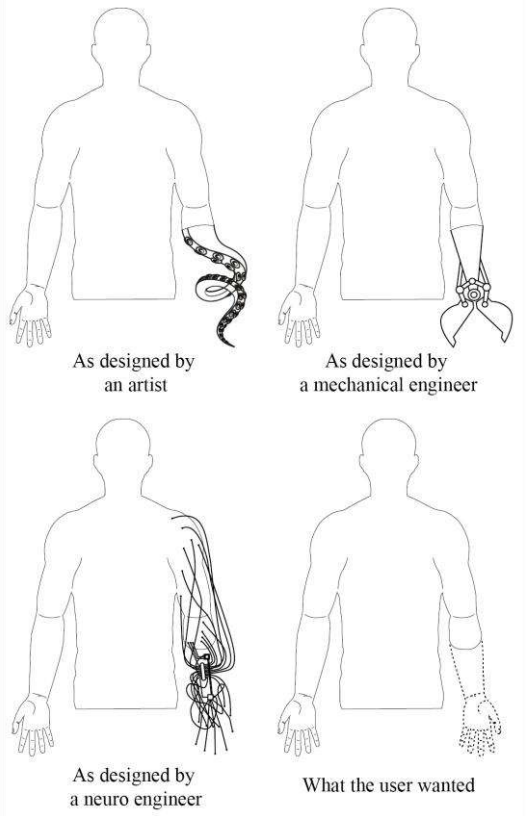

Figure 1 Understanding the prosthesis need, adapted from [15]. The illustration depicts the contrast between prosthetic design perspectives and user expectations. Top left: conceptual design by an artist, focusing on creativity. Top right: engineering-driven design, emphasizing mechanical functionality. Bottom left: electronic system design, highlighting complexity of wiring to record bio-signals. Bottom right: the user's ideal prosthetic, prioritizing simplicity, usability, and human-like functionality.

further divided into body-powered, which utilize the motion of the residual limb, and myoelectric, which are battery-powered and controlled via surface electromyography [5]. Despite technological advancements, many users still prefer passive prostheses. Body-powered devices provide a reliable, lightweight, and intuitive experience, while aesthetic prostheses are favored for their ability to symmetrically replicate the missing arm. However, myoelectric prostheses may offer, on the paper, greater functional restoration of the missing hand. Despite this advantage, 20% to 50% of users abandon these devices [4]-[8]. These factors point to a significant gap in prosthetic design that hampers user satisfaction and long-term usage [9], [10]. Numerous surveys have explored the needs of individuals with limb loss (here a recent review [3]), yet translating these insights into practical prosthetic solutions remains unsatisfactory. State-of-the-art robotic prostheses still face significant limitations, including poor controllability and functionality, lack of sensory feedback, inadequate aesthetics, and discomfort during wear [4]-[11]. These shortcomings result in unintuitive devices that many users perceive as impractical for daily use. So, it stands to reason that a fundamental misunderstanding of user needs is a primary reason for the high abandonment rates of hand prostheses (Figure 1). The limited adoption of co-creation models, such as the one proposed by Jones et al. in 2021 [12], is probably a key factor contributing to this issue. Given the individualized nature of prosthetic requirements, user-centered design is crucial in prosthesis development. For example, the HAAT - Human Activity Assistive Technology model demonstrates how integrating human, technological, and environmental factors can enhance user experience and prosthesis functionality [13]. Prostheses must accommodate different levels of amputation by incorporating compatible, commercially available components. For example, trans-humeral amputations require not only a hand but also a wrist, an elbow, and appropriate connection components. Some of the prosthetic elements are highly personalized to account for the specificity of the single patient. This is the case for the socket, whose primary function is to offer a secure anchoring of the prosthesis to the body and is molded based on the cast of the residual limb. In contrast, off-the-shelf components should be designed to accommodate a broader user base while maintaining affordability through an optimal balance of engineering specifications. In various industrial sectors, one of the most widely used approaches for generating engineering specifications is Quality Function Deployment (QFD), developed in the 1970s [14]. This framework prioritizes customer needs and constructs a House of Quality (HoQ) to map the relationship between user desires and the engineering specifications required to fulfill them. To narrow the gap between user expectations and upper limb prostheses, we apply the QFD framework to this field. Specifically, this paper explores the complex and challenging process of identifying "universal" user needs as inputs for the QFD process to enhance prosthetic design. We hypothesize that adopting a more user-centered approach and integrating frameworks like QFD can better align user desires with the engineering specifications necessary for functional and comfortable upper limb prostheses.

The paper is structured as follows: the first section reviews the QFD methodology and its proposed adaptation for application in the prosthetic field. The second section employs the PRISMA methodology to systematically review the state-of-the-art regarding amputees' needs. The third section details how these needs were organized into categories and macro-categories, culminating in the development of a taxonomy that assigns relative importance to each. Finally, both the categories and macro-categories were prioritized using various methods. This structured approach provides a comprehensive overview of the population's needs, enabling targeted interventions to address the most critical areas effectively.

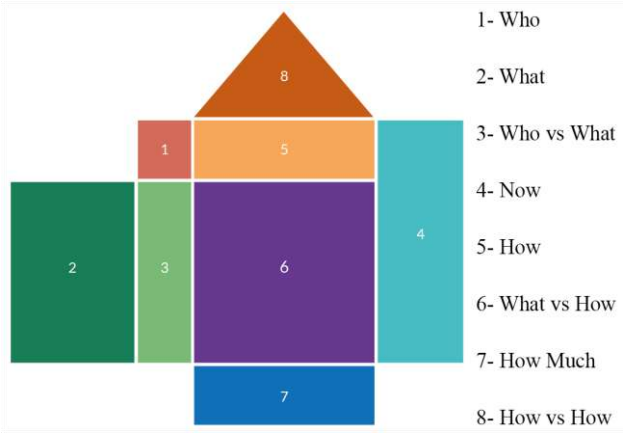

Figure 2 Organization of the House of Quality (i.e. QFD diagram). The diagram is organized in rooms, each containing information that are used to translate the customers' requirements into engineering specifications.

II. Background

A. Overview of the Quality Function Deployment (QFD)

The QFD method helps generate the necessary information during the engineering product definition phase of the design process through the creation of a HoQ (Figure 2). Each room in the diagram represents a step in the methodology for building the relationship between customer desires and the engineering specifications necessary to meet those desires. The framework is flexible and can be adapted to accommodate advancements in prosthetic technologies and emerging innovations. Specifically, in the technical specifications section of the HoQ, customizable specifications can be activated, deactivated, or added, ensuring that the design process evolves alongside technological progress and remains aligned with current user needs and capabilities.

The first step is identifying *who* (room 1) the customers are and *what* (room 2) they want the product to do. In developing this information, we also determine to whom the "*what*" is important—*who versus what* (room 3). Then it is important to identify how the problem is solved *now* (room 4), in other words, what the competition is for the product being designed. This information is compared to *what* the customers desire—*now versus what* (room 4)—to find out where there are opportunities for an improved product. Next, one of the more challenging steps in developing the house is determining *how* (room 5) you are going to measure the product's ability to satisfy the customers' requirements. *How* refers to the engineering specifications, and their correlation to the customers' requirements is given by *what versus how* (room 6). Target information—*how much* (room 7)—is developed in

the basement of the house and indicates the extent to which each technical requirement must be achieved to satisfy customer needs. Finally, the interrelationship between the engineering specifications is noted in the roof of the house—*how versus how* (room 8).

We aim to exploit the QFD [15] as a methodology to cluster the users' requirements and in future, through the requirements, identify the technical specifications for advance the design of upper limb prostheses.

B. Applications of the QFD for rehabilitation engineering

The QFD methodology has been previously applied in prosthetic design, such as in the 1994 study by Jacques et al. on child-sized myoelectric prosthetic hands [16]. The study involved multiple stakeholders—amputees, parents, and prosthetists—and used questionnaires to define functional requirements, rate their importance, and assess satisfaction with different models. The study highlighted the importance of including the amputee in the design process and identified the potential misalignment of prosthesis designs with patient needs due to varying interpretations of customer requirements.

C. Objective of the study

Our goal is to unify and prioritize the needs of amputees while also identifying those that can be personalized, considering advancements in manufacturing technologies. For the first time, we attempt to cluster needs identified in existing literature into a taxonomy, followed by their prioritization. The process was completed in three phases. First, we clustered 657 individual needs from the literature into 21 categories based on semantic similarity. Then, these 21 categories were further organized into 6 macro-categories for a higher-level understanding of user needs. Finally, we prioritized the categories based on term frequency in the literature and prioritized the macro-categories using insights from two major studies.

III. Application of QFD to the Design of Prosthetic Hands

In this work, we focus on room 1, 2, and 3 of the HoQ [15].

A. WHO: Identify the customers

The first step is the identification of the customers [15]. As with many products, prosthetics have more than one type of customer. For example, depending on a country's health services, the consumer (individuals with limb loss) may be different from the buyer, which could be a hospital or an orthopedic workshop. Given the prosthesis's lifespan, we identify five classes of customers: consumers, buyers, prosthetists, caregivers, and service technicians and clinicians. For the scope of this study, the primary customers are individuals who have lost an upper limb, focusing specifically on adults who wish to use a myoelectric prosthesis, which can restore both aesthetic and functional aspect.

B. WHAT: the amputees' requirements

Once the customers have been identified, the second step of the QFD method is to determine what aspects of the prosthesis need to be designed or improved—specifically, understanding customer needs [15]. In this step, we focus on identifying requirements, which refer to customer needs, rather than specifications, which are the detailed, often technical descriptions of how those needs will be met. To achieve this, we structured the process into three key stages: (i) performing a systematic literature review, (ii) categorizing customer needs into a taxonomy, and (iii) linking the identified needs to the relevant components of the prosthesis.

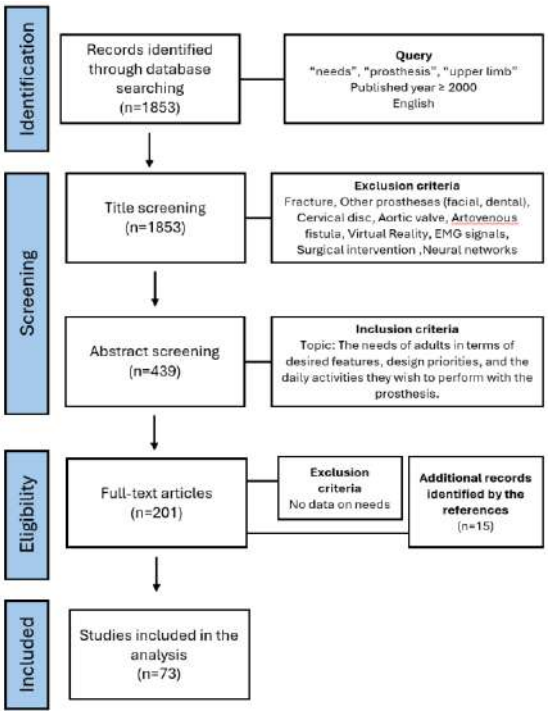

Figure 3 Flow diagram according to the PRISMA method.

Identification and screening of the needs

We systematically reviewed the scientific literature about the needs of individuals with limb loss according to the 'Preferred Reporting Items for Systematic Reviews and Meta-Analyses' (PRISMA) guidelines [17]. The flow diagram showing the process is depicted in Figure . The bibliography was retrieved by searching the Scopus database through query results on three words ("needs", "prosthesis", "upper limb") and their synonyms. The search encompassed conference papers, articles, book chapters, and reviews published between 2000 and 2023 in English. The search results were collected on October 25, 2023. The search yielded 1853 papers, which were subjected to an initial screening based on their titles. Then, records were selected according to the inclusion or exclusion criteria. This process reduced the output to 439 articles, which were subsequently divided into different groups based on topics. We then restricted the initial set to 201 papers considering only studies addressing the needs of adults in terms of desired features, design priorities, and the daily activities they wish to perform with the prosthesis. Based on the abstract, we excluded 143 papers since they did not report data on needs retrieved by questionnaires. This resulted in the identification of 58 papers [3], [4], [9], [10], [12], [17]-[69], that were deemed eligible for inclusion. Additionally, 15 papers [1], [6]-[8], [70]-[80], were included during this phase since cited by the studies and judged relevant according to our inclusion criteria. The final set of papers in our analysis

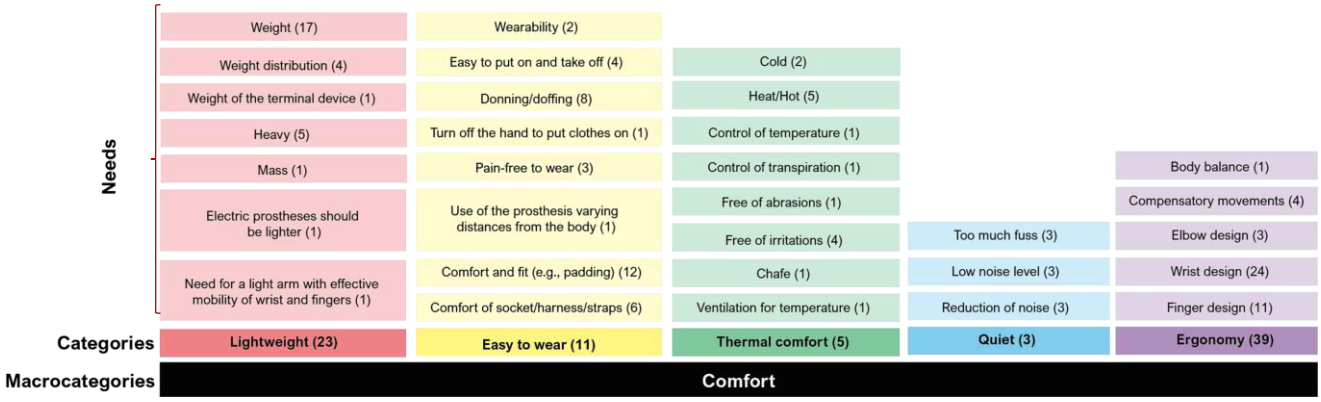

Figure 4 Rationale of the taxonomy of needs. The taxonomy is organized in three layers. The first layer is composed by all the needs that are semantically grouped into specific categories (second layer). The third layer is represented by the macro categories, which can provide a high-level understanding of the needs. In this example we report how the needs related to the macro category "Comfort".

consists of 73 papers. This set considered approximately 6646 amputees who were subjected to the questionnaires and the collected needs comprised 657 items.

Organization of the needs following a taxonomy

The taxonomy is structured into three hierarchical layers for clarity and usability (Figure 4). The first layer consists of all the individual needs, which are semantically grouped based on their similarities. Among the 657 needs identified, 470 can be considered as 470 user needs, while 127 are needs related to consequences and technical specifications. To maintain a focused analysis, we restricted our study to the 470 user needs, as they directly reflect the desires and priorities of the customers. In the second layer, these grouped needs are organized into specific categories, each representing a distinct aspect of the broader requirements. These were clustered semantically according to three main criteria: same denomination, synonym, or related concept. The clustering process resulted in 21 categories, leading to the taxonomy depicted in yellow in Table 1 (column 10). To better understand the process, here we report a description of the first five categories and examples of needs that were clustered within each category.

"Lightweight" describes the need to reduce the weight of prostheses, making them easier to use, and in turn enhancing comfort and mobility for the user. This category derives from prosthetic needs reported by users, such as for instance, "Weight", "Mass", "Heavy", "Weight distribution".

"Easy to wear" emphasizes the need for comfort, which includes the wearing process of the prosthesis and clothes. The terms selected underline the importance of the design to consider the wearer's daily life and activities, ensuring the prosthesis is not only functional but also comfortable and convenient to use. This category was defined based on needs reported as, for instance, "Comfort and fit", "Donning/Doffing", "Wearability".

"Thermal comfort" pertains to the desire to maintain a comfortable temperature at the residual limb and occurs as the need for "temperature regulation". The terms selected refer to the prosthetic's ability to prevent excessive heat buildup and promote adequate ventilation, ensuring that the area in contact with the residual limb remains at a comfortable temperature. This aspect is crucial for preventing discomfort, sweating and potential skin issues.

"Quiet" underlines the need for a prosthesis that operates without producing loud or disruptive sounds. This ensures that the user can move and interact without being disturbed or stressed by noise or feeling embarrassed during use.

"Ergonomics" refers to the needs aimed at reducing compensatory movements in activities of daily living caused, for instance, by a poor kinematic matching of the prosthesis. This is usually mentioned by amputees in surveys using terms like "Wrist design" or "Elbow design".

To provide a high-level understanding of the needs, the 21 categories have been further clustered into 6 macro-categories, as their combination represents a complex and interconnected system of user needs (Table 1, column 3). The clustering rationale followed a definition of each macro category:

- **Comfort** is a sense of physical or psychological ease, often characterized as a lack of hardship.
- **Function** describes what the product must do.
- **Control** pertains to the ease of controlling the prosthesis.
- **Appearance**: refers to the way the prosthesis looks, and how someone looks while wearing the prosthesis.
- **Reliability** pertains to the capability to perform its intended functions without issues e.g. unplanned movements, slipping of objects, failure/malfunction, breakage.
- **Cost & Service** includes the costs of purchasing and maintaining the prosthesis.

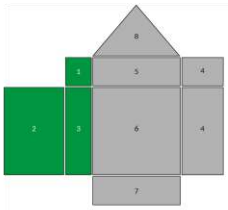
Division of needs within the components of the prosthesis

In upper limb prostheses, most of the engineering efforts focus on the design of the terminal device or on the development of algorithms inferring the user's intention. However, the prosthesis comprises different components,

each impacting a subset of needs. Therefore, the identification of the correlation between needs and components of the prosthesis plays a fundamental role. In this regard, we divided the prosthesis into four main elements, envisioning a trans humeral fitting: suspension system (socket and interface), elbow, wrist, and terminal device (hand) (Table 1, columns 4-7). By considering the comfort category, we note for instance that the need "Lightweight" refers to all components, while the category "Easy to wear" is mainly affected by the suspension system.

C. *WHO vs WHAT: Prioritization*

The third step in the QFD technique is to assess the relative importance of each customer requirement. This is achieved by assigning a weighting factor to each requirement. The weighting factor helps prioritize the level of effort, time, and resources needed to address each requirement [15]. The importance of the 6 macro categories was based on a subset of studies which included at least six needs related to our six macro categories. This led us to consider the papers Biddis et al. [21], and Nagaraja et al. [43]. Each of them reports its own prioritization in the form of a ranked list of needs: Biddis et al. [21] reports 14 needs, prioritized to a 10-point scale (including *ex aequo*), while Nagaraja et al. [43] reports 6 needs, prioritized to 6-point scale. We normalized the prioritization of the Biddis et al. needs to a 6-point scale. Then, the importance of the macro categories was retrieved using *Reciprocal Rank Fusion (RRF)* [82] algorithm, this technique combines multiple search systems or classifiers to generate a final ranking by assigning a score based on the position of each result in the rankings of the models used, following the equation:



$$RRF = \sum \frac{1}{r(d)}$$

Where $r(d)$ is the rank/position of the macro categories. Based on the *RRF*, the macro categories can be ranked on a 6-point scale, where 1 indicates the least important and 6 the most important (Table 1, column 2). Finally, these values were converted into percentages (Table 1, column 1) using the following formula:

$$\frac{Rank_i}{All} \times 100$$

Where $Rank_i$ is the rank of the macro category i, and All is the sum of all categories. Concerning the prioritization of the needs (here clustered in 21 categories), we hypothesized that the frequency of the terms (Table 1, column 9) provides an index of urgency. In other words, the more frequently a need is cited by amputees, the higher its priority should be in prosthesis design. For the computation of the frequencies, we analysed all the 73 papers included in this study, and we computed the occurrences of the items within each category. These values were converted into the relative percentage within the macro category (Table 1, column 8) using the following formula:

$$\frac{f_j}{\sum f_j} \times 100$$

Table 1 Customers, importance of needs and taxonomy of the amputee's needs. The data are rounded to the nearest whole number.

Where f_j is the frequency of the need j, and $\sum f_j$ is the sum of the frequency within the macro category considered. Finally, the absolute importance of each need (Table 1, column 11) is computed by combining its percentage within the macro category (Table 1, column 8) with the percentage of the macro category itself (Table 1, column 1) relative to the others.

IV. Discussion

We identified key user needs based on a broad cohort of studies addressing the needs of amputees. These needs were synthesized into a taxonomy organized into three hierarchical layers. This process serves two purposes: 1) standardizing terminology for needs within the scientific community, enhancing communication and comparison across studies, and 2) providing both high-level and detailed understanding of these needs. We integrated and followed different but established methodologies to ensure a rigorous prioritization. The importance of the macrocategories was obtained using two important studies (Biddis et al. [21] and Nagaraja et al. [43]) whose prioritization rankings were normalized to a common scale. We applied Reciprocal Rank Fusion (RRF) to reduce potential inconsistencies arising from variations in these rankings. For prioritizing the 21 categories, we assumed that needs that are frequently mentioned are also of higher concern to users. This method aligns with the guidelines of the PRISMA used to identify key themes [17]. Finally, we computed the absolute importance of each need by combining its relative percentage within its macro-category with the weight of the macro-category itself to ensure consistency.

"Function" emerged as the primary macro-area for improvement in myoelectric prostheses, with users reporting a lack of "precision and stability" in grasping. From an engineering perspective, addressing this issue requires enhancements in both hand design (e.g., increasing finger grip and adaptability to different shapes) and the user-prosthesis interface. Myoelectric prosthetic hands are typically controlled using two-channel surface myoelectric signals, whose performance depends on the activity of residual muscles that may not be accurate and reliable over time. "Cost & Service" is the second macro-area requiring major attention, particularly regarding the "affordability" of devices and the availability of "assistance." Affordability is a significant concern, especially for multi-grip hands, which cost approximately seven times more than single-grip hands. The demand for better "assistance" is closely linked to another macro-category, "Reliability", where users emphasize the importance of device "robustness". "Comfort" is primarily associated with the need for "ergonomics" and "lightweight" prostheses. The demand for ergonomics is driven by the compensatory movements amputees must adopt during daily activities, mainly due to limited wrist mobility or thumb abduction. Weight remains a well-known issue across the entire prosthetic system—hand, battery, and ancillary components often weigh more than the natural limb, with perceived weight further increased by common suspension systems like sockets. "Appearance" was considered less critical in the context of myoelectric prostheses. Without proper functionality, a myoelectric prosthesis serves only as a passive aesthetic device, adding unnecessary weight and cost. However, this may strongly depend on context and culture. It is not uncommon for amputees to use multiple prostheses for different situations—for instance, a task-specific or body-powered prosthesis for daily activities and a cosmetic hand for social events.

During the analysis of the results, we identified two main limitations of our work. First, the survey respondents were predominantly from Western contexts, which may have influenced the prioritization of needs. For example, cost may be a more pressing issue in developing countries. Second, merging needs from different surveys may have led to some needs being overemphasized. Further research is needed to ensure that these needs are fairly represented across different cultural contexts. Despite these limitations, we believe that the identified needs reflect the core requirements of users, as they appear consistently across various studies and patient populations, even in different cultural contexts. This demonstrates their universal relevance, marking a significant contribution in harmonizing previously fragmented findings into a unified set of prioritized requirements.

V. Conclusions and Future works

This article aims to consolidate previous efforts through the analysis of 73 articles. The goal—and the novelty of this study—is to systematically unify the needs of amputees and organize them into a taxonomy. The next steps involve completing the subsequent rooms of the House of Quality, focusing on the following tasks: i) Translating the needs into technical specifications that can be quantified; ii) Identifying the relationships between needs and technical specifications; iii) Benchmarking of off-the-shelf prostheses and components; iv) Identifying the needs and specifications that can be personalized for the individual, also considering the potential of new manufacturing processes, such as additive manufacturing technologies. These steps will establish a structured framework to guide prosthetic development, ensuring that design closely aligns with user needs. Specifically, we aim to identify which parts of the prosthesis can be easily personalized (e.g., cosmetic appearance) and adapt the HoQ to reflect user preferences. In the future, an online questionnaire integrated with the QFD framework will enable amputee users to regularly provide feedback on factors such as demographic data, emerging needs, and satisfaction with their prostheses. Specifically, we propose developing an online questionnaire structured within the QFD framework, allowing users to continuously share feedback on general factors, needs, and satisfaction, ensuring an ongoing update process. The ultimate goal of this work is to develop a new, personalized prosthesis. By integrating user preferences into the design process, we can ensure that the prosthesis not only meets functional requirements but also aligns with individual user needs and preferences.

Acknowledgment

The authors would like to thank Leandro Giordani for the insightful discussion on the House of Quality as well as the reviewers for their valuable suggestions for improvement.

Abstract— **Stroke significantly impairs motor function, often causing abnormal synergies and muscle weakness. Clinical assessments are vital for diagnosing impairment and guiding treatments but are labor-intensive and time-consuming. Moreover, the supply of clinicians cannot keep pace with the growing number of individuals affected by stroke. This study presents a more efficient strategy to assess motor function, substantially reducing the time and effort required for assessment while eliminating the need for direct accessor involvement. Our proposed method leverages wrist position probability distribution during two minutes of free upper-extremity movements of individuals with chronic stroke, tracked by a markerless motion capture system. Two probabilistic models, rectilinear and icosahedron-based, revealed stroke survivors spend significantly less time in four posterior zones and more time in the anterior-inferior-medial zone. The icosahedron model identified abnormal flexion synergies in 10 stroke survivors (52.6%), two more than the rectilinear model. Conversely, the rectilinear model demonstrated stronger associations with clinical scores, with three zones showing strong correlations (R>0.70) compared to one in the icosahedron model. These findings highlight the promise of wrist position probability distribution models as tools to detect movement deficits and abnormal synergies in stroke survivors. Future work could integrate joint angles to improve clinical insights.**

Keywords—stroke rehabilitation, abnormal synergies, markerless joint tracking, probability distribution, human movement analysis, biomechanics and robotics in physical rehabilitation

I. INTRODUCTION

Each day, more data is coming in and we do not know how to use it. As stroke is a debilitating event that can damage the ipsilesional corticospinal tract and hence volitional controls, large data sets of volitional actions are of interest. A variety of robotic, wearable technology can track and store full body and large free actions of such large body actions, but a critical question is how we might reliably analyze such data to answer questions about disease mechanisms and recovery pathways.

Stroke often leads to reliance on alternative pathways including the reticulospinal tract [1], [2]. Those neuroanatomical changes lead to significant motor impairment, including abnormal coactivation across muscles, termed the flexion synergy and extension synergy, in the extremities [3], [4], [5]. These abnormal synergies involve functional limitations in hand/arm manipulation by binding the motions of more distal joints with that of the shoulder joint. Since abnormal synergies provide critical insight into the neuroanatomical progress in each individual with stroke and guide therapy, the need for a quantitative and effective assessment has arisen [6].

Current methods of evaluating upper extremity range of motion consume valuable therapy time. Occupational therapists use a variety of upper extremity assessments to assess motor function impairment [7] and stroke-caused abnormal synergies [8], and fine and gross motor ability [9], [10]. Yet, some of these assessments can take upwards of 45 minutes, they are not appropriate for cognitively impaired participants, and using only the aforementioned capacity measures are insufficient at measuring rehabilitation effectiveness [11], [12] and underlying muscle synergies.

Many have turned to the use of technology to aid in the measurement of upper extremity impairment, but it oftentimes falls short. Sensors in electromyography (EMG) can objectively quantify upper extremity impairment and synergies [13], [14], [15], [16]; but sensor placement can be time consuming, it requires a skilled user, and they are prone to noise in dynamic movements. IMUs can assess movement diversity and longitudinal use of arms and hands, [17], [18] but they also run into accuracy challenges because of their sensitivity to noise. The gold-standard for robustness in kinematic measurements, marker-based joint tracking, is far too expensive and the complex setup in a lab space make it inaccessible to clinics [19].

Here, we present a markerless joint tracking analysis to explore movement impairments in stroke survivors with hemiplegia. We hypothesize that probability distribution analysis of two minutes of free exploration wrist position data will reveal underlying abnormal synergies and identify limited mobility regions in chronic stroke survivors. Prior work employed rectilinear-based models to convert position data into probability distributions for upper extremity and tongue movement [20], [21]. Since the shoulder is a ball-and-socket joint and thus wrist range of motion follows a spherical shape, a more anatomically aligned model could better identify clinically relevant deficits. To our knowledge, we are the first to propose an icosahedron instead be used to segment the spherical wrist position data about the shoulder joint.

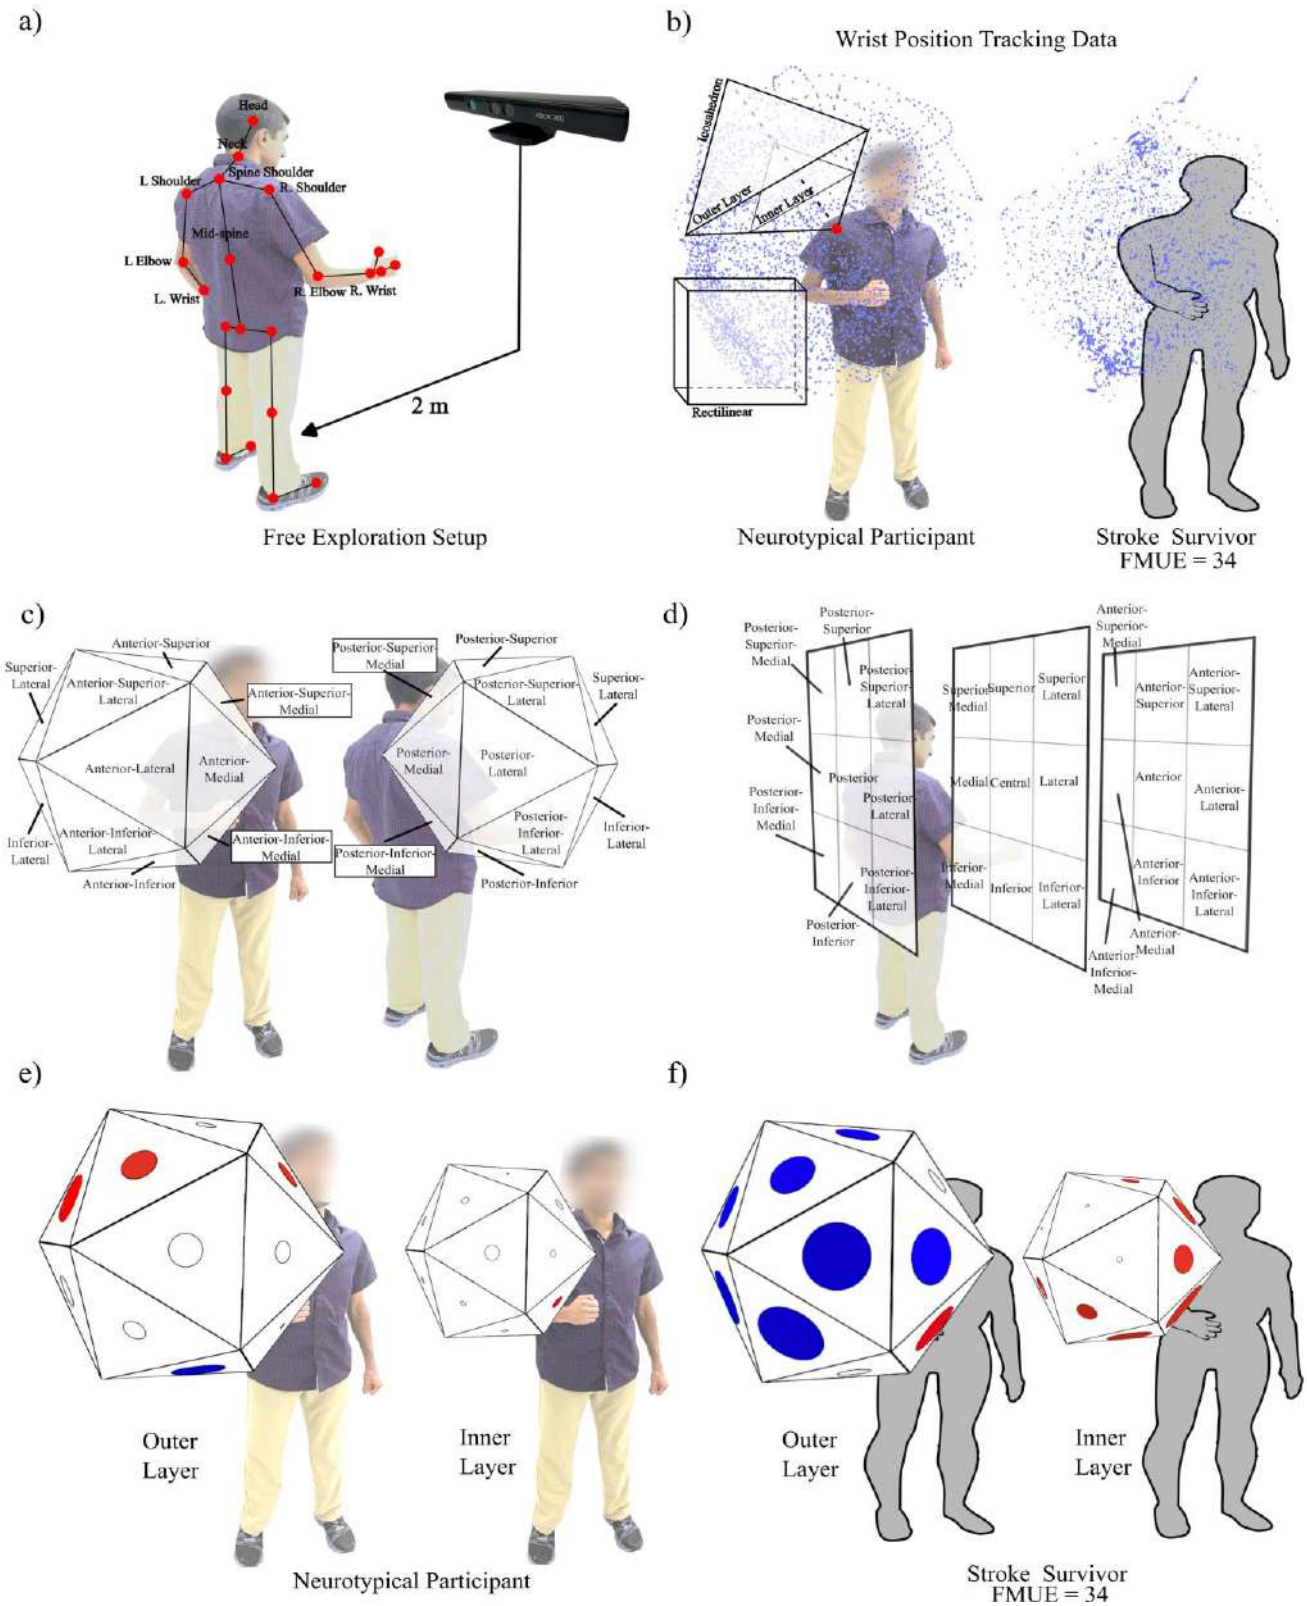

Figure 1: (a) Participant performs two minutes of free exploration in front of Kinect v2. (b) 3D wrist position sample frame data for a neurotypical individual and a stroke survivor (FMUE=34). (c) Icosahedron-based model's wrist position compartments labeled as anatomical zones. (d) Rectilinear-based model's wrist position compartments labeled as anatomical zones. (e) Sample probability distribution of neurotypical participant. Icosahedron faces categorize each wrist position frame into 20 zones. Half radius further splits zones into outer and inner layers. Probability calculated as percent time per zone. Red filled circles reflect that participant spent significantly more time than neurotypical individuals. Blue filled circles reflect significantly less time. Difference from neurotypical median is represented by circle radii. (f) Sample probability distribution of a stroke survivor (FMUE=34).

II. Materials and Methods

A. Study Design

19 chronic stroke survivors (7 female, 8 right side impaired, age: 53.4 +/- 12.3 [standard deviation] years) and nine neurotypical individuals with no history of stroke (5 female, 7 right-handed, age: 31.9 +/- 15.2 years) were recruited, and all gave written informed consent. The experiment was approved under the Institutional Review Board of Northwestern University (STU00216062).

Stroke survivors and neurotypical participants completed a free upper-extremity exploration task with their dominant arm, or affected extremity for 2 minutes, respectively. During the task, they were asked to move their arm towards all reachable areas with their upper extremity, as much as possible, at their own selected speed (Fig 1a) [15].

B. Data Acquisition and Analysis

We collected kinematic data using Kinect v2 (Microsoft, Seattle, WA), a markerless motion capture system, placed about two meters in front of the participant. The Body2Basics software provided estimates of 3-dimensional positions for 24 joints of the upper extremity, including the bilateral shoulders and wrists. Data were low-pass filtered using a 5th-order Butterworth filter with a cutoff frequency of 6 Hz . Cutoff frequency was selected based on literature recommendations for analyzing faster arm movements [22]. Data from participants left-impaired or dominant were reflected across the sagittal plane. All joints were then translated such that the shoulder joint of the affected arm (stroke group) or dominant arm (neurotypical group) was set as the origin.

To partition the wrist position data based on an icosahedron model, we first calculated a radius equal to the furthest point of the wrist from the shoulder during free exploration. The vertices of the icosahedron were determined using the golden ratio and scaled by the radius. Each of its 20 faces serves as the base of a tetrahedron with the shoulder joint as the apex. The radius is also used to categorize the wrist position data into two layers – inner and outer – with a cutoff set at half the radius. The combination of 20 tetrahedrons and two layers form 40 zones from which probability distribution is calculated as the percentage of time an individual spends in each of these zones.

To segment the wrist position data in the 3-dimensional rectilinear model, a maximum distance from the gleno-humeral joint is calculated, and the x, y, and z axes are bounded by this distance with the shoulder as the origin. This cube-shape is then split into 27 zones with equal volume by splitting each axis into 3 layers (Fig 1b). Probability distribution is then calculated as percent time a participant's wrist is in each of these zones.

We used Python SciPy library to calculate 95% confidence intervals (CI) for the percent time spent in each zone based on data from neurotypical participants. A stroke survivor was considered significantly higher or lower than neurotypical individuals if their percent time fell outside these CIs. The number of participants with stroke outside the CI was counted and categorized as higher or lower for each zone. The Cochran-Armitage test was performed to determine if stroke survivors were more likely to spend less time in superior zones compared to inferior zones, suggesting sensitivity to gravity. In the icosahedron model, flexion synergies were identified if a stroke survivor spent more time in two of the following zones: inferior-lateral, anterior-inferior-lateral, anterior-lateral, and anterior-superior-lateral. In the rectilinear model, flexion synergies were present if more time was spent in the central zone.

To compare zone probabilities between stroke survivors and neurotypical individuals, unpaired Welch's t-tests with unequal variances were conducted using the Python SciPy library. We performed nonparametric correlation analyses to evaluate the associations between specific zone probabilities and clinical scores including Fugl-Meyer Upper Extremity (FMUE) score, FMUE synergy sub score (FMUE-SS), and Action Research Arm Test (ARAT) score. The significance level was set at 0.05.

III. Results

In the icosahedron-based model, neurotypical participants spent most time in the outer layer's anteroinferior (12.81 ± 6.40%), anterior-inferior-lateral (9.96 ± 4.92%), and posterior-inferior-lateral (9.57 ± 7.46%) zones. They spent the least amount of time in the posterior-medial-inferior zone (0.01 ± 0.02%), superomedial (0.03 ± 0.08%), and inferomedial (0.03 ± 0.08%) zones. They spent 89.47 ± 6.51% of the two minutes in the outer layer. When segmented by the rectilinear model, neurotypical participants spent most time in the anterior (16.69 ± 8.22%), inferior (13.48 ± 8.49%), and inferolateral (10.57 ± 7.21%) zones, and spent least time in the posterior-superior-medial (0%), posterior-inferior-medial (0.01 ± 0.02%), and posterior-medial (0.03 ± 0.08%) zones.

A. Muscle Weakness

Per icosahedron-based model, Participants with stroke spent most time in the outer layer's anteroinferior (18.91 ± 13.19%) and anterior-inferior-lateral (12.74 ± 8.94%) zones. On average, they differed significantly compared to neurotypical individuals in five zones: the anterior-inferior-medial (9.46% vs. 5.12%, respectively; $p<0.01$), the posterior-inferior-lateral (3.03% vs. 9.57%, respectively; $p=0.03$), posterior-superior (0.43% vs. 2.45%, respectively; $p=0.04$), posterior-superior-lateral (0.52% vs. 2.74%, respectively; $p=0.02$), and posterior-lateral (0.26% vs. 1.13%, respectively; $p=<0.01$) zones (Fig 2a). Other outer layer zones and all inner layer zones were not significantly different.

When comparing four inferior zones (anterior-inferior-medial, anterior-inferior, anterior-inferior-lateral, and inferolateral) with their corresponding superior zones (anterior-superior-medial, anterior-superior, anterior-superior-lateral, and superolateral), stroke survivors were more likely to fall below the neurotypical CI in superior zones than in their inferior counterpart. In the anterior-inferior-lateral zone, 5 stroke survivors were lower and 8 higher whereas the superior counterpart had 11 lower and 2 higher ($Z=2.78$, $p=0.01$). For the anterior-inferior zone, 4 were lower and 9 higher, while the superior zone had 12 lower and 3 higher ($Z=3.01$, $p<0.01$). In the anterior-

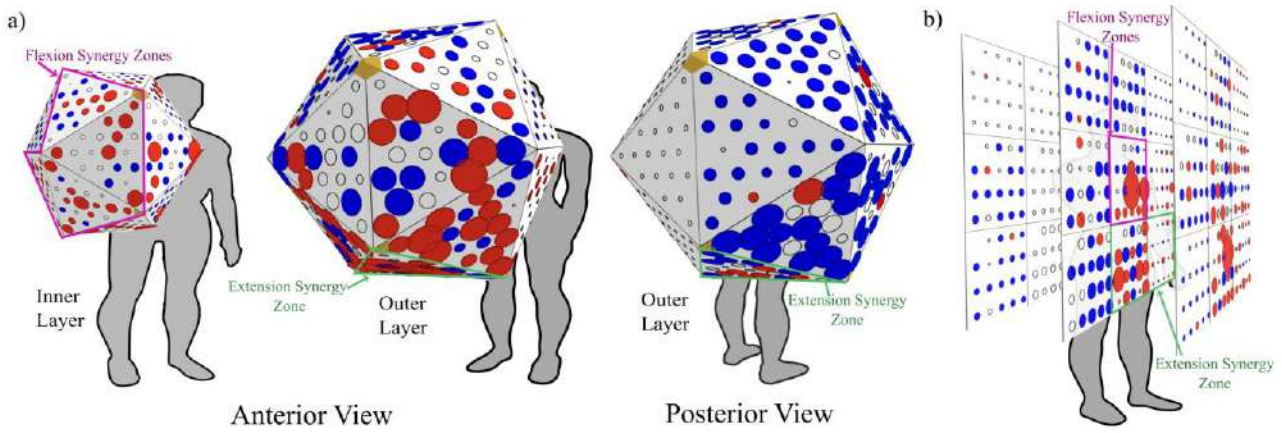

Figure 2: (a) All stroke survivors' probability distributions of wrist position partitioned by icosahedron where individuals have the same location on each face. Orientation marked by golden triangles. Red filled circles convey significantly more time than neurotypical individuals. Blue filled circles represent less time. Anterior view's inner and outer layer and posterior view's outer layer is presented. (b) All stroke stroke survivors' probability distribution of wrist position when segmented by the rectilinear model. Participants have same location in each zone.

inferior-medial zone, 6 participants were lower and 12 higher than the CI compared to 6 lower and 6 higher in the corresponding superior zone ($Z=1.14$, $p>0.05$). Finally, in the inferolateral zone, 11 were lower and 1 higher compared to 13 lower and 1 higher in the superolateral zone ($Z=0.55$, $p>0.05$).

Per rectilinear model, stroke survivors spent most time in the inferior (18.35 ± 13.21%) and anterior (17.45 ± 9.08%) zones. On average, they spent less time than neurotypical participants in four zones: superior (2.66% vs. 6.33%, respectively; $p=0.04$), superolateral (1.18% vs. 3.84%, respectively; $p<0.01$), posterior-lateral (0.73% vs. 2.73%, respectively; $p=0.02$), posterior-inferior-lateral (0.51% vs. 2.06%, respectively; $p=0.03$). Stroke survivors spent more time in the anterior-inferior-medial zone (2.11% vs. 0.56%, respectively; $p=0.02$) (Fig 2b).

In the anterior-inferior-medial zone, 10 stroke survivors were higher than the 95% CI and 4 lower, while the corresponding superior zone had 5 higher and 0 lower ($Z=0.35$, p=ns). In the anterior-inferior zone, 12 were higher and 4 lower whereas the anterior-superior zone had 3 higher and 10 lower ($Z=3.26$, $p<0.01$). The anterior-inferior-lateral zone had 1 higher and 14 lower, and the corresponding superior zone had 1 higher but 12 lower ($Z=-0.56$, p=ns). The inferolateral zone had 1 higher and 13 lower, and the superolateral zone had 2 higher and 16 lower ($Z=0.58$, p=ns).

B. Abormal Synergy

With the icosahedron model, 10 stroke survivors spent more time than the 95% CI in at least two of the inner layer's inferolateral, anterior-inferior-lateral, anterior-lateral, or anterior-superior-lateral zones. While, on average, stroke survivors did not spend more time than neurotypical participants in these four zones (7.10% vs. 4.37%, respectively; p=ns), these 10 stroke survivors did (11.49% vs. 4.37%, respectively; $p < 0.001$). Five in this group spent more time with their wrist in the posterior-inferior zone, and five spent more time in the anterior-inferior zone. Seven of the 10, however, spent less time in the outer layer's inferolateral zone (Fig 2a).

Per the rectilinear model, eight stroke survivors spent more time than the 95% CI in at least two of the middle layer's central, inferior, and inferomedial zones. Of these eight stroke survivors, two spent over 75% of the time here, and six of them were significantly less likely to have their wrist in the inferolateral zone. Seven of them overlapped with the 10 stroke survivors identified by the icosahedron model. On average, stroke survivors did not spend more time in these four zones compared to neurotypical participants (32.23% vs. 18.72%, respectively; p=06), but the eight stroke survivors did (52.78% vs. 18.72%, $p<0.01$) (Fig 2b).

C. Association to Clinical Scores

Six zones in the outer layer of the icosahedron model were positively associated with FMUE and ARAT scores. Of the zones in the outer layer, the percent time spent in the posterior-superior-lateral zone demonstrated strong positive correlation to FMUE ($R=0.70$, $p<0.0001$), FMUE-SS ($R=0.71$, $p<0.0001$), and ARAT ($R= 0.73$, $p<0.0001$). Percent time in the superior-lateral zone was moderately correlated with FMUE ($R = 0.57$, $p<0.01$), FMUE-SS ($R=0.59$, $p<0.001$), and ARAT ($R=0.58$, $p<0.01$), and time in posterior-superior zone was also moderately correlated with FMUE ($R=0.59$, $p<0.001$), FMUE-SS ($R=0.63$, $p<0.001$), and ARAT ($R=0.56$, $p<0.001$). The posterior-inferior-lateral, posterior-lateral, and inferior-lateral zones also had moderate correlation with all clinical scores (Fig. 3). The anterosuperior zone was moderately correlated with FMUE ($R=0.52$, $p<0.001$) and FMUE-SS ($R=0.55$, $p<0.001$), but not ARAT. The anterior-superior-lateral zone was also moderately correlated with FMUE ($R=0.44$, $p=0.02$), FMUE-SS ($R=0.51$, $p<0.01$), but not ARAT. Time in the anterior- inferior zone was negatively associated with ARAT ($R=-0.41$, $p=0.03$).

When segmented by the rectilinear model, percent time in the superolateral zone was strongly correlated with FMUE ($R=0.72$, $p<0.0001$), FMUE-SS ($R=76$, $p<0.0001$), and moderately correlated with ARAT ($R=0.69$, $p<0.0001$). Percent time in the anterior-superior-lateral zone was also strongly correlated with FMUE ($R=0.70$, $p<0.0001$), FMUE-SS ($R=0.72$, $p<0.0001$), and moderately correlated

with ARAT (R=0.61, p<0.001). The time in posterior-superior-lateral zone was strongly associated with ARAT (R=0.74, p<0.0001) and moderately associated with FMUE (R=0.64, p<0.001), FMUE-SS (R=0.66, p<0.001). In the posterior layer, percent time in the posterior-lateral, posterior, posterior-inferior-lateral, and posterior-inferior zones all had moderate association with all three clinical scores. In the anterior layer, time in the anterior-superior, anterior-lateral, anterior-inferior-lateral, and the anterior-inferior zones had moderate correlation to some of the three clinical scores. In the middle layer, the superior, superior-medial, and inferolateral zones had moderate correlation to some of the clinical scores (Fig. 3).

IV. Discussion

This study analyzed wrist position data during 2-minute upper-extremity free exploration in nine neurotypical individuals and 19 stroke survivors. An icosahedron-based model and a rectilinear-based model were then applied to segment the data and calculate probability distributions for each participant. Each model's identification of muscle weakness and abnormal synergies, and the correlation of probability in each zone to clinical scores was assessed.

Both the icosahedron and rectilinear model capture the tendencies of neurotypical participants to explore the inferior zones more during the 2-minute period. The over 10% discrepancy in probability between some lateral and medial zones in both models is likely due to the participant's body being positioned inferomedial to the shoulder joint, obstructing wrist movement in these regions. The approximately 70% difference in the icosahedron model between the outer and inner layer may be categorizing wrist position data with <90 degrees elbow flexion into the outer layer.

A. Muscle Weakness

Though stroke survivors showed the highest probabilities in the anterior-inferior and anterior-inferior-lateral zones, both the icosahedron and recitlinear models did show a significant drop in percent time in several posterior zones, including the posterior-lateral, posterior-inferior-lateral, posterior-superior-lateral, and posterior-superior zones. While the rectilinear model indicates that deficits are in the superior and the superior-lateral zones, the icosahedron-model clarifies that these deficits are specifically in the posterior direction. It identifies the posterior-superior-lateral zone to be the strongest movement deficit, on average, with an about 2% difference between neurotypical participants and stroke survivors. The results suggest the weakness of muscles involved in the flexion and abduction of the shoulder [23]. Both models agreed that stroke survivors compensate for decreases in percent time in the posterior regions with increase in percent time spent in the anterior-inferior-medial zone. This may be a generic sign of weakness in stroke survivors whose range of motion has been shown to decrease after stroke.

We expected the stroke survivor group to spend less time in the anterior-superior zones compared to neurotypical participants, but this was not the case. Still, compared to the 95% CIs of percent time based on

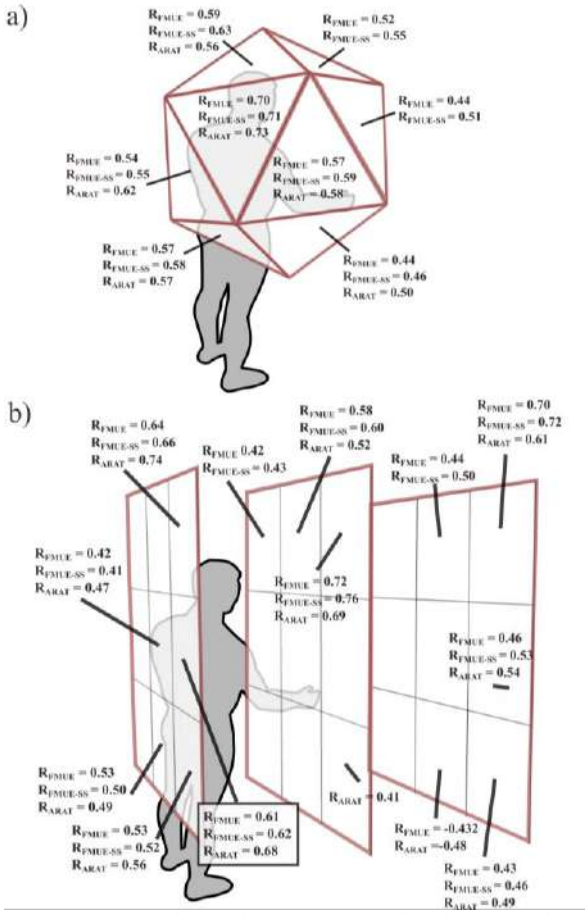

Figure 3: a) The eight icosahedral zones significantly correlated with FMUE, FMUE-SS, and/or ARAT are presented with their Spearman's correlation coefficient. The anterior-inferior zone not shown here had moderate negative correlation. All other zones were not significant when tested. b) The 14 rectilinear-based zones significantly correlated with clinical scores are displayed. Zones without Spearman's correlation coefficient displayed were not significant when tested.

neurotypical participant data in the icosahedron model, individual stroke survivors were more likely to fall below the interval in the anterior-superior and anterior-superior-lateral zones, spending more time in their inferior counterparts. The rectilinear model was aligned with the results in the anterior-superior direction. These results suggest that stroke survivors were more affected by gravity compared to neurotypical participants, indicating muscle weakness even in the anterior field. The icosahedron model identified muscle weakness in the anterior-superior-lateral. Meanwhile, the rectilinear model failed to detect it. This discrepancy may be due to the rectilinear model's grid-based structure, which likely struggles to capture the spherical data's corners effectively. The icosahedron model may offer an advantage due to its superior directional specificity in these regions.

B. Abnornal Synergy

Per the icosahedron model, 10 stroke survivors were found to spend significantly more time in at least two of the inner layer's inferolateral, anterior-inferior-lateral, anterior-lateral, and anterior-superior-lateral zones. These results may originate from the influence of the flexion synergy. As

literature suggests [24], this abnormal movement pattern can be observed as involuntary elbow flexion when the shoulder is abducted, which the icosahedron model reveals as higher percent time in the inner layer in these four regions. Meanwhile, abnormal synergies in the other 9 stroke survivors were not identified. This may be due to the inner layer's radius being small or too exclusive. Adding joint angle data of the shoulder abduction and elbow flexion may be beneficial to confirm this or improve the diagnostic quality of this model. The model also identifies that five of the 10 stroke survivors whose flexion synergy may have been observed spend more than the 95% CI in the posterior-inferior and anterior-inferior zones. This may be a sign of the extensor synergy in this group, which previous studies predict overlap in patients with the flexion synergy [1], [3] or it may be a sign of muscle weakness. However, though these subjects are able to flex their shoulders in the anterior zones, seven of the 10 stroke survivors could not abduct their shoulder to even the inferolateral zone. The combination of their flexion synergy where elbow flexion is seen with shoulder abduction and the extensor synergy where elbow extension is paired with shoulder adduction may be the cause of stroke survivors' inability to reach this inferolateral zone.

The rectilinear model found eight stroke survivors who spent more than the 95% CI in two of the middle layer's following zones: central, inferior, inferomedial. This model also found that six of the eight participants spent significantly less time in the inferolateral zone. The combination of these findings may be a sign of the flexion and extension synergies. Of note, seven of these eight overlapped with the icosahedron model, indicating that these models observe the same abnormal synergies in slightly different perspectives. The large difference of about 35% between these eight survivors in comparison to neurotypical participants may be due to the rectilinear model's single central zone which sums all the icosahedron's inner layer's zones into one. However, the icosahedron model's splitting of this zone may have allowed it to find a couple more stroke survivors who exhibit these stereotypical movement patterns. Overall, the icosahedron model is potentially more sensitive at identifying synergistic behaviors in stroke survivors.

C. Association to Clinical Scores

In the icosahedron model, eight zones were associated with FMUE and ARAT with one zone, posterior-superior-lateral, having a strong correlation of greater than 0.70. A few zones including the posterior-superior and the superior-lateral had correlations greater than 0.60. Other zones like the anterior-superior showed moderate correlation linked possibly by muscle weakness in these stroke survivors. The consistent compensation of stroke survivors in the anterior inferior medial zone was again identified here with a moderate negative correlation to ARAT.

The rectilinear model, meanwhile, related 14 zones to these clinical scores. Two zones (superolateral and anterior-superior-lateral) demonstrated strong association with FMUE and ARAT of greater than 70. Unlike the icosahedron model, the posterior-superior-lateral zone only strongly correlated well with ARAT. Six of the 14 zones showed significant but less than 0.50 association to the clinical scores maybe due to the generalized weakness as well. The consistent relation of rectilinear-based zones may suggest a superiority to the icosahedron model for clinical score prediction. Both models had a higher correlation with FMUE-SS in comparison to FMUE, which may indicate that both models' segmentation of the data are capturing how different muscles work independently of one another via wrist position in each zone.

D. Limitations and Future Work

In this analysis, with the group of nine neurotypical participants and 19 stroke survivors, flexion and extension synergy patterns are claimed to have been identified. The small sample size may limit however the generalizability of these patterns. Also, while Welch's t-tests accounted for unequal variances, the imbalance in group sizes may still introduce bias, potentially overestimating the differences between groups. Additionally, the repeatability of the free exploration data is unchecked. Future work may compare each participants' probability distributions to other instances of free exploration in follow up data collection. The study is also retroactively performed so the instructions of free exploration may have been unclear and the intention of subjects when they are they are in regions claimed to signify synergistic patterns cannot be ascertained.

Weakness and synergistic patterns are inferred in this analysis based on clinical presentation and FMUE scores. Confirmation using EMG was not performed, which may limit the validity of the findings. This analysis could be performed in future work. All data were assessed in comparison to the glenohumeral joint with left impaired stroke survivors or left dominant neurotypical individuals' wrist position reflected across the sagittal plane. This potentially misses shoulder movement and trunk compensation, which may have strengthened the link to flexion and extension synergies. Future work may consider joints external to the wrist in the context of joint angles to corroborate the hypotheses made in this study. Findings from this paper suggest that differences in probability distributions can be used across various movements to identify movement deficits and evaluate the effectiveness of new devices designed to assist other movements such as supination and plantar flexion [25], [26].

V. Conclusion

This study compared icosahedron-based and rectilinear-based probability distributions for identifying arm movement deficits in stroke survivors using wrist position data from two minutes of upper extremity free exploration. While both models revealed shoulder flexion weakness in the zones directly anterior to the body and shoulder abduction weakness, the icosahedron-based model identified an additional flexion movement deficit anterolaterally in stroke survivors. Furthermore, this model detected abnormal flexion and extension synergies in 10 stroke survivors, two more than the rectilinear model. However, the rectilinear-based model demonstrated superiority in predicting clinical scores with 14 zones correlating to FMUE or ARAT compared to just 8 in the icosahedron model.

The icosahedron model's alignment with anatomical movement makes it a promising framework for

individualized upper extremity assessment. Meanwhile the rectilinear model's performance in correlating to clinical scores highlight its utility in broader score-based evaluations. A hybrid of both models may equip therapists to identify movement deficits and to estimate clinical score within two minutes of evaluation, saving them time to treat patients effectively, potentially improving care and reducing therapist burnout. A key limitation of this study was the unchecked repeatability of the data and a relatively small sample size. Future research could address these limitations by validating results in follow up free exploration data and incorporating joint angles to contextualize wrist position further.

Mapping the Neural Control of Force and Impedance of Wrist Movements Using Robotics and fMRI

Kristin Schmidt and Fabrizio Sergi

***Abstract*—While robots are becoming increasingly valuable tools in neurorehabilitation, our limited understanding of the brain's response during human-robot interaction tasks restricts advancements in training programs to restore neural pathways after injury. Co-contraction is characteristic of several neuromuscular disorders, such as stroke and cerebral palsy, and it is often targeted by assessments or rehabilitation programs. Despite its importance, the neural mechanisms underlying co-contraction remain poorly understood. To address this gap, this study investigates the neural substrates of muscle co-contraction via functional magnetic resonance imaging (fMRI) during a dynamic motor task with an MR-compatible wrist robot.**

To establish suitable fMRI experimental conditions, we first conducted a behavioral study assessing muscle activity during a wrist-pointing task with four participants. Participants reached toward a target while experiencing four main perturbation conditions (no force, divergent force, constant force up, and constant force down), designed to elicit distinct force and impedance responses. Following this behavioral validation, five additional participants performed the wrist-pointing task during fMRI. Our results suggest localization of force and impedance control within the cortico-thalamic-cerebellar network. These findings provide new insights into the neural mechanisms of co-contraction, supporting the development of neurorehabilitation paradigms.

I. Introduction

Motor control is essential for performing skilled movements in daily life, yet disruptions in this ability are associated with several neuromuscular conditions, such as stroke and cerebral palsy [1]. These neuromuscular disorders often feature altered muscle activation strategies, such as excessive co-contraction of agonist and antagonist muscles. This lack of precise regulation of muscle groups impairs movement efficiency and increases fatigue, making everyday activities more challenging. As a result, physical therapists sometimes target a reduction in muscle co-contraction as a goal for rehabilitation [1]. However, current therapeutic approaches to regulating muscle co-contraction are limited by our lack of understanding of how muscle co-contraction is controlled at the neural level. Addressing this gap is critical for identifying therapeutic targets and developing effective interventions to optimize muscle coordination and restore motor function.

Co-contraction plays an important role in maintaining joint stability [2], resisting external disturbances during movement [3], and may also facilitate the learning of new skills [4]. However, it is a metabolically demanding control strategy and is generally reserved for tasks that demand increased joint stiffness, such as those that are unpredictable or unstable. Conversely, tasks that involve learnable dynamics allow the central nervous system to predict dynamics with an accurate internal model, enabling a more efficient control strategy through the reciprocal activation of agonist muscles. Reciprocal activation generates direction-specific joint torques, which is useful for opposing forces with a predictable direction. While co-contraction and reciprocal activation are distinct motor strategies, they often occur simultaneously [5], [6], necessitating careful task design to isolate their control. Ultimately, disentangling these mechanisms at the neural level can enable more targeted therapeutic approaches in neurorehabilitation.

In this work, we first validate a set of experimental task conditions in a wrist-pointing task designed to decouple co-contraction and reciprocal activation, as estimated by electromyography (EMG). This EMG validation ensures the task conditions reliably differentiate between these mechanisms, a crucial step for distinguishing their underlying neural processes. Following this behavioral validation, we conduct an fMRI study using the same task conditions to investigate the neural correlates associated with torque and stiffness control. This work provides preliminary insights into the neural mechanisms responsible for muscle co-contraction and reciprocal activation during dynamic motor tasks, with potential implications for improving rehabilitation strategies.

II. Materials and Methods

In this work, we present findings from two studies, a behavioral study and a neuroimaging study, with similar methodologies; the primary distinction between the two studies is that the behavioral study was conducted in a mock MRI scanner with EMG, while the neuroimaging study took place in a real MRI scanner without EMG. In both studies, participants performed wrist-pointing movements using the MR-SoftWrist [7], an MR-compatible wrist robot, while lying supine (Fig. 1). The MR-SoftWrist enables wrist movements in flexion-extension (FE) and radial-ulnar deviation (RUD).

A. Participants

Four healthy young adults (2 male, 27.5±3.11 years) were recruited for the behavioral study, and five healthy young adults (3 male, 27.2±3.19 years) were recruited for the neuroimaging study. Participants had no history of neuromuscular disorders. This study was approved by the Institutional Review Board of the University of Delaware, IRB no. 1936400-3.

B. Experimental Setup

Participants' right hand was secured in the handle of the MR-SoftWrist, which enclosed the knuckles without limiting

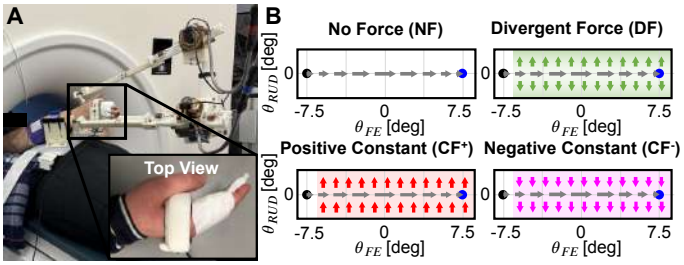

Fig. 1. A. MR-SoftWrist pictured in its operating condition. The enlarged image shows a top view of the handle with the paddle insert and tape around the participant's fingers. B. Experimental force conditions.

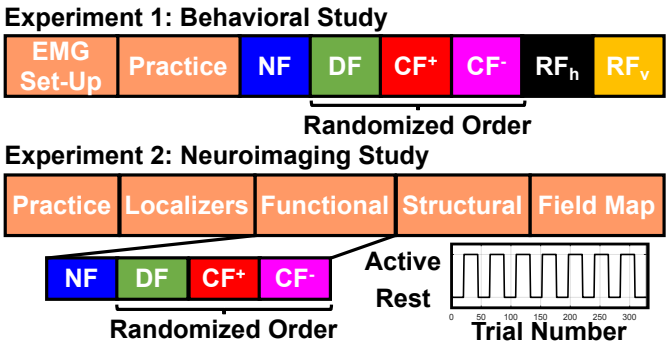

Fig. 2. Experimental protocol of the behavioral and neuroimaging studies.

finger movement. To promote a slightly flexed finger posture and reduce extraneous finger muscle contraction, their fingers were taped to a small paddle inserted into the handle (Fig. 1A). They were instructed to focus on making wrist movements while keeping their fingers and thumb relaxed. Their forearm rested on a rigid arm support placed on their stomach, with additional padding for shoulder and upper arm support. Participants viewed the task on a monitor through glasses with angled mirrors in the behavioral study or through an angled mirror attached to the imaging head coil during neuroimaging.

In all tasks, the goal was to move in a straight line between two circular targets. For horizontal tasks, these were located at ($\pm$7.5,0) deg, and for vertical tasks, these were located at (0,$\pm$7.5) deg, relative to the neutral hand posture in the FE and RUD axes, respectively. Each trial began with the target changing color from black to blue. After the participant moved the cursor 1 deg away from the starting target, the cursor was hidden to reduce corrections on real-time feedback. At the end of each trial, speed feedback was displayed by a change in target color to red if too slow (>0.45 s), green if too fast (<0.2 s), or black if within the desired time window. Error feedback was also displayed via a yellow cursor at the position of the maximum deviation from the straight-line trajectory.

During these movements, the robot applied forces perpendicular to the primary movement direction. The main force conditions used in this study were no force (NF), divergent force (DF), constant force up (CF$^+$), and constant force down (CF$^\infty$) (Fig. 1B). These conditions were all oriented as horizontal movements, so forces were applied in the RUD direction. NF was intended to assess baseline performance. In DF, the robot applied RUD perturbation torques proportional to the RUD wrist angle, up to a maximum torque, τ_m, such that $\tau_{RUD} = \min(k_v\theta_{RUD}, \tau_m)$, with $k_v = 0.085$ Nm/deg and $\tau_m = 1$ Nm. This unstable condition was designed to up-regulate muscle co-contraction [3]. In the CF conditions, torque was applied to push the wrist in the radial (positive, against gravity) direction (CF$^+$: $\tau_{RUD} = 0.3$ Nm) or in the ulnar (negative, with gravity) direction (CF$^\infty$: $\tau_{RUD} = -0.3$ Nm). These CF conditions were included to provide a clearer interpretation of DF, as the effects observed during DF could result from either the independent control of individual muscles or a higher-order mechanism regulating co-contraction [6]. Specifically, CF controls for radial muscle activation (u_R), primarily in response to CF$^\infty$, and ulnar muscle activation (u_U), primarily in response to CF$^+$.

1) Behavioral Study: EMG was used in the behavioral study only. We used Delsys Trigno Duo electrodes (sampling frequency: 2148 Hz), and the EMG signal was time-synced to task performance data (sampling frequency: 1000 Hz) via a common analog signal sent at the onset of each trial. EMG sensors were placed on the participant's four major wrist muscles: flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), extensor carpi ulnaris (ECU), and extensor carpi radialis (ECR). The forearm was prepared for electrode placement by shaving the arm hair and cleaning the skin with alcohol. Electrode placement was checked by observing large bursts of agonist muscle activity. A force-torque sensor (ATI mini40, ATI Industrial Automation, Apex, NC, USA) in the device handle was used to measure user-applied torques.

2) Neuroimaging Study: The neuroimaging study took place at the University of Delaware Center for Biomedical and Brain Imaging with a Siemens Prisma 3T scanner and 64-channel head coil. All functional images were acquired using a multiband T_{2*}-weighted EPI sequence (spatial resolution: 2×2×2 mm^3, 60 slices, TE=30ms, TR=1s, acceleration factor=4, Image Size=[110 110 60]). We also acquired a T1-weighted anatomical image (1×1×1 mm^3, TE=3.02ms, TR=2.3s, Image Size=[160 256 256]) for image registration and normalization and a GRE-field map (3×3×3 mm^3, TE=4.92ms, TR=400ms) for unwarping due to magnetic field inhomogeneities. We monitored physiological signals with an MR-compatible pulse oximeter and respiration belt (Siemens Physiology Monitoring Unit).

C. Protocol

After participants were positioned on the bed with the robot, they practiced the task in a transparent (NF) condition. During this time, they were instructed to practice making straight point-to-point movements within the cued time window. Participants were able to self-select when they felt comfortable enough with the task instructions and felt ready to end the practice session, after typically no more than 100 trials.

1) Behavioral Study: After familiarization, participants performed six blocks of 200 trials each, with about five minutes

of rest between blocks to reduce fatigue (Fig. 2). All but the final task block featured horizontal movements, and the final block featured vertical movements. The goal of the task was always the same, but the robot was commanded in different force modes across blocks. The first block was always an NF task to assess baseline task performance, followed by three randomly ordered DF, CF^{+}, and CF$^{\infty}$ blocks (Fig. 2). The final two blocks were added for EMG calibration, where participants were subject to viscous resistive forces (RF) during horizontal (RF$_h$: $\tau_{FE} = -\alpha_R \dot{\theta}_{FE}$ Nm) and vertical (RF$_v$: $\tau_{RUD} = -\alpha_R \dot{\theta}_{RUD}$ Nm) movements, where α_R=0.050 Nm/deg. The RF tasks were intended to elicit strong agonist activation in each direction, improving the signal-to-noise ratio for improved EMG calibration.

2) Neuroimaging Study: In the neuroimaging study, participants performed four tasks during functional imaging (Fig. 2). Each task consisted of 168 active trials divided evenly into seven blocks, interspersed with 19.5 s passive blocks. During these passive blocks, the robot locked in its current position, and participants were instructed to watch the virtual cursor make straight point-to-point movements between the targets. This condition acts as our visual control to match the visual stimulus seen during task performance. Within each task, all active trials were controlled under the same force mode, which corresponded to the same conditions used in the first four blocks of the behavioral EMG study. The first block was always NF, followed by a random order of DF, CF^{+}, and CF$^{\infty}$. The neuroimaging session also consisted of localizers and anatomical scans for image registration and unwarping.

D. Data Analysis

1) Trial Onset and Normalization: To consistently analyze data collected over multiple trials, we established three specific time windows: Early, Middle, and Late. The Early window spanned from 150 ms before trial onset ($t_{\propto 150}$) and lasted until trial onset (t_0). In our analysis, t_0 was defined as the instant when the cursor exceeded a position threshold of 1 deg away from the starting target in the direction towards the cued target. The Middle time window started at t_0 and ended at the point of maximum velocity (t_{vmax}). Finally, the Late time window covered the period from t_{vmax} until the end of the trial (t_{end}), defined as the time when the cursor reached a lateral position within 1 deg of the ending target. Task kinematics, kinetics, and EMG were normalized via resampling so that the instants of $t_{\propto 150}$, t_0, t_{vmax}, and t_{end} coincided across participants.

2) EMG-based Joint Torque and Stiffness Estimation: EMG signals were bandpass filtered at 30-500 Hz, rectified, and the envelope was taken via a 10 Hz low-pass, zero-shift 4th order Butterworth filter. Muscle moment arms (ρ) were obtained at each joint position using OpenSim [8].

For each muscle, we time-shifted the EMG signal (m) to synchronize with kinematic data, accounting for the electromechanical delay. We then related this delayed EMG signal ($m(t-t_d)$) to muscle forces (F_m) via a muscle-specific scaling factor (γ) (Eqn. 1). While this simplistic EMG-force relationship neglects the position and velocity-dependent effects of muscle activation, these effects may be negligible in our task because movements are small amplitude (range < 20 deg) and slow during the main region of interest (quasi-static in the Early window, $t_{\propto 150} : t_0$). Within this range, the peak active muscle force is predicted to change by 0.6-45%, as predicted by the force-length curves in the OpenSim wrist model [8]. We are primarily interested in relative differences across force conditions, where the muscle lengths and velocities are similar, so estimation errors across conditions should be comparable.

We calibrate γ at the joint level by relating task dynamics and predicted user-generated torques (τ_{pred}) to the force-torque sensor measured torques (τ_{meas}) via linear regression (Eqn. 2-3). For the calibration procedure, we included all active trials across all six force conditions.

$$F_{m_i}(t) = \gamma_i m_i(t - t_d), t_d = 90 \text{ ms} \tag{1}$$

$$\tau_{pred,j}(t) = I_j \ddot{\theta}_j(t) + b_j \dot{\theta}_j(t) + \sum_{i=1}^{4} \rho_{j,i}(\gamma_i m_i(t - t_d)) \tag{2}$$

$$\boldsymbol{\tau_{pred} - \tau_{meas} = 0} \tag{3}$$

In these equations, j refers to the degree of freedom (FE or RUD) and i refers to the muscle (FCR, FCU, ECU, or ECR). The system dynamics are modeled in Eqn. 2 as an inertial term ($I\ddot{\theta}$) with viscosity ($b\dot{\theta}$) and human-applied torque (ρF_{m_i}). The coefficients I, b, and γ are estimated by minimizing prediction errors via linear regression (Eqn. 3). Once γ was estimated for each muscle, we calculated human-generated torques in the radial direction only (u_R), ulnar direction only (u_U), and net RUD torque (τ_{RUD}) as:

$$u_R = \rho_{2,FCR}\gamma_{FCR}m_{FCR} + \rho_{2,ECR}\gamma_{ECR}m_{ECR} \tag{4}$$

$$u_U = \rho_{2,FCU}\gamma_{FCU}m_{FCU} + \rho_{2,ECU}\gamma_{ECU}m_{ECU} \tag{5}$$

$$\tau_{RUD} = u_R - u_U \tag{6}$$

where $\rho_{2,i}$ refers to the muscle moment arm in RUD.

Muscle stiffness is typically a function of its mechanical properties (i.e., stiffness of its cross-bridges), length, and cross-sectional area. However, it has been found experimentally that muscle stiffness within a small range can be directly related to force via a scaling constant α/l_0, where α=23.4 [n.u.] and l_0 is the optimal muscle fiber length at maximum activation [9]. We used this relationship to estimate muscle-level stiffness (Eqn. 7) and related it to joint-level stiffness via its moment arms (Eqn. 8), where $\boldsymbol{J}$ is the Jacobian matrix comprised of the muscle moment arms from OpenSim [8].

$$\kappa_{SRS,i} = \frac{\alpha}{l_0} F_{m,i} \tag{7}$$

$$\boldsymbol{\kappa} = \boldsymbol{J}\ \text{diag}(\boldsymbol{k}_{SRS})\ \boldsymbol{J}^T \tag{8}$$

$\boldsymbol{\kappa}$ reflects the force opposed by the participant when a unit displacement is applied, such that the magnitude of stiffness along a specific direction, *p*, is described as

$$\kappa_p = ||\boldsymbol{\kappa} \cdot [\Delta\theta_{FE}, \Delta\theta_{RUD}]^T|| \tag{9}$$

Thus, we extract RUD stiffness as $\kappa_{RUD} = ||\boldsymbol{\kappa} \cdot [0,1]^T||$.

Group-level differences were assessed using the average across all trials and analyzed using a linear mixed model. Significant force condition effects were followed by pairwise student's t-tests ($p < 0.05$). Statistics were computed using only the Early window ($t_{\propto 150} : t_0$) to assess anticipatory motor commands, with full-trial data included for visualization.

3) Statistical Analysis of Imaging Data: Neuroimaging data was preprocessed using SPM12 [10], following a standard pipeline: unwarping, field map correction, realignment, MNI normalization, and smoothing with an 8mm Gaussian kernel.

The neural response was modeled as

$$y = \beta_1 H_1 + \beta_2 H_2 + \beta_3 H_3 + \beta_4 H_4 + \beta_{nui} H_{nui} + \beta_0 \quad (10)$$

where H_1, H_2, H_3, and H_4 represent the task regressors for active blocks of NF, DF, CF$^+$, and CF$^\infty$ trials convolved with the standard hemodynamic response function. H_{nui} is a set of 25 nuisance regressors (18 physiological noise regressors, 6 head movement regressors, and 1 linear signal drift regressor). Physiological noise regressors were modeled using the RETROICOR algorithm via the TAPAS PhysIO Toolbox [11].

Analysis of the General Linear Model (GLM) (Eqn. 10) yielded maps of beta-weights, relating signal measured in each voxel to each regressor of interest (β_1, β_2, etc.). We report voxels that activate more in one condition relative to others, based on linear contrasts c_i of the extracted β coefficients. Due to the study's limited number of participants, we report voxels with t-scores exceeding 4. This threshold was selected as a representative level for significance found in our prior work with larger study sizes [12], [13]. Activation regions were labeled using the Juelich Histological atlas for cortical regions [14], Harvard-Oxford atlas for subcortical regions [15], and MNI FNIRT atlas for the cerebellum [16].

For ease of notation, we define four activation maps to describe voxels related to the physiological phenomena of interest, i.e. brain areas associated with force and impedance. Specifically, the K map identifies voxels that contribute to stiffness modulation, which we define as those whose BOLD signal is upregulated more during DF compared to NF ($c_K = \beta_{DF} - \beta_{NF}$). The u_R and u_U maps reflect torque regulation in the radial or ulnar direction, respectively, compared to baseline ($c_{u_R} = \beta_{CF^-} - \beta_{NF}$, $c_{u_U} = \beta_{CF^+} - \beta_{NF}$). The $|T|$ map isolates voxels specific to torque in any direction ($c_{|T|} = \beta_{CF^-} - \beta_{CF^+}$, where both positive and negative statistical parametric coefficients are evaluated). Finally, the CC map, related to co-contraction control, identifies voxels with greater activation in DF relative to baseline, that exceeds the upregulation due to CF conditions ($c_{CC} = (\beta_{DF} - \beta_{NF}) - (\beta_{CF^-} - \beta_{NF}) - (\beta_{CF^+} - \beta_{NF}) = \beta_{DF} - \beta_{CF^-} - \beta_{CF^+} + \beta_{NF}$). With this formulation, the intersection of the K and CC maps reflects voxels that tune to co-contraction.

III. Results

A. Behavioral Results

As confirmation of reasonable EMG to torque estimation, τ_{RUD} levels in the Early window ($t_{\propto 150} : t_0$) differed significantly across conditions in the expected directions ($p = 0.002$) (Fig. 3). Torque generated in CF$^\infty$ was significantly greater than all other conditions (CF$^\infty$–NF: $p = 0.002$, CF$^\infty$–DF: $p = 0.011$, CF$^\infty$–CF$^+$: $p < 0.001$), while τ_{RUD} was not significantly different between NF and DF conditions ($p = 0.263$). Torque in CF$^+$ was lower than both DF ($p = 0.026$) and CF$^\infty$ ($p = 0.002$), but not different than NF ($p = 0.176$).

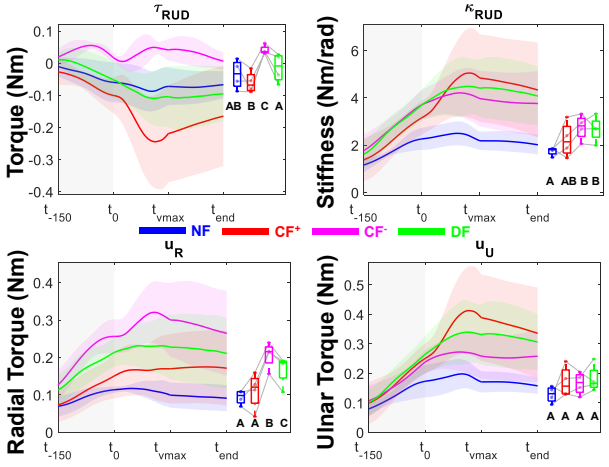

Fig. 3. Group-level torque and stiffness estimates. The boxplots show the distribution of each subject's mean activity in the shaded time window ($t_{-150} : t_0$). Significance is expressed in the connecting letters format, where pairs of conditions that do not share a letter are significantly different.

The torque relationships in the radial direction (u_R) follow a similar pattern (Fig. 3). The largest u_R magnitude occurred in the CF$^\infty$ condition, significantly exceeding NF ($p < 0.001$), DF ($p = 0.007$), and CF$^+$ ($p < 0.001$). There was no significant difference between NF and CF$^+$ ($p = 0.158$). However, despite aiming to match u_R levels between DF and CF$^\infty$ to test the muscle-level control hypothesis of co-contraction, u_R was significantly smaller in DF ($p = 0.007$).

For torque in the ulnar direction (u_U), there were no significant differences across conditions ($p = 0.218$) (Fig. 3). The desired relationship would be to match u_U levels between DF and CF$^+$ (where ulnar activation is agonist), and we are correctly not observing any significant difference between them. However, ideally we would like to see higher levels of u_U in CF$^+$ compared to CF$^\infty$ or NF to confirm that significant ulnar activation is necessary for the CF$^+$ task. In its current state, the gravitational force may be canceling out much of the applied force, requiring only small ulnar activation.

Stiffness (κ_{RUD}) was also significantly modulated by force condition ($p = 0.020$) (Fig. 3). While there was no significant difference in κ_{RUD} across pairs of the non-zero force conditions (CF$^+$–CF$^\infty$: $p = 0.097$, CF$^\infty$–DF: $p = 0.795$, CF$^+$–DF: $p = 0.148$), κ_{RUD} was smaller in NF than CF$^\infty$ ($p = 0.006$) and DF ($p = 0.009$). There was no significant difference between NF and CF$^+$ ($p = 0.115$).

B. Neuroimaging Results

Group-level fMRI results are shown in Fig. 4 and Table I. Activation for stiffness modulation (K map, green clusters in

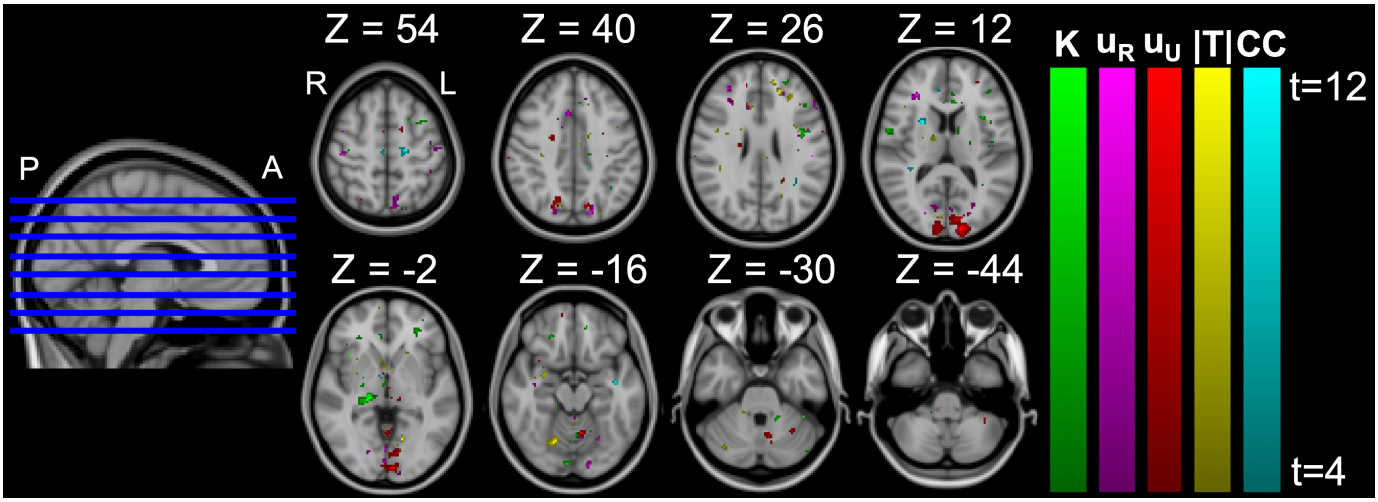

Fig. 4. Group-level t-score activation maps for task-based regressors. These maps refer to contrasts $c_K > 0$, $c_{u_R} > 0$, $c_{u_U} > 0$, $c_{|T|} = 0$,and $c_{CC} > 0$. For visualization of the t-score gradients, each contrast was thresholded between t={4,12}. Z coordinates refer to axial slices in MNI152 coordinates in mm.

Fig. 4) localized in the bilateral premotor cortices (Brodmann's Area 6), cerebellum (left V and vermis VI lobules), and the thalamus and subthalamic region across both hemispheres, including the pallidum, amygdala, and caudate. We also observed some activation clusters in the occipital lobe. Torque-related maps (u_R (magenta), u_U (red), and $|T|$ (yellow)) showed large regions of activation in the cerebellum and visual areas, including the lateral occipital cortex and visual cortex V2 (Brodmann's Area 18). The CC map (cyan), which describes the control of co-contraction, primarily resulted in active voxels in the bilateral premotor cortices, thalamus, and subthalamic regions (putamen, pallidum, and amygdala).

C. Task Performance Results

Task errors did not significantly differ between the two studies ($p = 0.660$, Fig. 5), suggesting that muscle activation in the behavioral experiment generally reflects the behavior during neuroimaging. While force condition had a significant effect on task errors ($p < 0.001$), there was no significant effect of interaction between force condition and study ($p = 0.055$).

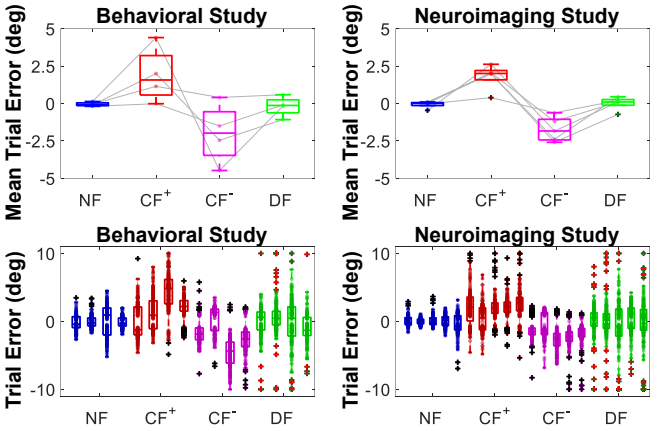

Fig. 5. Trial errors displayed at the end of each trial. The top row shows the distribution of each subject's average error in each force condition, and the bottom row shows the within-subject distribution of error across trials and conditions, where each boxplot represents one subject.

IV. Discussion and Conclusion

Our primary objective was to examine the neural substrates associated with force and impedance control during dynamic wrist-pointing. We showed that our task significantly modulates stiffness (κ_{RUD}) in DF relative to NF (Fig. 3), enabling the use of c_K to study stiffness modulation, albeit coupled with effects of increased muscle activation. To isolate torque generation in the radial or ulnar direction, we included the CF conditions to match agonist activation levels with those in DF. However, u_R was significantly greater in CF$^{\infty}$ than DF, despite our aim to match levels. Additionally, CF^{+} produced a weak u_U response due to gravity reducing the applied force magnitude. This suggests our contrasts c_{u_R} and c_{u_U} may not fully compensate for the effects of agonist activation. In the future, we will increase the instability of DF to provide more stiffness modulation relative to the CF conditions and a better match of u_R between DF and CF^{+}. We also plan to increase the magnitude of CF^{+} to overcome gravity. These changes should improve the relationships across conditions.

Our fMRI study revealed activation within the cortico-thalamic-cerebellar network (Fig. 4, Table I). Consistent with prior studies [17], clusters related to torque generation (u_R, u_U, and $|T|$ maps) were observed in the dorsal premotor cortex. We also observed activation clusters in the ventral premotor cortex in the K, u_R, u_U, and $|T|$ maps, supporting its role in voluntary co-contraction [17]. The overlap of the K and CC maps, reflecting co-contraction, identified only a few common voxels (left thalamus, left amygdala, and anterior intra-parietal sulcus). We will need additional participants to understand if these areas are truly significant. Additionally, cerebellar activation in the K, u_R, u_U, and $|T|$ maps aligns with the cerebellum's proposed role in managing complex

dynamics [18], [19].

We observed large activation clusters in the visual cortex in the u_R and u_U maps. This activation may result from inadequate matching across conditions of the error feedback displayed at the end of each trial. Because error magnitude and direction differed across conditions (Fig. 5), the feedback cursor appeared at a different location on the screen, invoking a unique visual response. For future studies, we will improve the visual control condition shown during rest by displaying errors that are representative of actual task performance and incorporating explicit error regressors into the GLM (Eqn. 10).

In conclusion, we demonstrated that the DF condition sufficiently modulates stiffness relative to NF, and the CF conditions properly modulate torque. However, while these relationships are sufficient to interpret joint-level neural activation, we need to refine the magnitudes of these conditions to fully control for muscle-specific activation (u_R and u_U). Our fMRI study revealed activation within the cortico-thalamic-cerebellar network, with notable areas including the premotor cortex, thalamus, and cerebellum.

Measuring actual arm use during soft-robotic glove use at home: single-case experimental design in patients with hand limitations

Anke I. R. Kottink, Leendert Schaake, Erik C. Prinsen, Johan S. Rietman and Gerdienke B. Prange

Abstract— **Patients with persistent hand function limitations in a chronic phase of their traumatic hand injury or neurologic disorder can benefit from wearable robotics to assist in their activities of daily life (ADL). Use of a grip-supporting soft-robotic glove as assistive device at home for six weeks has a therapeutic effect in addition to the direct assistance, with improved grip strength and hand function. The effect is thought to be related to an increase in actual arm use in daily life. This is investigated in an ongoing single-case experimental design (SCED) study among three patients with traumatic hand injury or a neuromuscular disorder. Actual arm use was measured using an accelerometer worn around each wrist for a week before, during and after six weeks of glove use at home.**

Three participants started concurrently. Two participants completed the study in compliance with the protocol, indicating feasibility for an SCED study in this setting. However, it needs attention during recruitment for participants' capacity to follow an intensive study schedule. Actual arm use increased during soft-robotic glove use in both participants, although to varying degrees, and decreased after cessation of glove use. This indicates that the arms/hands were used more intensively in daily activities during the period when the soft-robotic glove was worn. Further analysis is needed to assess whether a relation with hand function improvement and/or perceived benefit exists.

I. Introduction

Patients with persistent hand function limitations after traumatic hand injuries or due to neurologic disorders experience a permanent decline of their ability to perform activities of daily living (ADL), affecting their independence and wellbeing. Often hand strength is affected, resulting in a decreased ability to handle objects, which is crucial for ADL.

Technological advancements in wearable robotics (WR) have generated devices that are increasingly suitable to be used in daily life. Particularly, soft WRs are promising to improve uptake of wearable robots in daily life, due to their advantage regarding comfort, weight and bulkiness over rigid WRs [1], [2]. This enables prolonged use of a WR in daily life, providing direct support for assistance during ADL by supporting the patient's movement. By allowing longer or better performance of functional tasks, assistive WRs may also have a potential training effect, improving functioning without WR support [3].

This work was funded as part of the FutureGlove study under the Eurostars program, grant E!114821.

A. I. R. Kottink, E. C. Prinsen, J. S. Rietman, and G. B. Prange-Lasonder, are with Roessingh Research and Development, and University of Twente, Enschede, the Netherlands. L. Schaake is with Roessingh Research and Development, Enschede, the Netherlands. Corresponding author is G. B. Prange-Lasonder (g.prange@rrd.nl).

Recently, we demonstrated that use of a wearable soft-robotic glove as assistive device for 1,5 months during ADL by patients with hand function limitations resulted in a training effect on grip strength and the ability to perform functional tasks with the affected arm/hand (without the glove) [4], [5]. One of the hypotheses of the beneficial effect of assistive glove use in that clinical trial, as reported by the involved healthcare professionals, was that it stimulates increased use of the more-affected arm/hand in daily tasks instead of relying on the less-affected side, essentially reversing learned non-use. Therefore, in a consecutive study (as part of the FutureGlove study), we are investigating whether actual arm use changes during and/or after use of the soft-robotic glove at home (Figure 1).

Objectively measuring actual arm use, without having to rely on subjective recall of arm use by users themselves, of both arms separately can be done by employing accelerometers on the wrists [6], [7]. By wearing accelerometers on a wristband for multiple days, a good impression of actual arm activity in daily life can be obtained, including distinction between activity of the more- and less-affected arm and hand.

Figure 1. Soft-robotic glove Carbonhand (Bioservo, SV; bioservo.com)

The study design considered to be most appropriate for assessing whether increase in actual arm use is one of the mechanisms that can explain a therapeutic effect of assistive soft-robotic glove use in ADL, was a single-case experimental design (SCED). Since we already know that assistive soft-robotic glove use has a therapeutic effect on hand function from previous studies [4], [5], a large-scale clinical trial replicating a complex and expensive multicenter trial,

Figure 2. Single-case experimental design for measuring arm activity (using MotionWatch8, CamNTech UK) in daily life before, during and after use of a soft-robotic glove (Carbonhand, Bioservo SV) at home.

involving many patients with relatively few assessments, is not suitable for the objective of the current study. Instead, we are interested in more fine-grained information about actual arm use to better understand the potential underlying mechanisms. A study design increasingly advocated as method to examine the effect of rehabilitation or health interventions is an SCED [8], [9]. One of the main advantages of SCEDs for studying rehabilitation interventions is the ability to deal with a heterogeneous and small sample, and to detect an effect in a situation of (large) variability within an individual, as opposed to a more traditional form of evaluation in which only a few snapshots (e.g., pre, post, follow-up) are taken [8]. The evaluation of technological innovations has also been proposed as a particularly fitting application for SCEDs [10], making it a particularly interesting method for assessing interventions involving rehabilitation robotics in patients.

Therefore, in this paper we apply a SCED to measure accelerometry-based arm activity in daily life and assess its differences during and after use of a soft-robotic glove at home, in the first two participants with hand function limitations due to traumatic or neurologic disorders.

II. METHODS

A. Participants

Participants were patients (between 16 and 90 years) experiencing difficulties in performing ADL due to a trauma-related injury or neurologic disorder affecting hand function. Participants were recruited via the local rehabilitaton center and the rehabilitation department of the local hospital. They had to be in the chronic stage with stable hand function, to live independently, and to be able to activate the soft-robotic glove by grasping an object. They must not receive physical therapy specifically focused on arm/hand function during their participation in the study.

B. Study design

The SCED in the present study is a randomized multiple baseline variant, consisting of three phases (Fig. 2), a baseline phase (control condition) of 2-4 weeks, followed by a 6-week intervention phase, consisting of use of an assistive soft-robotic glove during ADL at home, and a subsequent follow-up phase of 4 weeks without glove use to assess retention. The duration of the baseline phase was determined randomly per participant after inclusion, by a random number generator, picking a number between 14 and 28 days. A concurrent multiple baseline process (i.e., the baseline phase starts at the same time for individual participants, while the duration of the baseline phase randomly varies between participants) is implemented to improve validity. As commonly recommended for multiple baseline SCEDs involving one change condition, at least 5 datapoints for each phase are collected [11]. Repeated assessment of grip strength, perceived functional ability and wellbeing was done at home throughout the three phases, remotely via (video) call contact between participant and researcher. Three additional pre-, post- and follow-up assessments were scheduled at the end of each phase with an extended set of clinical tests related to functional ability, perceived arm use and quality of life. The study was approved by Medical-Ethical Research Committee East-Netherlands, reviewed against Medical Device Regulation procedures. It is registered with ClinicalTrials.gov as NCT06033027.

In this paper only the methods and outcomes related to arm activity monitoring of the first participants of this ongoing study are detailed. Arm activity was monitored at the beginning of each phase for 7 consecutive days by wearing accelerometers around both wrists. During the arm activity monitoring weeks, the researcher verified during the home assessments whether the wrist bands were being worn, were operational and whether the right wrist bands were worn on the right sides.

C. Intervention

Participants used a soft-robotic glove at home for six weeks, during self-selected activities for a self-selected duration and frequency. The soft-robotic glove is an existing tendon-driven device (Fig. 1), Carbonhand (Bioservo; Kista, Sweden). It supports and empowers grip strength by actuating flexion of the thumb, middle and ring finger. The amount of flexion force is modulated proportionally via pressure detected by sensors in the fingertips, positioned at the finger tips, along the finger's ventral surface and in the palm of the hand, below metacarpal-phalangeal (MCP) joint 2. Release of actuation is achieved via the proportional force modulation: reducing pressure on the sensors reduces flexion forces generated by the glove, which essentially means that relaxing an active grip turns off the grip support gradually. The three actuators and batteries are located in the control unit, which can be worn with a hip belt (see Fig. 1) or as a small backpack. Glove settings

(e.g. maximum force, sensitivity, gain) per finger are tuned individually for each user via an app prior to the intervention by a trained researcher. Participants were contacted by the researchers between one and three times per week, depending on the study phase, via (video) call to check in on them and administer the home assessments of the SCED remotely (which are out of consideration for this analysis).

D. Outcome measures and data analysis

Actual arm use during daily life was measured by two MotionWatch8 devices (CamNtech; Cambridgeshire, UK), containing a 3D accelerometer, one around each wrist (Figure 3). They were worn for 7 consecutive days, to include both week and weekend days, during the first week of each phase (baseline, intervention, follow-up). The MotionWatches were worn day and night, and didn't need to be taken off during bathing. If participants did take them off during bathing or sleeping, they had to make sure to put the same MotionWatch on the same wrist each time. For this, the MotionWatches were labeled with a red sticker to denote right side and a white sticker to denote left side. During the home assessments via videocall, the researcher visually verified correct placement of the two MotionWatches.

Figure 3. Accelerometer on wristband for measuring arm activity (MotionWatch8, CamNtech, UK; camntech.com)

For processing of the activity data, the same method as in [6] was used. Even though the current version of MotionWatch has a 3D accelerometer, the option for collecting the 1D signal was used to align with the methods from [6]. From the accelerometer signal, the highest peak within each consecutive second was identified. Next, signal amplitudes for every 2 consecutive peaks are summed, resulting in units of 'counts'. Intensity of use is defined as the sum of counts (signal intensity per data point) within a given time epoch, thus producing the 'area under the curve'. For both the affected arm-hand and the unaffected arm-hand, intensity of use was calculated for each day (daily intensity). Data of the middle 5 days (day 2 – day 6) of the measurement period were summed to calculate total intensity, excluding days where the MotionWatches were potentially not worn for a full day. No distinction is made between weekdays and weekend. The ratio between total intensity of the affected arm and total intensity of the unaffected arm was calculated too, where 1 indicates equal intensity of use and values <1 indicate that the affected arm is used less than the unaffected arm.

Data analysis in an SCED concerns assessing changes over time on a case-by-case basis, and is done first and foremost via visual analysis of the time-series data: in this case analyzing whether actual arm use changes during and/or after glove use. During visual analysis, attention is paid specifically to potential differences in level and mean of data points around phase transitions, as well as the overall pattern in the results, the amount of variability within and between phases, and the number of replications of effects across participants [10]. This was quantified by calculating the average level of arm activity per day across all measurement days for each phase per participant, as well as its slope (i.e., slope of linear regression line through all datapoints per phase and per participant). Statistical methods can be used to assist in visual analysis of SCED data, but due to the limited number of participants in this study currently, analysis in this paper is limited to visual and descriptive analysis.

III. RESULTS

A. Participants and study compliance

Three participants have started the multiple baseline SCED concurrently. Two have had trauma-related hand injury with persistent symptoms (P01, female of 51 years old, and P02, male of 54 years old), both with their left hand affected (while right-hand dominant). P03 (female of 74 years old) had a neuromuscular disorder with the right (dominant) hand as more affected side, and the left arm affected to a lesser extent. P01 and P02 wore the glove on their left hand, P03 on her right hand. The randomized duration of the baseline phase was 22 days for P01 and P03, and 30 days for P02 (randomized as 28, but the associated visits were scheduled 30 days apart due to not scheduling visits during a weekend).

One participant (P01) dropped out after the second week of the intervention phase, due to the intensive study schedule (in particular the large number of (remote) assessments and different expectations of the trial and the glove). The other two participants completed the study in compliance with the protocol, with at least five datapoints collected (i.e., home assessments administered) per phase, having used the glove for at least six weeks and worn the wristbands for arm activity monitoring for at least seven consecutive days. The remote assessments were well tolerated by the participants, of which one was familiar with remote videocalls and one was not, and took between 5 and 10 minutes per assessment.

Arm activity monitoring using the MotionWatches worn via a wristband on both wrists was feasible and acceptable for

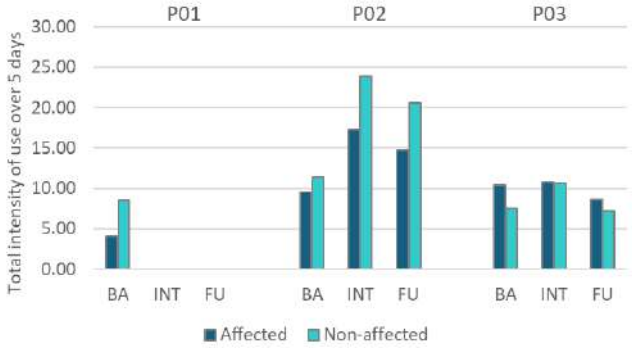

Figure 4. Sum of arm activity during ADL across 5 days during baseline (BA), intervention (INT) and follow-up (FU) per participant, for the affected and non-affected hand (glove was worn on affected hand: left hand for P01 and P02, right for P03).

all participants. The wristbands were worn continuously for at least seven days without issues, in three instances eight days of activity data was available. However, participant 01 developed a rash under the wristband, gradually during the last days of the baseline measurement period. After the wristband was removed, the redness and itch disappeared within a day. A wristband of different material was available but not used before the participant dropped out.

B. Intensity of arm use

The participants who were left-side affected (P01 and P02) showed higher intensity of use of the right (dominant unaffected) arm and hand (Fig. 4). P03 who had their dominant hand as more affected side demonstrated slightly higher intensity of use of the affected arm than the unaffected arm. This is also reflected in lower ratios of affected-to-unaffected arm use intensity in P01 and P02 compared to P03 (Table I).

Total intensity of arm use for both arms summated increased in both participants from baseline to intervention (Table I). This indicates that the arms/hands were used more intensively in daily activities during the period when the soft-robotic glove was worn compared to their activity between two and four weeks before the intervention. The increase was much more pronounced in P02 than in P03. In P02 intensity of use increased for both the affected (gloved) hand and the unaffected hand, whereas in P03 intensity of use of the more affected (gloved) hand remained roughly the same between baseline and intervention and predominantly the unaffected hand was used more intensively (Fig. 4). In both participants, intensity of arm use decreased from intervention to follow-up in both arms.

When looking at intensity of arm use per day across the study phases on a case-by-case basis (Fig. 5 and Table II), data of P02 shows an increase in average level of daily intensity of arm use from baseline to intervention, as well as a change in slope across days, with a more positive slope during the intervention phase compared to baseline. Towards follow-up, a decrease in both average level and slope can be observed, but to a lesser extent than during baseline. This is underlined by the changes in average phase level of intensity of arm use per day in P02, with a marked increase from baseline to intervention and a smaller decrease from intervention to follow-up (Table II). Also, differences in quantified slope of daily arm use intensity between phases underline the visual observations: a negative slope during baseline is followed by a positive slope during intervention, further suggesting a stimulation of arm use intensity when the soft-robotic glove was used. During follow-up, the slope of arm activity per day is negative, although to a smaller degree than during baseline. When looking at the time-series data for left and right arms separately, it is observed that both arms follow the same pattern of increased arm activity during intervention and a partial decrease during follow-up, although in the unaffected arm those changes are slightly more pronounced.

In P03, differences between phases are much less pronounced, although the quantified average level of arm activity per phase does show a small increase from baseline to intervention and decrease during follow-up. The slope of arm activity per day changes from slightly negative during baseline (close to 0, indicating roughly constant arm use per day during baseline) to a steeper negative during intervention, indicating a decline in arm activity during the first week of the glove use period. Since the average level of the intervention phase is slightly higher than baseline, this suggests a decline from an initially higher intensity of arm use at the beginning of the measurement period during the intervention, although this is not very clear in visual observation of the time-series data. During follow-up, arm activity increases across days as reflected in a positive slope. Visual analysis of the time-series data for left and right arms separately indicates that the observed pattern is more pronounced in the unaffected arm than in the affected arm.

TABLE I. TOTAL INTENSITY OF USE OF BOTH ARMS OVER 5 DAYS

ID	Phase	Total intensity L+R (activity counts x10^5)	Ratio total intensity (affected/unaffected)
P01	***BA***	12.7	0.48
	INT	-	-
	FU	-	-
P02	***BA***	20.9	0.84
	INT	41.2	0.72
	FU	35.4	0.72

IV. DISCUSSION

The present study applies an SCED to collect fine-grained information about actual arm use in daily life before, during and after soft-robotic glove use in ADL, as well as functional outcomes and patient-reported outcomes on their hand function and wellbeing. With this information, we aim to better understand underlying mechanisms of the therapeutic effect of assistive use of a soft-robotic glove at home as

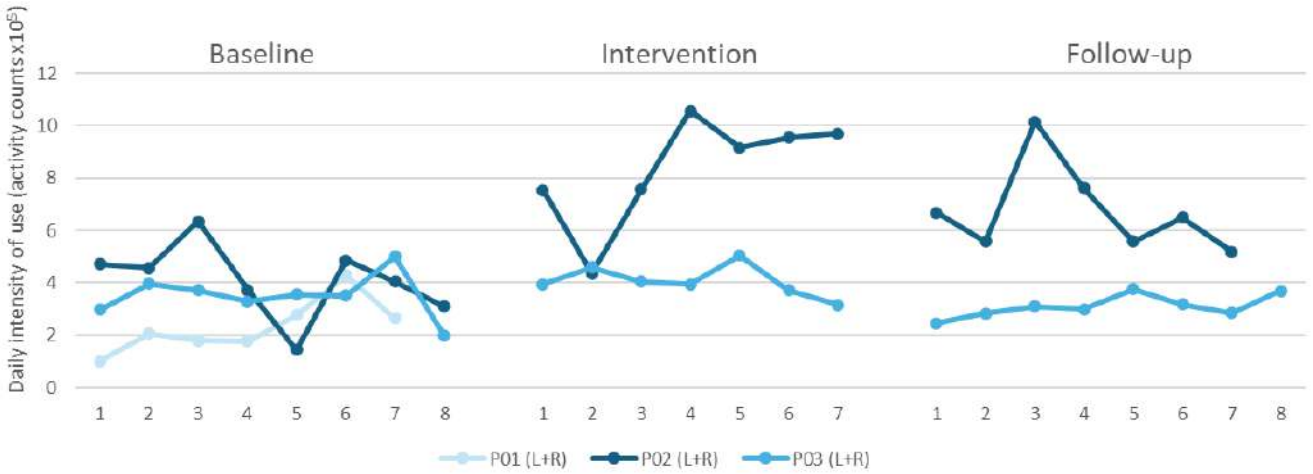

Figure 5. Time-series data of intensity of arm use per day per participant, left and right arm summated, in each study phase

demonstrated earlier [4], [5]. The present findings show that measuring actual arm use in daily life is feasible and enables gathering of valuable information that can be used to improve understanding of the potential mechanisms involved in the effect of the soft-robotic glove.

Study execution among the first three participants shows that compliance to the SCED study set-up was high in both participants who completed the study, following the intervention schedule as planned and without missing assessments. However, one out of the first three participants dropped out due, at least partly, to the intensive and relatively complex study schedule. This suggests on one hand that the choice for an SCED can limit who can and wants to participate in such a trial, increasing the risk for selection bias. Practically, this means that specific attention should be given to the ability of the candidate to comprehend the study logistics and adhere to its schedule during selection of suitable candidates for participation, especially considering the small sample size involved in SCEDs. On the other hand, the advantages of a SCED in understanding how a technological intervention influences patients' functioning and activity in much more detail [10], balances a potentially increased selection bias, as long as this is taken into account with interpretation and generalization of results. Especially in populations and/or outcomes that show a high variability, this approach has its merits [9]. The intra-subject variation in the time-series data of intensity of arm use (Figure 5) emphasizes this merit and highlights the limitations of a pre-post design with fewer data points.

Actual arm use as measured in the first participants of the current ongoing study indicates that intensity of arm use during ADL increases during soft-robotic glove use in both participants, although to varying degrees. Intensity of arm use decreased after cessation of glove use in both participants, but in one participant the activity level remained higher during follow-up than the activity level during baseline. This suggests that arm activity in daily life is stimulated when the soft-robotic glove is used in the present two participants. Differences in population (neuromuscular disorder and traumatic hand injury) might contribute to the differences observed between participants. Also, personal factors and differences in environment and events are likely to influence the outcomes of this SCED. For instance, P02 participated in the study during the time that a home renovation project was carried out, which might have influenced the amount and type of arm use with respect to their average behavior.

It is notable that in both participants intensity of use of the unaffected side seems to be stimulated to a slightly larger degree than the affected side on which the soft-robotic glove is worn. This may suggest that use of the soft-robotic glove promotes engaging in bimanual tasks more than unimanual use of the affected (gloved) hand. On the other hand, this could also indicate that P03 didn't extend their affected arm use to other or more activities when wearing the glove, while P02 started doing more and/or other activities with the affected hand when using the soft-robotic glove. Further analysis of affected vs unaffected arm use intensity (distinguishing between uni- and bimanual activity), including duration of use, and assessing changes in functional outcomes and (perceived) gains in capacity or performance of the arm and hand, is needed to obtain a full understanding of mechanisms involved in the effect of soft-robotic glove use.

The current observations so far are not dismissive of the hypothesis that use of the soft-robotic glove is associated with an increase in actual arm use. If this coincides with hand function improvement and/or perceived benefit, this may be one of the mechanisms underlying the therapeutic effect of assistive glove use demonstrated in previous studies [4], [5].

Performance in daily life must be assessed when evaluating effects of (neuro)rehabilitation interventions in addition to clinical measures of functioning (capacity) [12]. This includes perceived performance, for instance using patient-reported outcomes, and actual performance [13]. Measuring actual arm use in daily life is important to extend clinical measures of capacity and performance with ecologically valid measures of real-life arm activity [14]. Accelerometry has been proposed as a valid, practical and objective measure for actual arm use

in daily life since over a decade [7], [13], [15], however, standardized methods don't exist (yet). It has only been applied as outcome measure in a limited number of studies of upper extremity rehabilitation, mostly stroke [6], [16], [17].

To the best of our knowledge, only one other study investigated actual arm use in context of robot-assisted interventions for the upper extremity, showing no change in intensity and duration of arm use after robot-assisted task-oriented training in chronic stroke patients [6]. This contrasts the preliminary findings of the present paper. Besides a different population, a different intervention context may play a role, where application of the soft-robotic glove is intended to integrate robot-assisted 'exercises' in daily life activities at home as opposed to dedicated robot-assisted training sessions in a clinical setting, with potential differences in treatment dose and exercise content as well.

The findings presented in this paper are limited to intensity of arm use and are based on only the first two participants in this ongoing study. This obviously prevents conclusions to be drawn about changes in actual arm use in daily life due to soft-robotic glove use. Data of at least three participants is needed to increase SCED data validity [10]. Besides potential selection bias of participants capable to understand and adhere to the SCED protocol, the Hawthorne effect can also influence outcomes when people alter their behavior (e.g., use their affected arm more) when they know they are being observed.

This paper provides initial and promising information about the feasibility of measuring intensity of arm use continuously in daily life for seven days, and corresponding considerations and limitations. Currently we have no reference values of intensity of arm use to consider whether our findings constitute high or low intensity of arm use for the populations involved in this study and whether observed differences between phases are related to functional and/or perceived improvements in hand function. Investigating duration of arm use additionally, distinguishing between week and weekend days, and analyzing unimanual vs bimanual activity will improve interpretation of findings. These topics will be addressed as next steps in the ongoing study.

V. Conclusion

Actual arm use as measured in the first participants of the current ongoing study suggests that intensity of arm use during ADL increased during soft-robotic glove use in two participants, although to varying degrees. Intensity of arm use decreased after cessation of glove use in both participants. The current observations so far are in line with the hypothesis that use of the soft-robotic glove is associated with an increase in actual arm use. Further analysis should assess whether this coincides with hand function improvement and/or perceived benefit, before we can conclude whether increase of actual arm use is one of the mechanisms underlying the therapeutic effect of assistive soft-robotic glove use.

An advantageous array of air springs that attenuates aerial inherent nonlinearities for force sensing

Dongwon Kim, Jaeho Shin and Leah M. O'Shea

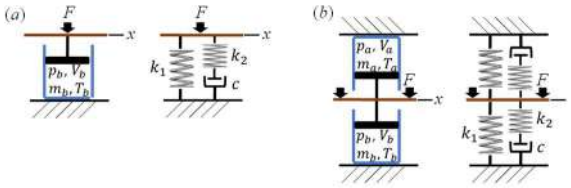
***Abstract*—Despite the inherent leakage issue, pneumatics is advantageous for device development in some respects. The use of air secures power transmission flexibility while it could alleviate structural complexity depending on the design objectives. Since air is compressible and can act as a spring, it is worth utilizing this for the development of a force sensing device. However, air's inherent nonlinearities cause a decreased linear relationship between the imposed force and deformation even at low frequencies. Those lead to irregular responses and eventually energy dissipation. We note that a serial deployment of two air springs can reduce the effect of aerial inherent nonlinearities since the arithmetic summation of the stiffnesses of the two air springs in the proposed deployment becomes linear over a wide range of displacement. In this study, we investigated the influences of the serial deployment of air springs in reducing the effect of aerial inherent nonlinearities. The Lyapunov exponent is employed to characterize the behaviors of air springs in response to external excitation. We found that the serial deployment efficiently promotes the linear relationship between the imposed force and deformation, indicated by a lower value of the Lyapunov exponent. These results suggest that the effect of aerial inherent nonlinearities is mitigated, in particular, at low frequencies where contacts with humans are considered to occur primarily. Experimental validation was performed.**

Keywords*—Air, force sensing, Lyapunov exponent, energy dissipation

I. Introduction

Typically, we estimate interaction forces through the relationship between the imposed force and corresponding deformation/displacement, often with the procedure of calibration. For example, series elastic actuators, which were specifically devised for safe interactions between the robot and the environment [1], [2], [3], use the deformation of their series elasticity measured with optical encoders to estimate the interaction force in the control loop [4].

Air is compressible and can act as a spring. Indeed, air is used in vehicle suspensions or exoskeletons to realize elasticity to minimize the effects of unwanted interactions from the environment or the power source [5], [6], [7], [8], [9]. Though air shows highly nonlinear properties, mathematical models of deformation relating to the pressure imposed on the system have been well developed [6], [7], [10]. Those models enable us to estimate the interaction force on the system by measuring the change in the volume of the contained air.



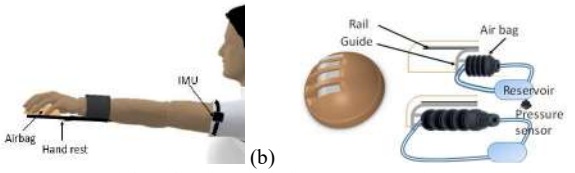


Fig. 1. Schematics of air springs and their linear models: (a) Case I- air spring with a single chamber and (b) Case II- air spring with two chambers connected in series and the plate on which an external excitation is imposed is placed in between.

However, the use of pneumatic elasticity is always followed by issues resulting from aerial inherent nonlinearities [8]. Such nonlinearities degrade the linear relationship between the imposed force and deformation, as well as, they lead to irregular responses, and eventually energy dissipation [11]. Force sensors that are exposed to irregular responses and energy dissipation may exhibit a low accuracy of force estimation that is achieved using the value of the deformation, especially when contacts occur irregularly and frequently. Since irregular responses and energy dissipation originate from air's properties, it is impossible to reduce energy dissipation, unless we change the volume, contact area, or temperature of the contained air. Meanwhile, we note that a certain structural deployment of air springs possibly reduces the effect of aerial inherent nonlinearities. The stiffness of air springs is a strictly increasing function of the displacement [8], which is primarily associated with inherent nonlinearities. If we deploy two air springs with chambers of the same volume and contact area such that one air spring is expanded while the other one is compressed (see Fig. 1(b)), the resultant stiffness, which is the arithmetic summation of the stiffnesses of the two air springs, can become linear over a wide range of displacement. This deployment could effectively reduce the effect of the inherent nonlinearities of air.

In this study, we demonstrate the beneficial aspects of the serial deployment of air springs in reducing the effect of inherent nonlinearities through a mathematical model. The Lyapunov exponent is employed to characterize the behaviors of air springs in response to external excitation at a

Fig. 2. Our potential application with force sensing using pneumatics (a) A schematic of the proposed system and (b) its hand part. An air reservoir is installed in the pneumatic circuit to modulate the driving-point impedance of the airbags. A pressure sensor measures the pressure of the internal air. Tubing is connected to both sides of the airbags. An inertial measurement unit (IMU) is used to estimate arm movement and configuration.

range of frequencies of interest. This measure enables us to investigate whether responses of air springs are periodic transient to aperiodic or chaotic behaviors [11], [12]. The Lyapunov exponent can be an indicator of irregularity and energy dissipation in air springs resulting from the inherent nonlinearities of air. This study will form the basis for developing a force sensing device using pneumatics. Fig. 2 depicts our potential application with force sensing using pneumatics. This device is designed to measure involuntary finger flexion during upper-extremity movement after a neurological damage (e.g., stroke).

II. MODEL DERIVATION

1. Nonlinear model

A. CASE I

First, we derive a model of the air spring with a single chamber (Fig. 1(a)) that entraps air with its pressure, volume, mass, and temperature of the entrapped air defined as P_b, V_b, m_b, and T_b, respectively. The equation of energy equilibrium can be derived as

$$\alpha A(T_{atm} - T_b) - p_b\dot{V}_b = \dot{m}_b C_v T_b + m_b C_v \dot{T}_b, \quad (1)$$

where α, $C_v$denote the heat transfer coefficient and constant volume-specific heat capacity, respectively. A and T_{atm} denote the area of the piston and the temperature of the environment, respectively. We assume that energy does not transfer through the walls of the chamber.

We employ the gas equation of state

$$P_b V_b = m_b R T_b, \quad (2)$$

where R is the universal gas constant,

and derivate it with respect to time:

$$p_b\dot{V}_b + \dot{p}_b V_b = \dot{m}_b R T_b + m_b R\dot{T}_b. \quad (3)$$

Assuming that $\dot{m}_b = 0$ (closed system), the combination of Eqs. (1) and (3) leads to

$$\frac{\alpha A}{C_p}(T_{atm} - T_b) - \frac{1}{R}\left(\frac{\dot{p}_b V_b}{\gamma} + p_b\dot{V}_b\right) = 0, \quad (4)$$

where C_p denotes constant pressure specific heat capacity and γ is defined as the ratio of C_p with C_v.

The volume of the air chamber can be obtained as

$$V_b = V_{b0} - Ax, \quad (5)$$

where V_{b0} is the initial volume and x denotes the displacement of the piston.

The force applied to the piston can be calculated as

$$F = A(p_b - p_{atm}), \quad (6)$$

where p_{atm} denotes the pressure of the environment. We assume that the area on which the pressure of the entrapped air is imposed is the same as that on which the pressure of the environment is imposed for convenience.

The relationship *F-x* can be obtained through combinations of Eqs. (1) to (6).

B. CASE II

Similarly, we derive a model of the air spring with two chambers deployed in series (Fig. 1(b)). Another chamber is added to Case I, with its pressure, volume, mass, and temperature defined as P_a, V_a, m_a, and T_a, respectively. The equation of energy equilibrium can be derived as, respectively,

$$\alpha A(T_{atm} - T_a) - p_a\dot{V}_a = \dot{m}_a C_v T_a + m_a C_v \dot{T}_a, \quad (7)$$
$$\alpha A(T_{atm} - T_b) - p_b\dot{V}_b = \dot{m}_b C_v T_b + m_b C_v \dot{T}_b. \quad (8)$$

The derivatives of the gas equation of state with respect to time for each chamber are obtained as Eq. (3) and

$$p_a\dot{V}_a + \dot{p}_a V_a = \dot{m}_a C_v T_a + m_a \mathrm{R}\dot{T}_a. \quad (9)$$

Assuming that $\dot{m}_a = 0$, the combinations of those equations lead to the following pair of equations:

$$\frac{\alpha A}{C_p}(T_{atm} - T_b) - \frac{1}{R}\left(\frac{\dot{p}_b V_b}{\gamma} + p_b\dot{V}_b\right) = 0, \quad (10)$$
$$\frac{\alpha A}{C_p}(T_{atm} - T_a) - \frac{1}{R}\left(\frac{\dot{p}_a V_a}{\gamma} + p_a\dot{V}_a\right) = 0. \quad (11)$$

The volume of each chamber varying with the displacement of the piston is calculated as

$$V_a = V_{a0} + Ax, \quad (12)$$
$$V_b = V_{b0} - Ax, \quad (13)$$

where V_{a0}, V_{b0} denote the initial volume of each chamber.

Finally, the resultant force applied to the pistons that are rigidly connected with each other is obtained as

$$F = A(p_a - p_b). \quad (14)$$

The pressures p_a, p_b are calculated from the gas equations of state and Eqs. (10) and (11).

2. Linear model

We present linear models of Case I and Case II to feature the nonlinear models as well as to address their appropriateness.

A. CASE I

Air springs with one chamber (Case I) can be modeled as a pure spring k_1 connected in parallel with a group of a spring k_2 and damper c connected in series, neglecting nonlinearities including the coupling term of the chamber pressure and piston velocity (see Fig. 1) [6], [7]. The derivation was presented elsewhere [6]. The resultant stiffness can be obtained in the frequency domain as

$$K(s) = k_1 + \frac{1}{\frac{1}{k_2}+\frac{1}{cs}} = \frac{(k_1+k_2)cs+k_1k_2}{cs+k_2}, \quad (15)$$

where s is a complex variable.

Eq. (15) suggests that at low frequencies ($s \to 0$), the resultant stiffness appears as k_1. At high frequencies ($s \to \infty$), the resultant stiffness appears as $(k_1 + k_2)/k_2$. The frequency where the transition of the resultant stiffness occurs is around k_2/c (rad/s). The transition frequency is proportional to $\alpha A/m_b C_v$ [6], suggesting that an air spring with a greater mass leads to the transition of the resultant stiffness at a lower frequency. Meanwhile, k_1 is proportional to $m_b \mathrm{R} T_b A^2/(V_{b0} - Ax)^2$, k_2 is proportional to $\gamma p_{b0} A^2/V_{b0}$, and c is proportional to $k_2 m_b C_v/\alpha A$ The equivalent stiffnesses and damping coefficient depend on the entrapped air's initial pressure, mass, and volume.

B. CASE II

For Case II, we obtain the stiffness by simply doubling K:

$$K'(s) = 2K(s) = \frac{2(k_1+k_2)cs+2k_1k_2}{cs+\ _2}, \quad (16)$$

Note that the stiffness is different from that of two springs in series. Eq. (16) suggests that at low frequencies ($s \to 0$), the resultant stiffness appears as $2k_1$. At high frequencies ($s \to \infty$), the resultant stiffness appears as $2(k_1 + k_2)/k_2$. The transition frequency is around k_2/c (rad/s).

Parameters	***Value***	***Unit***

Table I. System parameters.

III. NUMERICAL SIMULATION

The mathematical model for Case I is found excellent in reproducing the behaviors of real pneumatic systems at a wide range of frequencies [7], [10]. The stiffnesses of air springs follow a strictly increasing curve; the primary stiffness component k_1 is proportional to $m_b \mathrm{R} T_b A^2/(V_{b0} - Ax)^2$. Those stiffnesses nonlinearly increase as the deformation increases [8]. However, linearization eliminates such nonlinear properties, although those should be considered in analyzing air springs. We analyze the frequency-domain responses (F) to a chirp input (x) at a wide range of frequencies undergoing the thermodynamics addressed above, without linearization.

The behaviors of F versus x in the frequency domain are investigated using the *iddata* and *fft* functions in Matlab 2018a. Numerical integration is performed through the 4th-order Runge-Kutta method. The sampling time is set as 0.001 s, with step size 0.0001 s. The system parameters with fixed values are summarized in Table 1. We add variations to the initial volumes of the chambers to produce various stiffnesses: A×0.1, 0.3, 0.6, and 1.2 (m). The mass of the entrapped air in each chamber is calculated using the gas equation of state with the temperature and pressure of the environment. For Case II, the air springs of both chambers are assumed pre-loaded by compressing the entrapped air with a certain amount of displacement (0.02 m). This imposes simultaneous loading and unloading on the air springs of both chambers. The volumes of the chambers are reduced and expanded at the same time, while their masses remain the same (closed system). A chirp input with an amplitude of 0.01 m and an increment of 0.01 rad/s^2 is applied to the displacement for 10000 s.

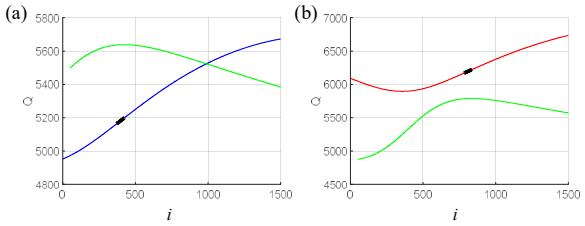

Fig. 3. Values of Q in Eq. (18) for (a) Case I (blue) and (b) Case II (red), with a chamber volume of A×0.1 (m), A is the piston area. The green curves are the slopes of the curves of 50 points of Q, amplified with an arbitrary constant gain to identify i that gives the maximum slope. The largest Lyapunov exponents are obtained from Q between K_{Min} and K_{Max} where the maximum slopes of the curves of Q is achieved. The black lines are a line connecting two points at $i = K_{Min}$ and $i = K_{Min} + 50$ ($= K_{Max}$).

Beyond the transition frequencies, a greater effect of hysteresis appears [7]. Obviously, significant energy dissipation is caused, because the damping effect is pronounced. In our study, we focus on responses under the transition frequencies. The Lyapunov exponent is employed to investigate whether the effect of aerial inherent nonlinearities on energy dissipation reduces, in particular, at the range of frequencies where the stiffness component of the air spring is dominant (i.e. low frequencies). The value of the

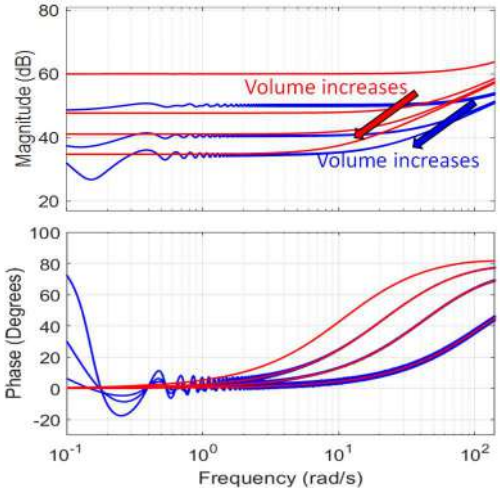

Fig. 4. Frequency-domain responses of the force over the displacement, for Case I (blue) and Case II (red). Chamber volumes are changed to produce various air stiffnesses: A×0.1, 0.3 and 0.6 (m) for Case I and A×0.1, 0.3, 0.6, and 1.2 (m) for Case II, where A is the piston area.

Lyapunov exponent is an indicator of the rate of convergence or divergence of the infinitesimally close trajectories (Fig. 3). A negative value of the Lyapunov exponent indicates convergence, while a positive value of the Lyapunov exponent indicates divergence and aperiodic behaviors. Responses of air springs that are transient to aperiodic behaviors mean that energy dissipation occurs. We assess the Lyapunov exponent of responses to a periodic input with its frequency varying. The varying frequencies emulate realistic contacts by a human with a force sensor. The value of the Lyapunov exponent is calculated as [13]:

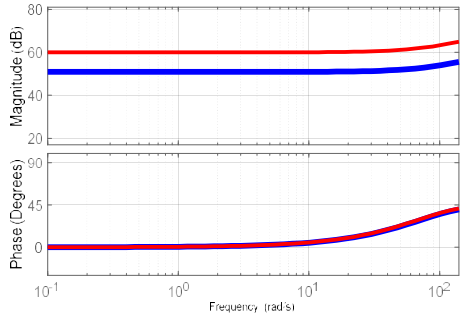

Fig. 5. Frequency-domain responses of the force over the displacement of the linear models, for Case I (blue) and Case II (red). Those models replicate the responses of the nonlinear models with a chamber volume of A×0.1 (m) for Case I and Case II, respectively, where A is the piston area.

$$\mathrm{LE} = \frac{1}{N}\sum_{i=1}^{N} Q(i), \tag{17}$$

$$Q(i) = \left(\frac{f}{K}\sum_{K=K_{Min}}^{K_{Max}} ln\frac{\|Y_{i+K}-Y_{i^*+K}\|}{\|Y_i-Y_{i^*}\|}\right), \tag{18}$$

where f is the sampling frequency and i^* denotes the nearest neighbor point of i outside the reciprocal of the mean frequency that satisfies min $\|Y_i-Y_{i^*}\|$. N is the number of the points of $Q(i)$.

We search the largest LE between K_{Min} and $K_{Min}+50$ ($\triangleq K_{Max}$) such that the coefficient of determination of the regression line forming the points of $Q(i)$ between K_{Min} and K_{Max} is greater than 0.98 (refer to Fig. 2). The search range is set as $1 \le K_{Min} \le 1450$, because it is recognized that the

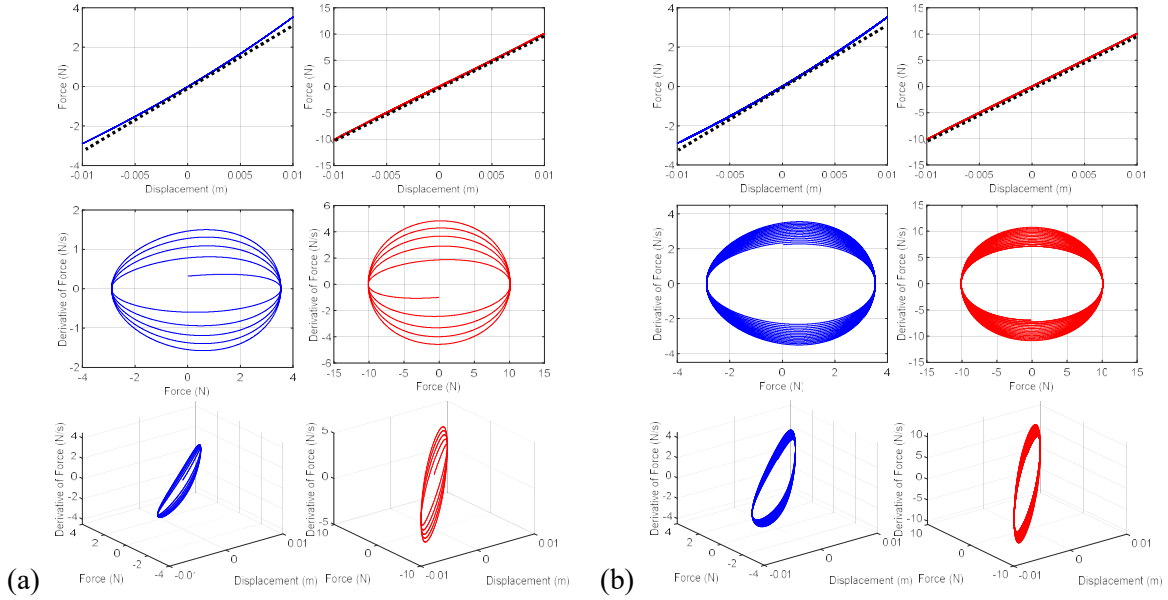

Fig. 6. Phase portraits of the force versus the displacement, the derivative of the force versus the force, and the derivative of the force versus the force and displacement, for Case I (blue) and Case II (red) in response to excitations with frequencies of (a) 0.1-0.3 rad/s and (b) 0.7-0.9 rad/s. The black dotted lines are to assess linearity of the relationship of the force versus the displacement. The largest LE=0.2765 (Case I):0.2257 (Case II) for frequencies of 0.1-0.3 rad/s. and the largest LE=2.1587 (Case I):1.1483 (Case II) for frequencies of 0.7-0.9 rad/s. The nonlinear models with a chamber volume of A×0.1 (m) for Case I and Case II, respectively, where A is the piston area, are used.

Case II	0.2257	0.2256	0.2221	0.2240	1.8307	1.7587	1.6361	1.5206	1.1483	1.2029	1.1442	0.9544

Table 2. Largest Lyapunov exponent of Case I and Case II. *A* is the piston area.

largest LE is detected within this range for Case I and Case II, respectively. N in Eq. (17) is 50.

Lastly, the influence of asymmetry in the initial volumes of the two air chambers is investigated. We evaluate how responses change depending on the degree of asymmetry in the chamber volumes (1:1, 0.95:1, and 0.90:1).

IV. Simulation Results

Fig. 4 shows the frequency-domain responses of the force over the displacement, for Case I and Case II, respectively, with the chamber volumes changing. The resultant stiffness of Case II is greater than that of Case I even when those use chambers of the same dimensions are employed. However, the frequencies where the transitions of the resultant stiffness occur are similar regardless of Case I and Case II. Those transition frequencies mainly depend on the initial mass of the entrapped air in one chamber (see the Model derivation section). Fig. 4 shows that as the initial mass, which mainly depends on the initial chamber volumes, increases, the transition frequency decreases.

We replicate the results of the nonlinear models using the linear models (Fig. 5). The apparent resultant stiffness of Case II in low frequencies ($\approx 2k_1$) for the linear model is set as 1000 N/m, while that of Case I ($\approx k_1$) is set as 350 N/m. The secondary stiffness k_2 is set as 1500 and 2250 N/m for each single chamber for Case I and Case II, respectively. The damping coefficient c is set as 3 and 4.5 N/ms for each chamber for Case I and Case II, respectively. Those settings lead to the same transition frequencies of 500 rad/s for Case I and Case II. Though the same chambers are used, the secondary stiffness k_2 and damping coefficient c, as well as the primary stiffness k_1, that characterize the behaviors of the air springs are not the results of the arithmetic summation of the stiffnesses between Case I and Case II. These results originate from how much the air springs are pre-loaded for Case II. Indeed, the equivalent stiffnesses and damping coefficient depend on the entrapped air's initial pressure and volume (see the Model derivation section).

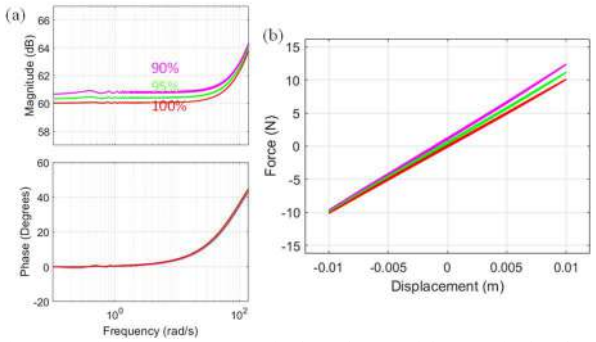

Fig. 7. Sensitivity to asymmetry in the volumes of the two air chambers for Case II: (a) Frequency responses and (b) overlapped curves of the force over the displacement. The percentage indicates the ratio of the volumes. The nonlinear models with a chamber volume of *A*×0.1 (m) for Case I and Case II, respectively, where *A* is the piston area, are used.

We note that the responses of Case I with the nonlinear model below the transition frequency are quite wavy and irregular in comparison to those of Case II (Fig. 4). Such responses were observed experimentally in the authors' previous study [5]. Those phenomena are impossible to observe with the linear models (Fig. 5). This response feature may originate from the inherent nonlinearities of air. We observe that the trajectories of the force over the displacement of Case I are curvy (strictly increasing). Such a nonlinear relationship is observed experimentally [6], [7]. Meanwhile, those of Case II are fairly linear, as seen in Fig. 6. The largest Lyapunov exponent suggests that generally, the transition to aperiodic behaviors occurs more strongly in Case I in response to periodic inputs, especially, at low frequencies, as presented in Table 2. The Poincaré maps (i.e. plot of the force and its derivative) show asymmetrical trajectories for Case I while showing fairly symmetrical trajectories for Case II. Also, the 3D plots of the derivative of the force versus the force and displacement exhibit that the bundles of circular trajectories for Case I tend to be a little bit bent in comparison to those for Case II. These results imply that more energy dissipation occurs in Case I. The trajectory of the response of Case I are transformed due to a change in energy (mainly through dissipation) within the system. This change may eventually result from aerial inherent nonlinearities. From these results, we could conclude that the serial deployment of air springs is effective in alleviating the effect of the inherent nonlinearities.

The sensitivity to asymmetry in the volumes of the two air chambers for Case II is presented (Fig. 7). We found that the linear relationships between the imposed force and deformation preserve even in the presence of asymmetry in the volumes of the two air chambers. However, we found that responses at low frequencies become more wavy as the degree of asymmetry increases. An increase in asymmetry in the volumes of the two air chambers leads to an increase in the effect of the inherent nonlinearities, as in an air spring with a single chamber.

V. Experimental Validation

We conducted experimental validation to evaluate the enhanced linearity in the relationship of the force versus the displacement for Case II. Enhanced linearity implies that the proposed deployment of air springs is effective in reducing irregular responses and energy dissipation. 3D-printed air chambers (made of Acrylonitrile Butadiene Styrene) were created, and airbags were used to entrap air. We ensured that

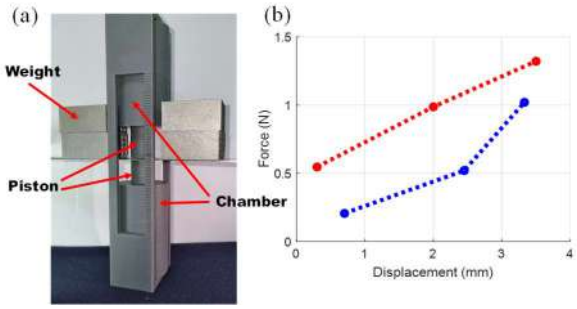

Fig. 8. (a) Experimental setup to assess the relationship of the force versus the displacement and (b) plot of the force versus the displacement for Case I (blue) and Case II (red). Changes in the force and displacement are caused by different 3 weights (filled dot).

no energy was used for expansion of the airbag surface. The friction effect between the piston and the wall of the chambers was minimized by giving a gap between them, while the piston prevented the airbag from escaping behind the piston. The radii of the chamber and piston were 10 and 9.9 mm, respectively. The inner depth of each chamber was 80 mm. Each piston weighed 21 g. For Case II, the airbag of each air chamber was preloaded (30 mm) using a structure that limited the total length of the two chambers in series. Three different weights were used to load the piston for Case I and Case II, respectively. Loading was imposed very slowly to guarantee low-frequency responses. For Case II, we considered all loading components that imposed load on the airbag inside the bottom chamber, including the airbag inside the top chamber, two pistons, weights, and their rest. For Case I, we considered loading components, including one piston, weights, and their rest. The displacement of the piston was measured using a ruler and a high-resolution camera. The experiment was conducted under a temperature of 298.15 K.

Fig. 8 shows the experimental setup and results of Case I and Case II. We found that Case II showed enhanced linearity in the relationship of the force versus the displacement in comparison to Case I. In Case II, the air springs were preloaded and the volumes of the two airbags were not exactly the same, so the force did not start at the origin. Based on these preliminary results, we will develop a force sensing system to measure the force imposed by a human finger for our future study (Fig. 2).

Real-Time Rehabilitation Tracking by Integration of Computer Vision and Virtual Hand

Parham Ahmadpanah[1] and Soroush Korivand[1]

***Abstract*— Rehabilitation is a critical component of healthcare services that often requires prolonged monitoring to achieve optimal outcomes. One of the major challenges in rehabilitation tracking is the necessity for patients to visit medical centers, which can be costly and time-consuming, especially for individuals in remote areas. Although telehealth solutions such as video conferencing have been introduced, they are predominantly qualitative and do not provide precise rehabilitation tracking. Consequently, there is a need for a robust, accessible, and accurate method for rehabilitation monitoring. To address this need, we introduce a quantified, easily accessible framework for extracting and analyzing human finger joint torques to enable virtual hand interaction. Hand landmarks from MediaPipe are integrated with the MANO hand model in PyBullet. The hand positions, rotations, and joint angles extracted from the landmarks are used as controller inputs to mirror human hand movements in a virtual environment. A PID controller was designed to accurately track joint angle trajectories, with its parameters optimized using genetic algorithms. The torques extracted from the metacarpophalangeal and proximal interphalangeal joints were validated, achieving mean squared errors of $4.346 \times 10^{-4}(N.m)^2$ and $1.506 \times 10^{-5}(N.m)^2$, respectively. This quantification and accessibility of human joint dynamics information is highly desirable for tracking rehabilitation progress using exoskeleton robotics.**

I. INTRODUCTION

Exoskeletons have become pivotal in rehabilitation engineering due to their ability to provide precise, controlled assistance during therapeutic exercises, thereby enhancing motor recovery outcomes [1], [2]. Specifically, finger exoskeletons address the critical need for restoring fine motor skills essential for daily activities such as grasping, writing, and manipulating objects. Impairments in finger function—often resulting from neurological conditions such as stroke, spinal cord injury, or neurodegenerative diseases—can significantly diminish a person's independence and quality of life [3]. By facilitating targeted, repetitive, and task-specific movements, finger exoskeletons promote neuroplasticity and motor relearning, which are essential for functional recovery [4]. Recent advancements have demonstrated that integrating finger exoskeletons into rehabilitation programs enhances the effectiveness of therapy, leading to improved dexterity and functional independence for patients [5].

To maximize the benefits of finger exoskeletons in rehabilitation, effective recovery also necessitates continuous monitoring and tracking of patient progress. Rehabilitation tracking is crucial for evaluating the efficacy of therapeutic interventions and for tailoring treatment plans to individual needs [6]. By systematically assessing improvements in motor function, clinicians can make informed decisions to adjust therapy intensity, duration, and specific exercises [7]. In the context of finger rehabilitation, accurate tracking allows for the optimization of exoskeleton parameters to match the patient's evolving capabilities, thereby enhancing the rehabilitation process [8]. Moreover, rehabilitation tracking provides valuable data that contribute to evidence-based practices, ultimately improving patient outcomes [9].

Within this framework, torque analysis emerges as a critical component for optimizing therapeutic outcomes in finger exoskeleton applications. The metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints are primarily responsible for the flexion and extension movements essential for hand functionality [10]. By analyzing the torques generated at these joints, clinicians and engineers can gain deeper insights into the biomechanical demands of finger movements, allowing for the customization of exoskeleton assistance to meet individual patient needs [10]. Accurate torque measurements at the MCP and PIP joints enable the development of precise control algorithms that can adapt real-time to a patient's capabilities, thereby enhancing the effectiveness of rehabilitation interventions [11]. Recent research has demonstrated that incorporating torque analysis into rehabilitation protocols significantly improves motor recovery and functional independence in patients with hand impairments [10]–[12]. Therefore, focusing on torque analysis at these critical joints not only advances the design and control of finger exoskeletons but also contributes substantially to the efficacy of rehabilitation programs. Despite the clear benefits of rehabilitation tracking and torque analysis, traditional methods often require patients to visit medical centers for assessments, which can be expensive and time-consuming [13]. This requirement poses significant challenges for individuals in remote areas or those with mobility limitations, potentially hindering consistent participation in rehabilitation programs. Consequently, there is a pressing need for innovative methodologies that facilitate remote rehabilitation tracking without sacrificing accuracy or effectiveness. Recent advancements in technology, such as computer vision and virtual simulation environments, offer promising solutions by enabling accessible and cost-effective monitoring of patient progress outside clinical settings. Unlike traditional exoskeletons that rely on embedded sensors, our approach leverages computer vision to extract joint torques, eliminating the need for additional hardware and improving accessibility for home-based rehabilitation. Additionally, this quantified data can help optimize exoskeleton

[1] Michael W. Hall School of Mechanical Engineering, Mississippi State University, MS, 39762, USA sa1983@msstate.edu, skorivand@me.msstate.edu

control strategies for personalized assistance. By integrating these technologies, it is possible to develop rehabilitation systems that reduce the burden on patients and healthcare providers while maintaining high-quality care. To address the mentioned challenges, researchers have explored various methods to facilitate remote rehabilitation tracking. In this regard, wearable sensor devices like data gloves equipped with flex sensors [14] or inertial measurement units [15] have been developed to capture hand movements for rehabilitation purposes. However, these methods often rely on specialized hardware that can be expensive and cumbersome for patients to use at home, limiting their accessibility and practicality. In addition, while some studies have utilized depth cameras and infrared sensors to track hand gestures without physical markers, these approaches may lack the precision required for detailed torque analysis of the MCP and PIP joints, which is crucial for customizing exoskeleton assistance.

Furthermore, computer vision-based techniques have gained attention for their potential in remote rehabilitation. Systems leveraging standard RGB cameras and algorithms can track hand movements and recognize gestures. However, many of these solutions focus primarily on high-level gesture recognition or qualitative assessments rather than extracting precise biomechanical data such as joint torques and angles. Consequently, they do not fully address the need for accurate, quantitative tracking necessary for optimizing exoskeleton control algorithms and enhancing therapeutic outcomes.

To address these gaps and challenges, in this study, we propose and verify a novel framework for extracting human finger joint torques by combining motion capture data from MediaPipe [16] with a simulated robotic hand model based on MANO hand model [17] in PyBullet environment [18]. Precise control of the hand model was achieved by employing a proportional–integral–derivative (PID) controller, with its gains optimized through genetic algorithms. This approach facilitates accurate modeling of human hand dynamics and provides valuable data for further advancements in rehabilitation and human-computer interaction. Moreover, because this method utilizes readily available open-source software and requires only a single camera, it is both cost-effective and accessible, making it suitable for telehealth and telerehabilitation tracking.

II. METHODOLOGY

The framework of the proposed system is divided into several stages, as shown in Fig 1. (a) Initially, MediaPipe is employed to detect hand landmarks for gesture recognition. (b) These detected landmarks are then utilized to compute the input joint angles. (c) A controller calculates the necessary torques for each joint by comparing the input angles with the simulation angles. (d) Genetic algorithms are subsequently applied to optimize these torques using validation data, thereby enhancing their accuracy to emulate human-like finger joint torques. (e) The optimized torques are integrated into the MANO hand model within the PyBullet simulation environment. The final outcome is the user-controlled virtual hand, which allows for the extraction of finger joint torques.

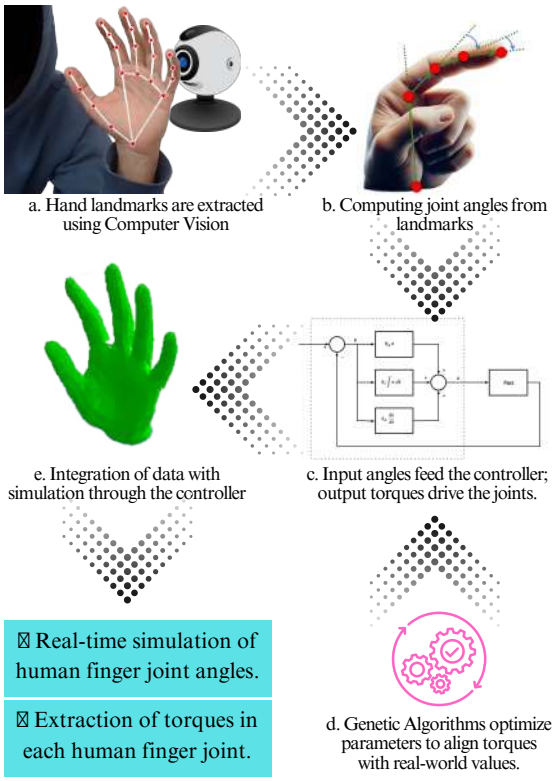

Fig. 1. Framework of the Proposed System. The system integrates hand gesture recognition (a), pose estimation (b), torque computation (c), and optimization (d) to simulate and control the virtual hand model (e), with extraction of human hand finger joint torques.

A. Simulation Environment

The simulation environment was developed using PyBullet [18], a robust physics engine widely employed in robotics and simulation research. PyBullet supports rigid body dynamics, collision detection, and advanced robotic control features, enabling seamless integration and testing of diverse robotic models within a unified framework. By applying joint torques and tracking the resulting model responses, this environment provided a realistic, real-time platform for analyzing hand dynamics.

In this simulation environment, we integrated the MANO hand model [17] to emulate hand movements. MANO is a parametric hand model that provides a detailed representation of both hand shape and motion. Its capacity to capture inter-individual shape variations and a wide range of pose configurations has led to its widespread adoption in hand pose estimation, virtual reality interactions [19], and imitation learning for robotic manipulation [20]. In this study, the MANO model was integrated with PyBullet [21], utilizing three degrees of freedom for each finger and six degrees of freedom for the overall position and rotation of the hand.

B. Hand Landmarks and Poses

MediaPipe was used to extract 21 hand landmarks with a built-in laptop's single 720p HD camera at 15 frames per second. These landmarks included the wrist, as well as

the MCP, PIP, DIP, and fingertip points of each finger, as illustrated in Fig. 2. This figure also depicts the joint angles, their anatomical locations, and the corresponding directions. Positional data were obtained directly from an individual landmark, while rotational information was derived using three key landmarks: the wrist, index MCP, and pinky MCP.

To compute joint angles, displacement vectors were formed between consecutive landmarks, and the angles between these vectors were subsequently calculated. Using landmarks of wrist, MCP, PIP, DIP, and fingertip, vectors are constructed between consecutive landmarks. These vectors are wrist (**w**), MCP (**m**), PIP (**p**), and DIP (**d**) which are illustrated in Fig 2.

By connecting a given joint to its two adjacent joints, we define two vectors $\mathbf{v}_1$ and $\mathbf{v}_2$. The angle θ between these vectors can be computed as:

$$\theta = \arccos\left(\frac{\mathbf{v}_1 \cdot \mathbf{v}_2}{\|\mathbf{v}_1\|\|\mathbf{v}_2\|}\right) \tag{1}$$

For instance, the angle at the PIP joint is obtained by:

$$\theta_{\text{PIP}} = \arccos\left(\frac{(\mathbf{m}) \cdot (\mathbf{p})}{\|\mathbf{m}\|\|\mathbf{p}\|}\right) \tag{2}$$

The calculated joint angles were employed as input trajectories for the controller, guiding the simulated hand's movements within the virtual environment.

Each finger's joint—MCP, PIP, and DIP—has a range of motion in the simulation that reflects its biomechanical role in the hand dynamics. The initial joint angles in the fully extended position are close to 0° for all joints. As the finger flexes, the joint angles increase to follow the natural biomechanics of the hand. The min and max possible values for the range of motion of each joint in the simulation are summarized in Table I. This information is crucial for defining motion trajectories and evaluating joint function.

TABLE I
RANGE OF POSSIBLE MOTION FOR FINGER JOINTS IN THE SIMULATION

Joint	Minimum Angle (°)	Maximum Angle (°)
MCP	-10	90
PIP	-4	100
DIP	0	90

C. Torque Extraction

With the extracted input angles and the MANO dynamic model, a PID controller is used to compute the torques required to drive the virtual hand. In other words, the controller continuously tracks the input joint angles of the user by comparing them with the simulated joint angles and calculating the error between the two. This error serves as the controller's input, while its output torques adjust joint positions accordingly, effectively simulating the forces a human would exert to control finger joints.

The PID controller's gains are optimized to minimize discrepancies between the simulated and real-world behaviors, employing a genetic algorithm to iteratively refine the gains. A fitness function evaluates both the accuracy of angle tracking and the fidelity of the torque output relative to that of an actual human joint. After 50 iterations, the algorithm selects the best set of PID gains. Table II summarizes the resulting gain values for the MCP and PIP joints of the index finger, and Fig. 2 provides a visualization of the joint angles, their locations, and directions.

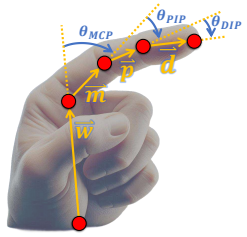

Fig. 2. Illustration of the MCP, PIP, and DIP finger joints, highlighting their angular configurations, anatomical locations, and directions.

TABLE II
OPTIMIZED PID CONTROLLER GAINS FOR THE MCP AND PIP JOINTS OF THE INDEX FINGER

Parameter	Kp	Ki	Kd
MCP	3.446×10^{-1}	9.440×10^{-3}	4.784×10^{-3}
PIP	3.772×10^{-2}	8.911×10^{-4}	4.620×10^{-4}

This methodology facilitates precise and responsive control of the simulated hand's motion through the use of input joint angles. Although these angles are initially derived from MediaPipe landmarks, for validation purposes, they are obtained from the reference dataset [22], ensuring a robust evaluation of system performance.

D. Validation Experiment

To validate our results, we used torque data from Agarwal et al. [22], which represents the torque at each joint of the index finger over multiple movement cycles. This data was extracted using an exoskeleton device on the index finger. It was used both for validating our results and optimizing the system parameters. The resulting torque outputs simulated human-applied forces at the MCP and PIP joints, enabling controlled movement and facilitating the evaluation of rehabilitation strategies and joint torque behaviors.

For the comparison, similar to the reference model, our simulation was programmed to follow sinusoidal trajectories with identical frequencies and durations over a predefined period. Torque profiles at the MCP and PIP joints were measured and analyzed to assess tracking performance and the accuracy of torque generation. Consistent movement patterns are maintained across both models to enable a direct comparison of torque outputs and control effectiveness.

III. RESULTS

A. Validation

The torques at the MCP joint and the PIP joint of the index finger are extracted and compared between the simulation

and the validation data. The actual torques for the validation data are obtained from [22]. The simulated torques are computed using the proposed methodology in Section II.

Based on the input joint angles from the validation data, the simulated joint angles are shown in Fig 3. This plot illustrates the cyclic motion of the index finger, from an open hand to a fist, repeated over four cycles in an 8-second interval. The corresponding torques from the validation data and the simulation for the index MCP and PIP joints are shown in Fig 4. These torque plots directly relate to the input angles displayed in Fig 3.

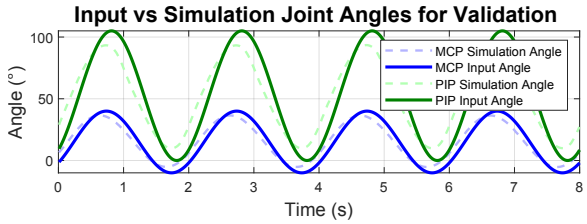

Fig. 3. The input angles from the validation data and the joint angles from the simulation over four cycles within an eight-second interval.

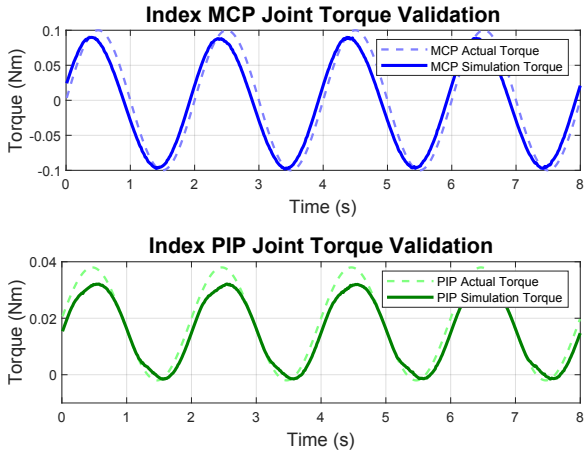

Fig. 4. Comparison of torque measurements of validation data with simulated torque outputs for the MCP and PIP joints. The simulated torque, derived from the input angles shown in Fig. 3, represents the controller's output and corresponds to the torque extracted from the human finger joints.

The simulated torque for the MCP joint closely follows the validated actual torque, achieving a mean squared error (MSE) of 4.346×10^{-4} and an accuracy of 91.32%. This demonstrates the effectiveness of the system in simulating human hand finger joint torques. Although minor deviations are observed during peak torque phases, the overall torque trends remain consistent. This is because the errors are primarily caused by the lag between the actual amount and the simulated amount, rather than a lack of accuracy. These results validate the simulation's accuracy in replicating the torque profiles of the MCP joint under sinusoidal motion trajectories. Similarly, the PIP joint of the index finger demonstrates a comparable trend to that of the MCP joint. The MSE values for both torque and angle errors in the index finger are presented in Table III.

TABLE III
MSE AND DIFFERENCE OF MAXIMUM VALUES FOR THE MCP AND PIP JOINTS IN THE INDEX FINGER

Parameter	MSE	Difference of Max Values
MCP Joint Torque	4.346×10^{-4}	$1.014 \times 10^{-2}(N.m)$
PIP Joint Torque	1.506×10^{-5}	$5.899 \times 10^{-3}(N.m)$
MCP Joint Angle	8.654×10^{-3}	$6.043 \times 10^{-2}(rad)$
PIP Joint Angle	6.357×10^{-2}	$2.010 \times 10^{-1}(rad)$

B. Torque Simulation for Other Finger Joints

After validating our results with the available experimental data for the index finger, the MCP, PIP, and DIP joints of the index, middle, ring, and pinky fingers were simulated using the input angles illustrated in Fig. 5. This figure depicts a single cycle of joint motion over a 4-second interval, serving as the input trajectory for each finger.

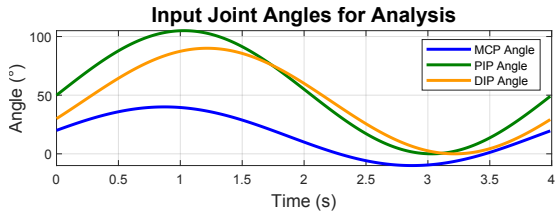

Fig. 5. MCP, PIP, and DIP joint input angles over one oscillation in 4 seconds for extracting torques of different fingers.

The resulting torque profiles for the MCP and PIP joints of the index, middle, ring, and pinky fingers are presented in Fig. 6. These plots compare the simulated torques across different fingers, highlighting the dynamic behavior of each joint under the specified input angles. The observed variations in torque among the MCP and PIP joints can be attributed to the distinct biomechanics and functional roles inherent to each finger.

The index and middle fingers exhibit higher torque values due to their primary roles in precision and power grips [23]. Additionally, these fingers possess stronger musculature and tendon connections [24], which contribute to their increased torque generation. In contrast, the ring and pinky fingers demonstrate lower torque values, reflecting their secondary roles in grip stabilization and support. These findings illustrate the simulation's capability to generalize and accurately model the dynamics of multiple finger joints, underscoring its potential for broader applications in rehabilitation and human-computer interaction.

IV. DISCUSSION

Accurate estimation of MCP and PIP joint torques and angles is essential for effective rehabilitation tracking with exoskeletons. Precise measurement enables personalized rehabilitation programs that adapt to patient progress, ensuring appropriate assistance or resistance. This aids in tracking motor recovery for neurological injury patients, such as stroke survivors [25]–[27]. Integrating torque and angle estimation also allows real-time feedback and adaptive control

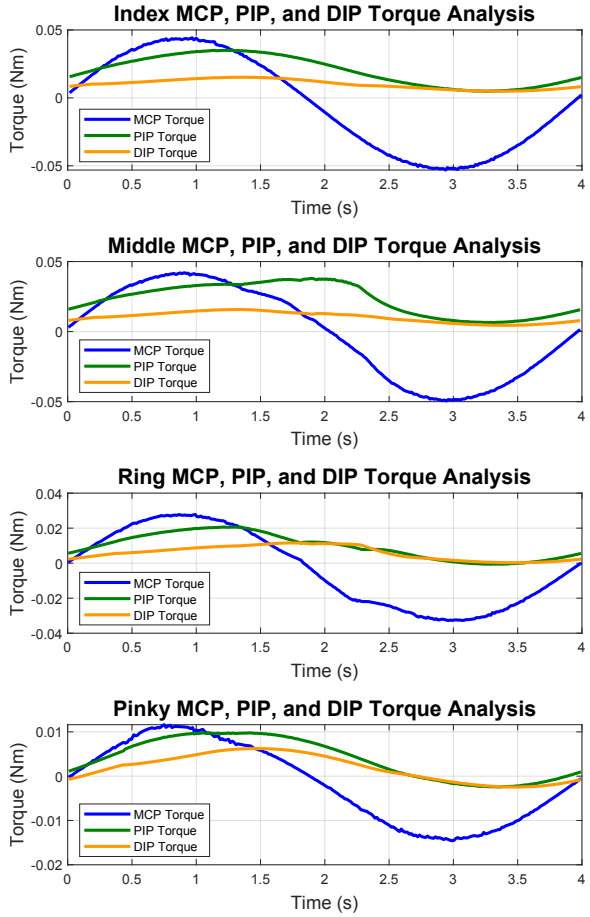

Fig. 6. MCP, PIP, and DIP joint torques analysis based on the input angles in Fig 5 for index, middle, ring, and pinky fingers.

in exoskeletons, which leads to efficient motor learning and recovery while providing clinicians with quantitative data for optimizing rehabilitation outcomes.

However, current methods for measuring MCP and PIP joint angles and torques, such as optical motion capture, electromagnetic tracking, and instrumented sensor gloves, face significant limitations. These systems require expert supervision, specialized medical facilities, and controlled environments, making routine clinical use and home rehabilitation impractical. Additionally, high costs, sensitivity to interference, calibration requirements, and user discomfort further restrict their accessibility. While these technologies provide valuable insights into joint kinematics, their real-time capabilities are largely confined to basic angle calculation, limiting their applicability for dynamic rehabilitation scenarios that require the key component of torque estimation. Advanced imaging techniques such as MRI and ultrasound offer precise structural and biomechanical measurements but remain expensive and unsuitable for frequent monitoring.

The proposed novel method employing a virtual hand model integrated with computer vision techniques has demonstrated a high degree of agreement between the estimated MCP and PIP joint torques and those obtained from previous experimental studies. Specifically, the MSE of our method is 4.346×10^{-4} for MCP torque and 1.506×10^{-5} for PIP torque when comparing with experimental results. This strong correlation validates the reliability and accuracy of our methodology in extracting human joint dynamics.

The system relies on a camera (e.g., laptop) with no complex calibration, requiring only basic data on hand size and mass. The distance to the camera is not critical as long as the resolution is sufficient to extract hand landmarks. The user simply positions the camera to capture the area above and places their hand within the frame. The successful estimation of MCP and PIP torques underscores the potential of our approach as a viable alternative to traditional measurement methods, often constrained by the need for direct expert supervision, specialized equipment, and clinical settings.

The validation data from Agarwal et al. [22] represents controlled finger movements within a typical range of motion and speed relevant to rehabilitation applications. Compared to daily activities, where finger motion speeds can vary significantly—from slow, precise manipulations (e.g., typing, grasping small objects) to rapid dynamic movements (e.g., gripping, flicking)—the speeds used in our study fall within a moderate range. While higher speeds could introduce additional challenges, such as increased torque fluctuations and motion blur in vision-based tracking, our approach is designed to adapt to varying movement speeds through its physics-based modeling. Preliminary tests indicate that the system can estimates joint torques at different speeds, but further validation is needed to assess its performance across a broader spectrum of daily activity motions.

In prosthetic design, torque data plays a pivotal role in developing devices that closely replicate natural hand movements, thereby enhancing adaptability and functionality for users. Understanding these forces also aids in optimizing material properties and actuation mechanisms, leading to improvements in efficiency and user comfort.

In the realm of robotic hand control, extracted torque data is essential for designing algorithms that replicate human-like movements. Integrating computer vision allows various hand models, including pre-built robotic hands, to be incorporated into the control system. Additionally, this setup supports training reinforcement learning models, enabling robots to learn precise and efficient hand motions. These advancements enhance applications in assistive technology, automation, and human-robot interaction, resulting in more responsive and functional robotic systems.

Although the proposed approach offers several advantages, it is subject to certain limitations. A primary constraint is the reliance on a single camera for data acquisition, which restricts the ability to capture the full range of hand poses, particularly during movements where occlusions occur. However, this limitation can be partially mitigated if the user follows predefined movement protocols to maintain optimal visibility. Additionally, unintentional hand displacement beyond the camera's field of view may disrupt continuous tracking, potentially reducing the reliability of the extracted motion data. While future enhancements, such as multi-camera fusion or depth estimation techniques, could improve

robustness and mitigate these challenges, they introduce a trade-off with the simplicity and ease of deployment that make the current approach accessible and user-friendly.

Furthermore, patients with significant movement limitations may exhibit restricted joint displacement, reducing the accuracy of estimated torques due to lower variation in extracted kinematic data. While our approach provides a markerless, vision-based solution for rehabilitation tracking, it is not inherently designed to support patients with severely impaired mobility unless integrated with an exoskeleton device. In such cases, our system could complement exoskeleton-assisted rehabilitation by tracking joint dynamics in response to robotic assistance, enabling more precise monitoring of rehabilitation progress. However, without direct access to an exoskeleton, the applicability of our setup for patients with minimal voluntary movement remains limited.

For future work, we aim to enhance the system by incorporating multiple cameras, sensor fusion, and intelligent camera placement algorithms to improve joint angle estimation and mitigate occlusions when tracking complex movements involving additional joints (e.g., spinal cord, knee, shoulder, wrist). While the single-camera setup remains the primary low-cost solution, multi-camera configurations and additional sensors (e.g., electromyography, stereo vision cameras) will serve as optional enhancements for clinical or research applications requiring higher accuracy. AI-driven occlusion handling techniques will further optimize tracking without significantly increasing hardware complexity. However, these improvements introduce a trade-off with simplicity, ease of deployment, and cost-effectiveness. Future efforts will focus on maintaining this balance to enhance tracking while preserving the system's practicality for remote rehabilitation.

Implementing and Testing the Novel REHAB-PAL System on Unimpaired Population: Towards Rehabilitation Engagement at Home with a Socially Assistive Robot for Pediatric Adherence

Matilde Antonj, Giulia Corniani, Kathy Piela, Leonard Eusebi, Maura Casadio, Alessandra Sciutti and Paolo Bonato

***Abstract*— This study introduces the REHAB-PAL system, an interactive solution for home-based rehabilitation in children with cerebral palsy. To verify its functioning and usability, the system was tested with physical therapists and rehabilitation specialists simulating patient roles. The system was evaluated for its ability to track users' movements during rehabilitation exercises and assess the quality of their performance. A look-up table was developed to correlate kinematic movement characteristics with clinical scores that quantify exercise quality. To enhance exercise performance and promote adherence, the system integrates NAO social robot, programmed to provide verbal instructions, demonstrate exercises, and deliver personalized feedback based on users' movement quality. Feedback delivery was guided by a decisional strategy, prioritizing specific kinematic variables tracked by the system. Participants were asked to perform a rehabilitation session under three experimental conditions: 1) Interaction with the physical NAO robot, 2) Interaction with a virtual robot displayed on a computer screen, and 3) Receiving instructions without the use of a robot. The REHAB-PAL system accurately detected participants' kinematics and automatically generated correct movement scores. Questionnaires revealed participants' preference for the interaction with the physical robot, associated with highest levels of engagement and seen as the most effective means of delivering exercise instructions.**

I. Introduction

Cerebral palsy (CP) is the most common motor disability in childhood, affecting 500,000 children under the age of 18 only in the United States, and 10,000 babies born each year are diagnosed with this pathology [1]. Cerebral palsy originates from an injury that occurs during the brain development in the prenatal, perinatal, or postnatal period [2]. Due to this neurological condition, patients are affected by motor disabilities, often accompanied by potential sensory and cognitive impairments; therefore, repeated sessions of rehabilitation are prescribed for the improvement in balance [3], gait [4], posture [5] and flexibility [6]. Every year, a substantial number of children require sessions of rehabilitation to improve their motor skills. However, the limited time of physical therapy in the hospitals and the families' support in terms of time and funding is challenging [7]. At-home sessions of rehabilitation could help children with cerebral palsy perform extensive and repetitive rehabilitative exercise, promoting the adherence to the therapy [8].

Unfortunately, maintaining adherence with at-home rehabilitation is often difficult: for this reason, new methods of training have been developed and tested to increase the level of engagement in children with motor impairment. Video games for rehabilitation have been demonstrated to be a valid alternative to increase users' engagement with therapy and to induce motor learning [9]. As well as encouraging the improvement of motor skills, results from playing with Active Video Game (AVG) revealed that children with cerebral palsy could achieve specific therapeutic goals with a low-cost and commercially available technology [10]. However, AVG lacks socially interactive skills, which could help engage users in their motor exercises through human-like abilities, such as speech and gestures. Socially Assistive Robots (SARs) aim at covering this gap in rehabilitative technologies [11]: by benefiting human social drives, children could increase their level of engagement through interaction with a robot characterized by social attitudes [12]. Although the use of virtual agents has already helped children maintain focus on rehabilitation, SAR has been demonstrated to induce greater effects on users' engagement and motor performance [13]. Novel methods of rehabilitation have been developed with the use of social robots that could encourage children with CP during their training [14]. Thanks to Socially Assistive Robots, children with cerebral palsy could be motivated in performing repetitive physical exercises [15], promoting the improvement of their non-verbal communication with their peers and caregivers [16]. However, current solutions do not involve comprehensive systems aimed at coaching patients during the training, establishing social interaction through customized feedback during the performance, and retrieving

movement assessments of the rehabilitation, which could be reviewed by parents or physical therapists remotely.

To address the aforementioned problem, this study presents the implementation and testing of the REHAB-PAL system, a novel solution that assists children with cerebral palsy in at-home rehabilitation through the interaction with the social robots NAO [17], maintaining high levels of engagement during the training. Through tight collaboration with physical therapists, a look-up table was developed to associate kinematic characteristics with a score reflecting the quality of movement. Therefore, the REHAB-PAL system was developed to track users' movement during the interaction and generate a movement assessment in real-time during the training. Moreover, during rehabilitation sessions, the robot was programmed to show the exercise to perform and provide users with customized feedback to achieve the correct position. Physical therapists and rehabilitation specialists participated in an experiment to test the system functioning and evaluate the results of tracking, movement assessment and delivery of feedback. Moreover, these stakeholders tested the system through the interaction with the physical robot NAO, with the virtual robot, and without robot, to demonstrate that the interaction with the physical robot could increase users' engagement during the exercise execution.

II. METHODS

A. REHAB-PAL system

The REHAB-PAL system is designed to engage patients in motor skills training at home, without the need for direct supervision by physical therapists. The system integrates a variety of rehabilitative exercises with the humanoid robot NAO. The interaction between the robot and the patient aims to replicate the experience of working with a physical therapist. To achieve this goal, the system tracks patients' movements, provides performance feedback, and stores movement assessment, based on joint angles during rehabilitation sessions.

The setup prioritizes simplicity to facilitate future deployment in patients' homes. It consists of a PC with pre-installed software, a screen, the NAO robot, and an external camera positioned in front of the participant. To enhance usability, the system features an intuitive graphical user interface that allows parents to easily initiate rehabilitation sessions. The interface also offers customization options, such as entering the patient's personal details and selecting the types and number of exercise repetitions.

The REHAB-PAL system is developed in Python, utilizing PyGame to create an engaging and colorful interface designed to appeal to children. The interface transitions through shades of green to orange, evoking a game-like experience. This interface is displayed on a screen positioned behind the NAO robot and in front of the participant. Key training information is clearly shown on the screen, including a yellow counter indicating the remaining focus time. In the center, real-time tracking of the participant's movements is displayed. The name of the exercise appears at the top of the screen, while the robot's vocal feedback is transcribed at the bottom to assist participants in completing the exercises.

B. Target Population and Stakeholders

The system is designed to target children with cerebral palsy aged 7–14 years and classified at levels I or II of the Gross Motor Function Classification System (GMFCS) [18]. Impaired population was involved in the pilot study in order to decide the rehabilitative exercises to implement in the system and define a consistent method for the movement assessment.

Once the development was completed, 11 stakeholders (i.e., physical therapists and rehabilitation specialists) tested the functioning and usability of the system.

The study was approved by the Institutional Review Board at Mass General Brigham (protocol number 2021P002424).

C. Upper Body Movement Assessment

Since children with cerebral palsy present impaired range of motion [19], during rehabilitation sessions active exercises have been demonstrated to improve their motor abilities [20]. In collaboration with physical therapists, three upper-body exercises were selected for rehabilitation training to ensure broad applicability and focus on motor skills (Fig. 1):

- *Hands Up*: raising both hands towards the ceiling;
- *Hands T*: extending both arms outward to form the shape of the letter T;
- *Hands Y*: raising both arms upward and outward to form the shape of the letter Y.

Following the inclusion criteria of the target population, in a pilot study six pediatric patients performed these rehabilitation exercises for one repetition and maintained the position for 30 seconds. Due to high variability in patients' motor skills, above all, their capability of standing up, these exercises were chosen to target the upper body and to make the rehabilitation accessible to most patients while being suitable for home-based use.

To quantify movement performance during these exercises, the study utilized the MediaPipe Pose Landmarker [21], a pre-trained machine learning model that tracks 33 key body landmarks from video captured by a front-facing camera. The movement of the upper body was assessed considering the shoulders, elbows, wrist, and hip position, associated with MediaPipe skeleton landmarks. Each performance was evaluated in terms of shoulder abduction, elbow flexion, and shoulder tilt in the 2D experimental scene. Shoulder abduction was calculated for each side of the body as the

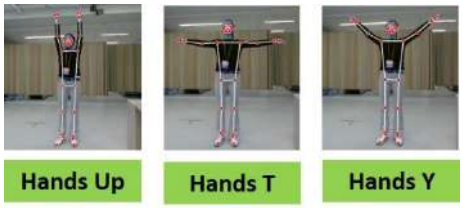

Figure 1. Rehabilitative exercises in REHAB-PAL system. Three different positions, considering the upper body, were selected as rehabilitative training for motor skills in the REHAB-PAL system: Hands Up, Hands T, Hands Y.

joint angle between the elbow, shoulder, and hip. Elbow flexion was measured as the joint angle between the wrist, elbow, and shoulder. Additionally, shoulder tilt was determined by measuring the vertical displacement between the right and left shoulders. Through a tight collaboration with physical therapists, participants' movements were inspected by analyzing joint angles: both normative and compensatory strategies were identified and used to develop a look-up table (TABLE I). This table associates performance levels—accurate, mild, moderate, and severe—with quantitative measures of joint angles and body displacements. Each each clinical label was associated with a score from 0 to 3: the smallest value corresponded to a severe label, while the highest number to the correct one. The system was designed to provide real-time feedback on performance, enabling parents and remote physical therapists to immediately assess the effectiveness of the motor training. Through this process, the REHAB-PAL system was refined to autonomously evaluate upper-body motor performance, offering a clinically informed and practical tool for home-based rehabilitation.

TABLE I. LOOK-UP TABLE FOR MOVEMENT ASSESSMENT

Physical Exercise	Shoulder Abduction	Elbow Flexion	Shoulder Tilt
Hands Up	**[170° , 180°]**	**[0°, 9.9°]**	**[0, 0.0049]**
	[165°, 169.9°]	**[10°, 14.9°]**	**[0.005, 0.0099]**

Label	Accurate	Mild	Moderate	Severe
Score	3	2	1	0

D. *Customized Feedback*

To emulate the interaction between the patient and the physical therapist, the system was endowed with the capability of providing participants with customized suggestions. To choose simple and effective feedback, a physical therapist was involved in the decision of the appropriate feedback for pediatric rehabilitation. During the exercise, suggestions were given every 5 seconds so that participants had the time to receive the comments of the system and fix their erroneous position. The same tracking modality used for the development of the look-up table was implemented, in order to track participants' movement in each instant of the interaction (II.C). Relying on the assessment of patients' performance during the training, the REHAB-PAL system provided different instructions in real-time, which suggested the way to correct specific body angles or tilt (i.e., shoulder abduction, elbow flexion, and shoulder tilt). In case of multiple errors during the execution of the exercise, the delivery of suggestions was prioritized: first, participants could receive suggestions on the position of their shoulders, then on the location of their elbows, and eventually on the alignment of their shoulders. After the feedback was delivered, the system continued tracking the participant's movement: if they did not manage to correct the position, participants were provided with the following suggestion in the scale of priorities (See Fig. 2 for the complete decisional strategy of feedback delivery implemented in REHAB-PAL system). In this way, the REHAB-PAL system could avoid patients' frustration in hearing the same feedback two consecutive times and maintain children's engagement. If patients performed the exercise correctly, they were encouraged to maintain the position, thanks to the delivery of variable words of exhortation. At the end of each exercise, participants received a score for the performance, considering the number of times shoulder abduction, elbow flexion, and

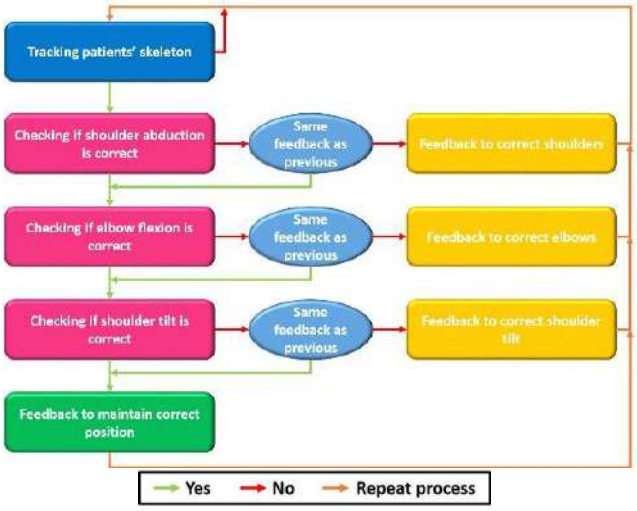

Figure 2. The decisional strategy of feedback delivery implemented in REHAB-PAL. At each instant of the interaction, the REHAB-PAL system tracked participants' movement and, every 5 seconds, provided them with customized feedback according to their performance. Feedback was delivered by prioritizing shoulder abduction, followed by elbow flexion and shoulder tilt, but two identical consecutive suggestions were avoided to maintain subjects' engagement.

shoulder tilt were associated with each label: the more accurate labels were gathered during the execution of the movement, the higher the score obtained. Over the trials, points were accumulated, and the total score was communicated to participants at the end of the training.

E. Robot Characterization

To enhance engagement during rehabilitation sessions, the REHAB-PAL system was integrated with the humanoid robot NAO, developed by Aldebaran – United Robotics Group. At the start of each session, the robotic agent greeted participants and provided instructions for the exercises. Leveraging its 25 degrees of freedom, the robot could demonstrate the exercises and perform them alongside the participants to encourage active participation (Fig. 3). The robot's movements were programmed using the Choregraphe application. Initially, the actions were created, tested, and refined on the corresponding virtual robot. Once finalized, these actions were recreated on the physical robot, enabling it to replicate the three rehabilitative positions – Hands Up, Hands T, and Hands Y – with a human-like appearance. During the exercises, participants were instructed to replicate the movements of the robot, striving to achieve the correct positions as accurately as possible. During participants' performance, the REHAB-PAL system tracked their movements and communicated to the robot the customized feedback to deliver. In this way, each time, the human-robot interaction could vary, according to participants' performance, with the final result of increasing engagement in the rehabilitation session. To increase engagement and improve the execution of the exercises, the robot informed participants of the score computed by the system at the end of each performance and the total amount of points when the training finished.

Figure 3. The interaction with the robot NAO, realized by the REHAB-PAL system. The image shows the interaction between a participant and the robot NAO: the embodied agent shows the Hands Up position and the subject has to replicate its movement. Thanks to the customized feedback of the robot, participants can adjust the position to correct the erroneous movement.

F. Testing System

The novel system REHAB-PAL was tested on 11 unimpaired adults, enrolled among physical therapists and rehabilitation specialists, to verify the functioning of the system and gathering feedback from a potential stakeholder population. Participants performed each exercise (i.e., Hands Up, Hands T and Hands Y) in three different trials in the following order:

1. *Accurate round*: participants had to achieve the position in the most accurate way;
2. *Correction round*: subjects were asked to display shoulder abduction in Hands T, elbow flexion in Hands Up, and elbow flexion and shoulder tilt in Hands Y, and correct their position, following the feedback of the system;
3. *Erroneous round*: participants performed the exercise by varying their joint angles and tilt without achieving the correct position.

Thanks to the structure of this experiment, participants could test the system functioning in detecting participants' movement, the association of clinical labels to their joint angles and tilt during the performance, and the delivery of feedback.

To have additional proof that the implemented interaction with the robot was perceived as an engaging tool for rehabilitative sessions, the experiments were repeated in three different modalities:

- *Physical robot*: the embodied agent performs the exercises in front of the participant and, through vocal comments, corrects participants' movements with tailored feedback;
- *Virtual robot*: an artificial virtual agent shows the motor exercise and provides customized feedback by displaying a textual comment on the screen;
- *No robot*: participants interacted just with the feedback and information reported on the graphical user interface without any virtual or physical agent.

The order of the three conditions was randomized among participants. Within each session, 30-second exercises were executed in the same sequence: all the three positions were performed in each round, avoiding consecutive repetitions to increase engagement in the training. To avoid differences in the understanding of the exercise, the positions were shown before starting the whole experiment.

G. Skeleton and Questionnaire Data

For each participant, the positions of MediaPipe skeleton landmarks were collected, and joint angles and tilt for the upper body were computed and saved at each instant of the experiment with a sampling rate of 30 Hz. To avoid outliers, clinical scores in the first and last 5 seconds of interaction were excluded. Shoulder abduction, elbow flexion, and shoulder tilt were inspected to verify how the association of clinical labels worked during the experiment: in particular, participants' performance was verified to be associated with the clinical labels, corresponding to the instructions of the round. First, each participant's mean clinical scores were computed, considering all three different conditions (i.e., without, virtual robot, and physical robot), and mean values among participants were found for each joint angle and tilt. In addition, since no detection of skeleton data corresponded to missing movement assessment (i.e., labels and scores), number of times the system identified the users' body landmarks were calculated. Moreover, at the end of each condition, participants were asked to evaluate the type of interaction with a Likert scale from 1 (minimum score) to 7 (maximum score), considering 5 different items: enjoyment, usefulness, encouragement, helpfulness, and fun. Since the three different interactions shared the same content in the customized feedback, at the end of the whole experiment, participants were also provided with a questionnaire aimed at evaluating the system, using Likert scales from 1 (minimum score) to 7 (maximum score) and general questions to gather impressions about the system. In particular, in the final questionnaire, participants had to rate the usefulness and the engagement associated with the delivery of customized feedback, the usefulness in priority of feedback, the rewarding method (i.e., communication of individual scores at the end of the exercise and the total amount at the end of the condition) and accuracy in associating labels to joints.

III. Results

This study led to the development and testing of the novel REHAB-PAL system: through a tight collaboration with physical therapists, a new method to provide rehabilitation sessions was created through the interaction of the humanoid robot NAO. During the training, the embodied agent showed the rehabilitative exercise and gave customized feedback according to the participants' performance. Moreover, the novelty of the system consists of having a real-time movement assessment of the exercise execution: the user's joint angles and shoulder tilt could be associated with four different levels of performance and motor impairment (i.e., accurate, mild, moderate, and severe). Participants performed the exercises in front of the robot and the camera: the system managed to detect their joint angles 100% of the time, and associate a clinical label, confirming the stability of the method.

A. Testing Movement Assessment

In the first round of exercises, participants had to perform the three exercises for the upper body (i.e., Hands Up, Hands T, Hands Y) in the most accurate way. The system was tested to verify if participants' performance was associated to clinical labels, corresponding to accurate motor behavior. Results showed that in the execution of the Hands Up position, the association of clinical labels worked correctly: as shown in Fig. 4, mean clinical score for each joint and tilt varied between score 2 and 3, indicating a mild-accurate behavior (left shoulder: 2.1 (0.2 SE), right shoulder: 2.4 (0.2 SE), left elbow: 2.6 (0.2 SE), right elbow: 2.5 (0.2 SE), shoulder tilt: 2.9 (0.1 SE)). Although the exercise was shown before starting the experiment, participants often slightly decreased their joint angles for shoulders and elbows, also caused by the long duration of exercises. The same analysis was carried out also for the other two positions: the Hands T was demonstrated to be a more intuitive exercise to perform, particularly in the alignment of the shoulders. Also in this case, the system was able to assess correctly participants' performance from mild to accurate behavior (left shoulder: 2.6 (0.1 SE), right shoulder: 2.6 (0.1 SE), left elbow: 2.8 (0.1 SE), right elbow: 2.2 (0.2 SE), shoulder tilt: 3.0 (0.01 SE)). For what concerned Hands Y, results showed that the system correctly assessed a mild-moderate behavior (left shoulder: 1.5 (0.3 SE), right shoulder: 1.5 (0.3 SE), left elbow: 2.7 (0.2 SE), right elbow: 2.7 (0.2 SE), shoulder tilt: 2.9 (0.1 SE)) because participants challenged to find the accurate position, by varying the width of the Y shape. To prove the consistency of the system, results in the first round were compared to the last two series of exercises. Results demonstrated that the clinical score, associated with participants' performance, correctly decreased their value. Considering Hands Up as representative position, the assessment of the system was compared among the three rounds of exercises: in the second repetition, participants' shoulder abduction was meanly categorized as severe-

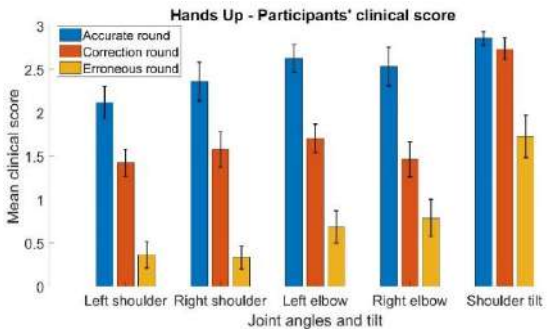

Figure 4. Comparison of clinical score in Hands Up among the three rounds. This image compares the clinical score in the different rounds: blue bars represent participants' performance in the accurate round, while orange and ocher graphs refer to their scores, in the correction and erroneous round, respectively. Left and right shoulder abduction, left and right elbow flexion and shoulder tilt achieved higher results in the first round, where the system managed to evaluate their performance as a mild-accurate behavior. In the second round, participants had to perform Hands Up position varying the elbow flexion, which also led to the variation of the shoulder abduction and tilt. During the performance, participants had the possibility of correcting their position. Results showed that the system categorized their behavior in a severe-moderate mode for the shoulders and a moderate-mild behavior for the elbows and shoulder tilt. In the last round, participants never corrected their position: the system correctly evaluated their behavior as severe-moderate for shoulders and elbows, with a slight variation of shoulder tilt remaining in a moderate-mild mode. The black error bars identify the standard error of the mean.

moderate behavior, while elbow flexion and shoulder tilt were associated with moderate-mild labels (left shoulder: 0.9 (0.2 SE), right shoulder: 0.9 (0.2 SE), left elbow: 1.9 (0.2 SE), right elbow: 1.7 (0.2 SE), shoulder tilt: 1.6 (0.1 SE)). Clinical score significantly decreased in the last round, where participants have not the possibility to correct their position, moving closer to severe behavior, with a slight modulation of the shoulder tilt (left shoulder: 0.4 (0.2 SE), right shoulder: 0.4 (0.1 SE), left elbow: 0.8 (0.2 SE), right elbow: 0.8 (0.2 SE), shoulder tilt: 1.6 (0.1 SE)). These differences in movement assessment among rounds were verified through a Repeated Measures ANOVA (all p's < 0.001).

B. System Evaluation

The aim of performing different rounds of the exercises consisted of letting participants understand how the REHAB-PAL system could provide them with useful suggestions in case of error or just with encouraging comments to maintain the correct position. In the evaluation of the entire system, questionnaire results showed that participants rated the delivery of customized feedback with a mean score of 5.7 for its usefulness and 5.3 for its engagement, with the suggestion of incrementing the number of feedback for more challenging positions, such as Hands Y. Most of the participants highlighted the importance of giving priority to the different body parts with the final goal of achieving the correct positions: indeed, they averagely evaluated the usefulness of priority in feedback delivery with 5.6. Since each participant obtained a score at the end of each exercise, in the questionnaire they were asked to evaluate this rewarding method: the assessment reached the mean value of 5.3, also proposing a visualization method to help children visualize their improvement over time. Only for this experiment clinical labels for each joint were displayed on the screen so that participants could evaluate how the clinical assessment was working during the trials. Participants were satisfied with the association of correct clinical labels to each joint, evaluating the method with a mean score of 6.

C. Interaction Evaluation

To assess how the system was engaging for the target population, at the end of the whole experiment, participants were asked which type of interaction they preferred: 100% of participants confirmed that the interaction with the robot was more appropriate to achieve the goal, compared to the interaction with the virtual robot or without robot. Moreover, participants' questionnaire results were analyzed for the evaluation of the interaction in different conditions: computing the mean values for each item, in Fig. 5 results showed that participants rated the highest values for all the items, belonging to the interaction with the physical robot (enjoyment: 6.7 (0.2 SE), usefulness: 6.6 (0.2 SE), encouragement: 6.3 (0.3 SE), helpfulness: 6.3 (0.3 SE), fun: 5.9 (0.3 SE)). On the contrary, participants rated with lower scores the interaction with the virtual robot (enjoyment: 5 (0.4 SE), usefulness: 5.8 (0.4 SE), encouragement: 5 (0.4 SE), helpfulness: 5.5(0.4 SE), fun: 4.4 (0.4 SE)), followed by the score achieved without robot (enjoyment: 4.8 (0.4 SE), usefulness: 4.8 (0.4 SE), encouragement: 4.4 (0.5 SE), helpfulness: 4.6 (0.3 SE), fun: 3.5 (0.4 SE)). These results demonstrated that the presence of the robot NAO, able to show the movement and give useful suggestions during the performance of the exercises, was fundamental in the engagement of the training (Repeated Measures ANOVA, all p's < 0.001).

IV. Discussion and Conclusions

The implementation of REHAB-PAL system presents a novel method to deliver sessions of rehabilitation for children with cerebral palsy, with the final aim of improving their motor skills for the upper body. The system was developed to imitate the interaction between patients with physical therapists. Therefore the system integrated the humanoid robot NAO: the embodied agent was manipulated to show the motor exercises to replicate. Thanks to a tight collaboration with physical therapists, the REHAB-PAL system was endowed with the capability of creating a real-time movement assessment of participants' performance: shoulder abduction, elbow flexion, and shoulder tilt were associated with clinical labels, according to their performance during the execution of the task. Moreover, in case of errors, the robot was able to give customized suggestions in order to help participants achieve the correct position. By testing the REHAB-PAL system with a group of physical therapists and rehabilitation experts, the movement assessment was demonstrated to work properly during the session of rehabilitation. The customized feedback was appreciated by participants when they had to correct their position: for most challenging exercises, an increase in the number of feedback was suggested. To demonstrate the importance of the interaction with robots for engagement in rehabilitation, the system was compared in three different modalities: with the physical robot, with the virtual robot and without robot. All the participants evaluated the interaction with the physical robot as superior to the other two conditions, in terms of enjoyment, usefulness, encouragement, helpfulness, and fun. In line with previous findings [22], these results confirmed the benefit of physical appearance in users' environment during an

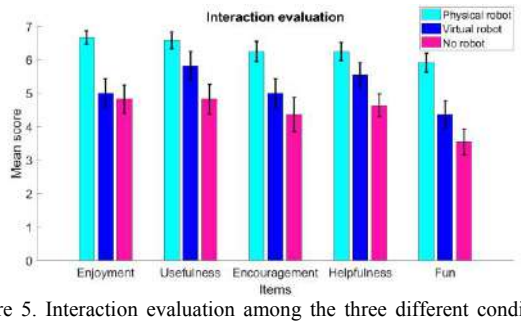

Figure 5. Interaction evaluation among the three different conditions. Participants had to evaluate the interaction with the REHAB-PAL system in the three different modalities: with the physical robot, the virtual robot and without robot. The interaction with the robot was assessed with highest scores (cyan bars), followed by the interaction with the virtual robot (blue bars). On the contrary, the modality without robot received the lowest scores (magenta bars). The black error bars represent the SE of mean score.

interaction, demonstrating the potential increase of engagement in rehabilitation settings. In comparison to the existing technology [23], the REHAB-PAL system simultaneously covers the rehabilitation needs of training users' motor abilities, establishing an engaging interaction through customized feedback, and providing a movement assessment, which could be reviewed by physical therapists and parents. Based on the results of this research, the system will be further evaluated in terms of validity and usability with the target population (i.e., children with cerebral palsy). Although the use of a social robot could seem a financial barrier for at-home rehabilitation, their presence could provide impaired population with distant care [24]: therefore, an effective rehabilitation with REHAB-PAL system could reduce the financial burden of families in physical therapy and optimize the hospital workflow. In conclusion, this study proposed a new comprehensive method aimed at the delivery of at-home rehabilitation for children with cerebral palsy through interaction with a socially assistive robot able to show the exercises, give customized feedback, and store the movement assessment obtained during the training.

ACKNOWLEDGMENT

The authors would like to thank all the participants in the pilot study and in the experiments for their commitment.

Impedance-Controlled Knee Orthosis: Transitional Movements and their Effect on Knee Kinematics and Muscular Activity

Marc-Anton Scheidl[1], Hannah Braun[1], İsmail Berkay Akarsu[1], Claudio Castellini[1,2]

***Abstract*— This study investigated the effects of an impedance-controlled active knee orthosis on knee kinematics and muscle activation during transitional movements, focusing on Sit-To-Stand and Step-Up tasks. A custom hardware and software setup employed an EMG-driven impedance controller to modulate joint stiffness real-time. Four healthy participants performed Sit-To-Stand and Step-Up tasks under assisted and non-assisted conditions. The results indicated that the orthosis reduced muscle activity in stable, bilateral tasks like Sit-To-Stand, leading to lower average EMG amplitudes in the assisted leg. In contrast, for more unstable, unilateral tasks such as Step-Up, changes in velocity and muscle activity were more variable. Inter-participant differences in body mass and movement strategy influenced outcomes, and the device's interference with normal muscle patterns highlighted the need for improved sensor attachment and personalized parameter tuning. These findings underscore that while EMG-based impedance control can lessen physical effort under certain conditions, its benefits depend on the task's nature and individual user characteristics. Future work should refine hardware stability, improve data quality, and explore adaptive algorithms for personalized assistance.**

I. Introduction

Active knee orthoses (AKOs), in particular, have gained increasing attention over the last few years as assistive devices for individuals with lower-limb weakness [1], [2]. Mobility-related disabilities, such as hemiplegia, cerebral palsy, hemiparesis, diplegia, and spinal cord injuries, often require the use of lower limb orthotics to stabilize, support, and even reduce energy expenditure [3], [4]. Addressing structural joint issues and reducing strain on the lower limbs can also benefit an aging population in tasks of daily living, reducing the risk of injury while potentially alleviating geriatric issues such as cartilage degeneration [5], [6], [7], [8].

These systems are designed to augment knee extension during demanding activities such as standing up from a chair or climbing stairs [9], [10], [11], which require significant knee torques $0.38 - 0.9\,\mathrm{Nm/kg}$ [12], [13]. Therefore, these cannot always compensate for the entire load due to technical limitations and trade-offs [9].

Impedance control, based upon a variety of high to low-level control paradigms and even advanced biomechanical model approaches, allows an attached exoskeleton or AKO to modulate its stiffness and damping in response to the user's movements, ensuring safe and adaptive human-robot interaction [14], [15], [16]. To achieve intuitive user control, recent studies propose the usage of electromyography (EMG) signals from the user's muscles to adjust assistance in real time [17] and provide feedback on biomechanics and muscle recruitment [18], [19]. In a post-stroke case study, proportional EMG control with a knee exoskeleton significantly decreased muscle effort and improved balance metrics by up to 29.3% during sit-to-stand attempts [20]. Similarly, a lightweight AKO reduced EMG activity by roughly 19% on average during step-up trials in healthy adults [2]. Such findings indicate that EMG-driven augmentation of knee joint torques in active knee orthoses can effectively compensate for deficits in muscle strength arising from aging, injury, or neurological conditions, facilitating recovery by promoting neuroplasticity and restoring motor function [21].

This paper explores the application of impedance control in AKOs to reduce muscle strain during Sit-To-Stand and Step-Up exercises in four healthy participants. By leveraging EMG signals to dynamically adjust the joint's impedance, our system delivers intuitive, user-centered assistance that minimizes muscular effort. Additionally, our device requires minimal calibration, is lightweight, and is based on a CE-certified, medical-grade knee orthosis that utilizes off-the-shelf components to keep costs low and maintain minimal weight. In the following sections, we present the methodology, experimental setup, and initial findings of our study.

II. Methodology

A. Hardware-Setup

The core component of our setup (Figure 1) is a modified Sporlastic GENUDYN® CI STEP THRU Knee Orthosis [22] equipped with an electric actuator (AK80-9, CubeMars) [23], which provides industry-grade torque, position, and velocity sensing capabilities thanks to the MAB Robotics MD80 v2.1 controller [24] with a peak torque of $18\,\mathrm{Nm}$ and $9\,\mathrm{Nm}$ sustained ($\approx 2\,\mathrm{kg}$ total, Orthosis incl. $1.4\,\mathrm{Ah}$ 6s Lipo and AK80-9). The actuator is mounted to the orthosis's center of rotation via a specifically designed and custom-built 3D-printed brace, which is available open-source [25]. Since the gear shape of the orthosis mimics the changing center of rotation of a knee joint, the brace employs a linear element to adjust for transitional changes during movement while maintaining easy movability and proper torque transmission.

Eight Trigno® Avanti sEMG sensors from Delsys Inc. were fitted to the participant's anterior and posterior side of the thighs to monitor muscle activity. The placement of EMG

sensors followed the SENIAM guidelines to ensure accurate and consistent signal acquisition. Sensors were positioned on four key muscles of the lower limb: the Rectus Femoris, Vastus Lateralis, Biceps Femoris, and Semitendinosus. The electrodes were aligned with the muscle fibers and placed using anatomical reference points (see Figure 1) with the limitation of occlusion by the orthosis in mind [26], [27].

B. Software-Setup

The EMG signals are sampled at 2148 Hz, amplified, rectified, and low-pass filtered at a cut-off frequency of 1 Hz. The Average Rectified Value (ARV) was down-sampled to 50 Hz and forwarded into a ridge regression algorithm to map resting and maximum voluntary contraction (MVC) of the right leg extensor muscles into a continuous high-level control signal $(0-1)$ (see Figure 2). Further, this is used as $control_{EMG}$, indicating muscle activation levels for the mid-level control.

A custom control policy was implemented to manage the impedance controller based on the EMG prediction. Figure 2 shows the control parameters for the Gaussian stiffness modulation, which aims to define an adaptive stiffness modulation policy for a motorized actuator. The weighted stiffness (k_P) is dynamically adjusted based on the actuator's position and user intent through muscle activation, while the derivative gain k_D was held constant at 0.3. The baseline stiffness $k_{P,0}$ was varied to examine the effect of different stiffness levels on user comfort and the system's range of assistive torque.

1) **Gaussian-Based Stiffness Calculation:** The stiffness profile is modeled using a Gaussian function centered at the midpoint of the motion range (μ), with $x_{inflection}$ shifting the peak stiffness forward or backward. This allows us to tune the point of maximum amplitude in the output function. σ determines the spread of the Gaussian, controlling the rate at which stiffness decreases as the motor position (θ) moves away from μ.

$$\mu = \frac{range}{2} * (1 + x_{inflection}) \tag{1}$$

$$k_P(\theta) = k_{P,0} \exp\left(-\frac{(\theta-\mu)^2}{2\sigma^2}\right) \tag{2}$$

2) **Scaling Factor:** An empirically determined scaling factor modifies the stiffness based on the motor position's relative distance to μ. $control_{slope}$ shapes how stiffness changes as the motor moves away from μ. High values cause sharper stiffness decay (or increase), providing a steeper gradient.

$$k_{P,scale} = k_P(\theta)\left(\frac{\theta}{\mu}\right)^{control_{slope}} \tag{3}$$

3) **EMG-Control Signal Influence:** The overall stiffness is linearly scaled by $control_{EMG}$. This allows the stiffness to reflect the user's muscle activation and intent proportionally.

$$k_{P,final} = k_{P,scaled} \times control_{EMG} \tag{4}$$

4) **Ramping Logic:** The algorithm limits the rate of stiffness change between consecutive calculations to ensure smooth transitions and prevent abrupt changes in stiffness.

$$\Delta k_{P,increase} = k_{P,prev} + increase_{max} \tag{5}$$

$$\Delta k_{P,decrease} = k_{P,prev} - decrease_{max} \tag{6}$$

5) **Boundary Conditions:** Finally, the stiffness values are clamped to non-negative values to maintain system stability and safety of the participants:

$$k_{P,final} = \max(0, k_{P,final}) \tag{7}$$

A Graphical User Interface (GUI) was implemented to allow participants to select between different exercise modes and to guide them through the movements. Two progress bars provide participants with information about when to begin the exercise and the appropriate speed for progressing through the movements, as well as when to take a break. This interface was designed to assist participants, promoting consistent, uniform movement across all exercises and repetitions by visually separating transitions and resting phases.

C. Study Protocol

Four healthy participants, with a 50:50 gender distribution and a mean age of 28.75 ± 3.5 years, participated in the study. Additional information about height ($177 \pm 10.2\,\mathrm{cm}$), weight ($80.2 \pm 19.8\,\mathrm{kg}$), and thigh circumference ($55.5 \pm 3.9\,\mathrm{cm}$) were collected to examine their potential influence on the study results (see Table I).

TABLE I
DEMOGRAPHIC INFORMATION OF PARTICIPANTS

	Age	**Height** (cm)	**Weight** (kg)	**Thigh Circ.** (cm)	**Femur** (m)
A	34.00	190.00	108.00	61.00	0.50
B	27.00	166.00	67.00	55.00	0.50
C	27.00	179.00	81.00	54.00	0.50
D	27.00	173.00	65.00	52.00	0.50

The orthosis is calibrated by fully extending the leg to establish the reference position (Position 0) and resting the leg with a 90-degree angle (Position 1) while seated. For each position, $3.00\,\mathrm{s}$ of EMG signal is acquired to train the Ridge Regression predictor. In the Sit-To-Stand exercise, participants sit on a standard chair with feet flat on the ground and knees at a 90-degree angle. They are instructed to stand up fully, within the timeframe given by the trajectory guidance GUI, maintain the standing position, and then sit back down in a controlled manner. This sequence constitutes one complete repetition. Each participant performs five repetitions. This is repeated with five different conditions, *No Orthosis*, *Orthosis OFF*, and *Orthosis ON* with stiffness gains of 40, 60, and 80 Nm/rad with resting phase after each repetition of the movement. Each phase is set to last 1.3 seconds. The second exercise, forward Step-Up, evaluates the activation isolated to the right leg under increased load. Participants stand next to a $30\,\mathrm{cm}$ elevated platform. They start by resting the right leg on the platform (see Figure 1). Then, they follow the same procedure as in the Sit-To-Stand, while data on muscular activity, position, velocity, and torque are collected. The metrics analyzed included the ARVs and right leg encoder kinematics.

III. RESULTS

A. ARV Analysis of Activities: Sit-to-Stand and Step-Up

Evaluation of the normalized muscle activity across every participant during the full Sit-To-Stand activity, displayed in Table II and Figure 3, suggests a significantly decreased muscle activity from the extensor muscles of the assisted leg (right) when the device is worn and increasing slightly from there with the stiffness gain. Compared to the non-assisted leg (left), the ARVs are reduced slightly ($\approx 10\%$), as well as the variance in the signal, suggesting some degree of compensation. The standard deviation of the right leg increases with the device attached.

TABLE II
SUMMARY OF THE EMG DATA (LEFT/RIGHT). IQR OUTLIER CURATION REMOVED $\approx 9\%$. THE MODE COLUMN LISTS ALL TRAIL CONDITIONS WITH NO ORTHOSIS WORN (-), ORTHOSIS OFF (IDLE), AND THE STIFFNESS GAIN VARIATIONS k_P.

	Left Leg		**Right Leg**	
Mode	**Mean ± Std**	**Median**	**Mean ± Std**	**Median**
-	1.000 ± 0.305	0.934	1.000 ± 0.438	1.158
Idle	0.932 ± 0.182	0.940	0.784 ± 0.621	0.657
$k_{P,40}$	0.899 ± 0.092	0.926	0.842 ± 0.636	0.710
$k_{P,60}$	0.906 ± 0.089	0.926	0.861 ± 0.681	0.750
$k_{P,80}$	0.909 ± 0.087	0.922	0.845 ± 0.640	0.674

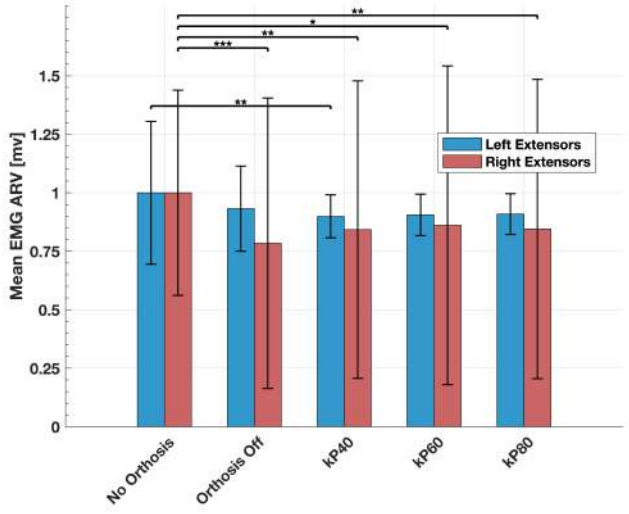

Fig. 3. Average Rectified Muscle Activity (ARV) in the non-assisted leg (left) vs. the assisted leg (right) of the knee extensor muscles during the Sit-To-Stand exercise across all participants. Whiskers indicate the standard deviation. IQR outlier curation removed $\approx 9\%$

B. Inter-Phase Assistance Comparison

The activities are segmented into the transitioning states *Sit-To-Stand* (Up-Phase: P1) and *Stand-To-Sit* (Down-Phase: P2) as illustrated in Figure 4 for the Sit-To-Stand and Step-Up activities, focusing on the most physically demanding phases. The conditions evaluated included *No Orthosis*, *Orthosis OFF*, and *Orthosis ON* with spring stiffness gains of 40, 60, and 80 $k_{P,0}$. Participants C and D had to be excluded due to significant velocity variability during testing that are especially pronounced when isolating the phases. The complete comparison can be retrieved from Table III.

All data consistently failed the Shapiro–Wilk normality test ($p < 0.05$), so nonparametric Kruskal–Wallis tests were

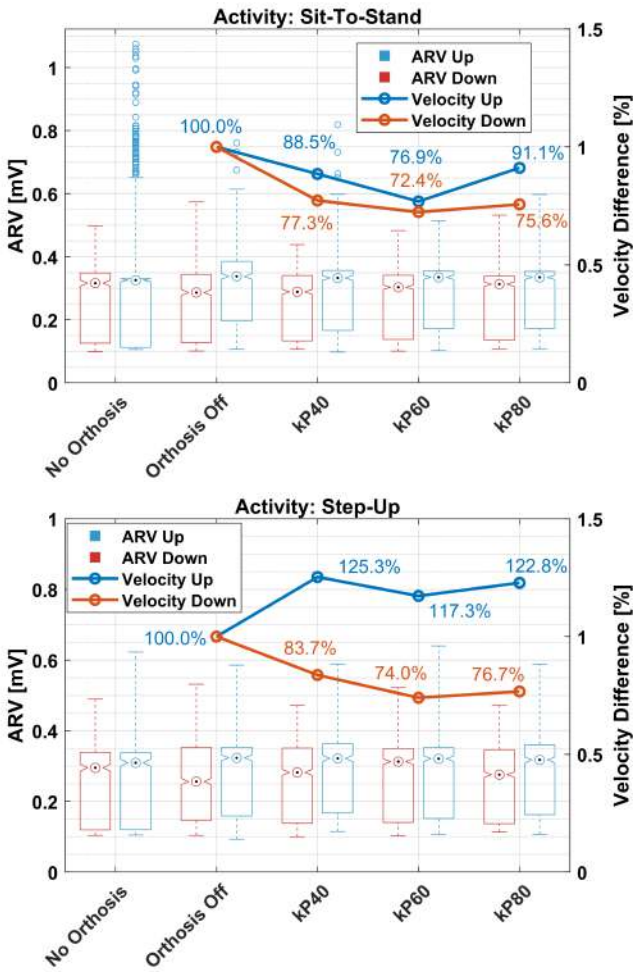

Fig. 4. Assisted leg extensor muscle ARVs of Participant A and B, with no Orthosis, Orthosis Off and Orthosis On conditions comparing the Stand-To-Sit: Down (red) and Sit-To-Stand: Up (blue) phases during Sit-To-Stand (top) and Step-Up (bottom) activities. The solid lines show the normalized mean velocities relative to Orthosis OFF.

employed. Table IV provides sample p-values for Velocity and ARVs, separately for Up-Phase (P1) and Down-Phase (P2), across both Sit-to-Stand and Step-Up activities.

1) Sit-To-Stand Activity: Figure 4 (top) and Table III compare *No Orthosis*, *Orthosis Off*, and various *Orthosis On* conditions (with stiffness gains $k_{P,40}, k_{P,60}, k_{P,80}$) for the Sit-to-Stand activity. From the velocity perspective, introducing orthosis assistance shows a trend of around a 20% decrease in mean velocity (particularly noticeable at $k_{P,60}$) compared to the Orthosis Off idle condition. In the Up-Phase (Stand-To-Sit), these velocity reductions are less consistent overall, but still hover around 9–13%. Simultaneously, ARVs in the Up-Phase tend to be higher under orthosis assistance (by up to 13% in some cases), whereas in the Down-Phase the ARVs remain comparatively lower to the baseline measurement. Statistical tests (Table IV) confirm that most velocity and ARV metrics in the Up-Phase (P1) differ significantly between the reference idle conditions (Orthosis Off) and the higher stiffness gains. Conversely, the Down-Phase (P2) often does not

TABLE III

METRICS FOR SIT-TO-STAND AND STEP-UP ACTIVITIES ACROSS DIFFERENT STIFFNESS GAINS, SEGMENTED BY UP-PHASE P1 (SITTOSTAND / ASCENDING) AND DOWN-PHASE P2 (STANDTOSIT / DESCENDING).

Idle	1.00	1.00	0.338	0.286	1.00	1.00	0.323	0.256
$k_{P,40}$	0.885	0.773	0.333	0.289	1.253	0.837	0.322	0.282
$k_{P,60}$	0.769	0.724	0.335	0.303	1.173	0.740	0.321	0.313
$k_{P,80}$	0.911	0.756	0.335	0.313	1.228	0.767	0.317	0.276

TABLE IV

SIGNIFICANCE ANALYSIS (P-VALUES) FOR SIT-TO-STAND AND STEP-UP ACROSS DIFFERENT STIFFNESS GAINS BY SIT-TO-STAND UP-PHASE (P1) AND STAND-TO-SIT DOWN-PHASE (P2). SHOWN ARE GLOBAL VALUES FOR VELOCITY AND ARV.

	Sit-to-Stand				Step-Up			
	Velocity		ARV		Velocity		ARV	
Mode	**P1**	**P2**	**P1**	**P2**	**P1**	**P2**	**P1**	**P2**
k_{P40}	0.0053	0.0029	$< 10^{-10}$	0.11	0.656	0.025	$< 10^{-6}$	$< 10^{-6}$
k_{P60}	0.0120	0.0042	$< 10^{-8}$	0.10	0.6556	0.0696	0.0005	0.0000
k_{P80}	0.05	0.01	$< 10^{-5}$	0.12	1.000	0.40	0.0000	0.0000

reach significance in ARVs, implying that the leg-muscle activation during the descent is less affected by these stiffness variations.

2) Step-Up Activity: Figure 4 (bottom) and Table III illustrate the Step-Up movement under the same orthosis conditions. Here, ARV medians across the Up-Phases remain close, yet higher than the baseline with no orthosis, with only subtle differences among the stiffness gains. In contrast, the Down-Phase shows overall lower ARVs during assistance. While the ARVs do generally increase somewhat under assistance, pairwise statistical tests still show significant contrasts between the references and certain stiffness levels. For velocity, the Up-Phase increases under orthosis assistance (by up to 25%), whereas the Down-Phase velocity decreases by up to 26%. According to Table IV, these Down-Phase velocity changes are often significant, while the Up-Phase velocity differences do not consistently reach significance. Thus, the orthosis stiffness exerts a more evident effect on the descending movement than on the ascent during the Step-Up task.

IV. DISCUSSION

A. Assessment of Data Quality

Initial observations indicate that the motorized knee orthosis effectively reduces muscle activity (see Figure 3); nevertheless, a closer inspection of the ARV distributions

(see Figure 4) suggests that, in certain conditions, the device may interfere with normal muscle activation, paradoxically increasing overall ARV. Several factors likely contribute to this outcome. First, the adhesive-based Trigno® Avanti EMG sensors frequently detached when the skin was stretched near rigid orthosis contact points, necessitating repeated trials. Second, unintended device contact introduced noise, especially if the orthosis slipped on participants with smaller leg circumferences (see Table I). These challenges underscore the inherent limitations of EMG in mechanically demanding setups rather than an issue specific to our study. Future real-world applications should explore gel electrodes, alternative sensor placements, or complementary sensing technologies to mitigate these artifacts.

B. Assessment of the Study Design

Beyond data quality, the overall study design was largely exploratory, aiming to dynamically adjust joint stiffness for high-demand tasks without rigid state machines. This approach inherently involves a learning component, as users may gain finer control with repeated exposure. Nevertheless, EMG signals are still prone to noise, especially under external pressure, suggesting that multi-pronged control strategies could yield more robust performance in future studies. To isolate user adaptation effects, it may be worthwhile to hold assistance levels constant across trials or gradually increase them over weeks based on each participant's MVC. Moreover, participant weight differences highlight the importance of hardware sizing: heavier users require stronger actuation, whereas lighter individuals could be overburdened by excessive hardware bulk. Finally, although Sit-to-Stand is already a strenuous task, Step-Up may be too challenging for clinical populations. Future experiments might prioritize more straightforward activities like walking and shifting the focus to gait parameters rather than EMG reduction alone.

C. Efficiency of Motorized Assistance

The motor hardware provides up to $18\,\mathrm{Nm}$ of sustained, controller-enforced torque, which translates into roughly 37% offloading for an average-weight participant (assuming $0.6\,\mathrm{Nm/kg}$ for Sit-To-Stand. Although this is a noticeable contribution, it remains relatively modest for high-demand movements. The device's $1.57\,\mathrm{rad}$ range of motion means that the chosen stiffness gains ($k_{P,0} = 40, 60, 80$) primarily shape the slope of assistance rather than pushing the upper torque limit. As such, the orthosis offers measurable torque augmentation but does not fully compensate for the user's total effort during Sit-to-Stand. These parameters reflect a design philosophy favoring simplicity, low cost, and minimal weight. Future designs requiring more substantial support for heavier or more impaired users may need significantly higher torque capacity, potentially at the cost of increased mass or complexity. In its current iteration, the system is thus best suited for torque augmentation rather than complete torque compensation.

D. Stable vs. Unstable Activities

Building on our ARV findings, we compared Sit-to-Stand and Step-Up tasks to see how activity stability affects motion execution. For healthy participants, Sit-to-Stand generally offers bilateral support and load-sharing, making it relatively stable, whereas Step-Up is inherently more unstable due to unilateral load and higher balancing demands. Additionally, the Up-Phase of each activity relies heavily on knee and hip extensors to overcome gravity, while the Down-Phase requires deliberate braking to ensure accuracy and prevent abrupt descent.

In the stable Sit-to-Stand, participants did not appear to leverage the orthosis's additional power effectively, only showing significant ARV reduction during descent (see Table IV). Overall, the movement velocity was reduced significantly in both phases, contributing to the picture of slow and controlled movement. By contrast, the unstable Step-Up saw a clearer response to the device: the extra power in the Up-Phase led to higher velocities, whereas the Down-Phase velocity was significantly slowed or dampened. This suggests that impedance modulation may offer the greatest benefits in tasks where dynamic adjustments are crucial, and a strategy combining higher stiffness during ascent with additional damping during descent could be promising.

It is worth noting that all participants here were able-bodied and performed the movements with relative ease. Individuals with mobility impairments may not exhibit the same adaptive strategies or might struggle to complete a Step-Up at all, underscoring the need to tailor tasks and parameters for clinical populations.

Moreover, our velocity metrics in the Step-Up activity showed lower statistical significance than accomplished by the ARV measure (see Table IV), indicating that orthosis stiffness had a limited effect on gross movement speed. The dominant influences of gravity and high load appear to overshadow any velocity changes the orthosis can augment. While the device effectively modulates the force response for stability and control, its ability to substantially alter velocity remains constrained in unilateral, high-demand scenarios.

E. Implications for Rehabilitation Robotics

The results from both stable and unstable tasks demonstrate the motorized knee orthosis's potential to reduce muscular effort, especially in activities that demand precise, real-time control. However, differences in users' muscle strength, body weight, and movement strategies underscore the importance of tailored parameter tuning to maintain both efficiency and comfort. By carefully calibrating stiffness and damping thresholds in response to each individual's biomechanics, the system can better accommodate the unique demands of different bodies and tasks.

Looking ahead, efforts should focus on refining adaptive assistance that updates in real-time based on EMG or kinematic signals, thereby minimizing variability and aligning torque output with the requirements of specific movement phases. Designing control architectures that learn from changing user inputs over longer periods can also refine

stiffness modulation, promising more effective support in rehabilitation programs. At the same time, it will be critical to widen the participant pool, especially to older adults or individuals with severe motor impairments, to confirm the suitability of these technologies in broader clinical contexts. As sensor attachment and device stability remain central challenges, future prototypes must incorporate improved electrodes or supplementary sensing modalities to ensure that movement artifacts do not undermine performance or comfort in day-to-day tasks. By integrating these improvements, next-generation knee orthosis systems could offer robust, user-specific assistance and help a wider range of patients perform challenging tasks with greater safety and independence.

V. Conclusion

Our pilot results suggest that EMG-driven impedance control can reduce muscle effort and enhance movement efficiency, especially under high-load conditions. However, further testing and improved hardware are necessary to validate these benefits for a wider population.

A Passive Mechanical Add-on for Treadmill Exercise (P-MATE) in Stroke Rehabilitation

Irene L. Y. Beck[1, 2,*], Belle C. Hopmans[1, 3], Bram Haanen[1], Levi Kieft[1], Heike Vallery[2, 3, 4], Laura Marchal-Crespo[1, 2], and Katherine L. Poggensee[1, 2, 3]

***Abstract*— Robotic rehabilitation can deliver high-dose gait therapy and improve motor function after a stroke. However, for many devices, high costs and lengthy setup times limit clinical adoption. Thus, we designed, built, and evaluated the Passive Mechanical Add-on for Treadmill Exercise (P-MATE), a low-cost passive end-effector add-on for treadmills that couples the movement of the paretic and non-paretic legs via a reciprocating system of elastic cables and pulleys. Two human-device mechanical interfaces were designed to attach the elastic cables to the user. The P-MATE and two interface prototypes were tested with a physical therapist and eight unimpaired participants. Biomechanical data, including kinematics and interaction forces, were collected alongside standardized questionnaires to assess usability and user experience. Both interfaces were quick and easy to attach, though user experience differed, highlighting the need for personalization. We also identified areas for future improvement, including pretension adjustments, tendon derailing prevention, and understanding long-term impacts on user gait. Our preliminary findings underline the potential of the P-MATE to provide effective, accessible, and sustainable stroke gait rehabilitation.**

I. Introduction

Stroke is one of the leading causes of disability worldwide, affecting twelve million people annually [1]. Up to 75 % of people who have had a stroke are left with lower-limb somatosensory and motor impairments three months post-stroke [2]. Individuals with more severe impairments experience a greater negative impact on their quality of life and participation in everyday activities [2].

High-dose physical therapy can enhance motor recovery following a stroke [3]. However, individuals often receive less therapy than recommended due to, among other factors, a shortage of trained personnel [4]. Conventional gait interventions—where therapists physically assist or resist an individual's limb movements—often require more than one therapist per patient [2]. Work-related injuries can result from the physical demands placed on therapists [5]. These shortcomings in current lower-limb rehabilitation practices are expected to worsen with an aging population and global physician shortage [6].

This work was supported by the Health and Technology Convergence Alliance of TU Delft, Erasmus MC, and Erasmus University Rotterdam and the H2020-MSCA-RISE project CoSP- GA No 101106071 and Hocoma provided the Lokomat.

The two prototypes of the interface are highlighted in **B**: the cuff around the shank and **C**: the bandage around the foot.

Robotic rehabilitation provides a promising solution to these challenges by delivering high-intensity therapy while reducing physical demands on therapists. Several robotic devices have already been developed to support gait rehabilitation, offering controlled, high-intensity training as a way to lower therapists' workload while objectively tracking patient progress [7], [8]. However, factors such as set-up time and cost hinder the introduction and adoption of robotics into the clinic, calling for more affordable and simpler devices [5]. Despite advances in the design of lightweight exoskeletons [9], these current robotic solutions can limit the active participation of patients, which is crucial to enhance neurorehabilitation [7], [10].

Tendon-based devices also show promise in providing effective resistance and assistance for gait rehabilitation [5], [11], [12], although how to best route the cables without impeding the unimpaired leg's range of motion is still an open question. One option is to attach a single tendon to the

impaired leg, which tensions a spring in a controlled way during the stance phase of the impaired leg and subsequently releases the stored energy during swing [13]. However, the mechanism still requires an active brake, electronics, and control to compensate for the movement of the impaired leg during stance and to avoid tensioning of the spring during the entire stance phase.

We aimed to address the aforementioned challenges by designing and evaluating a purely mechanical solution that exploits the reciprocating movement of both legs to assist in the gait rehabilitation of the paretic leg. This is done by attaching both legs to elastic tendons, guided by a set of pulleys optimally located around a treadmill to leverage the movement of the non-paretic leg and the treadmill. This low-cost system could be implemented on existing treadmills, does not require any actuators or control, and allows for the individual's active participation.

II. Design

A. System Overview

We developed the Passive Mechanical Add-on for Treadmill Exercise (P-MATE) for use in stroke gait rehabilitation. The P-MATE was designed to provide support during treadmill walking, particularly for individuals with hemiparesis, a condition that affects gait symmetry by impairing one side of the body. The add-on combines four elastic tendons attached to both legs and guided by pulleys. The pulleys are optimally located around a treadmill to assist the paretic leg as needed during the swing phase while the non-paretic leg is moved backward by the treadmill during stance, but without impeding physiological leg motion. A schematic overview of the P-MATE's working principle is presented in Fig. 1A.

Two human-device interfaces were designed to attach the elastic tendons to different points on the user: one at the shank (*cuff prototype*) and the other at the foot (*bandage prototype*), see Figs. 1B and 1C, respectively. The entire system was designed and evaluated via two datasets, both of which were approved by the Human Research Ethics Committee of TU Delft, and all participants provided written informed consent prior to the start of the study.

B. Pulley Location Optimization

The goal of the P-MATE was to assist the paretic foot's movement in the three translational degrees of freedom, with coordinate directions forward (x), lateral (y), and upward (z) (Fig. 2). Therefore, at least four elastic tendons are required due to the underconstrained behavior of tendons (i.e., only pulling) [14]. Furthermore, to promote gait symmetry, the pulley and tendon arrangement is symmetrical across the sagittal plane.

The P-MATE was designed to avoid interfering with unimpaired gait, i.e., in the case of natural walking, no resistive nor assistive forces should be transmitted to the participant. To achieve this, a simulation-based optimization was run to determine the optimal pulley locations that minimize the "parasitic" forces, i.e., any forces (in all directions) acting on the legs during "normal gait" for six participants. The optimization used a cost function that minimized the sum of the root mean square of each of the Cartesian forces (in x-, y- and z-directions) acting on the left and right legs over time. At each frame (collected at $100\,\mathrm{Hz}$), the Cartesian forces were derived from the "parasitic" tendon forces, which were computed using a Jacobian based on the location of the legs and the pulleys.

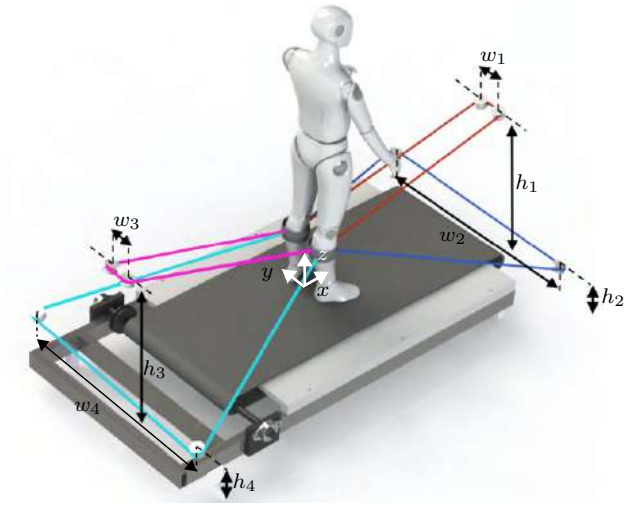

Fig. 2: The optimization setup with the eight parameters to determine optimal pulley location.

These "parasitic" tendon forces originate from the elongation of the elastic tendons during unimpaired walking. Based on preliminary research of commercially-available elastic ropes, we chose to set all tendons to the same stiffness of $300\,\mathrm{N/m}$. The slack length, or the length at zero-force, of each tendon was chosen as the shortest tendon length observed per participant.

The optimization parameters describe the locations of eight pulleys around the treadmill, two pulleys per each of the four tendons, while a simulated human was placed in the center of the treadmill. The pulley locations were assumed constant in the x-direction at $0.75\,\mathrm{m}$ in front of and behind the individual, based on conventional treadmill length. Additionally, the location of each pair of pulleys was assumed to be the same height. These assumptions reduce the optimization parameters to only the distances between the pulleys per pair in y-direction (w_j) and their heights (h_j) (see Fig. 2), resulting in four widths and four heights. The search space of the parameters was constrained to $w_{1,3} \in [0, 0.1]$, $w_{2,4} \in [0.4, 0.8]$, $h_{1,3} \in [0.5, 1.0]$, and $h_{2,4} \in [0.1, 0.3]\,\mathrm{m}$. Initial conditions were set to the average of each constraint bound. The optimization of the pulleys was executed for lower-body optical motion capture data collected from six unimpaired young adults walking on a treadmill at $1.0\,\mathrm{m/s}$ (see Table I). We used the genetic algorithm function (`ga`) from the Optimization Toolbox in MATLAB (R2023b, Mathworks, USA). The optimization stopped after 100 generations or when the average relative change in the cost function was smaller than $1 \times 10^{\circledast 6}\,\mathrm{N}$.

F	M	30	1.81	71.0

TABLE II: The optimal pulley locations for each participant from the simulation-based optimization and the final implemented values (Imp) in the mechanical design. All measurements are in meters.

ID	w_1	h_1	w_2	h_2	w_3	h_3	w_4	h_4
A	0.00	0.50	0.40	0.10	0.00	0.74	0.56	0.10
B	0.00	0.50	0.40	0.10	0.00	0.76	0.40	0.10
C	0.00	0.57	0.80	0.10	0.00	0.69	0.80	0.10
D	0.00	0.50	0.74	0.10	0.00	0.62	0.40	0.10
E	0.00	0.56	0.40	0.10	0.00	0.78	0.80	0.10
F	0.00	0.56	0.40	0.10	0.00	0.79	0.55	0.10
Imp	0.00	0.50	0.80	0.13	0.00	0.50	0.80	0.13

The main contributors to the cost function were the forces in x-direction, with median anterior and posterior forces of $28.4\,\mathrm{N}$ and $34.0\,\mathrm{N}$, respectively. The optimal pulley location parameters per participant are shown in Table II. The optimal solution for both w_1 and w_3, i.e., the width between the two sets of upper pulleys, was $0.00\,\mathrm{m}$ for all participants, reducing the overall system from eight to six pulleys.

C. Mechanical Design

1) Frame: A frame was built to fit around a modified Lokomat (Hocoma AG, Switzerland) treadmill to realize the P-MATE based on the optimization results. The frame consists of extruded aluminum Profile 8 40x40 profiles (item, Germany) of various lengths anchored to the treadmill frame. The total dimensions of the P-MATE were $1.8\,\mathrm{m}$ long by $1.0\,\mathrm{m}$ wide by $1.2\,\mathrm{m}$ high.

2) Pulleys: Based on the optimal solutions found in the simulation, six pulleys were used (diameter $50\,\mathrm{mm}$, groove $6\,\mathrm{mm}$) (105140, Waelbers, Netherlands). Three pulleys were attached to the front part of the frame, and three pulleys to the back, with one higher pulley in the middle and with two pulleys just above treadmill height on either side of the participant. The implemented pulley locations (Imp in Table II) were kept as close to the optimal solution, subject to the setup constraints. This included a slight increase in the height of the lower lateral pulleys and lowering of the upper back pulley, while the x-position of all pulleys was increased to $\pm 0.9\,\mathrm{m}$. The final layout of the pulleys was symmetrical in the sagittal and coronal planes.

3) Elastic tendons: The elastic tendons are commercially available with a diameter of $8\,\mathrm{mm}$ (5411387036028, Ledent, Corbeo NV, Belgium), chosen in an effort to match the assumptions from the simulation. Four stainless steel carabiners (432712, Seilflechter, Germany) connected the elastic tendons to the human-device interface. The slack length of the elastic tendons can be adjusted via a rope tightener for each elastic tendon (CAMJAM™ XT™, Nite Ize, USA).

4) Safety harness: The harness of the Lokomat's body weight support (BWS) system was used to ensure safety against falls with enough slack to allow for free movement. However, any safety harness or BWS system could be used in combination with the P-MATE.

5) Human-device interface: The P-MATE requires a human-device interface to effectively transfer the elastic tendons' forces to the user while promoting comfort, ease of use, and adjustability. To identify user requirements for the interface, observations of training sessions and interviews with a neurorehabilitation physical therapist ($27\,\mathrm{years}$ experience) were conducted at a stroke rehabilitation center (Rijndam Revalidatie, the Netherlands). These activities indicated a need for a quick and easy setup for rehabilitation devices to maximize the therapy time. This included not only a maximum of five minutes for the donning and doffing of the system on the patient but also reduced complexity compared to existing robotic exoskeletons. Additionally, the system should accommodate patients typically seen in the clinic, ranging in demographics and severity of disease. We therefore designed two prototypes, namely a *cuff* and a *bandage* design. The cuff prototype encloses the shank via an aluminum C-shaped profile around the back of the shank and a rectangular aluminum plate at the front (Fig. 1B). The aluminum is covered by a layer of cold foam padding with an exterior layer of synthetic leather to allow for a comfortable but close-fitting attachment to the participant's leg. The bandage prototype (see Fig. 1C) consists of two straps, one around the ankle and one in a figure-eight pattern wrapping around the sole of the foot. To mitigate shearing between the strap and the ankle, cold foam padding covered in synthetic leather was added.

The amount of Velcro used to secure both prototypes to the participant was chosen to withstand the worst-case scenario, i.e., where the participant was at the limits of the treadmill and the pulling forces were the highest. To facilitate donning and doffing, stainless steel buckles at the front and back of the interfaces secured the elastic tendons using carabiners.

III. Experiment

A. Experimental Protocol

We conducted a feasibility study with eight adults without physical impairments (see Table III) to evaluate the P-MATE and the two interface prototypes. Each participant received a demonstration from the experimenter on how to don and doff the two prototypes while sitting comfortably in a chair. They were then invited to walk on the treadmill and select their comfortable walking speed and pretension. They were then asked to walk at their selected speed for five minutes while wearing the safety harness but without any prototype (baseline). Following the five-minute baseline, participants took a minimum five-minute rest while seated, during which

the experimenter attached one of the prototypes to the participant.

Participants then walked for $20\,\mathrm{minutes}$ at their chosen speed with each prototype, in a randomized order. After each session, participants completed three questionnaires to evaluate the prototype's design while resting for at least five minutes. During this break, the experimenter doffed the first prototype and donned the second, timing each transition.

After both walking sessions, participants practiced donning and doffing each prototype independently. The experimenter timed these actions, and participants completed the final section of the questionnaires.

The neurorehabilitation physical therapist, who helped identify user requirements, also participated in a shortened experimental protocol. Baseline walking measurements were taken for one minute, followed by ten-minute walking sessions with each prototype. At the therapist's request, a second ten-minute session with the bandage prototype was conducted with lengthened anterior elastic tendons.

B. Outcome Metrics

During the baseline and the two walking sessions, biomechanical data regarding the right leg were collected. In particular, forces at the front and back of the leg were recorded with two load sensors (KD40S 1000N, ME-Meßsysteme, Germany). One load sensor was positioned between the two anterior tendons and the human-device interface on the front of the right leg, and the other between the two posterior elastic tendons and the same interface on the right leg.

To evaluate whether the P-MATE changed the participants' gait, a depth camera (ZED mini Stereo Camera, StereoLabs, USA) with the onboard software detecting anatomical landmarks was used to capture the kinematics of the right leg in the sagittal plane. Step length and step height were extracted from this kinematic data and averaged over the trial. The force and kinematic data were synchronized offline. Additionally, the first and last minute of the sessions were disregarded as warm-up and cool-down periods, so early and late periods were defined as minute 2 and 19, respectively.

To evaluate setup time, the experimenter timed every donning and doffing action, either performed by the experimenter themselves or the participant. Data on participants' user experience and acceptance of the prototypes, and system usability were collected using three questionnaires: the Van Der Laan Acceptance Questionnaire [15] (AQ), the System Usability Scale (SUS) [16], and a modified version of the User Experience Questionnaire (UEQ) [17], respectively. The questions in the UEQ were modified to target the experience with the P-MATE. The AQ and UEQ were answered on a Likert scale from -2 to +2, with -2 indicating a negative response (e.g., "useless") and +2 a positive response (e.g., "useful"). The SUS was answered on a Likert scale from 1 to 5: 1 indicating "Strongly disagree" and 5 "Strongly agree," resulting in an overall score between 0 and 100. Each questionnaire was filled out for both interface prototypes. The experimenter also wrote down any comments made by the participants during the study.

TABLE III: Demographic data of experiment participants and their chosen treadmill walking speed. T: Therapist

ID	**Sex**	**Age/**yr	**Height/**m	**Mass/**kg	**Speed/**$\mathrm{km/h}$
1	F	63	1.60	79	3.0
2	F	23	1.65	70	3.0
3	M	26	1.85	72	2.5
4	M	61	1.73	79	3.5
5	M	22	1.86	94	3.5
6	M	24	1.91	86	3.5
7	F	24	1.67	70	3.0
8	F	60	1.63	71	2.5
T	M	49	1.81	73	3.0

C. Experimental Results

For both prototypes, the highest anterior tendon forces occurred at toe off (determined as the instance the foot was farthest back), while the highest posterior tendon forces were recorded near heel strike (conversely the instance the foot was farthest forward). In the cuff prototype, the highest average peak anterior and posterior forces across all participants were $118\,\mathrm{N}$ and $110\,\mathrm{N}$, respectively. For the bandage prototype, these forces reached $141\,\mathrm{N}$ and $114\,\mathrm{N}$, respectively.

All participants showed larger differences between the maximum and minimum forces with the bandage prototype compared to the cuff prototype. Over time, comparing early and late in the session, the cuff prototype visually appeared to exert consistent forces at the front and back of the leg, whereas the forces from the bandage prototype started higher and tended to decrease as time passed.

Preliminary kinematic analysis indicated a reduced step length for both prototypes: the median of the average was $0.58\,\mathrm{m}$ at baseline, compared to $0.53\,\mathrm{m}$ with the cuff and $0.53\,\mathrm{m}$ with the bandage. Step height also changed with the system: the median of the average at baseline was $0.16\,\mathrm{m}$, compared to the cuff at $0.15\,\mathrm{m}$ and the bandage at $0.10\,\mathrm{m}$.

Donning and doffing for both prototypes took under five minutes. Experimenter donning times improved with practice: cuff prototype times decreased from $135\,\mathrm{s}$ to $74\,\mathrm{s}$, and bandage times from $235\,\mathrm{s}$ to $127\,\mathrm{s}$ (Fig. 3A). Doffing times remained consistent between $30\,\mathrm{s}$ to $40\,\mathrm{s}$. Participants averaged $87\,\mathrm{s}$ to don the cuff and $217\,\mathrm{s}$ for the bandage (Fig. 3B), with doffing averaging $30\,\mathrm{s}$ for the cuff and $41\,\mathrm{s}$ for the bandage (Fig. 3C).

The questionnaire results are presented in Fig. 4. Both prototypes received generally positive feedback on user experience (UEQ), with median scores of 0.8 for the cuff and 0.6 for the bandage prototype, indicating a more favorable user experience with the cuff. Based on the responses on usability (SUS), the cuff prototype was rated as highly usable, scoring 85 out of 100, while the bandage prototype scored lower at 62.5 out of 100. Similar to the other questionnaires, both prototypes generally received positive ratings on both usefulness and satisfaction ($\mathrm{AQ_U}$ and

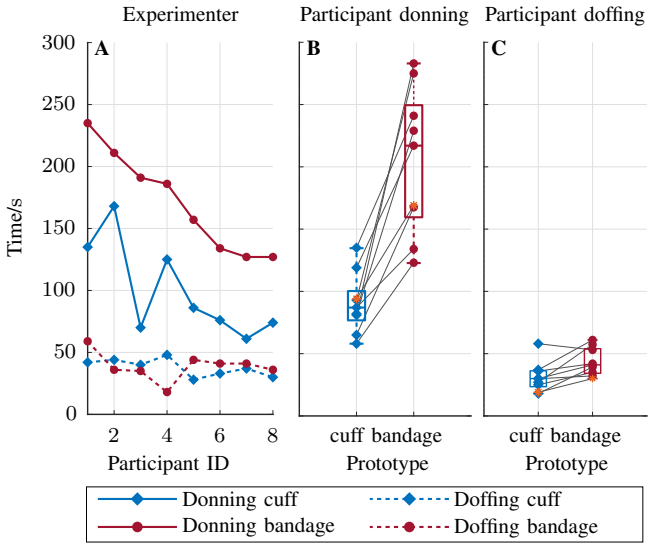

Fig. 3: Donning and doffing time of both prototypes. **A**: Donning (solid) and doffing (dashed) by the experimenter over time for the cuff (blue diamond) and bandage (red circle) prototype. Donning (**B**) and doffing (**C**) of the two prototypes by the participants and therapist (orange star) are also shown.

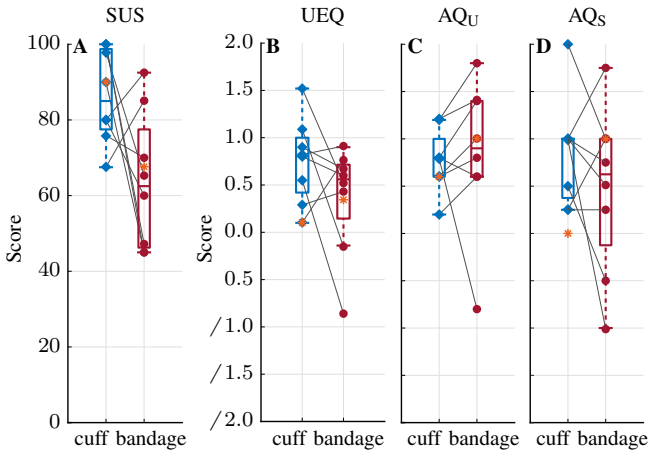

Fig. 4: Questionnaire results for the cuff (blue diamond) and bandage (red circle) prototypes and therapist (orange star). The System Usability Scale (SUS) (**A**) is ranked on a scale from 0 to 100, and the User Experience Questionnaire (UEQ) (**B**), Acceptance Questionnaire on Usability (AQ_U) (**C**) and Satisfaction (AQ_S) (**D**) on a scale from -2 to 2.

AQ_S), with the cuff prototype rated more highly than the bandage prototype. In the study, one participant lost balance within the first minute of using the bandage prototype. Analysis of the kinematics indicated that the participant was taking longer steps just before the loss of balance, generating a strong forward pulling force from the elastic tendons (235.6 N), causing instability in the subsequent step. Following this incident, the study was temporarily paused, and the participant restarted with an elongated anterior tendon and a reduced treadmill speed. No further incidents occurred for the remainder of the study.

While the therapist liked the bandage prototype more than the cuff, both were preferred over a rigid exoskeleton due to their greater freedom of movement and more natural gait. Walking in both prototypes became "easier with practice," though he "needed to adjust the gait timing" with the cuff prototype to align with the P-MATE. He also recommended moving the front attachment of the bandage prototype closer to the toes, noting that the lengthened elastic tendon provided "more guidance than control" over foot placement.

IV. Discussion

In this study, we designed, built, and evaluated two prototypes of the Passive Mechanical Add-on for Treadmill Exercise (P-MATE). This system could assist stroke patients during their gait rehabilitation by leveraging the non-paretic leg to facilitate the swing phase of the paretic leg using an elastic tendon-and-pulley system. The system was optimized in simulation to minimize parasitic forces acting on the user during natural treadmill walking.

The optimization aimed to determine the optimal pulley locations. However, due to setup constraints, the final configuration deviated from these results. Furthermore, we decided to focus the optimization on the pulley locations for assistive rehabilitation rather than exploring configurations for resistive treatment. We also chose a single, constant-stiffness tendon pretension for the optimization, but relaxing these constraints may allow for more targeted, personalized rehabilitation.

Results from a feasibility study with eight adults without physical impairments and one physical therapist indicate differences in user experience between the two human-device interfaces. Higher anterior pulling forces were measured with the bandage prototype compared to the cuff interface. This aligns with the therapist's observation of "feeling more guided" using the cuff and a "more controlling" perception when wearing the bandage prototype.

Some design elements of the current setup could be improved further. A general solution for the location of the pulleys was applied for all participants. However, variations in user experience, pretension, and walking speed preferences suggest that incorporating user-specific configurations could improve the experience of using the P-MATE for gait rehabilitation. Additionally, the pulleys have a fixed orientation, which prevents dynamic adjustments of the guiding of elastic tendons throughout the gait cycle. This limitation may cause friction and wear on the tendons, potentially affecting both their durability and the user's kinematics.

The initial pretension differed per participant, influencing the interaction forces of the P-MATE. In the case of the participant who lost their balance and the therapist, the anterior tendons were lengthened to reduce the pretension. Both the participant and therapist reported feeling in more control with the longer tendons compared to the original

tendon length, possibly as a result of the reduced forces from the device. All participants claimed that walking became easier with practice, particularly when using the bandage prototype, in line with the observed reduction in the interaction forces. A future system should allow for rapid customization of the pulley locations and pretension of the elastic tendons to maximize the clinical impact of the system.

While the depth camera allowed for a quick and cheap data collection, we likely need to optimize the setup and use different sensors to collect more meaningful data. First, the current experimental setup only collected kinematic data from the right leg, limiting insights into the full impact of the P-MATE prototypes on the overall gait pattern. There are indications that participants adapted to the system, as illustrated by changes in interaction forces throughout the trial and between prototypes. However, the specific mechanisms of this adaptation cannot be determined from this setup, particularly because the camera did not consistently and reliably track the ankle position. It is also important to note the two load cells used in this study measured the combined forces from the two anterior and two posterior elastic tendons, respectively, making it impossible to distinguish the individual pulling force contributions from each tendon acting on the leg. Participant feedback also suggested biomechanical changes that could not be validated by our dataset, including perceiving changes in balance and energy expenditure, so relevant sensors should be added to the future protocols.

Further research is needed to better understand the P-MATE's impact on the gait of people who have had a stroke. Insights from these experiments would help assess whether P-MATE promotes healthy muscle engagement, which is essential for motor learning and rehabilitation while ensuring active participation from users. Additionally, the long-term effects of the P-MATE on both the quantity of training and quality of movement should be considered to ensure that the P-MATE does not lead to negative outcomes, such as over-reliance on the device or compensatory movement patterns that could hinder recovery.

V. Conclusion

We presented the design and evaluation of a passive mechanical treadmill add-on, the P-MATE, for gait rehabilitation following a stroke. The system employs elastic tendons, pulleys, and treadmill actuation to create a dynamic connection between legs, in order to leverage the movement of the non-paretic leg to assist the paretic limb. The P-MATE was evaluated on kinematics and forces alongside unimpaired participants' feedback on the system acceptance, usability, and user experience.

Although differences were observed between normal treadmill walking kinematics and walking with both P-MATE human-device interfaces, participants responded positively regarding the usability and overall experience with the device, showing promise toward accessible gait therapy. However, several design aspects require refinement, including addressing pulley derailing, optimizing tendon pretension, and conducting a more detailed kinematic analysis. Future work will also focus on further improving usability and clinical impact.

Ground Perturbation Detection via Lower-Limb Kinematic States During Locomotion

Maria T. Tagliaferri[1], Leonardo Campeggi[1], Owen N. Beck[2], and Inseung Kang[1]

***Abstract*— Falls during daily ambulation activities are a leading cause of injury in older adults due to delayed physiological responses to disturbances of balance. Lower-limb exoskeletons have the potential to mitigate fall incidents by detecting and reacting to perturbations before the user. Although commonly used, the standard metric for perturbation detection, whole-body angular momentum, is poorly suited for exoskeleton applications due to computational delays and additional tunings. To address this, we developed a novel ground perturbation detector using lower-limb kinematic states during locomotion. To identify perturbations, we tracked deviations in the kinematic states from their nominal steady-state trajectories. Using a data-driven approach, we optimized our detector with an open-source ground perturbation biomechanics dataset. A nine-subject cross-validation demonstrated that our model distinguished perturbed from unperturbed gait cycles with 95.5% accuracy and only a delay of 33.1% within the gait cycle, outperforming the benchmark by 49.4% in detection accuracy. The results of our study offer exciting promise for our detector and its potential utility to enhance the controllability of robotic assistive exoskeletons.**

***Index Terms*— Ground Perturbation Detection, Lower-Limb Kinematics, Locomotion, Gait Stability**

I. Introduction

Dynamic postural control during locomotion is regulated by anticipatory and reactive neuromuscular mechanisms that work to maintain stability [1]. During daily ambulation tasks, these physiological systems handle occasional perturbations (i.e., sudden changes in walking stability) caused by factors such as unexpected changes in environmental contexts [2], [3]. Maintaining stability in response to disturbances requires the rapid integration of sensory inputs and motor outputs to execute gait pattern adjustments, reducing the risk of falling [4], [5]. Fall prevention strategies for older adults must compensate for delayed reaction times by detecting disturbances and initiating gait stabilization adjustments faster than the physiological response [6], [7]. Lower-limb exoskeletons designed for balance correction offer a promising solution to achieve this type of fall prevention [8]–[10]. However, progress is limited by the lack of consensus on a standard metric for detecting ground perturbations during locomotion [11], [12].

A simple approach to detect walking perturbations is to identify when the person's body center of mass (COM) moves outside the area bounded by both feet [12], [13]. However, this detection mechanism is unsuitable for exoskeleton control due to the challenge in defining consistent boundaries throughout the gait cycle (e.g., single vs. double stance) during locomotion [14]. Whole-body angular momentum (WBAM) is commonly proposed as an alternative metric to detect perturbations during walking [15]. WBAM represents the combined rotational momentum of all body segments around the person's COM. Humans tightly regulate WBAM during steady-state walking; therefore, perturbations can be identified by observing a sudden increase in WBAM [16], [17].

While this metric is effective for perturbation detection in retrospective gait analyses, it is not well suited for real-time control of exoskeletons [15]. Calculating WBAM involves complex kinematic analyses to determine the momentum of each limb segment in the sagittal and frontal planes. This requires substantial time and computational resources, leading to delays when monitoring the instantaneous value of WBAM [17]. Another drawback is that steady-state WBAM varies significantly between walking conditions (e.g., incline walking) and subjects. Therefore, WBAM must be normalized by each subject's walking speed, body mass, and body height to maintain its accuracy [18]. Thus, in the context of perturbation detection for assistive exoskeletons, a large amount of additional gait data may be required to calibrate a WBAM perturbation threshold across subjects and walking speeds [19].

Direct tracking of lower-limb kinematic states can be a promising solution to ground perturbation detection for exoskeleton control [1]. The key anatomical points involved in walking balance, such as the foot and COM, exhibit predictable patterns during stable locomotion. Deviations in the position and velocity of these points, relative to their steady-state trajectories, serve as clear indicators of disturbances during locomotion. These deviations can be quantified with minimal time and computation using data from motion capture systems or wearable sensing [20].

In this paper, we propose a novel ground perturbation detector during level-ground walking. Our model tracks 16 lower-limb kinematic states in a local coordinate system and quantifies the variation of each state from its value during steady-state walking. For our detector, we use a single threshold value to identify the perturbation onset timing across subjects and perturbation types. We evaluated our model's detection performance in 64 unique ground perturbations. We hypothesize that a ground perturbation detector using lower-limb kinematic states will outperform a WBAM-based model by achieving faster and more accurate detection. Our underlying rationale is that the kinematic states are highly

[1]M. T. Tagliaferri, L. Campeggi, and I. Kang are with the Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, 15213 USA (e-mail: mtagliaf@cmu.edu).

[2]O. N. Beck is with the Department of Kinesiology and Health Education, The University of Texas at Austin, Austin, TX, 78712 USA.

sensitive to gait disturbances, allowing efficient and accurate tracking in real-time with minimal computation [21], [22]. The development of an improved walking perturbation detector will directly support advancements in balance-assistive exoskeletons and potentially reduce the risk of falls in aging adults.

II. Methods

A. Open-Source Gait Perturbation Dataset

We utilized an open-source gait biomechanics dataset to investigate how individuals respond to ground translation perturbations during locomotion [23]. This dataset contained motion capture marker data, ground reaction forces, and whole-body angular momentum for 11 able-bodied subjects (4 females, age of 24.5±3.4 years, height of 175.1±7.2 cm, leg length of 91.3±5.1 cm, and body mass of 73.3±11.0 kg). The trial conditions included three sessions of 96 unique ground translation perturbations. The perturbations were varied in eight directions with three distinct magnitudes (i.e., ground translations of 5, 10, and 15 cm) using a 6 degrees of freedom actuated platform. Ground perturbations occurred at varying points within the gait cycle: 1) 50% of the double stance phase and 2) 25%, 50%, and 75% of the single stance phase. Gait phase was varied because it directly impacts subject's response to perturbations [23]. Our post-hoc analysis revealed that, in response to 5-cm magnitude perturbations induced in the direction of walking, the kinematic states largely remained within their nominal trajectories. Consequently, we focused on medium- and large-magnitude perturbations and excluded all 5-cm perturbation trials from analysis. Additionally, two subjects were omitted because they exhibited jump responses to perturbation.

B. Tracking Kinematic States in a Local Coordinate System

Humans tightly regulate the relative distance between the COM and the foot, as well as the velocity of each, to maintain stability during locomotion [24], [25]. Therefore, we tracked the relative position and velocity of the COM and both feet to detect the perturbation onset. A local coordinate system was chosen to minimize the effect of natural global positional drift during walking and to automatically scale the tracked kinematic states to the anthropomorphic dimensions of each subject (Fig. 1).

To track the state of each foot, we used the subject's heel markers. The heel position was calculated within a coordinate system centered at the global COM in 3 axes (Fig. 1). The global COM position was calculated as the average of the positions of four pelvic markers (right/left anterior/posterior superior iliac spine markers). The relative COM position was determined by projecting the global COM vertically downward onto a coordinate system centered at the instantaneous midpoint between the feet in the horizontal plane (Fig. 1). The vertical axis was omitted because the vertical position of the COM is minimally sensitive to ground translation perturbations [12], [24]. The velocity states were calculated by differentiating the global position over time. A dimensionality reduction technique using Principal Component

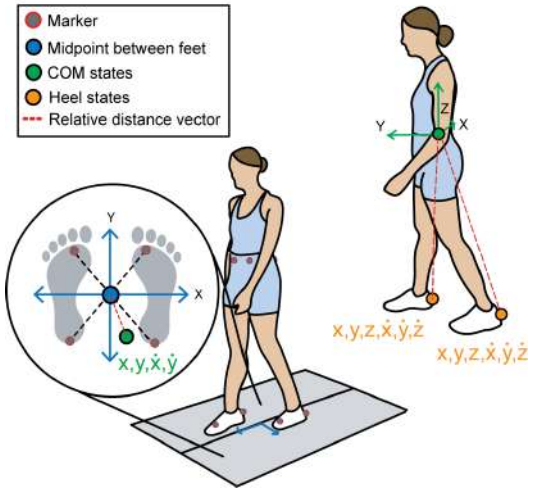

Fig. 1. Kinematic state-based perturbation detection. The relative distance between the body's COM and each foot was calculated to track the kinematic state (right). Eight relative position states and eight velocity states were tracked. A local coordinate system was established at the estimated midpoint between the feet in the horizontal plane. The COM position was then projected into this coordinate system, with a vector (red dashed lines) tracking the relative distance between the COM and the feet over time (left).

Analysis (PCA) was implemented. This analysis provided a simplified visual inspection of the overall state response to perturbations (Fig. 2). It also provided qualitative validation of our prediction that the selected states would exhibit rapid and distinct deviations from steady-state behavior following a perturbation. Two different perturbation trials from the open-source dataset, one in the mediolateral direction (Fig. 2A) and one in the anteroposterior direction (Fig. 2B), were chosen for visual evaluation.

C. Quantifying Kinematic State Variance

The mean and standard deviation of each state were calculated as a function of the gait cycle using state values from 3 steady-state walking cycles. We chose 3 cycles given that the current gait literature states that 2-3 strides are sufficient to capture the natural variance of healthy gait [26]. For subsequent gait cycles, the current value of each state was compared to the mean and standard deviation to quantify variance using Eq. 1,

$$\alpha_i = \begin{cases} 0, & \text{if } |\bar{x}_i - x_i| \leq 2\sigma_i, \\ x_i - (\bar{x}_i \pm 2\sigma_i), & \text{otherwise.} \end{cases} \quad (1)$$

where $\bar{x}$ and σ represent the mean and standard deviation of the current state at a given time point, α denotes the deviation of the individual state from its natural range of variance, and i indicates the current time step. During walking, α was assigned a value of zero if the current state value was within ± 2 standard deviations of the mean. Otherwise, α was calculated as the Euclidean distance from the current state value to 2 standard deviation above or below the mean (Fig. 2C). A value of α close to zero indicates that the subject's kinematic states are within a stable basin, corresponding to steady-state walking.

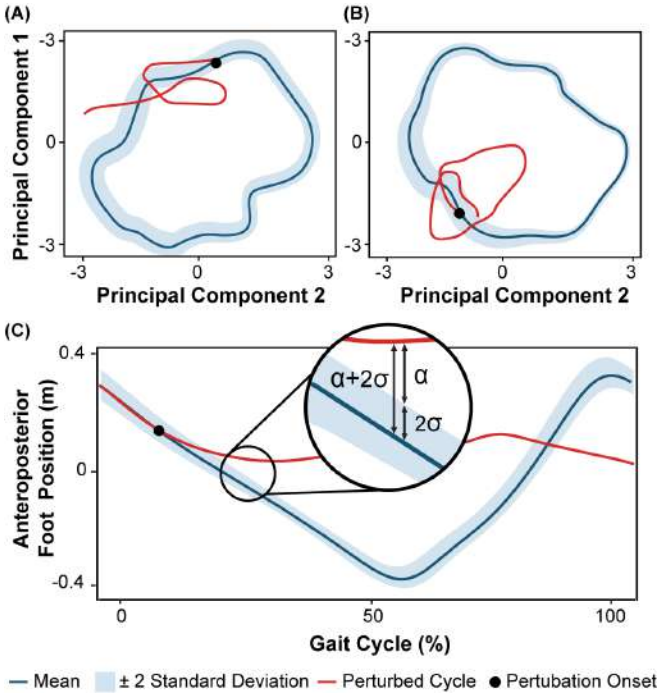

Fig. 2. (A) Principal Component Analysis for a single representative trial of an (A) anteroposterior and (B) mediolateral perturbation. For both cases, perturbations with a magnitude of 15 cm occurred during the double stance phase. (C) Visual representation of state variance calculation (Eqs. 1 and 2). α is the Euclidean distance between the current state value and the edge of 2 standard deviations (σ) from the mean.

Next, α was used to calculate an instantaneous ratio of current to natural state variance (Fig. 2C). This ratio ensured that a state with a lower natural variance contributed more significantly to the total stability deviation value and prevented a state with a large natural variance from disproportionally skewing the total value. The standard deviation of each state was normalized using the coefficient of variation formula, Eq. 2a,

$$C_i = \frac{\sigma_i}{\bar{x}_i} \tag{2a}$$

to account for the differences in unit and scale between states [27]. C represents the coefficient of variation. The ratio for each state was then computed and linearly aggregated using Eq. 2b,

$$\varphi_i = \frac{1}{n}\sum_{j=1}^{n} \frac{\alpha_i}{2C_i + \alpha_i} \tag{2b}$$

where φ represents a single stability deviation value that characterizes the subject's perturbation state and n is the total number of tracked kinematic states. By monitoring the single variable, φ, we determined whether a subject was perturbed (i.e., deviating from their natural variance) by selecting an appropriate threshold value.

D. Threshold Optimization

To calculate the optimal threshold value for φ, which denotes a perturbation onset, we conducted a parameter sweep using the open-source perturbation dataset [23]. Values increasing by a step size of .001 from 0.5 to 4 were used as a threshold for perturbation detection. Detection performance was evaluated on accuracy and delay at each threshold. We determined accuracy by calculating the number of gait cycles that were correctly labeled as perturbed or unperturbed. We defined delay as the percentage of the gait phase that elapsed between the onset of the perturbation and the time when φ crossed the detection threshold. For parameter sweep, we rewarded threshold values that minimized false detections (false positives) and undetected perturbations (false negatives), aligning with the target application of our approach for lower-limb exoskeleton control. Incorrect exoskeleton stability assistance, whether unnecessarily initiated due to false detection of a perturbation or omitted due to an undetected perturbation, carries a significant risk of user injury [28].

E. Baseline Benchmark Implementation

A perturbation detection model using WBAM was implemented and evaluated as a baseline comparison for our model [15], [29]. We replicated this method using the instantaneous sagittal and frontal WBAM values provided in the open-source perturbation dataset. For each trial, the mean and standard deviation of WBAM were calculated using data from the 3-5 steady-state gait cycles that preceded the induced perturbation. A detection threshold of ± 4 standard deviations was chosen according to the recommendations of a previous literature on WBAM [29]. Perturbation detection occurred when the instantaneous WBAM value exceeded this threshold. We evaluated the performance of this model on both the detection accuracy and the delay.

F. Cross Validation

We conducted a nine-subject cross-validation using the open-source perturbation biomechanics dataset to evaluate the model's performance. Following a leave-one-out approach, one subject was systematically withheld at a time. The perturbation threshold was then optimized using data from all 64 perturbation types of the remaining eight subjects, following the threshold optimization method outlined previously. The optimized threshold was subsequently applied to the withheld subject to assess the model's accuracy and detection delay. This procedure provided a measure of the model's generalizability.

III. Results

A. Perturbation Detection Performance Using Cross Validation

Across all nine leave-one-out cross-validations, the average optimal threshold for φ was determined as 0.131 (Fig. 3). The model classified gait cycles as either perturbed or unperturbed for each withheld subject, achieving an average per-subject accuracy of $94.10 \pm 1.46\%$ and detection delay of $33.14 \pm 0.91\%$ of the gait cycle (Fig. 4A). When aggregating all gait cycles across the nine subjects into a single confusion matrix, the overall model accuracy was 95.52% (Fig. 4B).

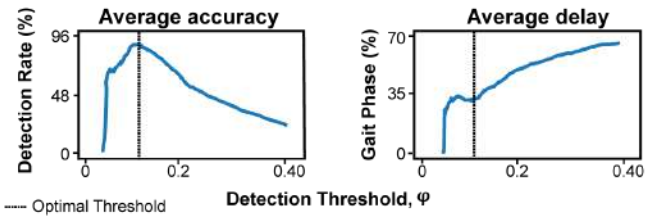

Fig. 3. Parameter sweep result to determine a perturbation detection threshold, φ. A threshold value of 0.131 (black dashed lines) was determined as the average optimal value following cross validation.

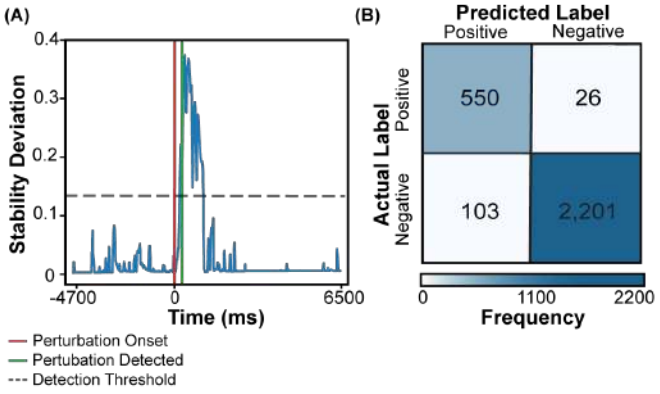

Fig. 4. (A) A representative trial of our model performance in the ground perturbation biomechanics dataset. The red line represents the perturbation onset and the green line represents the time when our model detects the perturbation (detection threshold shown with the dashed grey line). (B) A confusion matrix summarizing our model performance across all leave-one-out validations. Positive and negative labels indicate perturbed and unperturbed gait cycles, respectively.

B. Baseline Model Comparison

Implementation of the baseline WBAM-based model performed with 49.4% less accuracy than our method for the open-source dataset. However, it resulted in a 21.1% faster detection within the gait cycle. The WBAM-based results were obtained by taking the average across sagittal and frontal planes to provide a representative analysis (Fig. 5) [29].

IV. Discussion

In this paper, we proposed a novel perturbation detection model, which utilizes 16 lower-limb kinematic states and their deviations from steady-state gait dynamics. We established a local coordinate system to track relative positions to avoid misinterpreting natural drift in the state during walking. Using a data-driven approach, we optimized a

single threshold value to detect ground perturbations, φ. We hypothesized that our kinematic state-based detection model would outperform the WBAM-based model under varying perturbation conditions across subjects. To test this hypothesis, we evaluated the performance of our model and the WBAM-based benchmark in detecting 64 ground translation perturbations. Our study results corroborate our initial hypothesis that the ground perturbation detection model using kinematic states detected perturbations more accurately than the WBAM-based model. In the open-source dataset analysis, our model showed a 49% improvement in detection accuracy compared to that of the WBAM-based model (Fig. 5). However, contrary to our initial hypothesis, the WBAM-based model outperformed our model in the detection delay, demonstrating a faster response on average by 21% earlier within the gait cycle. It is important to note that this delay was only calculated in instances of successful perturbation detections and may not be representative of the remaining 54% of perturbations that the WBAM-based model failed to detect. Furthermore, since this was an offline analysis, it did not consider the time required to calculate WBAM.

The generalizability of our model across subjects and perturbation conditions showcased the potential benefit of integrating our approach into lower-limb exoskeleton control (Fig. 6A). The average stride duration across subjects in the open source dataset was 1002.5 ± 7.2 ms. Biomechanics literature states that older adults can require up to 469 ms to complete a stabilizing step in response to perturbations. Given that the detection timing of our model was 332 ms, our result indicated that the detection was early enough for an exoskeleton to respond (with assistance) within a single stride [3], [4], [30]. Moreover, the generalizability of our model and its consistent performance across subjects showed that the system can potentially be deployed to exoskeletons with minimal user-specific tuning [31]. In future work, we aim to make our model fully autonomous by tracking kinematic states using on-board wearable sensors (e.g,. inertial measurement units) from an exoskeleton.

Additionally, we plan to extend our model to determine

both the direction and magnitude of each perturbation. The instantaneous sign and magnitude of each α value can provide an estimate of the direction in which the individual's feet and COM were perturbed as well as the relative magnitude of the perturbation (Fig. 6B). We will evaluate the accuracy of these estimations and explore their potential to enhance the precision of perturbation responses in lower-limb exoskeletons. We will also evaluate our model under diverse ground perturbation conditions and subject demographics in real-time to improve the generalizability. Although our model was trained on healthy young subjects, its performance at the same walking speed is likely comparable in healthy older adults. Given their longer reaction times, our method could be especially valuable for assisting balance in older adults [32]. However, additional data collection from older adult subjects is needed to evaluate the model's performance in this target population.

V. Conclusion

We developed a novel perturbation detection model by tracking lower-limb kinematic states and their deviations from steady-state gait dynamics during walking. Our model employed a weighted sum of state deviations and used a data-driven threshold to detect ground perturbations. In a nine-subject cross-fold validation, our model achieved 95.5% detection accuracy with a delay of 33.1% within a gait cycle after a perturbation onset, outperforming the benchmark WBAM-based model. These results highlight the potential of our model to enable lower-limb exoskeletons to provide fast and precise balance support, particularly for older adult users.

Rehabilitation of Chronic Stroke Using Neurofeedback, Functional Electrical Stimulation and Cerebrospinal Direct Current Stimulation

Teodiano Bastos-Filho, Aura Ximena Gonzalez-Cely *Student Member, IEEE*, Sheida Mehrpour, Fernanda Souza, Ana Cecilia Villa-Parra, Fernando Cabral

***Abstract*— This work presents the application of a rehabilitation protocol using a novel Non-Invasive Brain Stimulation (NIBS) technique, called cerebrospinal Direct Current Stimulation (csDCS), together with the use of a Brain-Computer Interface (BCI) based on Motor Imagery (MI) with Neurofeedback (NFB), and applying Functional Electrical Stimulation (FES) plus the use of a pedal exerciser. This protocol uses the concept of Alternating Treatment Design (ATD), in which a chronic post-stroke subject is submitted to these techniques to recover his left hand and leg movements. The rehabilitation progress was verified through metrics, such as Fugl Meyer Assessment (FMA), Functional Independence Measure (FIM), Ashworth Scale, Muscle Strength Grading (MSG), and surface Electromyography (sEMG). Results from these metrics include a 41% gain in hand function recovery, a 5% gain in performance in motor and cognitive/social domains, and a 50% improvement in both wrist extensor muscle strength and finger extensor muscle strength. In addition, there was a 17% gain of Maximum Voluntary Contraction (MVC) for the tibialis anterior muscle of the patient's left leg. On the other hand, there was a worsening in some values of EMG, probably due to the participant having received application of botulinum toxin in his hand.**

I. Introduction

A study by the United Nations forecasts that, by 2050, the population of individuals aged 65 and older will reach 1.5 billion, constituting 16% of the total population [1]. This demographic shift is accompanied by an increase in age-related health concerns, notably stroke, as the likelihood of experiencing a stroke doubles roughly every 10 years after turning 55 [2]. Stroke, a clinical condition marked by insufficient blood flow to the brain, leads to cell death. Stroke can be ischemic (80% of cases), caused by reduced blood flow, or hemorrhagic, due to bleeding, whose impact largely depends on the location and its severity. Individuals recovering from a stroke may face varying degrees of neural injury affecting motor functions in both upper- and lower-limbs [3].

The effects of a stroke on the upper limb can be a weakness (hemiparesis) or paralysis (hemiplegia) on one side of the body (often seen on the opposite side to where the stroke occurred); loss of fine motor skills of fingers and hands; spasticity (increased muscle tone or stiffness in the affected arm); sensory changes (such as numbness, tingling, or a "pins and needles" sensation); and difficulty with the coordination of shoulder, elbow, wrist, and fingers. On the other hand, the lower limb effects can be weakness or paralysis (similar to the upper-limb) in one leg, affecting the ability to walk and perform weight-bearing activities; impaired balance and coordination while standing and walking, increasing the risk of falls; spasticity (due to tightness and stiffness in the muscles of the affected leg, making walking and movement challenging); foot drop (the foot cannot be lifted properly due to weakness or paralysis of the muscles that control dorsiflexion (lifting the foot upwards), which can lead to dragging the foot while walking); and altered gait patterns (such as a limp, scissoring gait – legs crossing over each other –, or circumduction – swinging the leg out to the side while walking). After a stroke, rehabilitation for impairments in both the upper and lower limbs typically consists of a blend of physical therapy, occupational therapy, and sometimes speech therapy. The goal is to improve strength, range of motion, coordination, and functional abilities to enhance independence in Activities of Daily Living (ADL) [4],[5].

Early intervention is vital for optimal outcomes in upper- and lower limb rehabilitation, capitalizing on the brain's adaptability known as "neuroplasticity". Traditional therapies focus on strength, range of motion, motor control, and ADL performance [6]. Such therapies form the foundation, but advancements like technology-enhanced therapies offer new possibilities for optimizing training intensity, repetition, progress evaluation, and patient-specific treatment [7].

Recent years have shown innovations that can transform stroke rehabilitation, such as the use of robot-assisted therapy, which provides feedback and tracks progress for personalized rehabilitation [7],[8]. Rehabilitation involving a Brain-Computer Interface (BCI) is another innovation that provides a groundbreaking approach. In fact, BCI establishes direct communication between the brain and the rehabilitation equipment [9]. Moreover, studies have shown that BCIs based on Motor Imagery (MI) of upper- and lower-limb movements can improve motor learning and increase neural plasticity [10],[11]. These motor patterns can be analyzed through Event-Related Synchronization (ERS)/Desynchronization (ERD), which are associated to indicate neural changes, specifically a power increase or decrease in the brain's electrical signals, respectively [12]. Thus, BCIs can translate these detected MI into commands for external devices, enhancing motor function and independence for stroke

survivors [5]. As part of such MI-BCI therapy, the inclusion of Neurofeedback (NFB) has shown improvements in neuroplasticity, as this technique measures and shows to the subject their brain wave activity to help them self-regulate their brain function and enhance specific targets [13].

Another novelty in this field is the use of Functional Electrical Stimulation (FES) to induce peripheral activation to enhance muscle contraction, through suitable pulse amplitude, duration and frequency, to generate stimuli triggering action potentials in intact peripheral nerves [14]. As well as a new Non-Invasive Brain Stimulation (NIBS) technique (cerebrospinal Direct Current Stimulation –csDCS), which is a promising novelty to exciting, simultaneously, the brain and the spinal cord. This technique uses a low-level continuous current (2 mA) to modulate the activity of the brain and spinal cord. This technique uses a pair of electrodes, where the anode is placed on the M1 region of the affected hemisphere, and the cathode is placed on the spinous apophysis of the thoracic vertebra over T11 (T10-T12) upon palpation.

We present here the results from the application of this novel NIBS technique together with the use of a MI-BCI with NFB, and applying FES plus the use of a pedal exerciser. It is worth mentioning that our protocol uses the concept of Alternating Treatment Design (ATD), in which a chronic post-stroke subject is submitted to these techniques to recover his left hand and leg movements. The evaluation of his rehabilitation progress was conducted using typical metrics used in this field, such as Fugl Meyer Assessment (FMA), Functional Independence Measure (FIM), Ashworth Scale, Muscle Strength Grading (MSG), and Electromyography (EMG).

II. Study Design

This study is based on the concept of ATD, which is a single-case research design study that typically involves a single subject, later replicated individually in other research participants. In this kind of study design a baseline assessment phase is used to track the problem before intervention or treatment. Different interventions are applied in a randomized, semi-randomized order, or predetermined sequence, to assess whether one treatment is more effective than the other and, further, making decisions to determine the specific treatment being implemented. In this method the participant acts as both the control and the treatment group [15], i.e., each participant is considered as his/her own control in sham phase.

In our recent study [16], we explored the rationale behind the ATD as a suitable research design for neurorehabilitation objectives. As the most common concern with NIBS trials is related to incomparable outcomes, the ATD adopted here allows for future comparison of the outcomes with other studies. We consider that such an approach may help to some extent to address the study of a single subject. Additionally, we consider results from recent studies after stroke, which claim that the total brain volume decreases in a heterogeneous manner, which is known as brain atrophy rates [17],[18]. From such studies it was inferred that the brain atrophy rates may impact the density current distribution and, in turn, the cortical excitability during stimulation. Therefore, based on our previous studies [19], in this study it was postulated that using a subject-specific stimulation protocol that varies the current intensity and duration of intervention, depending on the brain tissue volume for the subject, would reduce the variability of the NIBS results. Using this justification, the approach used here employs a single-case research design in which the same participant receives both the real and the sham stimulations. Thus, it is believed that the influence of brain atrophy rates can potentially be mitigated by examining the stimulation (real or sham) on a single case, leading to more reliable and comparable outcomes [16].

III. Matherials And Methods

A. Brain-Computer Interface (BCI)

Given its broad adoption and accessibility, all the protocols presented here rely on the use of an electroencephalography (EEG) cap, enabling the real-time streaming of EEG data. Following an initial stage of signal pre-processing, a stage of feature extraction, and a final stage of classification, control signals are transmitted to the NFB system on a computer screen as well as to the FES device, which is applied to the paretic arm of the participant (Fig. 1).

The BCI used in our study is composed of an EEG wireless board (Open BCI Cyton-Daisy, OpenBCI, USA). This electronic board samples, at 125 Hz, the signals that are acquired from sixteen EEG electrodes located on: FP1, FP2, F3, F4, FC3, FCz, FC4, C5, C3, C1, C2, C4, C6, CP3, CPz, CP4, including two references at earlobes (A1 and A2). It is important to emphasize that we modified the original locations of the original EEG cap, so that the electrodes used in our research are grouped on the Supplementary Motor Area (SMA), Primary Motor Cortex (M1), and Pre-Motor Area (PMA) of the brain motor area, which are related to motor mental tasks (Fig. 1). These EEG channels were selected because the signals recorded from these channels show a tight relationship to activity of the most relevant sensorimotor areas. In our protocol, scalp-electrode impedances are maintained below 20 kΩ, which is suitable to have a good quality of the EEG signals, in addition to accelerating the participant preparation time.

B. Neurofeedback (NFB)

NFB was implemented here to provide the subject with his success rate related to the MI recognition in both calibration and online stages while he imagined performing limb movements. For that, his EEG signals were processed using a 1-s window, and Relative Power Changes (RPC) were calculated in mu and beta bands, using a Laplacian filter around C_3 and C_4 electrodes, such as done by [20], [21]. Using this method, an RPC value is generated, which is translated to the screen in front of the subject to show him, as on-line feedback, the success rate in recognizing his MI, thus

motivating him to improve his performance in generating high RPC values.

To detect the MI, first there is a calibration stage (with the subject in rest) using the EEG dataset as input to recognize MI and resting classes, where the period of baseline is considered as the resting class. The calibration stage considers the use of a 5-fold cross-validation to avoid overfitting, data leaking, and generalize better the system, such as done by [20], [22], [23]. This stage generates the classification model to be used in the online stage.

In a second stage there is a data segmentation to split the dataset into 80% for training, and 20% for testing. From the previous 80%, a new split is performed to obtain new training and validation datasets. With each segment of data, a 1-s sliding window (with 50% overlap) is applied to segment the data for processing, as done in [20], [24], [25]. Using each window of data, a Butterworth zero-phase band-pass filter is used between 7 to 30 Hz to isolate the mu and beta bands [3]. In the final stage, the technique of Riemannian Geometry (RG) is used for feature extraction, as done in [20], [23], and Linear Discriminant Analysis (LDA) is used for classification, such as done by [20], achieving a mean ACC of 0.72, while recognizing MI and resting classes.

C. Participant recruitment

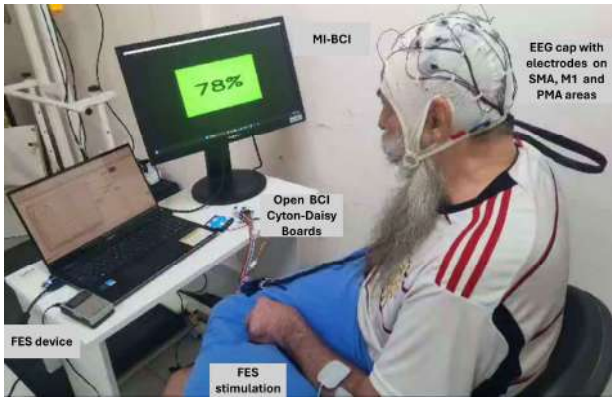
Before recruiting the post-stroke participant for our study, specific inclusion and exclusion criteria were established. The participant of our study was required to have a diagnosis of stroke resulting in hemiparesis of their upper and/or lower limbs, the ability to maintain balance in a seated position, and the capacity to perform passive movements with the paretic limb in both the upper and/or lower limbs. Participants with a clinical history indicating other neurological diseases, two or more stroke episodes, uncontrolled blood pressure or angina, and a history of convulsions were excluded from our study. Additionally, the participant was required to meet another inclusion criterion: he needed to have sufficient auditory, visual, cognitive, and language skills to understand and follow instructions. Based on such criteria, a 59 years-old man affected by chronic ischemic stroke on December 22, 2021 was chosen for our experiments. His stroke caused hemiparesis in his left hand and leg, with distal brachial predominance.

The participant voluntarily participated in the experiments and signed the informed consent in accordance with the Declaration of Helsinki and the experimental protocol approved by the Ethics committee of the Federal University of Espirito Santo (UFES/Brazil) under the number CAAE: 39410614.6.0000.5060.

D. Experiments

Before starting our protocol, the participant was injected 1000 units of botulinum toxin (brand Dysport) into his left hand to relax his hand muscles and joints, in a single application, due to his high hand muscle stiffness provoked by the stroke. Afterwards, the participant was submitted, for two weeks, to the hand protocol using MI-BCI-NFB plus FES (Fig. 1).

In this protocol the participant was worn with the EEG cap and instructed to imagine his paretic arm movement. Thus, once the BCI was able to recognize his MI, the NFB calculation was performed, and the participant was able to watch on the screen in front of him the RPC value. A FES device (Balego EMS Digital Neuromuscular) was used to target the flexor muscles of the fingers and wrist, and the extensor muscles, simultaneously, with the following parameters: synchronous mode, 1-s ramp, 7-s on-time, 8-s off-time, frequency of 20 Hz, and pulse width of 200 μs. The stimulation intensity was adjusted based on the participant's comfort level.



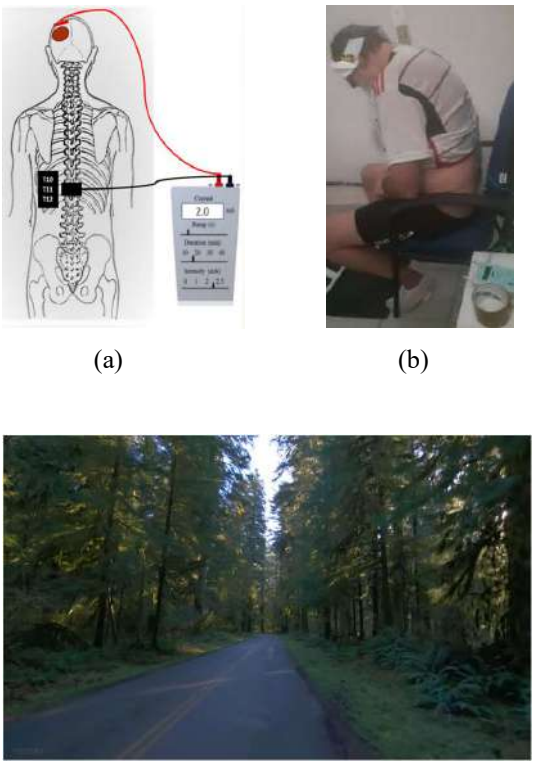


Fig. 1. Neurofeedback provided to the subject, according to his performance in generating MI values.

Fig. 1 shows the participant during the experiment, in which he is verbally guided to focus on the MI task, in order to increase the RPC value during NFB. This procedure was also held five times a week for two weeks.

After that, the leg protocol started (Fig. 2), in which csDCS was applied to the participant for 20 min (five days a week, for two weeks, with current intensity of 2 mA, and fade-in and fade-out periods of 30 s each) via two conductive-rubber electrodes (35 cm^2) enclosed in perforated sponges pocked soaked with saline connected to the equipment (DC-Stimulator Plus, NeuroConn, Ilmenau, Germany). In this technique one electrode (anode) is located on the M1 region of the affected hemisphere, and the other electrode (cathode) is located on the spinous process of the thoracic vertebra over T11 (T10-T12) by palpation. It is worth mentioning that during the cerebrospinal stimulation (20 min) the participant watched a video projected in front of him with pedaling content, and was instructed to imagine himself pedaling (to strength his mu and beta bands related to MI), in addition to pedaling a pedal exerciser (Mini Exercise Bike, from Himaly, USA). Fig. 2 shows the participant receiving csDCS through electrodes in specific location, and a screenshot of the video projected on the wall to stimulate the participant to generate his MI.

To evaluate the efficacy of our protocol, the patient was assessed by an experienced physiotherapist, using the same methodology to ensure reliability, at the beginning, middle and the end of the experiment, using the following metrics: Fugl Meyer Assessment (FMA), Functional Independence Measure (FIM), Ashworth Scale, Muscle Strength Grading (MSG), and surface Electromyography (sEMG). The sEMG data were acquired with a wireless Miotec device (New Miotool Face model), 16-bit resolution, between 20 and 500 Hz, at 3k samples per second.

IV. RESULTS

A. *For Upper-Limb*

- Fugl Meyer Assessment (FMA)

A 41% gain in the left participant's hand function recovery was observed in terms of functionality, range of motion, sensitivity, pain, proprioception and speed (Fig. 3).

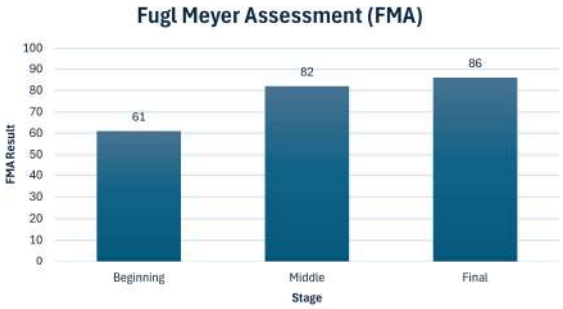

Fig. 3. Results for Fugl Meyer Assessment (FMA).

- Functional Independence Measure (FIM)

A 5% gain was observed in performance in motor and cognitive/social domains in the following aspects: eating, personal hygiene, bathing, dressing the upper half of the body, dressing the lower half of the body, using the toilet, controlling urine, controlling feces, transferring to bed, chair, wheelchair, transferring to toilet, transferring to bathtub or shower, locomotion, locomotion on stairs, understanding, expression, social interaction, problem solving, and memory. Fig. 4 shows the results obtained for the metric FIM.

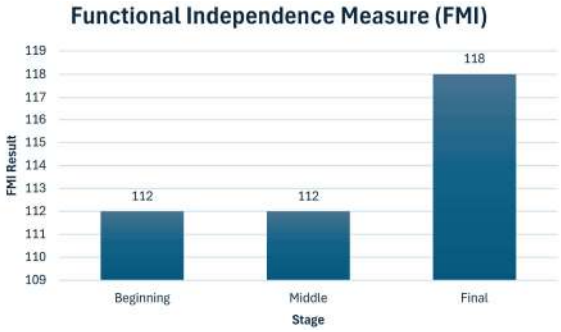

Fig. 4. Results for Functional Independence Measure (FIM).

- Ashworth Scale

In this metric, which assesses the intensity of hypertonia and therapeutic response, there was a 33% improvement in the values measured at the beginning and the end of the protocol, which indicates a decrease in the patient's level of spasticity. Fig. 5 shows the three values of the Ashworth scale measured along the protocol.

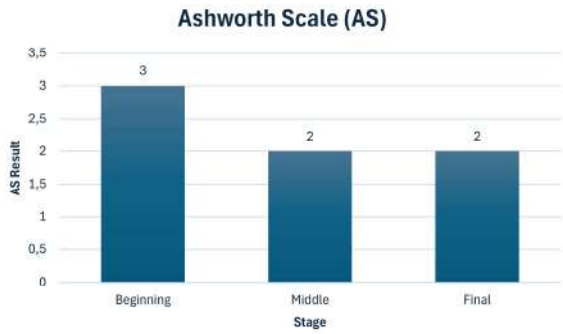

Fig. 5. Results for Ashworth Scale.

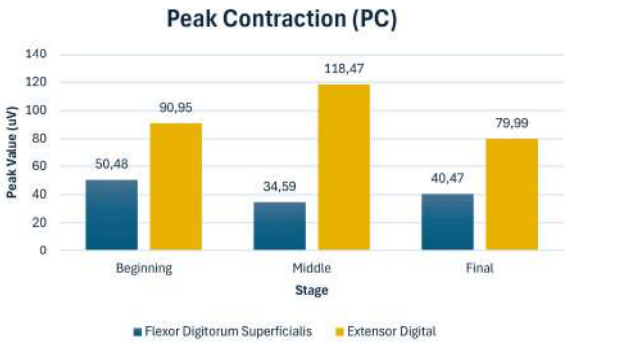
- Muscle Strength Grading (MSG)



This metric assesses the muscle strength of the wrist flexors, wrist extensors, finger flexors and finger extensors. There was no improvement either in wrist flexor strength or in finger flexor muscle strength, but there was a 50% improvement in both wrist extensor strength and finger extensor muscle strength, such as shown in Fig. 6.

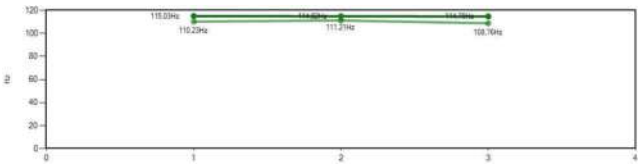


Fig. 6. Results for Muscle Strength Grading (MSG) of wrist flexor muscle strength, finger flexor muscle strength, wrist extensor muscle strength and finger extensor muscle strength.

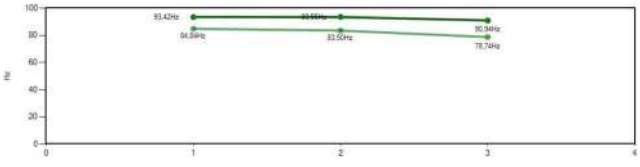
- surface Electromyography (sEMG)



Such as shown in Fig. 7, after an improvement of 30% in the peak of flexor contraction of the fingers (flexor digitorum superficialis), there was a worsening of 32%. In relation to the contraction of the extensor digitorum muscle, there was also a worsening of 32% in its peak. In addition, no significant variation was observed in the mean and median frequency. We believe that this was due to the application of botulinum toxin in the left arm of the participant.

Results for surface Electromyography (sEMG): a) peak value (μV) for flexor digitorum superficialis muscle and extensor digitorum muscle; b) Mean (dark green) and median (light green) frequencies for flexor digitorum superficialis muscle; c) Mean (dark green) and median (light green) frequencies for extensor digitorum muscle.

B. *Lower-Limb*

Regarding the lower limb, there was a 17% gain of Maximum Voluntary Contraction (MVC) for both the left extensor and flexor tibialis anterior muscles of the participant. Fig. 8 shows the results for these muscles.

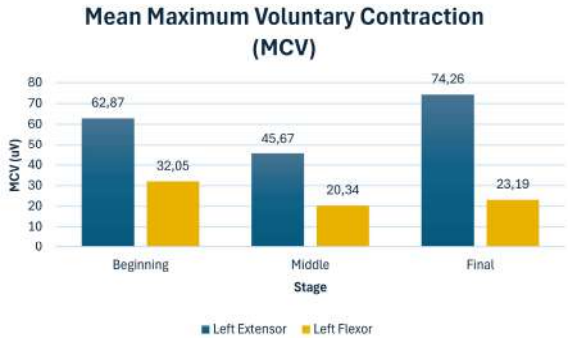

Fig. 8. Results for Maximum Voluntary Contraction (MVC) for the left tibialis muscle.

V. Conclusions

This work presented the application of a rehabilitation protocol using csDCS together with the use of MI-BCI-NFB, and applying FES. This protocol used the concept of ATD, in which a chronic post-stroke subject was submitted to these techniques to recover his left hand and leg movements. Results from these metrics showed a 41% gain of the participant's left hand function recovery, a 5% gain in performance in motor and cognitive/social domains, and a 50% improvement in both wrist extensor and finger extensor muscle strength.

Regarding the lower limb, there was a 17% gain of Maximum Voluntary Contraction (MVC) for the left tibialis anterior muscle. We believe these improvements were due to our therapy, which facilitated neuromodulation, enhancing the excitability of the motor cortex and improving muscle activation, as well as reducing spasticity and allowing for greater voluntary contraction during assessments. It is worth commenting that there is a limitation in this study, which evaluated only a single participant. On the other hand, this study does not present comparisons with other studies, as we believe that this is the first study using a combination of csDCS, MI-BCI-NFB and FES for post-stroke rehabilitation, therefore, more studies are needed to confirm the results with a wider sample, as well as conducting the research by blinded evaluators. Following this therapy, the next step of this research is to include transcranial Alternate Current Stimulation (tACS) and Transcranial Magnetic Stimulation (TMS) in our protocol.

Comparative Analysis of Temporal Difference Learning Methods to Learn General Value Functions of Lower-Limb Signals

Sonny T. Jones, Grange M. Simpson, Wyatt M. J. Young,
Kylee North, Patrick M. Pilarski, Ashley N. Dalrymple

***Abstract*— Millions of people in the United States suffer from paralysis, resulting in significant deficits in motor function. Restricted mobility due to these deficits and the lack of adaptive rehabilitative solutions make traversing complex and challenging terrains unsafe. Exoskeletons offer a promising solution, but their effectiveness could be greatly enhanced by incorporating reinforcement learning algorithms for real-time adaptation to changing environments and the user's unique gait biomechanics. This study explored different temporal difference learning methods for predicting signals recorded from sensors on the lower-limbs, including muscle activation from electromyography, underfoot pressure, and joint angles from goniometers. Specifically, the performance of the temporal difference learning methods TD(λ), TOTD, and SwiftTD to quickly and accurately predict these signals was examined. From initial findings, SwiftTD generally converged faster, while TOTD typically achieved lower convergence errors. These outcomes varied depending on the specific signal that was being predicted, highlighting the need for careful consideration of algorithm choice depending on the signal, accuracy, and speed. The results, therefore, support the informed selection of specific algorithms for providing predictive knowledge to adaptive, machine learning-controlled assistive rehabilitative technologies. These findings will enable the selection of appropriate predictive algorithms, leading to the development of better exoskeletons and other assistive devices to enhance the mobility and quality of life of individuals with motor paralysis.**

I. Introduction

There are an estimated 5.4 million individuals currently in the United States who suffer from motor paralysis, with stroke and spinal cord injury as the leading causes [1]. People with impaired motor function often suffer from muscle stiffness, muscle spasms, and altered muscle activation, including weakness, impaired coordination, and reduced endurance [2]. Many individuals adapt to their restricted mobility, but experience difficulties while walking on more complex terrains such as slopes, curbs, stairs, uneven surfaces, and while turning. There is a critical need to provide personalized adaptive solutions to navigate changing and challenging terrains. The lack of adaptive solutions for rehabilitative devices to navigate changes in terrain transitions limits safe, reliable ambulation in complex environments. Developing responsive rehabilitative solutions can improve overall autonomy and mobility in people with motor impairments.

Current state-of-the-art control methods rely on static approaches such as state machines or kinematic models to define control parameters, which are not predictive and cannot anticipate changes of terrain in dynamic environments [3], [4]. Reinforcement Learning (RL) is a type of machine learning that can both learn and adapt sensorimotor predictions over time [5]. Because of this property, RL-based controllers for exoskeleton control promise to enable adaptation to individual users and varying environmental conditions [6], [7]. RL utilizes a trial-and-error learning paradigm that chooses the best actions and behavior based on learned expectations about future success (i.e., reward) [5]. This allows behavior to beneficially change before future events occur. RL also facilitates adaptation to unforeseen events via mechanisms of exploration and meta-learning [8]. Therefore, RL holds promise for more adaptable exoskeleton control, especially in dynamic environments [7]. Adaptability is particularly important for community ambulation, where individuals encounter various terrains and obstacles that require real-time adjustments to maintain stability and safety.

For adaptable RL-based controllers of exoskeletons, accurate and real-time signal prediction is essential. Temporal difference (TD) learning—the main learning process underpinning RL in both animals and machines [5]—has been shown to learn reliable predictions of various gait-related signals, including electromyography (EMG), underfoot pressure, and joint angles, for applications in prosthesis and exoskeleton control, as well as spinal cord stimulation [9]–[11]. However, there remains a gap in identifying the most effective TD algorithms for approximating these gait-relevant sensor signals. Closing this gap is necessary for enhancing the accuracy and functionality of RL-based controllers that rely on these predictions for real-time decision-making.

This present study explores and compares different TD learning algorithms for the prediction of walking kinetic and kinematic signals relevant to exoskeleton control, including muscle activation from EMG, underfoot pressure, and joint angles. The approach aims to predict these complex biomechanical signals while people walk across different terrains. By providing methods to determine the most appropriate algorithm for this task, groundwork can be laid for future applications that leverage the predictive capabilities of RL to anticipate transitions between different types of terrains dur-

Experimental setup showing a study participant equipped with the sensor suite. a) EMG sensors are placed on the TAL, TAR, LGL, LGR, VLL, VLR, BFL, and BFR to capture muscle activations during walking. Goniometers are placed on the LK and RK to capture joint angles. b) Pressure insoles with the divided bins.

ing walking. The goal is to create adaptive control strategies for lower-limb exoskeletons that adapt to the user's unique biomechanics and facilitate safe gait over variable terrains.

II. Methods

A. Participants

Nine healthy participants (3 female, aged 19 - 31 years) with no known neuromuscular deficits were recruited for this study. All participants provided written informed consent following the University of Utah Institutional Review Board (IRB00171076).

B. Data Acquisition and Processing

Participants were fitted with 8 wireless EMG sensors, 2 wireless goniometers (Trigno, Delsys, Natick, MA, USA), and 2 wireless pressure-sensing insoles (XSensor, Calgary, AB, Canada). EMG sensors were placed bilaterally on the tibialis anterior (TAL/TAR), lateral gastrocnemius (LGL/LGR), vastus lateralis (VLL/VLR), and biceps femoris (BFL/BFR), with 'L' or 'R' at the end of each abbreviation indicating the left or right leg, respectively. Before sensor placement, each muscle belly was cleaned with abrasive gel and alcohol (LemonPrep, Mavidon, Flat Rock, NC) and treated with conductive electrode gel (Signagel, Parker, Fairfield, NJ). Sensors were secured with double-sided Delsys adhesive and Medipore medical tape (3M, Saint Paul, MN). Each EMG sensor sampled data at 1926 Hz. Goniometers were placed bilaterally on the lateral knee joint (LK and RK) with Medipore tape and sampled joint angle data at 519 Hz. Pressure insoles were placed in the participant's shoes and sampled underfoot pressure at 33 Hz. The sensor setup is illustrated in Figure 1a. Hardware and data collection were controlled using a custom graphical user interface (GUI) built in Python (version 3.8.1, Python Software Foundation, Wilmington, DE) running on a computer with an Intel Core i7 CPU and 32 GB of RAM. Data were collected online and saved for offline analysis.

EMG data were processed using a 4th-order Butterworth bandpass filter (10 Hz high pass, 450 Hz low pass, the function *scipy.signal.filtfilt* doubles filter order). The filtered signal was rectified, and a moving average (window size of 0.1 times the EMG sampling rate) was applied to obtain the signal envelope. The resulting envelope was down-sampled to 33 Hz to match the insole sampling rate. EMG data were normalized to each muscle's maximum voluntary contraction (MVC), where participants maximally contracted the muscle isometrically [12]. Pressure data were normalized to the participant's weight. The pressure insoles contain 235 total sensors. The foot was divided into 5 different regions, and the average value of each region was taken at each time step (Figure 1b) [13]. Pressure signals were smoothed using an exponential moving average with a filter size equal to 11 samples. Goniometer data were down-sampled to 33 Hz and were normalized to [0, 1].

C. Machine Learning Approach

1) Selective Kanerva Coding: Selective Kanerva Coding (SKC) is a function approximation method to reduce a high-dimensional continuous state space into a binary feature vector, shown to be useful with stochastic sensor data in rehabilitation settings [10], [11], [14]. Thirty sensor signals formed the state space: 8 EMG signals, 20 underfoot pressure signals (regions and moving averages), and 2 goniometer signals [10]. Sensor signals were normalized to [0, 1].

SKC was initialized by randomly distributing $K = 2500$ prototypes across the state space. Prototype positions were held constant after initialization. The c closest prototypes to the current state were found according to the Euclidean distance between the current state and the prototypes, sorted with Hoare's quickselect [14]. 3-c values were utilized, such that the resulting binary feature vector had a length equal to $len(c)*K$ long with $sum(c)$ active features, for more flexible representations and more granularity of the state space [10].

2) General Value Functions: Traditionally, RL allows an agent to explore an environment, learning to assign value to actions and states according to the expected, or predicted, future reward. [5]. The value function approximates the expected return, the future cumulative discounted sum of rewards an agent can expect from a particular state. Value functions can also be used to estimate the future values of any arbitrary signal of interest, called the cumulant (Z) [15], [16]. These functions are called General Value Functions (GVFs; [16]). GVFs have previously been used to quickly predict walking-related signals, including EMG, ground reaction forces, and angular velocity [9], [10].

3) Temporal Difference (λ) Learning: Temporal Difference (TD) learning is a fundamental RL algorithm where an agent learns from experience without relying on a model

of the environment [17]. TD learning is the key method used to update predictions of GVFs [16]; it provides good performance and low computational complexity [5], [18]. TD learning adapts the predicted future rewards for a specific state. It uses the observed reward for the current state and the predicted value of the next state to adjust the current prediction, making it closer to the observed reward plus the discounted value of the next state. The core component of this update is the TD error (δ), which calculates the difference between the current state estimate (V) and an estimate of the future state (V'). TD learning uses a discount factor (γ, $0 \leq \gamma \leq 1$) that determines whether the algorithm estimated more immediate or long-term reward.

TD(λ) extends basic TD learning by introducing an additional decaying parameter (λ, $0 \leq \lambda \leq 1$) that determines whether the algorithm prioritizes previous learning or current value estimations to update the predictions [5]. This decaying parameter is combined with an eligibility trace (e) to assign credit to previous states for the current reward or error. The TD(λ) algorithm is outlined in black in Algorithm 1. While TD(λ) is powerful, it can be sensitive to divergence in the online setting from the mathematically optimal solution in settings where function approximation is used, especially with larger step sizes. [18]. TD(λ) uses an accumulated trace to update e, which can lead to unbounded updates. The combination of unbounded updates and large step sizes causes the learning algorithm to become unstable, leading to divergence and poor prediction performance.

4) True Online Temporal Difference Learning: True Online Temporal Difference (TOTD) learning solves the divergence problem of TD(λ) learning by adding extra terms to the update rule for the eligibility trace and weight vectors [18]. The additional components introduced by TOTD are shown in red in Algorithm 1. Specifically, TOTD uses a Dutch trace to update the eligibility trace, which bounds the eligibility update. Additionally, TOTD introduces a TD error correction to account for the change in the estimates of the predictions over time. This correction helps to maintain consistency with the online mathematical update, leading to more accurate predictions without divergence. These improvements enable more stable learning, particularly with larger step sizes. TOTD is also computationally more efficient than TD(λ), especially with larger state spaces [18].

5) SwiftTD: SwiftTD aims to improve TD(λ) learning by introducing adaptive step sizes with maximum bounds that decay over time [19]. This approach solves the problem of large step size sensitivity in TD methods, allowing faster learning while maintaining stability. Instead of updating the weight vector with a single step size, this algorithm uses a custom step size to adjust each weight. SwiftTD dynamically adjusts each step size based on the magnitude of previous updates, helping to overcome slow learning from small updates. A meta-step size (θ) is employed to update the step sizes of the weights. A step size bound (η) and decay (ϵ) are introduced to combat divergence from overly large updates. The additional components added by SwiftTD are highlighted in blue in Algorithm 1.

Algorithm 1 Learning GVFs with TD Methods

Indicators: TD(λ), TOTD, SwiftTD
Input: $\lambda, \gamma, \alpha, \theta, \epsilon, \eta, \alpha_{init}$
Initialize: $w, x, V_{old}, S, e, \bar{e}, p, h \leftarrow 0, \beta \leftarrow \alpha_{init}$
Repeat every time-step:
Generate next state S' and cumulant Z'
$x' \leftarrow SKC(S')$
$V \leftarrow w^T x$, $V' \leftarrow w^T x'$
$\delta \leftarrow Z + \gamma V' - V$ {TD Error}
$T \leftarrow e^T x$
$E \leftarrow max(\eta, \alpha^T x^2)$
$V_{diff} \leftarrow V - V_{old}$
$e \leftarrow \gamma\lambda e + x - \alpha\gamma\lambda(e^T x)x$ {TD(λ), TOTD}
$w \leftarrow w + \alpha(\delta + V_{diff})e - \alpha V_{diff} x$ {TD(λ), TOTD}
for i = 1, 2, ..., n **do**
  $\alpha_i \leftarrow e^{\beta_i}$
  $e_i \leftarrow \gamma\lambda e_i + \frac{\eta}{E}\alpha_i x_i - \alpha_i\gamma\lambda T x_i$
  $w_i \leftarrow w_i + \delta e_i - \alpha_i x_i V_{diff}$
  $p_i \leftarrow \gamma\lambda p_i + x_i h_i$
  $\beta_i \leftarrow \beta_i + \frac{\theta}{\alpha_i + e^{-8}}\delta h_i$
  $\bar{e}_i \leftarrow \gamma\lambda\bar{e}_i + \alpha_i x_i[1 - \gamma\lambda T - \gamma\lambda x_i \bar{e}_i]$
  $k \leftarrow h_i$
  $h_i \leftarrow h_i[1 - \alpha_i x_i^2] - h_i^{old} x_i[e_i - x_i\alpha_i] + \delta\bar{e}_i - x_i\alpha_i V_{diff}$
  $h_i^{old} \leftarrow k$
  $if(E > \eta \; and \; x_i \neq 0) \; : \; \beta_i = \beta_i - ln(\epsilon)$
end for
$V_{old} \leftarrow V', x \leftarrow x'$

TABLE I
LEARNING PARAMETERS FOR TD ALGORITHMS

Parameter	TD(λ)	TOTD	SwiftTD
λ	0.5	0.5	0.9
α	0.015	0.015	NA
α_{init}	NA	NA	0
θ	NA	NA	-2
ϵ	NA	NA	0.9
η	NA	NA	0.2

6) Learning Parameter Selection: The learning parameters used for each algorithm were selected using a grid search on a subset of data to minimize prediction error, comparing the predicted GVF and the actual return on a subset of the data (Table 1).

D. Experimental Protocol

Participants performed MVCs for each muscle group for EMG signal normalization. Participants walked across designated tracks with various terrains, including even ground, uneven ground, up and down ramps, upstairs, downstairs, and left and right turns (Figure 2). The experiment was comprised of a total of 10 trials. Participants first walked across Track 1 four times, then three times across Track 2, and concluded by walking across Track 3 three times. Continuous data were collected from all sensors while participants transversed the terrains during the walking trials. Transitions between terrains were synchronously marked when the participant first stepped onto a new terrain surface.

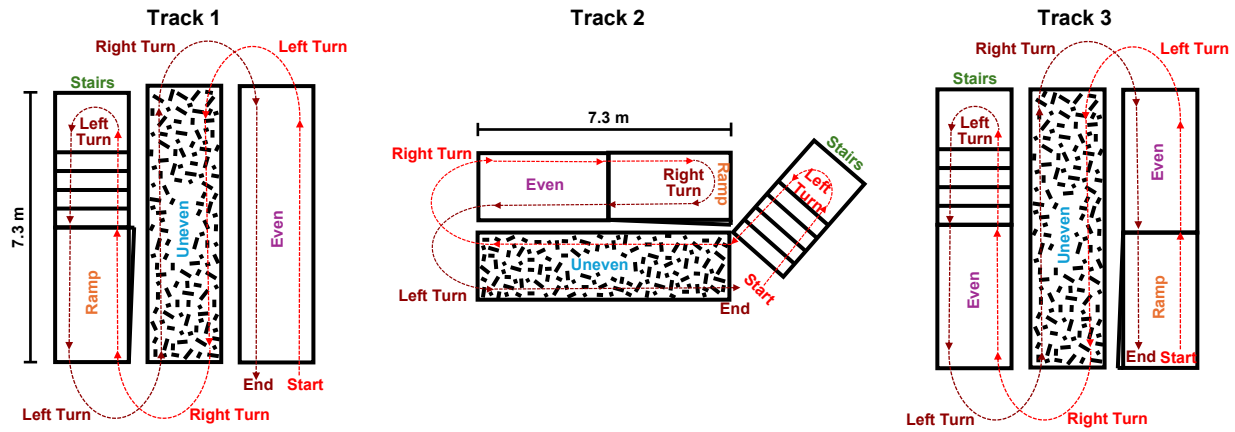

Fig. 2. Participants begin walking on the track from the 'Start' and follow the arrows until the 'End' mark. The straight portion of the terrain track was 7.3 m long. Terrain tracks include even ground, uneven ground, up and down ramps, upstairs, downstairs, and left and right turns. Participants first began walking on track 1 four times, followed by three times on track 3, and finished with three times on track 3.

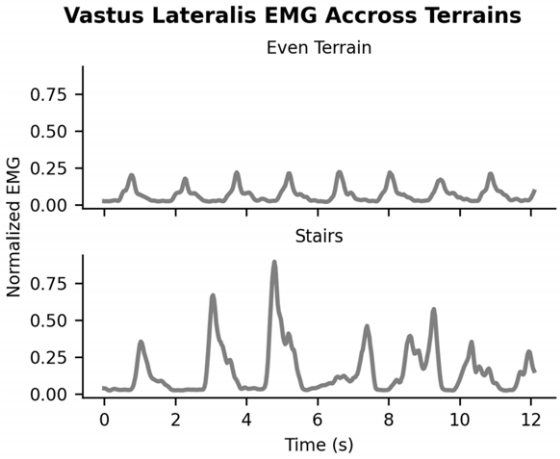

Fig. 3. Representative EMG captured from the VLL muscle from P3 walking on different terrains, showing larger VLL activation on stairs compared to even ground.

E. Analyses and Statistics

Each TD learning method was used to obtain GVFs for EMG, pressure, and goniometer signals as cumulants at multiple time scales: 0.25, 0.5, 1.0, and 2.0 seconds. In total, 360 GVFs were learned in parallel [16]. The γ values were calculated using $\gamma = 1 - \frac{1}{T}$ where $T = fs * timescale$ and were 0.879, 0.940, 0.970, and 0.985, respectively [10]. These time scales capture the immediate and longer-term dynamics of the sensor signals.

The performance of each algorithm was evaluated by comparing the convergence time and the root mean squared error (RMSE) between the expected and predicted returns. [15], [20]. This was done by fitting the learning curve with a single breakpoint piecewise regression, where the second line was fitted to the flat, stabilized error of the learning curve. The x-value, corresponding to timesteps, at 10% along the second fitted line was taken as the convergence time, and the y-intercept was taken as the convergence error. This enabled the assessment of the speed and accuracy of learning GVFs using each TD learning method.

Normality was assessed using the Shapiro-Wilk Test. Data were found to be non-normally distributed; therefore, the Kruskal-Wallis test was used to compare the convergence times and errors between the TD learning methods. Metrics were compared using Dunn's Test with a Holms-Sidak correction to correct for multiple comparisons.

III. Results and Discussion

The time to featurize the data and obtain predictions using GVFs was 9.8 $\pm$ 0.8 ms for TD(λ), 13.9 $\pm$ 0.9 ms for TOTD, and 22.3 $\pm$ 1.6 ms for SwiftTD. Therefore, the computation times allow for real-time implementation within our 33 Hz (30.3 ms) loop time.

A. Sensor Signals Differ Between Different Walking Terrains

As participants walked across the terrains, the sensor signals exhibited distinct differences in shape and amplitude. For example, during stair ascent, larger activations of the VL muscle were required to lift the individual up the stairs (Figure 3). Larger VL activation was additionally associated with an increase in underfoot pressure towards the forefoot and hallux as they pushed off the ball of their foot during stair ascent. Although this was the most noticeable example, there were differences in all signals between terrains.

B. SwiftTD Outperforms TOTD in Convergence Time But Can Have Higher Convergence Error When Learning GVFs

The expected return was compared to the predictions of the raw signal by the TD methods (Figs. 4 and 5). Figure 5 shows the raw signal, expected return, and predicted return from the TD learning algorithms. The expected return represents a temporal abstraction of the cumulative discounted signal, which TD learning methods try to predict [15]. Generally, the expected return anticipated the rise and fall of the raw signal, demonstrating successful signal prediction.

Convergence error and time were derived from RMSE curves, comparing the predicted signal to the expected return for each sensor signal. The predictions for TD(λ) and TOTD were nearly identical (Figure 5), and there was no statistical difference in convergence time and error between both methods; therefore, TD(λ) was excluded from further

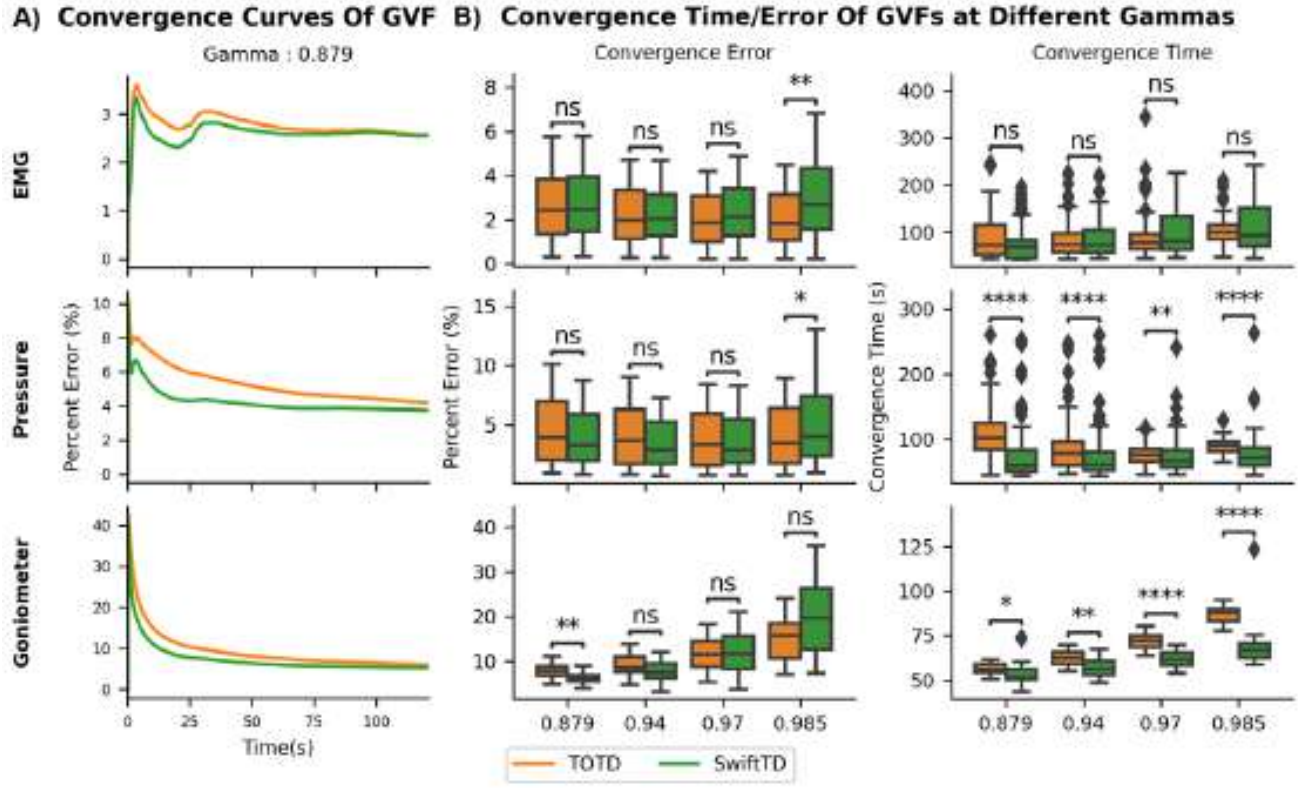

Fig. 4. Convergence error and convergence time performance metrics for evaluating TD learning algorithms. (A) The average RMSE convergence curves for EMG, underfoot pressure, and goniometer signals at the discount factor (γ) of 0.879. Error is reported as the percentage of the maximum cumulant value. (B) Boxplots contain the convergence errors and times for EMG, underfoot pressure, and goniometer signals (ns: $p \geq 0.05$, *: $p < 0.05$, **:$p < 0.01$, ***: $p < 0.001$, ****:$p < 0.0001$). Statistical annotations done using the *Statsannotation* package (v0.2.3) [21]

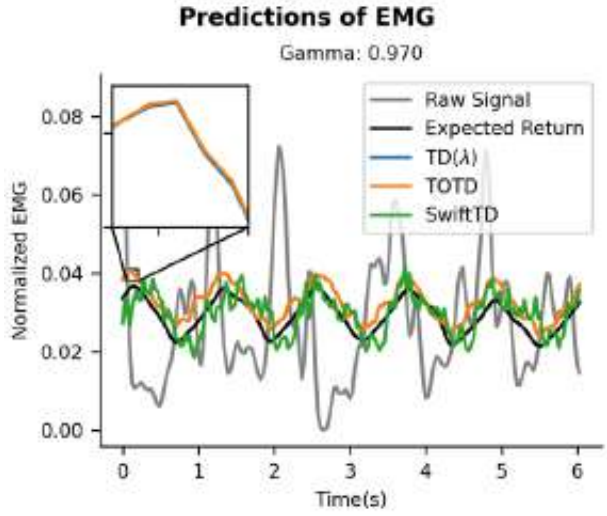

Fig. 5. Comparison of representative EMG signal, the expected return of predictions, and predictions made by three TD learning algorithms (TD(λ), TOTD, and SwiftTD) of P2's TAL muscle. Note the varying degrees of accuracy and anticipatory behavior exhibited by each algorithm compared to the expected return. TD(λ) predictions overlap the TOTD predictions.

analyses, and all comparisons were made between TOTD and SwiftTD. Figure 4A illustrates the convergence curves from TOTD and SwiftTD for three different sensor signals.

For EMG prediction, no significant differences in convergence error were observed across γ values of 0.879 (0.25s), 0.94 (0.5s), and 0.97 (1s) ($p = 0.996$, $p = 0.931$, $p = 0.267$). At γ = 0.985 (2s), however, TOTD demonstrated a 27.0% lower error than SwiftTD ($2.08\% \pm 1.2\%$ vs $2.85\% \pm 1.6\%$) ($p = 0.007$). Convergence times for both algorithms were not different across all γ values ($p = 0.495$, $p = 0.870$, $p = 0.516$, $p = 0.895$). TOTD generally minimized error when learning GVFs on EMG signals with higher γ values. The lack of difference in convergence time indicates that both algorithms sufficiently learned GVFs of EMG signals.

Convergence errors for predicting underfoot pressure were not different across γ values of 0.879 (0.25s), 0.94 (0.5s), and 0.97 (1s) ($p = 0.216$, $p = 0.246$, $p = 0.975$). However, at γ = 0.985 (2s), TOTD outperformed SwiftTD with a 21.4% lower convergence error ($3.98\% \pm 2.50\%$ vs. $5.06\% \pm 3.25\%$, $p = 0.034$). SwiftTD converged faster than TOTD in all cases, with the largest performance increase at γ = 0.879, where SwiftTD converged 33.9% faster ($71.0s \pm 36.4s$ vs $105.5s \pm 40.6s$) ($p = 0.003$, $p < 0.001$, $p < 0.001$, $p < 0.001$). Based on these results, GVFs of pressure signals learned using TOTD at γ = 0.985 minimized the convergence error. For lower γ values, SwiftTD minimized the convergence time with errors similar to those of TOTD.

The most noticeable convergence error difference for predicting joint angle signals was at γ = 0.879 (0.25s), where SwiftTD converged with a 20.5% lower average error compared to TOTD ($6.31\% \pm 1.27\%$ vs $7.94\% \pm 1.58\%$) ($p = 0.009$). SwiftTD converged faster than TOTD in all cases, with the biggest performance increase at γ = 0.985,

with SwiftTD converging faster by 19.1% ($69.7s \pm 13.8s$ vs $86.2s \pm 5.2s$) ($p < 0.001$). These results suggest that a lower γ value of 0.879 for the joint angle prediction task was suitable for minimizing convergence error with SwiftTD. Additionally, SwiftTD excelled in convergence time. For learning GVFs of goniometer signals at higher γ values, SwiftTD minimized convergence time with similar convergence errors compared to TOTD.

These results extend prior work using TD methods for predicting kinetic and kinematic signals [9], [10]. The current work showed that choices in prediction timescale and learning algorithms affect prediction accuracy and learning time of GVFs. Convergence error increased with higher γ values, indicating a potential trade-off between temporal abstraction and prediction accuracy. This highlights the importance of careful algorithm selection and parameter tuning based on the application requirements and type of signal.

Although valuable insights are extracted from this comparative analysis, it is important to acknowledge some limitations. This analysis compared convergence speed and error as primary evaluation metrics, but other factors may be relevant in real-world applications. For example, the computational complexity of each algorithm is not discussed but may be pertinent to real-time implementation. Additionally, the TD algorithms chosen for this comparison were a focused subset of those currently in use. Future studies could add other TD algorithms, such as Gradient TD, for a more comprehensive analysis. Future research will assess the prediction performance across each terrain to understand how a changing environment impacts learning.

IV. Conclusion

There currently remains a gap in empirical evidence regarding the most effective TD algorithms for predicting lower-limb sensor signals during walking. This study assessed the performance of TD learning algorithms for predicting walking-related sensor signals during walking tasks relevant to the control of exoskeletons and related standing-and-walking rehabiltiation technology. As a main contribution, evidence was found in this setting that SwiftTD favors learning efficiency, while TOTD favors learning accuracy. Careful consideration of TD learning algorithms is essential to balance the trade-off between accuracy and temporal abstraction when deployed. Future work includes assessing the impact of TD-learned predictive knowledge online in an exoskeleton controller to provide adequate and timely assistance for individuals with motor deficits. These findings reinforce the idea that an exoskeleton controller integrated with RL could adapt to an individual's unique biomechanics, paving the way for truly personalized assistive technologies.

Effort generation capabilites mapping for personalized robotic assistance of the elbow

Maël Gallois[1], Maxime Manzano[2], Sylvain Guegan [3], Nicolas Vignais [4], Marie Babel [2] and Charles Pontonnier[1]

***Abstract*— This study explores the use of a robotic aid to improve the mobility of people with neuromuscular or neurodegenerative disorders, who have reduced motor skills. It aims to compare the use of either a musculoskeletal model or a torque-angle joint model in a shared control framework of an upper limb exoskeleton in order to assists elbow flexion/extension movements. The method consists of measuring the effort-generating capacities of the elbow using an isokinetic ergometer. Data were then used to calibrate the two models. Both were integrated into an exoskeleton control law to estimate online user isometric capacities during a mass-holding task performed in various positions. Four experimental conditions were compared: without exoskeleton, with exoskeleton without assistance, with assistance computed from the quadratic model and from the musculoskeletal model. In order to test the method against individual variability, the study was conducted with nine participants. The results show a decrease in muscular activity for the biceps in both assistance conditions. In extrapolating effort-generating capacities outside the ergometer's measured range, the musculoskeletal model is more robust than the torque-angle joint model. Its estimations are more consistent with the literature, while torque-angle joint model errors induces unintended triceps activation. In conclusion, this study highlights the potential of combining a musculoskeletal model with shared control for assisting elbow.**

I. INTRODUCTION

Upper limb assistance is essential for individuals with neuromuscular or neurodegenerative disorders, which hinder their ability to perform daily tasks and reduce their autonomy. Robotic assistance can then help restore independence by partially or fully supporting the user's actions.

Currently, shared control is a widely used approach in the field of robotic assistance. This collaborative method involves to share the control responsibility between the human and the robot during task execution. An effective implementation requires accurately interpreting the user's intentions and generating commands tailored to the task and the user's specific needs. Admittance control is a common strategy of shared control for assitive robotic: it adjusts the robot position or velocity in response to the measured interaction forces or torques [1].

However, designing efficient shared control systems requires to adapt the provided assistance to the user capabilities, and can be challenging in particular for users that face multiple mobility impairments. To alleviate this issue, one solution is to accurately estimate the effort-generating capacity of users and take this information into account in the assistive control, thus enhancing user experience [2].

Incorporating user capability estimates into exoskeleton control effectively adapts assistance, as it has been shown in a walking-assistance systems [3]. A similar strategy could benefit upper-limb assistance. In this case, for instance, effort capability estimators have been used in minimal assist-as-needed (mAAN) controllers for static poses [4]. However, the personalization of these estimations in the field of upper limb assistive robotics remains unexplored in the literature.

Nonetheless, works have already been made to represent effort generation capabilities. For example, joint torque generation capabilities have been represented as joint torque-angle relationships [5], specifically as a quadratic function in the case of the elbow [6]. Alternatively, such works have been used to calibrate musculoskeletal models with individualized parameters from experimental measurements [7], [8]. These models could then be used to estimate effort-generating capacities of the user [9]. In turn, these biomechanical representations can be used to personalize robotic assistance.

Here, we aim to integrate a personalized estimator of the user's effort generation capabilities into the shared control of an upper-limb exoskeleton. The objective of this study is then to compare two force capabilities representations, i.e. torque-angle model and musculoskeletal model. For instance, we focused in the context of elbow assistance. In Section II, we present two estimators based on experimental measurements. The first is a quadratic torque-angle model (TAM). The second is a personnalized musculoskeletal model (MSM) based on the Saul et al. upper limb model [10]. Then, a control law derived from these two effort generation capabilities representations is introduced and an experimental evaluation is proposed. Section III presents and discusses the evaluation results. Finally, Section IV provides a conclusion.

II. MATERIALS AND METHODS

This section presents two methods of effort generation capabilities estimators. Subsequently, an assistive control law utilising a effort estimator is described, as well as a proposed experimental protocol.

A. Torque-angle joint model (TAM)

The objective is to obtain the torque-angle relationship of the elbow. This requires to measure the maximum isometric

torque τ_{isom} in flexion ($\tau_{isom} > 0$) and extension ($\tau_{isom} < 0$) over the joint amplitude. Directly measuring isometric torque for each position in the workspace is time-intensive and may cause significant fatigue for the participant. To optimize the process and limit fatigue, we proposed to conduct isokinetic tests, i.e. at a constant speed. However, as muscles capacities are non-linearly coupled with speed values, these tests inherently alter the elbow torque values. To address this issue, we performed tests in two distinct configurations for each direction of efforts (flexion and extension), namely concentric (effort in the direction of movement) and eccentric (effort opposing the movement). These measurements τ_{mes} are obtained using an isokinetic ergometer (see Figure 1), a device designed for rehabilitation that measures joint capacities using a torque sensor aligned with the rotational axis of the participant's joint. The ergometer imposed a constant speed of 30 degrees per second, which was considered to be sufficiently low to ensure a near-linear relationship between torque and speed variation [5]. This linearity allowed us to approximate the isometric torque curve by averaging the results of both concentric and eccentric tests. Each of the four configurations was repeated three times, and for each elbow angle, we retained the maximum value measured.

Fig. 1. The isokinetic ergometer used for joint torque measurements (ConTrex, Medimex).

The experiment was validated by the Operational Committee for the Evaluation of Legal and Ethical Risks (COERLE) of the Inria institute. Nine participants took part in the study (height in cm: 175.3 ± 5.4, weight in kg: 70.3 ± 9.54, age in years : 25.8 ± 8.6). The joint range of elbow motion varied between participants, with a mean range of 60.2±3.2 to 126.8±5.8 degrees. Using the collected data, we fit two quadratic TAMs to the experimental isometric torque curves for both flexion and extension

B. Personnalized musculoskeletal model (MSM)

The MSM is composed of two layers. The first layer consists of an osteoarticular model describing geometrical and inertial properties of the upper limb. It is represented as a two-dimensional system composed of three rigid bodies: the trunk (considered as a fixed reference frame), the arm, and the forearm/hand. These rigid bodies are connected by two revolute joints, simulating the flexion/extension motions of the shoulder and elbow. The joint angles are denoted as q_1 (shoulder) and q_2 (elbow).

The second layer of the MSM is the actuation model, consisting in muscles lines attached to the osteoarticular model. The muscles behavior is based on the Hill-Zajac model [11], ans the model incorporates $N_m = 12$ muscles. Their insertion points and physiological properties following the description made by Saul et al. [10]. Each muscle line $j \in \{1; N_m\}$ is composed of three elements:

- a passive element modeling the tendon with a length of l_{sj}, assumed to be non-deformable to reduce computational complexity;
- an active element of lenght l_{mj} represents the contractile active force generated by the muscle F_{aj};
- parallel to the active element, a nonlinear spring models the passive properties of the muscle fiber producing F_{pj}.

The total muscle line j force is therefore $F_{aj} + F_{pj}$, and its total length is $l_{mj} + l_{sj}$.

Muscle lengths vary according to the position of the osteoarticular model. The force-length characteristic is defined by its maximum voluntary force F_{0j}, and the muscle length at which it can be produce, i.e. the optimal muscle fiber length l_{0j}. We define $\tilde{l}_{mj} = \frac{l_{mj}}{l_{0j}}$ as the normalized muscle fiber length. As did [12] and [7], we also defined the minimum (resp. maximum) length of the force-length characteristic: $\tilde{l}_{minj}$ (resp. $\tilde{l}_{maxj}$). This two length parameterize the shape of the characteristic without modifying the anatomic values of l_{0j} and l_{sj}, so that

$$F_{aj}(\tilde{l}_{mj}) = \begin{cases} F_{0j}\left(\frac{\tilde{l}_{minj}^2(\tilde{l}_{minj}-3)}{(\tilde{l}_{minj}-1)^3} + \frac{6\tilde{l}_{minj}}{(\tilde{l}_{minj}-1)^3}\tilde{l}_{mj} - \frac{3(\tilde{l}_{minj}+1)}{(\tilde{l}_{minj}-1)^3}\tilde{l}_{mj}^2 \right. \\ \qquad \left. + \frac{2}{(\tilde{l}_{minj}-1)^3}\tilde{l}_{mj}^3\right) \qquad \text{if } \tilde{l}_{mj} < 1 \\ F_{0j}\left(\frac{\tilde{l}_{maxj}^2(\tilde{l}_{maxj}-3)}{(\tilde{l}_{maxj}-1)^3} + \frac{6\tilde{l}_{maxj}}{(\tilde{l}_{maxj}-1)^3}\tilde{l}_{mj} - \frac{3(\tilde{l}_{maxj}+1)}{(\tilde{l}_{maxj}-1)^3}\tilde{l}_{mj}^2 \right. \\ \qquad \left. + \frac{2}{(\tilde{l}_{maxj}-1)^3}\tilde{l}_{mj}^3\right) \qquad \text{if } \tilde{l}_{mj} \geq 1 \end{cases} \tag{1}$$

for active forces, and

$$F_{pj}(\tilde{l}_{mj}) = \begin{cases} 0 \qquad \text{if } \tilde{l}_{mj} < 1 \\ F_{0j}\left(\frac{5}{4(\tilde{l}_{maxj}-1)^2} - \frac{5}{2(\tilde{l}_{maxj}-1)^2}\tilde{l}_{mj} + \frac{5}{4(\tilde{l}_{maxj}-1)^2}\tilde{l}_{mj}^2\right) \\ \qquad \text{if } \tilde{l}_{mj} \geq 1 \end{cases} \tag{2}$$

for passive forces. The figure 2 shows the normalized characteristic behavior of this Hill-Zajac model. Then, each muscle $j \in \{1; N_m\}$ exerts a torque around joint $i \in \{1; 2\}$ defined as

$$\tau_{i,j}^{model} = \left[F_{aj}(\tilde{l}_{mj}) + F_{pj}(\tilde{l}_{mj})\right]\frac{\partial l_{mj}}{\partial q_i}. \tag{3}$$

In order to personalize this MSM, two successive steps were implemented. First, segment and muscle paths were scaled simultaneously, adjusting muscle length parameters (l_{0j} and l_{sj}) to match participant segment sizes (Figure 3). Maximum voluntary forces F_{0j} were then linearly adjusted based on the initial Saul model's torque maximal capacity and the ergometer's maximal measured torque, ensuring consistency between model geometry and muscle capacities. The scaling used the same measurements as those defining the TAM in II-A.

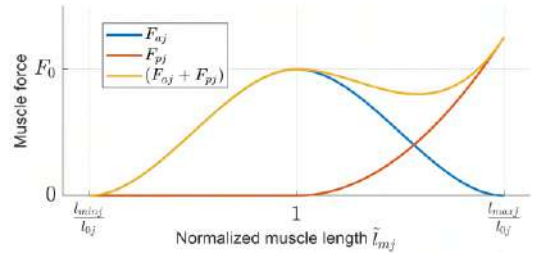

Fig. 2. Normalized force-length characteristic of a muscle line model [7].

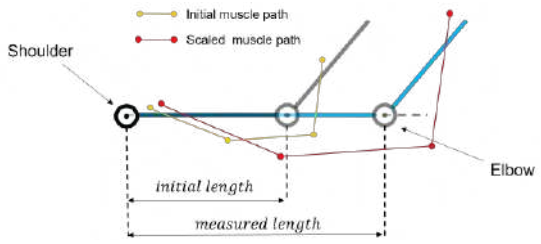

Fig. 3. Schematic diagram of arm scaling and muscle pathway scaling.

The second step consists of calibrating muscle parameters $\tilde{l}_{minj}$ and $\tilde{l}_{maxj}$ using ergometer torque measurements. This involved an optimization process to minimize the difference between the measured torque τ_{mes} and the MSM estimated muscle torques around the elbow, such that

$$\min_{\mathbf{F_0},\tilde{\mathbf{l}}_{\mathbf{min}},\tilde{\mathbf{l}}_{\mathbf{max}}} \left(\tau_2^{model} - \tau_{mes}\right)^2, \quad \text{with } \tau_2^{model} = \sum_{j=1}^{N_m} \tau_{2,j}^{model}. \quad (4)$$

$\{\mathbf{F_0}, \tilde{\mathbf{l}}_{\mathbf{min}}, \tilde{\mathbf{l}}_{\mathbf{max}}\} = \{(F_{0j}), (\tilde{l}_{minj}), (\tilde{l}_{maxj})\}_{i=1}^{N_m}$ are the optimisation variables. As they do not have the same same order of magnitude, we successively optimized the length parameters and the force parameters until the problem converged.

C. Assistance control law

The control scheme employs an admittance filter for torque control. Furthermore, two modes have been implemented: transparent and assisted.

Transparent mode, as defined by W. van Dijk et al. [13], eliminates the interaction forces between the user and the robot, ensuring the robot does not resist against user movements. To do that, two strategies are discussed in the literature [14]. The first aims to compensate the dynamics of the exoskeleton. In this work, only the exoskeleton gravity $\mathbf{G}(\mathbf{q})$ was computed and compensated. The second strategy is to use force measurement to impose a zero interaction force. The control scheme shown in figure 4 was therefore used for this work, where J is the exoskeleton Jacobian. In the case of transparent mode, the reference torque input τ^* is set to 0.

The assisted mode (with a non zero τ^*) aimed to provide assistance according to the effort required by a task, in order to limit the user's contribution to a predefined percentage of their maximum force. The torque required for the task τ_{task} was estimated statically with

$$\tau_{task} = g(m_{obj}L_f + m_f L_{fmc}), \quad (5)$$

knowing the mass of the object carried by the user m_{obj} and the mass of his forearm m_f. The forearm length L_f was measured at the start of the experiment and the lever arm of the forearm's center of mass L_{fmc} was known from the osteoarticular model. g is the gravity acceleration.

The assistance principle is illustrated in Figure 5 and is obtained by computing

$$\tau^* = \begin{cases} 0 & \text{if } |\tau_{task}| < 0.03 \times |\tau_2^{model}| \\ \tau_{task} - 0.03 \times \tau_2^{model} & \text{otherwise.} \end{cases} \quad (6)$$

This combines the advantages of a transparent mode (preserved user control) and a physical assistance (reduced fatigue). We set this threshold at 3% of the maximum voluntary force τ_2^{model} estimated by either the TAM or MSM. This threshold is lower than the recommendations of [15], which suggest a maximal value of 10% to avoid fatigue. This value remains then completely adjustable. Effort generation capacities are then estimated in real time using either the TAM or the MSM according to equation (3).

D. Experimental setup

Nine participants, whose elbow torque generation capabilities were measured (II-A), sat in a stationary power wheelchair on which the exoskeleton is attached. The setup included an optoelectronic motion capture system (Nine Qualisys Miqus) sampled at 100 Hz. Fifteen markers, each with a diameter of 14 mm, were placed on the participant at standardized anatomical landmarks following the guidelines of the International Society of Biomechanics [16]. The exoskeleton is capable of assisting the abduction of the shoulder and the flexion of both the shoulder and the elbow [17]. In the present case study, shoulder movements are locked. Figure 6 illustrates the experimental setup. In addition, electromyographic sensors (EMG) were placed on the following muscles, according to the SENIAM standard [18]: Triceps Long Head, Anterior Deltoid, Posterior Deltoid, Medial Deltoid, Biceps. These sensors operated at 1259Hz. Once installed in the wheelchair, the participant's arm was positioned in the exoskeleton using a 3D-printed support in which the arm rests, and the forearm was positioned using a 3D-printed orthosis. A screen was positioned in front of the participant. This screen displayed feedback on the angular position of the elbow and a target zone. For position feedback, data from the encoder of the exoskeleton were used. The position feedback delay was less than 20ms. The control was fully implemented in a dSPACE system running at 5 kHz. Motion capture and EMGs were not used for control, but only for evaluation. F_{mes} is measured with a NF742 force sensor.

Participants were asked to perform a task involving moving/holding a cylindrical object with a mass of 1kg. The set trajectory comprised five consecutive 10 seconds steps at 20°, 60°, 100°, 60° and 20°. It was performed in 4 configurations:

- No-Exo mode: the participant performs the task without the exoskeleton;
- Transparent mode: the reference torque τ^* is set to 0;
- Torque-Angle based Control (TAC) mode: the reference torque τ^* is computed from the TAM;

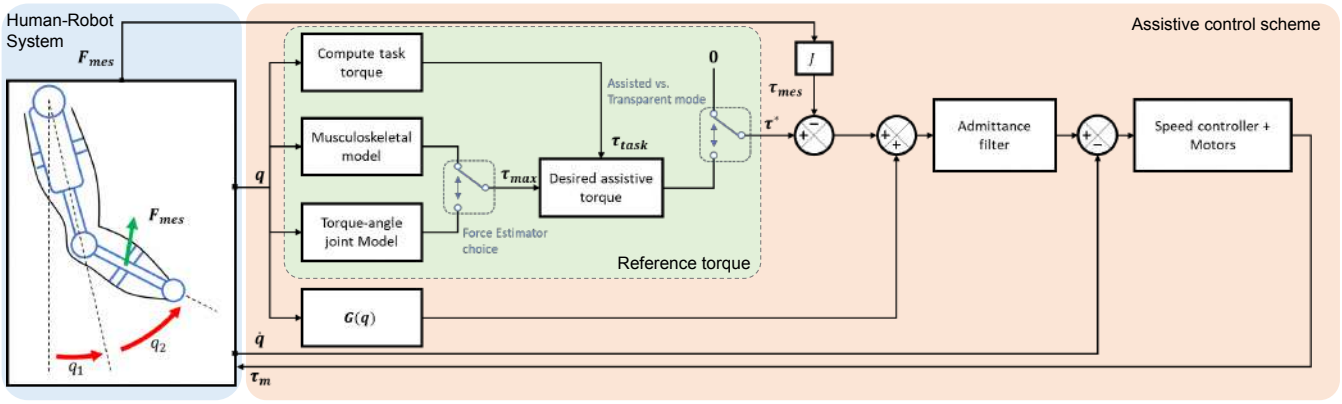

Fig. 4. Architecture of the assistive control. Human-robot interaction force is measured for torque control, and robot gravity is compensated. J is the exoskeleton Jacobian.

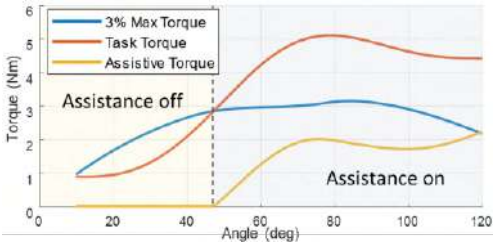

Fig. 5. Principle of the assistance provided by the exoskeleton according to the torque required by the task.

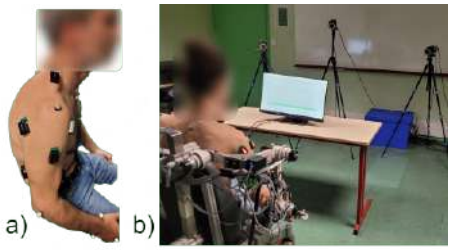

Fig. 6. a) Six EMG on arm and shoulder muscles and markers. b) Experimental setup. The participant is positioned in the exoskeleton, which is mounted on an power wheelchair. A display shows the angle to be reached with feedback on the position in real time.

- Musculoskeletal based Control (MSC) mode: the reference torque τ^* is computed from the MSM.

E. Data processing

The EMG data were rectified and filtered with a Root Mean Squared (RMS) filter to obtain the signal envelope with a 500ms window. The filter window was deliberately chosen to correspond to slow or static tasks, as recommended in the literature [19]. For each participant and for each EMG sensor, the signal was normalized to the highest value of the envelope recorded during the No-Exo test.

Data from the optoelectronic system were converted into joint angles using the OpenSim software [20]. The osteoarticular model used for this step is the one developed by Seth *et al.* [21]. This kinematic model enables the investigation of potential shoulder translational motion when the subject wears the exoskeleton.

An estimate of the torque provided by the participant was made by taking the difference between the torque of the task τ_{task} and the measurement of the torque exerted by the exoskeleton. It is given by

$$\tau_p = \tau_{task} - \tau_{mes}. \tag{7}$$

All the data set was temporally normalized over the duration of one repetition of the task. As the timing was imposed, identically lasting 50 seconds.

Finally, we conducted a statistical analysis for each of the levels (20°, 60°, and 100°) to compare the control modes. According to the Shapiro-Wilk test, the distribution of the data was not normal ($p > 0.15$). We therefore compared the situations two by two using a Mann-Whitney test.

III. RESULTS AND DISCUSSIONS

Figure 7 displays the personalized MSM parameters $\{\mathbf{l_s}, \mathbf{l_0}, \mathbf{F_0}\}$ for the elbow muscles. The parameters' values remained consistent with to the parameters defined in the Saul model [10] and with values reported in the literature. However, the triceps muscles appeared to be more powerful (bigger F_{0j}) in our study compared to those described in the Saul model. This inconsistency was likely due to the testing position in the ergometer, in which participants were able to lean against the machine, artificially increasing the measured torque values. Figure 8 illustrates the mean estimated torques for the MSMs and TAMs. The torque-angle relationships generated by the two estimators were closely aligned within the range of experimental measurements. However, outside this range of measures, the estimations given by the two models divergeds. Near the lower limit of elbow joint motion, the TAM produced inconsistent effort-generating capacities, even changing sign for some participants. In contrast, the MSM exhibited a curve shape that is more closely aligned with the original Saul model that appears to be consistent with the actual capabilities of the elbow [5].

Figure 9 illustrates the estimated torque results for the participants. In both assisted configurations (TAC and MSC), as expected, the average torque supplied by the participants was lower than the one provided in the transparent configuration. During static phases, the 3% user effort limit was better maintained compared to the dynamic phases. Indeed one of the main challenges of admittance control is improving reactivity while ensuring stability, as noted by [1].

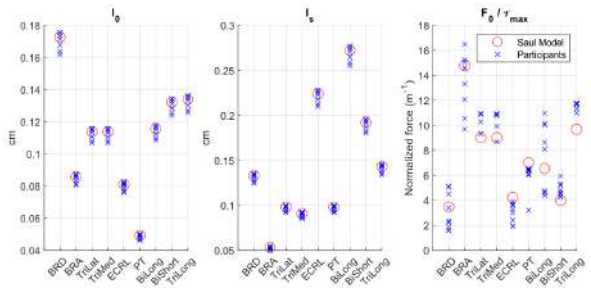

Fig. 7. Muscle characteristics of customized MSMs for muscles acting on the elbow. For each participant, each F_0 parameter is normalized to the maximum torque τmax that a participant can produce. Muscles are Brachioradialis (BRD), Brachialis (BRA), Triceps Lateral head (TriLat), Triceps Medial head(TriMed), Extensor Carpi Radialis Longus (ECRL), Pronator Teres (PT), Biceps Long head (BiLong), Biceps Short head (BiShort) and Triceps Long head(TriLong).

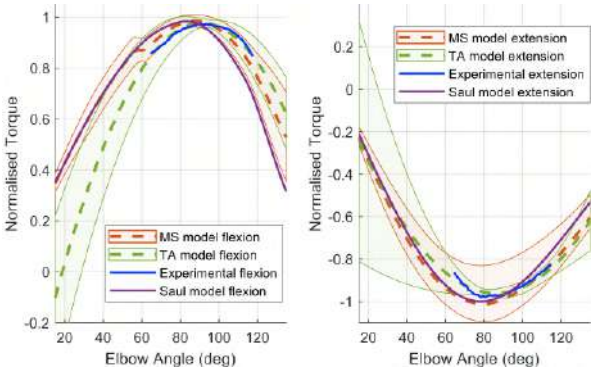

Fig. 8. Torque-angle relationships in flexion (left) and extension (right) obtained from the ergometer measurements. Torque is normalized by its maximum value, then averaged over all participants. Standards deviations of the MSM and TAM are plotted as a zone.

Figure 10 illustrates the mean EMG envelopes for biceps and triceps during the normalized cycle. The capacity estimators' values also differed, particularly at low elbow angles: this deviation was reflected in the biceps EMG envelopes. A low threshold has been set to highlight the effects of control, but it could be personalized depending on the endurance/fatigue of each individual or based on ergonomic criteria. The EMG data indicated increased triceps activation in the assistance with TAC, with this effect being more pronounced at low elbow angles. This may be explained by the fact that the torque estimator tended to over-assist the task by pushing the forearm upwards when it underestimated the effort-generating capacity for flexion. This imbalance shifted the workload between the flexor and extensor muscles, requiring the extensors to compensate by pulling the forearm down. The MSC therefore has a more robust behavior outside the model calibration range, and therefore a wider validity range. As illustrated in Figure 11, the statistical study of the biceps EMG reveals a significant decrease when comparing the TAC and MSC modes with the No-Exo mode.

In the transparent configuration, the EMG envelopes for the biceps and triceps were lower compared to the No-Exo configuration, despite the fact that the transparent mode was not assisting the user. Figure 12 illustrates the EMG envelopes for the shoulder deltoids. A similar reduction was observed for the anterior (DA) and medial (DM) deltoids.

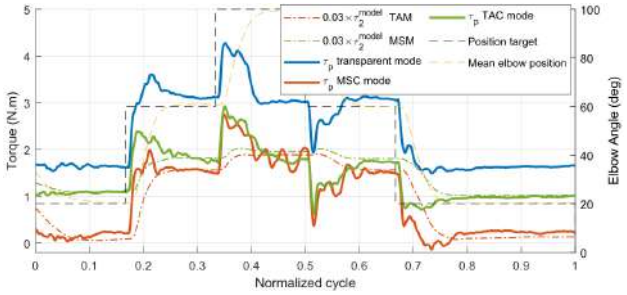

Fig. 9. Limit torques ($0.03 \times \tau_2^{model}$) averaged over all participants for TAM and MSM estimators. τ_p is averaged over all participants for transparent, TAC and MSC modes as a function of the normalized cycle.

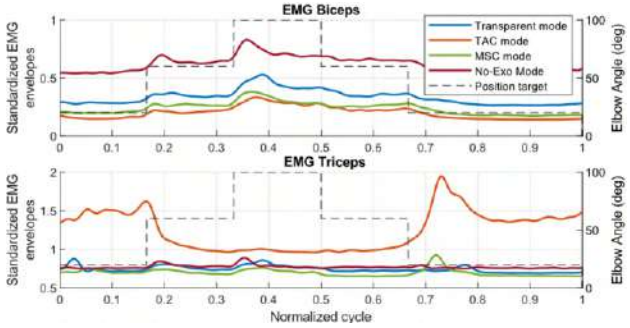

Fig. 10. EMG envelope averages for biceps (top) and triceps (bottom) and for each of the transparent, TAC, MSC and No-Exo modes.

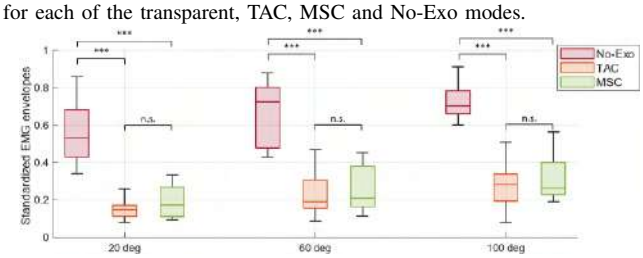

Fig. 11. EMG biceps results across the angles target and the control modes. The p-value of the Mann-Whitney test is indicated : '***' mean $p < 0.001$; 'n.s.' mean 'not significant' and $p > 0.2$.

In contrast, the posterior deltoid (PD) was more active with the exoskeleton. This can be explained by two factors: 1) the exoskeleton passive structure supported the shoulder,thus altering muscle stabilization, and 2) joint angle reconstruction showed differing shoulder positions between conditions (Figure 13), thus affecting muscle force capacity and complicating EMG comparisons. The reduction in EMG envelopes between transparent and assisted modes is therefore a more accurate representation of the assistance provided.

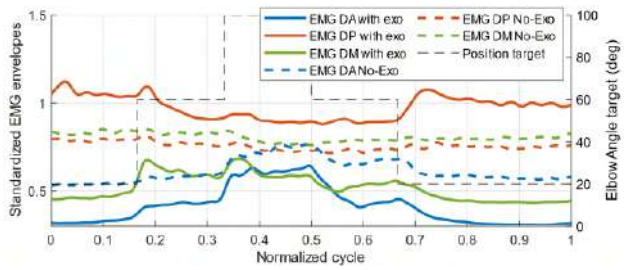

Fig. 12. EMG envelope averages normalized for Deltoid Anterieur (DA), Deltoid Medial (DM) and Deltoid Posterieur (DP) with the exoskeleton and whitout (No-Exo mode).

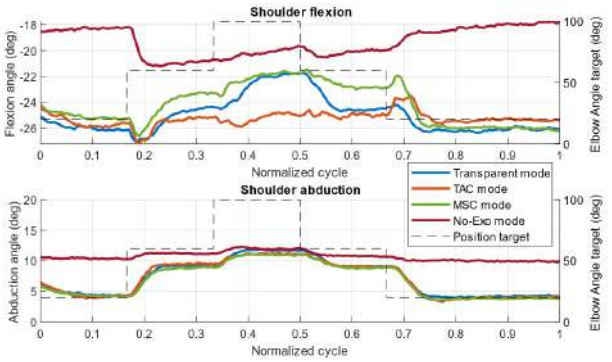

Fig. 13. Averaged shoulder flexion (top) and extension (bottom) for all participants and for each of the transparent, TAC, MSC and No-Exo modes.

Other limitations may be considered in this work. First, this study focused solely on static estimation. Effort generation capabilities are known to change dynamically during motion [11], and it raised issues in the admittance control during movement phases. A more accurate detection of intention therefore is then necessary. In addition, dynamic assistance requires on-line estimation of the user's kinematic state, that could be achieved by a reconstruction using inertial units or using a recurrent neural network or using a recurrent neural network for example. Secondly, the comparison between the joint model and the MSM was restricted to a single joint. As noted by [5], [6], the elbow torque capacity is significantly influenced by the shoulder position. However, linking joints within an articular model with a reasonable number of measurements is challenging. Consequently, MSMs may perform better when multiple joints are considered simultaneously. Lastly, we assumed a known object mass throughout the study. In real-world applications, estimating the mass of the object directly from the exoskeleton measurement will be essential. An auto-calibration phase could solve this problem in the future. Another possibility would be to use a sensor dedicated to the recognition of the grasped object, such as a force sensor in the hand or a RGBD camera [22].

IV. CONCLUSION

Incorporating an effort-generating capacity estimator into shared control systems allows for assistance tailored to the user's needs. Here, we compared two estimators: torque-angle joint model and musculoskeletal model. Both estimators were designed using an assistance control and evaluated with nine participants. The results showed similar performance when movements rely within the calibration range. However, outside this range, the torque-angle joint model proved less robust results than the musculoskeletal model, leading to unintended demands on antagonistic muscles. This preliminary study highlights the limitations of the torque-angle model and highlights the advantages of adopting more sophisticated approaches, such as musculoskeletal modeling.

***Abstract*—During daily life activities we not only gather information regarding the environment, but also regarding other humans which are performing similar actions. Even if not specifically required by the task, people affect other motion plans through different sensory modalities and may align their plans in a subtle way even if not required. This study explores the role of visual and auditory feedback in tasks with a sensory connection between partners. We used a dual robotic interface to test various visual and auditory coupling modalities, translating the spatial dynamics of the partners into distinctive feedback. Results from visual experiment showed that the explicit representation of the partner position along with own position greatly improves coordination between them. The auditory experiment emphasized the effectiveness of binaurally presented spatio-temporally discrete auditory cues. The current study provides insights relevant to the design of novel enriched rehabilitative protocols which rely on the mechanisms underlying interaction.**

***Index Terms*—Emergent coordination, planning, visual coupling, auditory coupling**

I. Introduction

The exchange of sensorimotor information between humans is crucial to efficiently interact and succeed in achieving a shared goal [1], [2]. For instance, during rehabilitation, a therapist communicates verbally while assessing the patient's posture and movements through vision and feels their strength through haptics. Coordination was found in joint action, but not in parallel action [3], suggesting that participants that receive visual information regarding the partner's action represents a collective goal motorically. However, even if people are not interacting in a joint task with a partner, it has been found that humans unintentionally coordinate their movements when performing rhythmic tasks facing a partner who is doing the same task [4]–[6]. Therefore, people observing the other people tend to imitate them even when not required by the task [7].

When pairs of participants, unaware of being interacting with another person in a reaching task, had incompatible subgoals [8], [9], the addition of the visual feedback, regarding the other agent, to a haptic connection greatly increase motor plans coordination. Also, in rehabilitative settings [10] dyads of patients and healthy individuals as well as healthy-healthy dyads coupled by visual link displayed on a screen coordinated in a force production game using sensor-based GripAble devices.

While much research demonstrated the role of visual and haptic cues in interaction [11], the role of auditory cues still needs to be explored.Non-speech sounds are information-rich, yet unintrusive way to communicate in interactive settings [12]. However, auditory cues may convey subtle information which affect others' motion plans even if not required to or necessary.

Music theory informs how different sound elements – such as tempo, rhythm, pitch, and harmony – can be manipulated to create various types of auditory feedback. Each feedback type carries distinct implications for cognitive processing and motor coordination [13], [14]. Stroke rehabilitation may benefit from a deeper understanding of how auditory feedback regarding others' action affect individual motor plans. Music and robot-aided therapy can significantly benefit motor training within the rehabilitation context [15].

This work aims at investigating the impact of visual and auditory feedback, from another person action, on individual motor plans.

We conducted two experiments to study various types of visual and auditory representations of partner during a via-

This research was supported by ICT 871803 CONBOTS, the Italian Ministry of Research, under the complementary actions to the NRRP "Fit4MedRob - Fit for Medical Robotics" Grant (# PNC0000007), and IES 2\232331 International Exchange Grant of The Royal Society.

point motor task. We investigate (i) whether the presence of visual or auditory information about the partner increases the motor plans alignment in space and time;(ii) which type of feedback leads to better coupling; and (iii) which feedback is preferred by participants the two modalities.

II. Materials and Methods

A. Participants

All participants signed the consent form before starting the experiment. We recruited a total of 20 participants (aged $21-34$ yo). Ten performed in the visual experiment and ten in the auditory experiment.

B. Experimental apparatus and protocol

The experimental setup consisted of two 2-DoF haptic interfaces (H-Man, Articares [16]), each with a separate control computer and a 28-inches LCD display for the presentation of visual feedback - see Figure 1a. Participants were seated in front of their individual planar robotic interface H-MAN and were separated by a curtain. They wore a noise-cancelling headset to prevent any auditory communication beside the presented sounds for the auditory group.

Each trial began with participants positioning their handle at a starting point, demarcated by a red arrow. After receiving the 'Go!' signal they were instructed to execute planar point-to-point movements, through four via-points in a clockwise direction, before returning to the initial starting position.

The protocol is presented in Figure 1b. In the first familiarization phase of 12 trials, participants received a visual cue representing a possible trajectory that they could use to solve the task. The displayed trajectory was different for the two players to manipulate their individual motor plans. For one subject, a 'circle' shape, and for the other – a 'diamond' shape was presented - see Figure 1a. In this initial phase, they received no sensory feedback from the other participant. In the auditory experiment, during this familiarization,in addition to the visual cue regarding a possible trajectory and the visualization of own moving cursor, participants were cued with an ambisonic pink noise that correlated with their cursor position.

After the familiarization phase, the training phase began (a total of 144 for visual and 96 for auditory). In the visual experiment we tested six visual feedback. While in the auditory we tested four conditions in a corresponding number of blocks. Each block consisted of a training part (18 trials), in which participants received either visual or auditory feedback, regarding their partner's position, and a wash-out part (three trials) without a connection with the partner. Wash-out trials in the auditory study included ambisonic pink noise. After the coupled phase and the wash-out, a post-test consisting of three trials without any visual or auditory feedback but in which the trajectory cue was presented again as in the familiarization. After completing all trials, participants in the two experiments ranked all forms of visual/auditory feedback, measuring their preferences among modalities.

C. Visual feedback conditions

We explored six different types of visual feedback representing the partner's position during a joint via-point task (see Figure 1c). These visual feedback conditions were designed to assess how different visual cues and the amount of information they provide about the partner's actions can influence joint coordination. The order of the visual modalities V1 to V6 was specified as shown in Figure 1c.

In the *'Cursor'* condition, (V1 in Figure 1c), the subjects' own hand position was represented on the screen as a green cursor. This minimal visual feedback was introduced as a control, to assess the participants' behavior in the absence of further visual information about the partner. In the *'Cursor + Line'* condition (V2 in Figure 1c), in addition to the cursor representing the player's position, a grey line was shown, indicating the distance and orientation between the participant and the other player.

In the third condition, called *'Cursor + Cloud'* (V3 in Figure 1c), participants saw their cursor and a noisy representation of the distance between partners visualized as a cloud of eight gray randomly moving dots, which introduced greater uncertainty on the perception of the partner's position as in [17].

The fourth to sixth conditions introduced a more complex visual feedback by adding specific information about the partner's position. In *'Cursor + Cursor'* (V4 in Figure 1c), participants could see two separate cursors representing the positions of the two players' hands position - the player's position in green and the partner's in gray. In *'Cursor + Line + Cursor'* condition (V5 in Figure 1c), participants could see a line representing the distance between the two players and a cursor for each player. Finally, in *'Cursor + Cloud + Cursor'* condition (V6 in Figure 1c), participants could see the two cursors representing the players positions on the workspace together with a points cloud, representing the distance between the two subjects with greater uncertainty respect to V5.

D. Auditory feedback conditions

We tested four different auditory conditions. Each mode presented unique auditory feedback which was chosen based on existing theories about the relationship between auditory stimuli and human behavior. The order of the four auditory conditions was specified, with similar modalities grouped together, and temporal and pitch-dependent tasks spaced out.

In the *Distance Pitch Dissonance* condition (A1), the distance between the two partners' positions is translated into dissonance between two pitches, achieved using three sine wave oscillators. When the distance is zero, the three pitches are identical, resulting in the perception of a single, stable pitch. As the distance increases, the pitches are detuned to increase dissonance. This design choice relies on the understanding that adults typically associate consonance with pleasantness and dissonance with unpleasantness [18]–[22]. Therefore, the increasing dissonance may be an intuitive signal for the subjects to adjust their positions.

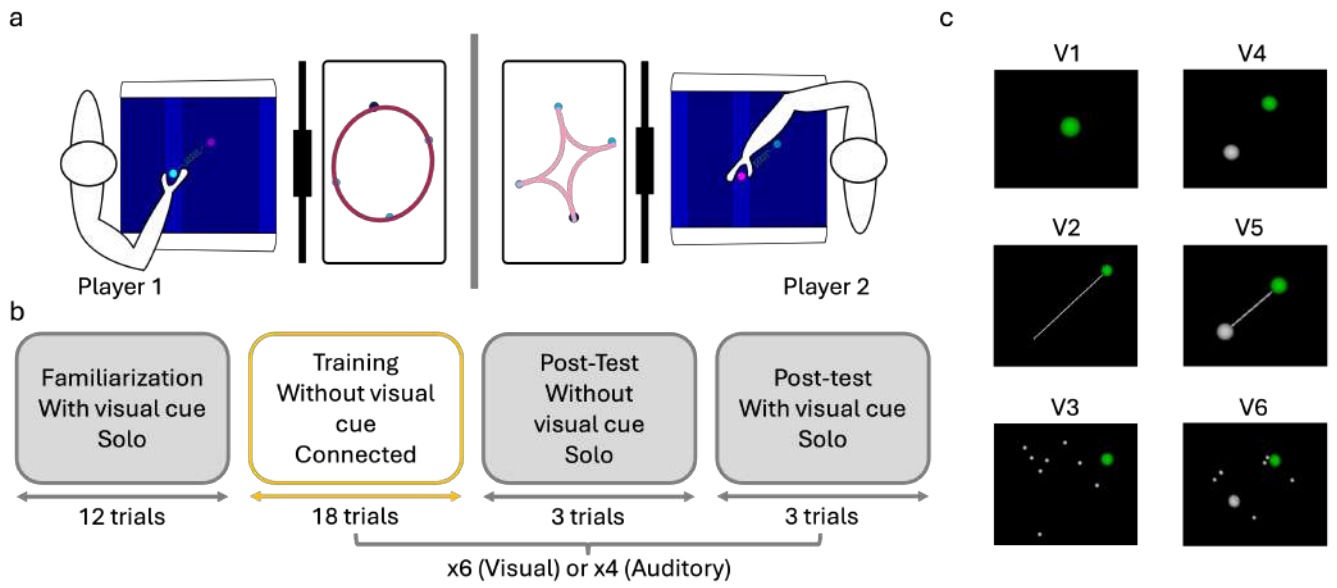

Fig. 1. Set-up and protocol. a) Two participants sat in front of a computer screen and a planar manipulandum. Participants were asked to perform reaching movement using the robotic handle from a start point (dark blue point on the left), by crossing a sequence of via-points in a clockwise order and finishing the movement at the endpoint (start point = endpoint). b) The protocol consists of a familiarization phase (12 trials) during which players receive a visual cue of a suggested solution ('circle' or 'star') before the 'Go!' signal. During the training phase players performed the same task without a solution cue, and with different visual/auditory feedback from their partner. During the post-test phase, players were not connected. This phase was divided into 3 trials without and 3 trials with the initial visual cue of a solution. c) Six modalities for visual feedback of the partner's positions. In V1 own cursor in green is shown. In V2 and V3 in addition to their own cursor a grey line and a cloud of dots, indicating the distance between the partners, are added respectively. In V4 own (green) and partner (grey) cursors are displayed. In V5 and V6, the two cursor configurations and a grey line (in V5) or a cloud (in V6) are displayed.

Visual Mode	**Input**	**Visual Cue**
V1) Cursor	own hand position	continuous cursor movement
V2)Cursor + Line	own hand position and partner hand position	own cursor and an attached line directed toward partner's hand position, whose length depends on distance from partner, are continuously displayed during the motion
V3) Cursor + Cloud	own hand position and partner hand position	own cursor and a dots' cloud directed toward partner's position, whose spread depends on distance from partner, are continuously displayed during the motion
V4) Cursor + Cursor	own hand position and partner hand position	own and partner's cursors are continuously displayed during motion
V5) Cursor + Line + Cursor	own hand position and partner hand position	own and partner's cursors are continuously displayed during motion and are linked by a line connecting the two
V6) Cursor + Cloud + Cursor	own hand position and partner hand position	own and partner's cursors are continuously displayed during motion and linked by a cloud of dots connecting the two

TABLE I
VISUAL FEEDBACK SUMMARY

In the *Distance Rhythmic Synchrony* modality (A2), the distance of the subjects' hand position correlates with changes in rhythmic synchronization achieved using a stereo percussive drum loop. When the distance is zero, the drum rhythms synchronize, resulting in a coordinated and musical pattern. As the distance increases, the signal in the right ear delays progressively, leading to an increasingly chaotic and unmusical rhythm. This design is grounded in the understanding that humans inherently perceive a regular pulse or beat in an auditory signal, a phenomenon referred to as 'tactu' in music theory, which aids in synchronizing movements with each other [23]. Furthermore, the salience of a pulse sensation, which is most prominent at moderate tempos, plays a crucial role in distinguishing musical rhythm from nonrhythm [24]. As such, manipulating the salience of the pulse sensation through the synchronization or desynchronization of the drum loop could significantly impact the subjects' perception of rhythm and their ability to coordinate their actions.

The *Target Impact Chime* condition (A3) employs a distinct bell sound when participants cross via-points. In particular, upon crossing a via-point, participants hear a distinct bell sound tuned to specific pitches: C3 for own crossing and E3 for the partner's crossing. Chimes are spatially presented through the application of ambisonics, allowing participants to distinguish the pace-based positioning of one another. The central hypothesis is that introducing discrete-time visually-linked auditory stimuli can increase spatial consciousness and rhythm in a joint task. The efficacy of such a mechanism relies heavily on the concept of crossmodal interactions and the consequential influence that auditory stimuli can impose on spatial perception. Increasing attention is being given to

exploring multisensory integration and the co-influence of auditory and tactile senses in spatial and non-spatial domains [25]–[29].

In the *Speed-Adaptive Tempo* condition (A4), each participant's progressing along path dynamically modulates a rhythmic drum beat's tempo. Those advancing faster experience a slowing drum tempo, signaling the need to decelerate and maintain synchrony with their partner. Conversely, those lagging, hear a progressively quickened drum beat, suggesting to fasten their pace. The change in tempo is scaled to the distance between the participants, creating a sonically intuitive guide for movement coordination. Previous studies [30] observed that faster music could lead subjects to cover longer distances on an exercise bike. Conversely, slower beats led to diminished walking distances [31], illustrating the direct impact tempo can have on the velocity of physical motion. Also, background music's speed can dictate the pace of motor behaviors [32]–[34].

Auditory mode	**Input**	**Auditory cue**
A1) Distance Pitch Dissonance	distance between hands position	sine wave frequencies alignment
A2) Distance Rhythmic Synchrony	distance between hands position	drums rhythms synchronization
A3)Target Impact Chime	discrete via-points crossing events	bell sound with different pitches for the two players
A4)Speed Adaptive Tempo	reciprocal velocity differences	continuous rhythmic signal

TABLE II
AUDITORY FEEDBACK SUMMARY

E. Coordination Metrics

To investigate temporal and spatial coordination within dyads, we analyzed asynchrony and Dynamic Time Warping (DTW). *Temporal asynchrony* assessed the synchronization of the times of crossing start and via-points. For each player i, with $i = \{1, 2\}$, the via-point j crossing time CT_{ij}, with $j = \{1, 2, 3\}$, was calculated as the time in which the player reached the (minimal) distance D_{ij} from via-point. We computed the absolute value of the differences of start time $\Delta ST = |ST_1 - ST_2|$ and the differences for each crossing time at each via-point $\Delta CT_j = |CT_{1j} - CT_{2j}|$. In the analysis, we considered the average of these timing differences. Small values of asynchrony indicate well-coordinated movements. To evaluate coordination in space, we considered *DTW*, which characterizes the distance between two-time series [35]. In our case, the input time series are the planar trajectories used by the two participants in each trial. Low values indicate that trajectories are similar in space.

F. Statistical Analysis

To understand whether receiving different visual or auditory cues about another person action affect motion plans leading to unintende coordination we considered the last twelve trials for each condition including the familiarization block as a control. A Shapiro-Wilk test showed that both metrics in both experiments were not normally distributed. We conducted one-way ART (Aligned Rank Transform) ANOVA using a linear mixed-effects model. For all dependent variables, we fitted a model with the fixed effect on the block and the random intercepts for the subject number. In case the block factor was significant, post-hoc comparisons using t-test contrasts with a Holm–Bonferroni adjustment were employed.

III. RESULTS

A. Plans alignment with visual feedback from partner

In the experiment in which participants received information regarding partner's action through vision, the type of the given feedback influenced both temporal asynchrony ($F(5, 410) = 28.736$, $p < 0.0001$) and DTW ($F(5, 410) = 21.78$, $p < 0.0001$) - see Fig. 2. In the familiarization, in which participants were cued with different path shapes before motion and did not receive visual signals regarding the partner, participants within dyads were less coordinated compared to all feedback conditions in terms of both time and space (all $p < 0.0001$). When participants could only see their own cursor (V1), they coordinated less in both space (DTW) and time (asynchrony) their movements within the dyads compared to the other conditions, in which they could see their and the partners' cursors as well as a connection between them (DTW: V1 vs. V5: $t(409) = 3.345$, $p = 0.0099$, V1 vs. V6: $t(409) = 4.771$, $p < 0.0001$; asynchrony: V1 vs. V5: $t(409) = 4.819$, $p < 0.0001$, V1 vs. V6: $t(409) = 6.041$, $p < 0.0001$). Even seeing the partners' position alone improved temporal alignment compared to its absence (V1 vs. V4: $t(409) = 2.835$, $p = 0.0348$). Moreover, in both conditions without explicit representation of the partner's position – own cursor and line (V2) or noise (V3) – participants were less coordinated in terms of DTW and temporal asynchrony with respect to those in which partner's cursor was displayed ($p < 0.05$ for all comparisons V2/V3 vs. V5/V6). Regarding asynchrony, noisy connection with both cursors increased alignment compared to the cursors representation (V4 vs. V6: $t(409) = 3.205$, $p = 0.0131$). No other differences between conditions were detected ($p > 0.05$).

B. Coordination with auditory feedback from partner

In the experiment in which participants received information regarding the partner's action through hearing, the temporal ($F(4, 291) = 26.477$, $p < 0.0001$, see Fig. 2) and spatial motion plans alignment ($F(4, 291) = 30.555$, $p < 0.0001$, see Fig. 2) was affected by the feedback type. The alignment in both metrics, DTW and asynchrony, was lower in the initial familiarization trials and increased when the auditory feedback was provided (all $p < 0.0001$ for pairwise comparisons between A1-A4 and familiarization). Analysis of DTW metric (coordination in space) showed that pitch dissonance modality (A1), which gave feedback on the distance between partners' positions, and target impact chime (A3), which presented a discrete auditory cue every time a participant or their partner crossed the via-point,

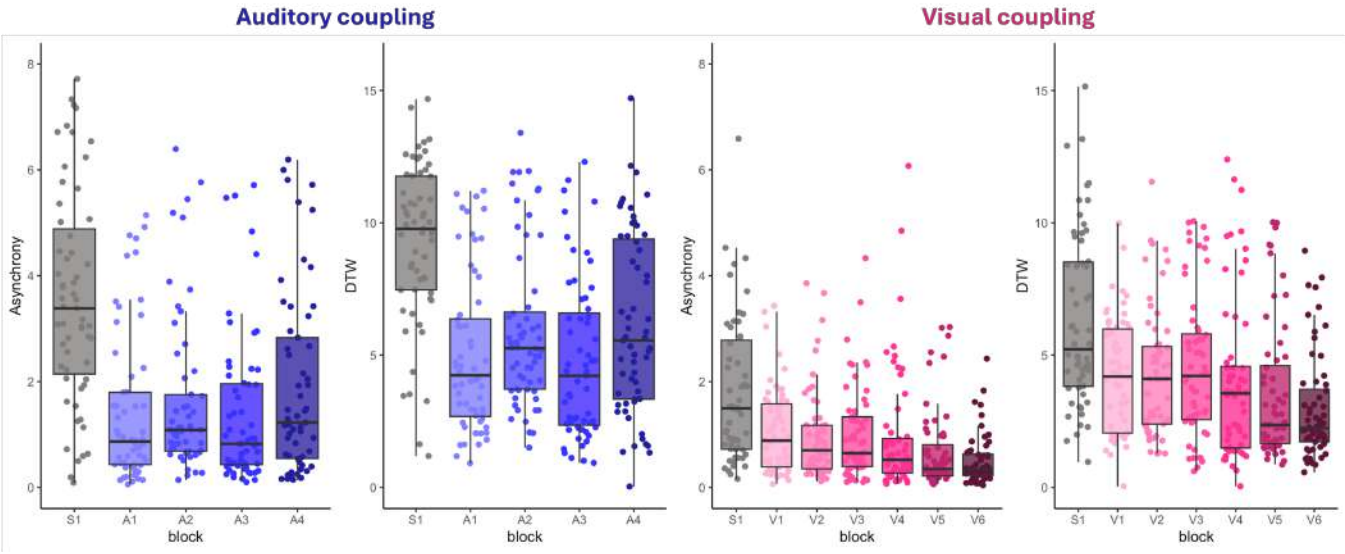

Fig. 2. Motion plans alignment results. Boxplots are reported for the two experiments. Points represent data for each trial included in the analysis. We reported in blue tints data related to the auditory experiment and in pink tints data related to visual experiments. Different tints in the two groups denote different experimental blocks corresponding to different feedback conditions.

increased the spatial coordination within a dyad compared to the speed-adaptive tempo (A1 vs. A4: $t(291) = -2.894$, $p = 0.0205$, A3 vs. A4: $t(291) = -3.098$, $p = 0.0128$) and distance rhythmic synchrony (A2) conditions (A1 vs. A2: $t(291) = -2.573$, $p = 0.0317$, A2 vs. A3: $t(291) = 2.778$, $p = 0.0233$). Similarly, for temporal asynchrony, speed-adaptive tempo condition (A4) resulted in a lower temporal coordination than distance pitch dissonance (A4 vs A1: $t(291) = -2.994$, $p = 0.0179$) and target impact chime (A4 vs A3$t(291) = -2.776$, $p = 0.0293$). Moreover, distance rhythmic synchrony (A2) leads to a higher asynchrony than distance pitch dissonance (A2 vs A1: $t(291) = -2.621$, $p = 0.0369$).

C. Ranking regarding preference of the feedback

At the end of the trial, we asked participants to rank all of the modalities in both experiments. In the visual study, six of ten people choose the 'Cursor + Line + Cursor' (V5) as their first preference. In the auditory experiment, nine of ten participants indicated the target impact chime (A3) as their preferred option. The majority of the subjects explained their ranking with the clarity of the feedback in these two conditions.

IV. Discussion

The goal of this research was to investigate the effect of visual and auditory cues regarding partner actions in a motor task. In particular, we were interested in understanding whether the various cues lead participants to align their plans, showing to be more effective in conveying information related to the partner's actions. We compared various types of visual and auditory representation in two different experiments where participants were required to perform the same via-points motor task that allowed spatial and temporal flexibility for both partners.

Consistent with previous literature [5]–[7], we observed that participants tended to coordinate their actions even if not required by the task when visual feedback was provided regarding another person's actions with respect to the solo conditions. However, with our study we also attempted to analyze which feedback mode was more efficient. This is crucial in rehabilitation [10] as it may provide insights for the design of more efficient interactive rehabilitation tools and enrich the interaction and the patient experience. We found that the preferred feedback is similar to the one used by [8] together with haptic feedback. Confirming that not only a cue regarding the distance and connection between interacting agents but also having full information regarding the partner's position is crucial for achieving a stronger alignment.

In the auditory study, pitch dissonance and target impact chime significantly increased coordination between participants, with the latter being the most preferred. This preference likely stems from its clear and simple feedback, which directly signaled when participants crossed the via-point. Conversely, speed-adaptive tempo hindered coordination, possibly because its mapping caused confusion—when one participant overtook the other, the beat slowed down. Similarly, distance rhythmic synchrony also reduced coordination, suggesting that rhythm-based feedback might be less effective. A key factor could be mental load, as continuous sound in most conditions (except target impact chime) may have increased cognitive demand, aligning with prior studies showing that background noise can impair performance in various tasks [36]–[38]. Additionally, it has been found that auditory signals reduced reaction time when presented before movement initiation [37]. This may explain why the target impact chime was so effective, as its discrete feedback helped

participants synchronize their movements precisely when crossing the via-point.

In general, both visual and auditory feedback about the partner's position lead to spatial and temporal alignment compared to the first solo block, supporting similar findings in the context of solo motor learning [39]. We observed a higher level of coordination when visual cues were presented, which can be explained by the dominance of the visual modality in perception [40] and the mapping complexity of the auditory feedback provided [39].

***Abstract*— This study explored the feasibility of using the auditory Stroop task to assess cognitive workload in a dual-task paradigm. Performance on two tasks—counting backward by 3 and the auditory Stroop task—was measured across two conditions: participants' own passive device and a direct EMG-controlled (dEMG) device. Results based on individual participants' data indicated that the auditory Stroop task effectively captured more consistent dual-task costs under cognitively demanding conditions, whereas the backward counting task exhibited minimal and less consistent performance deterioration. Participant interviews suggested that the backward counting task might be less sensitive to workload because participants could use strategies, while no strategies were reported for the auditory Stroop task. Although the findings are promising, this study was limited by a small sample size, which precluded statistical analysis. Future research should involve larger samples to confirm the auditory Stroop task's validity for measuring cognitive workload while using a lower limb prosthesis.**

Keywords— cognitive workload, dual-task paradigm, evaluation methods

I. Introduction

Like other rehabilitation robotics, lower limb prosthetics are using increasingly sophisticated mechanisms, such as direct electromyography control and finite state machine-based impedance control, to improve motor function for amputees. There is encouraging evidence of these advanced control methods replicating the natural limb control mechanism and increasing the sense of agency [1]. However, one of the significant challenges that comes with these newer prosthetic control methods is that it demands substantial cognitive resources to use them (for a review, see [2]). This poses difficulty as prosthesis wearers must consciously monitor and adjust their movements to ensure stability, especially during complex tasks like walking on uneven surfaces or navigating stairs [3, 4]. The increased cognitive load can lead to fatigue and impaired walking mechanics [5]. Studies have shown that attention and cognitive efforts are crucial for prosthesis users to manage both their movements and the external environment [4]. As a result, developing advanced lower limb prostheses that are easy, safe, and comfortable to use requires a precise way to measure cognitive workload during walking. Despite this strong need, there is currently limited methods for a precise, real-time, and continuous measure of cognitive workload associated with lower limb prosthesis usage.

Existing methods for quantifying cognitive workload during walking with a lower limb prosthesis face various challenges, such as not being real-time or precise, or facing high equipment and data processing barriers. Specifically, questionnaire measures such as the NASA-TLX [6] are valid and easy to use but can only be used to capture overall workload at the end of a session or condition. Physiological measures, like eye tracking and brain activity monitoring [7, 8], offer more precision but require significant investment in equipment setup and extensive data processing (i.e., high capability but also high equipment demand). The dual-task paradigm, which involves having participants perform a secondary task while simultaneously walking. This approach assesses the cognitive workload of walking by analyzing how well participants can manage both tasks simultaneously. It provides an alternative that balances the need for accurate cognitive workload measurement with the constraints of equipment feasibility. However, it still poses challenges in terms of selecting appropriate secondary tasks that effectively simulate real-world demands. Therefore, a balanced task is needed to achieve a better compromise between measurement capability and equipment demand.

This study was supported by the National Institutes of Health (NIH award # 1R01HD110519 - 01A1 and 02S1) to HH, JF and ML

In this paper, we discuss the literature background, including relevant methods and challenges in measuring cognitive workload using the dual-task paradigm in the context of lower limb prosthesis use. We then introduce auditory Stroop task that strikes a balance between equipment demand and measurement capability, presenting preliminary evidence of its effectiveness through data from three pilot amputee participants.

A. Dual-Task Paradigm

The dual-task paradigm is a commonly used approach to assess cognitive workload. This method involves having participants perform two tasks simultaneously, with one being the primary task, such as "time up and go" test (TUG), and the other as secondary cognitive task, such as solving arithmetic problems [9]. Depending on the instruction of task prioritization (i.e., ensure good performance on either the primary or the secondary task), the extent to which performance on the other task deteriorates indicates a dual-task cost. Studies have used dual-task cost to reveal cognitive workload with prosthesis use. For example, Shaw et al. [10] found that transfemoral amputees showed reduced performance on a visual secondary task while walking compared to sitting, whereas those with transtibial amputations displayed consistent secondary task performance in both seated and walking conditions. This suggests that walking with a prosthesis places greater cognitive workload on individuals with more proximal amputations.

While dual-task paradigms are widely used in previous studies, the selection of an appropriate secondary task requires careful consideration. For instance, visual secondary tasks used to evaluate cognitive workload can interfere with walking, limiting their feasibility to controlled environments like treadmill-based simulations [10]. Therefore, it is essential to identify a secondary task that enables precise measurement and continuous monitoring during walking.

B. A Clinical Task: Counting Backward

Counting backward is frequently used as a secondary task in the dual-task paradigm to introduce an additional cognitive demands because of its simplicity and capacity to challenge cognitive resources [11, 12]. In this task, participants are typically given a starting number and are asked to keep reporting the next numbers by continuously subtracting another number. For example, starting with 89 and counting backward by 3 would lead to answers 82, 79, 76, 73, 70, 67, and so on. This task involves cognitive components such as attention and working memory, and it is favored in clinical settings as a secondary task to identify risks in mobility and walking safety. For example, Vance et al. [13] found that adding counting backward to TUG improved the identification of fall risk in people with Parkinson's disease. In the context of amputation rehabilitation, Frengopoulos et al. [14] found that using counting backward as a secondary task affected amputees' walking performance similarly, regardless of their etiology, levels of amputation and time with the prosthesis.

Despite its usefulness, using counting backward to assess cognitive workload has limitations that impact measurement accuracy and precision. Potential confounding variables, such as individual math ability and stress-related math anxiety, could pose problems. For low performance individuals, it may be difficult to differentiate due to the floor effect. Given the participant has already performing poorly at baseline, there is little room to show the effect of increasing primary task demand leading to even worse performance. Furthermore, final counts of correct responses instead of response times are usually used as the performance measure for convenience, leading to issues of missing information about the workload dynamics. Given these limitations, it is perhaps not surprising that in some studies (e.g., [9]), no differential cognitive workloads were reflected in the counting backward task, even when participants perceived significantly different cognitive burdens. This suggests the possible lack of sensitivity of the task for evaluating the cognitive workload associated with different lower limb prosthesis technologies. As such, while counting backward is convenient, its limitations suggest the need for alternative or supplementary methods to provide a more precise and continuous assessment.

C. An Alternative Lab-Based Task: Auditory Stroop

The auditory stroop task presents a promising alternative to the counting backward task for assessing cognitive workload as the secondary task in dual-task walking. The auditory Stroop task requires participants to process conflicting auditory information, such as hearing the word "high" spoken in a low pitch and responding based on the pitch rather than the word's meaning [15]. The cognitive demand of resolving such conflicts taps into attention and executive function, making it a suitable concurrent task with walking [16]. In the context of prosthesis use, the auditory Stroop task has been shown to cause wider steps in participants with transfemoral amputation using microprocessor knees [17], suggesting increased cognitive workload associated with the dual-task condition as compared to the single task (i.e., walking-only) condition. Compared to counting backward, the auditory Stroop task minimizes potential impact from individual variability related to math skills. It is also highly relevant to daily tasks that require resolving conflicts among perceptual information. Furthermore, it maintains a predetermined timing of trials so sampling rate of response time and accuracy data can remain consistent throughout the walking task, instead of potential loss of data sample due to strategy use when performing the counting backward task (e.g., participant stopped doing the counting due to difficulty in counting or walking).

While existing evidence and considerations point to the promise of the auditory Stroop task, much remains to be examined. For example, to use this task to compare different prosthesis technologies, the task prioritization instruction needs to emphasize the walking performance being the priority. Then by observing participants performance on the Stroop task, we can quantify the cognitive workload associated with each prosthesis technology. Second, feasibility studies are needed to find out a proper setting of the auditory Stroop task, such as the pace of trials, to ensure the task effectively captures cognitive workload under different walking conditions. Third, the psychometric properties, such as sensitivity, need to be ensured. In the case of using auditory Stroop task to evaluate cognitive workload, sensitivity indicates how well the task can accurately capture changes in cognitive workload [18]. By comparing the results of the auditory Stroop task under different imposed workload

conditions, we can evaluate how sensitive the task detects the cognitive changes across varying conditions. Additionally, observations from prosthesis wearers are essential to validate the findings. These considerations call for expanded investigation of the feasibility and effectiveness of the auditory Stroop task as a cognitive workload measure in the dual-task paradigm.

D. The Current Study

The study aimed to explore the feasibility of using the auditory Stroop task as a tool to assess cognitive workload in a dual-task paradigm. Specifically, participants completed two tasks—counting backward by 3 and the auditory Stroop task—while operating two devices: their own passive device and a direct EMG-controlled (dEMG) device. In addition to task performance, interviews were conducted to gain qualitative insights into participants' experiences.

II. Methods

A. Participants

Three participants with transtibial amputations were recruited for this study (1 male, 2 females). Participants' age ranged from 29 to 70 years, the height ranged from 1.64 meters to 1.80 meters, and years of amputation were 5 to 18 years. The reason for amputation was edema, cancer, or trauma. All participants were recruited from the community.

B. Measures

1) Timed Up and Go (TUG)

Participants began the task by standing up from a chair, then walked 3 meters to a line marked on the floor, turned around, walked back, and sat down. They were instructed to walk as quickly and safely as possible. The time from standing up to sitting down was recorded using a stopwatch.

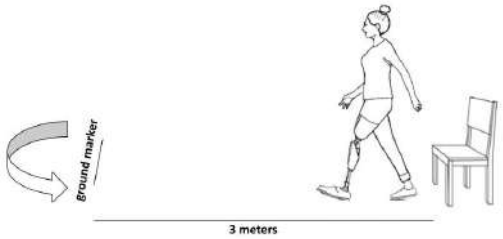

Fig. 1. Timed up and go setup.

2) Counting Backward by 3

Participants were instructed to count backward by threes from a randomly selected number. In the single-task condition, participants counted backward for 30 seconds. In dual-task condition, participants counted backward during the duration of the TUG. The number of correct responses were recorded and used to calculate accuracy. Counting speed was determined by dividing the total number of responses by the counting duration.

3) Auditory Stroop Task

The auditory Stroop task was programmed using OpenSesame [19]. Each trial began with a 200-millisecond break, followed by a 350-millisecond auditory beep, then a 150-millisecond interval. Participants then heard the word "high" or "low" spoken in either a high or low pitch. Then participants heard the word "high" or "low" spoken in either a high pitch or a low pitch. Using a clicker with up and down arrows, participants responded by pressing the up arrow for high-pitch sounds and the down arrow for low-pitch sounds.

Trials were organized into blocks. Each block consisted of four trials with unique combinations of words and pitches, presented in a random order. In the single task condition, participants completed four blocks, resulting in a total of 16 trials. In the dual-task condition, participants were asked to respond while performing the TUG. Therefore, the number of completed trials varied based on their TUG performance. The reaction time for each trial and the number of correct answers were recorded as measures of performance.

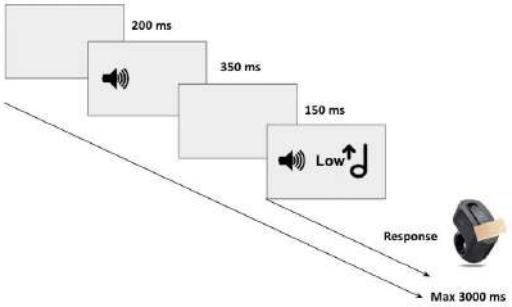

Fig. 2. Auditory Stroop task. The condition shown in the figure presents the word *low* in a high pitch, and the participant needed to respond by pressing the upper arrow on the clicker.

4) Dual-Task Cost

Participants were instructed to primarily focus on walking. Dual-task cost was defined as the percent change in performance relative to an individual's single-task performance [20]. A greater dual-task cost implicates greater performance deterioration under dual-task conditions. To reflect the cost in accuracy for the counting backward and auditory Stroop task, the dual-task cost was calculated as follows (1):

$$\frac{(single_task - dual_task)}{single_task} * 100\% \quad (1)$$

For speed and response time (2), dual-task cost was calculated as follows:

$$\frac{(dual_task - single_task)}{single_task} * 100\% \quad (2)$$

C. Procedure

The study protocol was approved by the Institutional Review Board of the university, and written informed consent was obtained from each amputee participant. The study was conducted as part of a larger investigation to understand the effects of a direct EMG-controlled (dEMG) powered prosthetic ankle compared to their prescribed passive prosthesis. Participants underwent performance evaluations through a series of clinical, cognitive, and biomechanical assessments using both their passive device and the dEMG device. Evaluations for the passive and dEMG devices were conducted on separate days. The reason for including both passive and dEMG devices is to examine measurement

sensitivity by comparing the two different cognitive measures. Patients are known to experience difficulties using dEMG devices without prior exposure [21]. If the measurement can detect these difficulties, it would demonstrate good sensitivity.

During the cognitive assessments, participants were evaluated on their performance in the TUG, counting backward by 3, and the auditory Stroop task. They also completed dual-task conditions, in which they performed the TUG concurrently with the counting backward or the auditory Stroop task. For all dual-task conditions, participants were asked to prioritize their focus on walking. Participants first practiced the TUG, followed by two trials to assess their performance. They then practiced counting backward by 3 and completed a 30-second counting task only while sitting as the baseline. Afterward, participants performed two trials of counting backward by 3 while simultaneously completing the TUG. After a brief break, participants were asked to practice and then perform the auditory Stroop task only while sitting, which was used as the baseline. Next, they practiced and completed two dual-task trials, combining the TUG with the Stroop task.

III. Results

Since each participant performed every task twice, the best performance was selected for analysis. For the cognitive tasks, the trial with the highest accuracy was chosen. If two trials had the same accuracy, the trial with the faster reaction time was selected.

A. TUG

1) Participant 1

For passive device, the TUG time was 17.50 seconds; with counting it was 23.00 seconds; and with Stroop was 20.20 seconds.

For dEMG device, the TUG time was 34.34 seconds When performed with counting, the TUG time was 33.00 seconds, and when combined with the auditory Stroop task, the time was 31.28 seconds.

2) Participant 2

Using the passive device, the TUG completion time was 7.95 seconds. With counting backward, the TUG time increased to 13.80 seconds. With the auditory Stroop task, the TUG time was 11.14 seconds.

With the dEMG device, the TUG time was 11.98 seconds. When performed with the counting backward task, the TUG time was 15.30 seconds, and with the auditory Stroop task, it was 12.55 seconds.

3) Participant 3

For the passive device, the TUG time was 9.78 seconds. With counting backward, the TUG time increased to 10.89 seconds. When combined with the auditory Stroop task, the TUG time was 11.96 seconds.

For the dEMG device, the TUG time was 14.08 seconds. With counting, the TUG time was 13.32 seconds, and with the auditory Stroop task, the TUG time was 14.07 seconds.

In summary, the pattern was consistent across all three participants, with both the passive and dEMG devices showing that walking speed was impacted by the dual-task conditions. Using dEMG device took longer than using their own passive device to walk (Fig. 3, upper panels).

B. Counting Backward by 3

1) Participant 1

For passive device, the baseline accuracy was 89% (8/9) and the counting speed was 3.33 seconds per number. When performed with the TUG, the accuracy was 100% (9/9) and the speed was 2.78 seconds per number. The dual-task cost of accuracy was -0.12, and the cost of speed was -0.17.

dEMG baseline showed a 100% accuracy (11/11) with a counting speed of 2.73 seconds per number. When performing with the TUG, this participant had 100% accuracy (7/7) and the speed was 4.71 seconds per number. The dual-task cost was 0% on accuracy and 73% on speed.

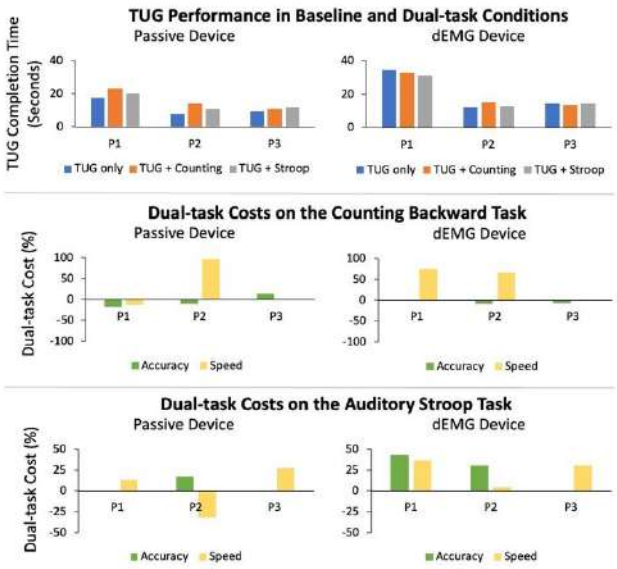

Fig 3. Performance on the Timed Up and Go (TUG) task and dual-task costs on the counting backward task and the auditory Stroop task from each of the three participants (P1, P2, P3) when wearing their own passive devices or a dEMG device. The upper panels show participants' TUG task completion time in the basline (TUG only) and dual-task conditions (TUG + Counting, TUG + Stroop). The middle panels show the dual-task costs (%) on the counting backward task. The lower panels show the dual-task costs (%) on the auditory Stroop task. A positive dual-task cost suggests the dual-task having a lower accuracy or taking longer to complete than the single task. Opposite directions of costs on speed and accuracy suggests a speed-accuracy trade-off (e.g., P33 on the counting backward task for both devices, and on the auditory Stroop task for the passive device). A greater and positive dual-task cost suggests an overall more demanding task condition (e.g., the dEMG device poses higher demand than the passive device for P1 as shown on the auditory Stroop task). Fewer negative costs and more consistent cost patterns across participants comparing the passive and dEMG devices suggest higher criterion validity and external validity of a measure. In general, based on this preliminary data from three participants, the auditory Stroop task presents more consistent and meaningful dual-task costs.

2) Participant 2

Using passive device, participant counted 11 numbers in 30 seconds with 1 error at the baseline. Accuracy was 91%. On average, the counting speed was 2.72 seconds per number. In the dual-task condition, participant counted 3 numbers with no error. Accuracy was 100% with a counting speed of 5.33 seconds per number. The dual-task cost was -10% for

accuracy and 96% for speed, meaning that this participant had higher accuracy but slower speed in the dual-task condition as compared to the baseline.

Using dEMG, participants counted 13 numbers in 30 seconds and had 1 error at the baseline. Accuracy was 92% with a speed of 2.31 seconds per number. In the dual-task condition, the participant counted 4 numbers with no error. Accuracy was 100%. The counting speed was 3.83 seconds per number. The dual-task cost was -9% for accuracy and 65% for speed.

3) Participant 3

In passive device, baseline accuracy was 100% for the 19 total counted numbers (19/19). Counting speed was 1.58 seconds per number. In the dual-task condition, this participant counted 7 numbers with 1 error (i.e., accuracy was 86%) with a speed of 1.56 seconds per number. The dual-task cost was 14% for accuracy and -1% for speed.

For dEMG device, the baseline accuracy for counting was 94% (17/18). The speed was 1.67 seconds per number. In the dual-task condition, this participant had 100% accuracy (i.e., all correct for the 8 total counted numbers), and a speed of 1.66 numbers per second. The dual-task cost was -6% for accuracy and -1% for speed.

In summary, the dual task costs for accuracy and speed varied across participants. Only one participant showed meaningful dual-task cost in accuracy, and two participants showed dual-task cost in speed. Many results showed improved performance under the dual-task conditions (Fig. 3, middle panels), suggesting weak sensitivity and measurement stability of this task.

C. Auditory Stroop Task

1) Participant 1

For passive device, the baseline accuracy was 50%, and the response time was 780 milliseconds. With TUG, the accuracy was 50% and response time was 883 milliseconds Therefore, the dual-task cost was 0% for accuracy and 13% for speed.

For dEMG device, of the baseline accuracy was 70% with a response time of 1219 milliseconds. In the dual-task condition, the accuracy dropped to 40% and the response time increased to 1651 milliseconds. Therefore, the dual-task cost was 43% for accuracy and 36% for speed.

2) Participant 2

When using the passive device, on the baseline, the participant had 100% accuracy and an average response time of 707 milliseconds. When performed with the TUG, the accuracy dropped to 83.33%, although with a shorter average response time of 484 milliseconds. The dual-task cost was 17% for accuracy and -32% for speed.

Using dEMG device, on the baseline, participant had an accuracy of 95% and an average response time of 696 milliseconds. When performing with the TUG, participant had an accuracy of 66.67% and average response time of 725 milliseconds. The dual-task cost was 30% for accuracy and 4% for speed.

3) Participant 3

In the baseline condition using the passive device, the participant was 100% accurate with 590 milliseconds response time. In the dual-task condition, it was 100% accuracy with 758 milliseconds response time. The dual-task cost was 0% for accuracy and 28% for speed.

dEMG baseline showed 100% accuracy and 665 milliseconds response time. In the dual-task condition, the participant had 100% accuracy and 864 milliseconds response time. The dual-task cost was 0% for accuracy and 30% for speed.

In summary, the results showed dual-task costs in both response time and accuracy, except one participant had faster responses when using the passive device as compared to baseline. The general patterns across the three participants also suggest consistently greater dual-task costs when using the dEMG device compared to the passive device (Fig. 3, lower panels). Overall, the Stroop task data captured consistent and meaningful dual-task costs.

D. Interview

Participants were asked to reflect on their experience with counting backward and auditory Stroop task, including the strategy they used, as well as the challenges and the difficulties they encountered.

For the strategies used during the tests, all three participants reported using strategies to assist with counting backward by 3. Two participants described using mental strategies to identify numerical patterns. For example, participant 3 explained, *"when we were counting backward from three, if we went down ten numbers, we would be hitting the same numbers … I was just trying to remember that."* Similarly, participant 1 noted, *"I've tried not to practice, but I'm getting a pattern in my head now."* Participant 2 explicitly recalled slowing down the pace and using fingers to aid in counting backward. In contrast, no participant reported any strategies used in the auditory Stroop task.

Regarding difficulties and challenges, participants 2 and 3 identified the mathematical aspect of the counting backward as particularly demanding, noting it was more challenging than the auditory Stroop task. Both participants attributed this to their mathematical abilities. For example, participant 2 mentioned, *"Maybe I'm not good at numbers, and it was all in your head". Similarly,* participant 3 stated, *"Numbers are not my thing … I had to think a lot more [than the auditory Stroop task] while I was doing it."* Participant 1 found the auditory Stroop task was more difficult than counting backward, remarking, "*I could argue with the voices sometimes.*" In addition to the cognitive demands, participants 1 and 3 pointed out issues with the clicker, especially when managing other physical demands. Participant 1 stated, "*The clicker is the most frustrating thing, because you're holding on to the walker and holding on [to it] and having to push a button at the same time.*"

IV. Discussion

The findings of the current study provide preliminary evidence that the auditory Stroop task could potentially become a valuable tool for measuring cognitive workload in a dual-task paradigm. Compared to the counting backward task, the auditory Stroop task demonstrated a consistent pattern of capturing greater dual-task costs under more

cognitively demanding conditions (i.e., using the dEMG device). In contrast, performance in the counting backward task did not show much deterioration during dual-task performance and the patterns were quite inconsistent across participants when comparing the passive and the dEMG devices. This aligns with previous research [9], which suggests that cognitive workload may not be effectively reflected in the counting backward task. While counting backward has proven to be an effective task for adding load in clinical assessments of mobility and safety, preliminary results from the current study suggest it may not be the most suitable method for evaluating cognitive workload for prosthetic technologies. Instead, the auditory Stroop task appears to be a more promising alternative.

Interviews further supported that as participants reported employing strategies by identifying patterns while performing the backward counting task, which may have contributed to its insensitivity in reflecting changing cognitive workload. For future studies, the setup of the auditory Stroop task can be enhanced. In the current study, participants used a presentation clicker to respond, and all participants reported that the clicker made the task more challenging. Addressing this usability issue may improve the task's effectiveness and participant experience.

As an initial feasibility study to explore the use of the auditory Stroop task in assessing cognitive workload with the dEMG device, the findings are promising. However, a key limitation of this study is its small sample size even though the participants were amputees, which precluded the possibility of conducting statistical analyses. Future research should address this limitation by incorporating a larger sample size to enable statistical testing.

ACKNOWLEDGMENT

The authors would like to thank Avery Murray, Austin Mituniewicz, Brendan Driscoll, and Pinar Onal from North Carolina State University, as well as Derek Frankena from Atlantic P&O for their assistance with the preparation and data collection for this study.

Fabric Sensing of Intrinsic Hand Muscle Activity

Katelyn Lee[1], Runsheng Wang[1], Ava Chen[1], Lauren Winterbottom[2], Ho Man Colman Leung[3], Lisa Maria DiSalvo[3], Iris Xu[3], Jingxi Xu[3], Dawn M. Nilsen[2,4], Joel Stein[2,4], Xia Zhou[3,4] and Matei Ciocarlie[1,4]

***Abstract*—Wearable robotics has the capacity to assist and rehabilitate hand function in stroke survivors. Many devices that use surface electromyography (sEMG) for control rely on extrinsic hand muscle signals, since sEMG sensors are relatively easy to place on the forearm without interfering with hand function. In this work, we target the intrinsic muscles of the thumb, which are superficial to the skin and thus potentially more accessible via sEMG sensing. Traditional, rigid electrodes can not be placed on the hand without adding bulk and affecting hand functionality. We thus present a novel sensing sleeve that uses textile electrodes to measure sEMG activity of intrinsic thumb muscles. We evaluate the sleeve's performance on detecting thumb movements and muscle activity during both isolated and isometric muscle contractions of the thumb and fingers. This work highlights the potential of textile-based sensors as a low-cost, lightweight, and non-obtrusive alternative to conventional sEMG sensors for wearable robotics.**

I. Introduction

Stroke-induced hemiparesis can cause chronic upper limb weakness and reduced hand dexterity [1][2], which can hinder a stroke survivor's mobility and independence. Wearable robotic devices can aid stroke survivors by assisting hand function and providing rehabilitation therapy. Because continued, active use of the paretic hand is a key element of effective robotic rehabilitation [3], there is great interest in developing devices that promote this active engagement.

Surface electromyography (sEMG) sensors can measure residual muscle activity during active use of the paretic hand, enabling ipsilateral, robotic orthosis control. These robotic orthoses commonly place sEMG sensors on the forearm to capture activity from extrinsic hand extensor and flexor muscles, which are responsible for many gross hand movements. This data is then processed by machine learning models to infer user intent [4][5]. While these methods work well on healthy participants, stroke complications like muscle spasticity, abnormal muscle co-activation, and neurological disorders [6], introduce challenges for sEMG-based intent inferral on stroke survivors.

Beyond the forearm, the intrinsic muscles in the hand offer an alternate sEMG sensing region for intent inferral. Muscles in the thenar eminence (TE) are responsible for some thumb movements during grasping and fine motor movements [7].

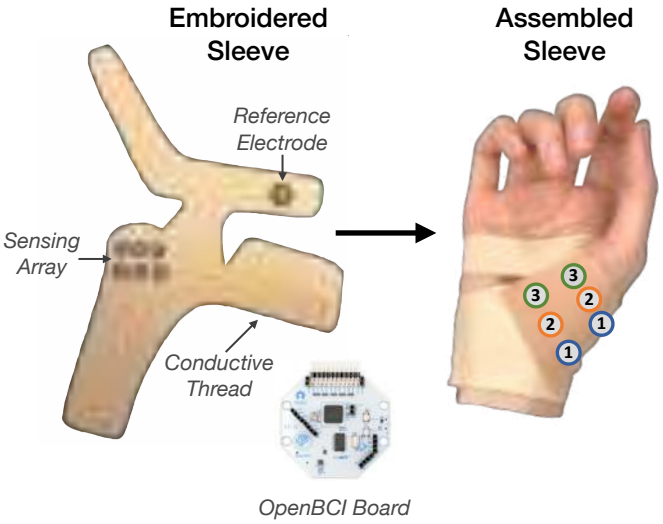

Fig. 1. The fabric sensing sleeve. After embroidering the fabric electrodes and conductive thread, which act as wires to connect the sleeve to the OpenBCI board, the sleeve is assembled into a wearable form. The sensor array is positioned on the thenar eminence of the thumb to detect when the thumb moves into abduction.

Research has suggested that in stroke survivors, the *abductor pollicis brevis* (APB) in the TE has reduced spasticity compared to other muscles in the hand [8], which highlights the TE's potential as a sensing region for stroke survivors.

Despite its advantage as a localized, grasping-specific muscle sensing region, the TE is underexplored due to its small size on a curved contour of the palm. Conventional sEMG sensors are often bulky and use stiff, adhesive pads that, when placed on the TE, can interfere with grasping and restrict thumb movement.

Textile sensors, made from conductive fabrics and threads, are an alternative sensing platform that is low-profile, non-adhesive, and comfortable for extended wear. Unlike conventional sEMG sensors, fabric electrodes are flexible and can conform to curved surfaces without adhesives on the skin.

In this pilot study, we introduce a novel, textile sensing array embroidered in a fabric sleeve to measure sEMG activity of the intrinsic thumb muscles. Our main contributions are:

- To the best of our knowledge, we are the first to use fabric sensors to measure surface EMG activity of intrinsic hand muscles. The fabric sensors are built with off-the-shelf fabrics and are optimized to mitigate motion artifacts and improve skin-contact quality without adhesive pads.
- We demonstrate that the textile sensors can distinguish

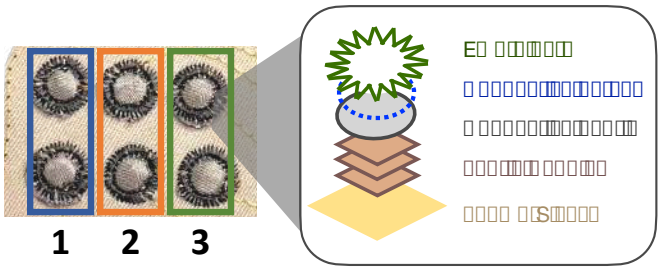

Fig. 2. The 3-channel textile sensing array, labeled by color and channel number. Each textile electrode is made of conductive fabric embroidered to a fabric substrate with internal padding to improve skin-electrode contact. Conductive thread is stitched around the perimeter of the electrode to connect the electrode to the bioamplifier board.

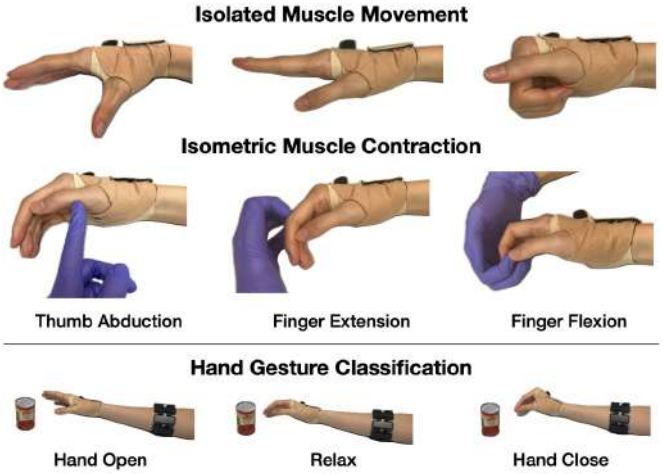

Fig. 3. Schematic of experimental protocol. During the Isolated Muscle Movement task, participants moved their thumb or fingers from rest to an engaged position as shown. The Isometric Muscle Contraction task required participants to resist external force from the experimenter's hand to engage the relevant muscles for the movement. Hand Gesture Classification data collection involved participants opening and closing their hands into a lumbrical grasp, as shown.

thumb muscle activity from finger movements. In addition, training a classifier with only the 3-channel sensing array achieves promising classification accuracy for detecting hand opening and closing.

- Our results demonstrate the fabric sensing sleeve's potential as an effective sEMG sensor for intent inferral, highlighting the value of intrinsic muscle sensing modalities for improving model classification performance in future work.

II. Related Work

Surface EMG sensing for intent inferral has been explored with various sensor configurations. Tacca et al. combined forearm sEMG sensing with a non-EMG data glove in a multi-modal system for hand gesture recognition [9]. Previous works with conventional sEMG sensors combined extrinsic and intrinsic hand muscle sensing for post-stroke rehabilitation exercises [10] and hand gesture recognition [11]. Multiple groups built fabric sleeves with textile electrodes for the forearm to measure extrinsic muscle activity for hand gesture recognition [12][13]. Lara et al. developed a PCB sEMG electrode array with a flexible polyamide substrate for intrinsic hand muscle sensing, though this system requires custom adhesive pads for use [14]. Across these works, however, intrinsic hand muscle sensing in a soft, wearable system remains underexplored.

To our knowledge, the only works related to fabric sensing of intrinsic hand muscles are a piezoresistive strain fabric sensor that measures muscle strain of the APB [15] and a graphite composite sEMG sensor extruded on a fabric substrate that measures APB muscle activity [16]. However, [15] measures muscle strain rather than sEMG activity, and [16] uses fabric as a substrate, rather than a sensing modality. This distinction highlights how fabric sEMG sensors for intrinsic hand muscles have not yet been directly explored, which our work aims to address.

III. Fabric Sensing Sleeve Design

The fabric sleeve presented in this work is a prototype 3-channel, fabric sEMG sensing sleeve that measures the intrinsic muscle activity of the thumb. The materials for fabricating the sleeve are off-the-shelf and low-cost (<$5 per sleeve) and takes about 2 hours to assemble, which enables modular design for project-specific sensing array customization and scalability.

The biopotential sensing electrode is made of a layer of conductive fabric [17] embroidered to an elastic fabric substrate. Three layers of fabric padding are placed between the conductive fabric and fabric substrate to increase electrode concavity and improve skin-electrode contact (Fig. 2). The reference electrode is 8 mm in diameter, and each sensing electrode is 6 mm in diameter, with a center-to-center electrode distance per channel of 9 mm. The electrodes were sized to fit comfortably on the TE and reduce motion noise during thumb movement.

We designed the fabric sleeve to place the 3-channel sensing array over the TE of the palm, with the reference electrode placed on the back of the hand (Fig. 1). The 3-channels array wraps around the curved TE to maintain skin contact and, similar to high-density electromyography methods, enable simultaneous sEMG measurements of one muscle for increased spatial resolution [14]. Each fabric electrode routes to a bioamplifier board (Cyton, OpenBCI) [18] via machine-sewn conductive thread [19], which is positioned on the outside of the sleeve and insulated with sports kinesiology tape to reduce noise reduce impedance and cross talk between wires and prevent off-target skin contact. Previous work using this conductive fabric as a biosensor found the material is robust to changes in signal strength after 50 wash cycles [20]. We confirmed the connectivity between the fabric electrode and the wiring adapter with a multimeter and measured an average resistance of $46.3\ \Omega \pm 3.3\ \Omega$ across all electrodes and conductive thread wires.

IV. Methods

We designed two experiments to evaluate the fabric sleeve's performance on nine healthy participants and one stroke participant. Our first objective was to determine

whether the sleeve could distinguish thumb-specific movements from overall finger movements and movement noise. The tasks chosen to evaluate this aspect included both dynamic and static thumb and finger movement conditions to isolate intrinsic thumb muscle activity. Our second objective was to explore whether signals measured by the fabric sleeve could be used for intent inferral. To test this, we trained a machine learning classifier to detect hand opening and hand closing from sEMG signals measured by the fabric sleeve.

A. Isolated Muscle Movement Task

The Isolated Muscle Movement Task distinguished between dynamic, thumb-only movement and coordinated finger movement. Participants moved either their thumb or all four fingers from rest into an engaged position with moderate effort for about 5 seconds (Fig. 3). To assess thumb-specific muscle activity, participants moved their thumb from rest into abduction. For finger-specific muscle activity, participants simultaneously moved all four fingers from a resting position into either extension or flexion.

B. Isometric Muscle Contraction Task

The Isometric Muscle Contraction Task targeted thumb-specific muscle activity in a static position. Participants performed the same actions as the Isolated Muscle Movement task with added resistance from the experimenter (Fig. 3). To minimize movement artifacts, participants resisted the external force for 5 seconds, without moving their thumb or fingers. For the thumb, the experimenter applied pressure with their finger to the lateral side of the participant's thumb MCP joint. For finger extension, the experimenter applied resistance on the dorsal side of their fingers at the head of the proximal phalanx. For finger flexion, the experimenter applied resistance on the palmar side of the participant's fingertips.

C. Hand Gesture Classification

To test whether signals from the fabric sleeve could be used for intent inferral, we collected data while participants performed a series of hand gestures. We instructed participants to open and close their hand as if they were to grasp a metal can, which we provided as a visual aid to encourage thumb abduction in a lumbrical grasp (Fig. 3). We collected two datasets for training and testing, during which the participant opened and closed their hand 8 times, each for 5 seconds, with 5 seconds of rest between each movement. The stroke participant performed an abbreviated set of 3 hand movements instead of 8.

D. Data Collection and Analysis

During data collection, participants were seated with their forearms resting on the table and elbows bent at a 90 degree angle. Participants donned both the fabric sensing sleeve and the commercial, 8-channel forearm sEMG armband (Myo, Thalmic Labs). Before donning the fabric sensing sleeve, we prepped the participant's hand by wiping their skin with a moist towelette and adjusted the position of the sensing array to lie over the TE of the thumb.

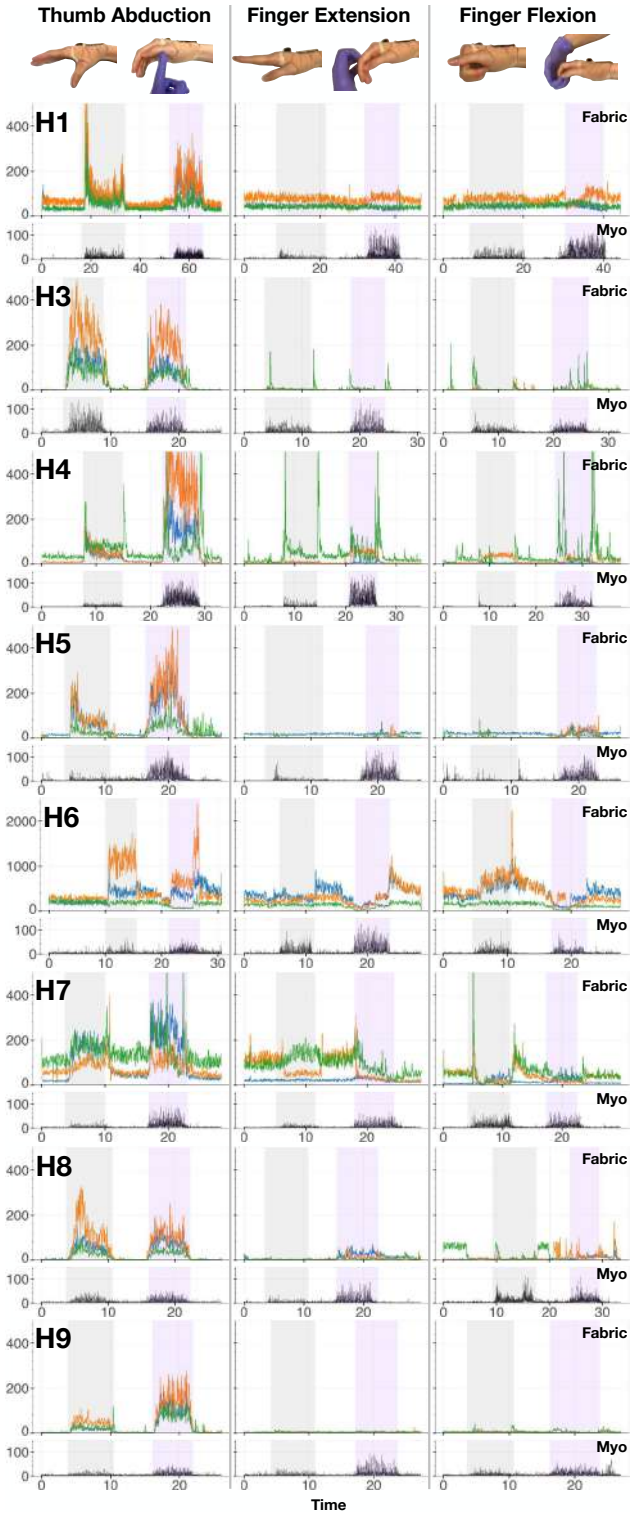

Fig. 4. (best seen in color) Data from our fabric sensing sleeve and commercial armband (Myo) during the Isolated Muscle Movement and Isometric Muscle Contraction tasks over time (s). Grey bars denote isolated movement, and purple bars denote isometric contraction. Each row depicts data from one healthy participant, and each column corresponds to a hand movement (Fig. 3). For each figure, the top plot shows the fabric sensor activity in μV_{rms} (blue = Channel 1, orange = Ch. 2, green = Ch. 3). Y-axis limit is 500 μV except for H6 (2,500 μV), and all cut-off peaks are below 1,000 μV. Bottom plot depicts corresponding Myo sensor activity in proprietary values (a.u.), with all 8 channels plotted in black.

Using the OpenBCI software, we measured the skin-electrode impedance to ensure sufficient contact and monitored the contact throughout the session. We collected raw voltage sEMG data from the fabric sleeve at 250 Hz and 1x amplification and used a 4th order Butterworth bandpass filter from 50 Hz to 115 Hz with a notch filter at 50 Hz and 60 Hz to eliminate environmental powerline noise. We collected sEMG data from the Myo armband at 200 Hz and did not perform any additional filtering of the output signal.

For the Isolated Muscle Movement and Isometric Muscle Contraction Tasks, we needed to to quantify changes in muscle activity between rest and active phases. To achieve this, we first rectified the raw EMG signal and passed it through a 40 Hz low-pass filter. Next, we found the average signal amplitude per sensing channel (3 channels in the fabric sensing sleeve and 8 channels in the commercial armband) to calculate the ratio of signal amplitude between the resting phase and the active phase of each of the two tasks.

For hand gesture classification, we processed the raw output from the OpenBCI board by extracting overlapping sliding windows of size 250 (1 second) with an offset of 10 samples. Each window was labeled with the ground truth at the end of the window, indicating the intent. From each window, we extracted both time-domain and frequency-domain features from each channel in each window, including Mean Absolute Value, Root Mean Square, Variance, Waveform Length, Zero Crossing Rate, Mean Frequency, Median Frequency, and Total Power. After feature extraction, we standardized features by removing the mean and scaling to unit variance using the training set.

We then trained three machine learning models to classify the extracted features: Linear Discriminant Analysis (LDA), Random Forest (RF), and a Multi-layer Perceptron (MLP). LDA was chosen for its simplicity and effectiveness with lower-dimensional data, RF for its ability to capture nonlinear relationships, and MLP for its capability to model more complex patterns. Each model was trained using subject-specific data, with distinct training and test sets.

E. Participants

We recruited nine healthy participants (five male, four female, ages 22-27)[1]. We also recruited a single stroke participant with chronic hemiparesis (male, right-hand impaired, scores of 1+ elbow flexors and 1 finger flexor on the Modified Ashworth Scale) for feasibility testing in a clinical setting under the supervision of an occupational therapist. Testing with all participants was approved by the Columbia University Institutional Review Board (IRB-AAAS8104).

V. Results & Discussion

We evaluated the sensor performance by finding the ratio between the average signal amplitude during the resting phase and the active phases. The raw data is visualized in Fig. 4[2], and Table I shows the average ratio values across all sensing channels measured by the fabric sleeve. In Table I, the hand movement labels are abbreviated: Thumb for thumb abduction, FE for finger extension, and FF for finger flexion.

TABLE I
Average Change in Signal Amplitude of Fabric Sensing Sleeve Relative to Relaxed State

Participant	Isolated Finger Movement			Isometric Muscle Contraction		
	Thumb	FE	FF	Thumb	FE	FF
H1	**2.2**	1.0	1.1	**2.4**	0.9	1.2
H3	**88.5**	4.1	2.1	**66.6**	2.9	2.6
H4	**4.9**	2.5	2.4	**18.9**	5.7	2.5
H5	**13.2**	1.2	1.1	**30.9**	3.5	4.8
H6	**2.4**	1.0	1.5	**1.9**	0.7	0.5
H7	**3.7**	1.0	1.4	**5.2**	0.8	1.6
H8	**20.5**	0.8	0.9	**22.0**	4.3	2.1
H9	**11.6**	1.2	1.4	**39.3**	1.2	1.2
Avg	**18.4**	1.6	1.5	**23.4**	2.5	2.1

We did not control for uniform force output exerted by each participant during the movement, so we posit that individual strength differences may have contributed to the varying sEMG signal amplitudes. Other factors that can be explored in future work include measurements of skin conditions and overall engagement with the task.

A notable outlier in signal quality from Fig. 4 was H6, whose baseline signal and overall signal amplitude was larger than all other participants. As a simple proxy for TE size, we measured the depth of the TE for each healthy participant between the palmar and dorsal sides of the hand. H6 had a TE depth of 25 mm, compared to the average TE depth of 34 ± 3.9 mm among all other healthy participants. Furthermore, we observed that H6 had drier skin compared to other participants. Thus, H6's hand size and skin condition could have affected skin-electrode contact with the fabric sleeve for reduced performance.

A. Isolated Muscle Movement Results

During the Isolated Muscle Movement Task, we observed the largest increase in signal amplitude during thumb abduction. For the thumb abduction condition, we report an average increase in signal amplitude by a factor of 18.4 from the relaxed position across all healthy participants. In contrast, the average signal amplitude change for the finger conditions were much smaller, with a factor of 1.6 for finger extension and 1.5 for finger flexion.

The difference in average signal magnitude between the thumb condition and the finger conditions demonstrated that the fabric sensing sleeve measured high activity during thumb activity and low activity when thumb movement was absent. Even during finger movement, the fabric sensors detected low activity as long as the thumb was not engaged.

To confirm the low activity detected by the fabric sensors during finger movement was not due to a lack of effort, we recorded the commercial sEMG armband values of concurrent extrinsic muscle activity in the forearm during finger extension and flexion (Fig. 4). The sustained peaks in signal activity measured by the commercial sEMG armband suggested greater activation of the extrinsic muscles than the

[1]H2 was later excluded from the study due to insufficient sEMG activity measured by the commercial armband.

[2]H1 performed a slightly extended active period of about 10 seconds for all tasks.

intrinsic muscles. During the finger movement conditions of the Isolated Muscle Movement task, the fabric sensor did not detect sustained activation during the 5 second period, indicating that the sensor was more sensitive to TE muscle activity than to finger movements.

We observed that three healthy participants had transient peaks at the start and end of each movement. However, the lack of sustained activation as observed in the thumb movement tasks supported the conclusion that the sensor primarily detected thumb muscle activity. These transient peaks could also be attributed to the participant's ability to maintain a relaxed thumb position during both the isolated finger movements.

B. Isometric Muscle Contraction Results

The Isometric Muscle Contraction Task focused on measuring TE muscle activity without finger movement to mitigate potential motion noise. With isometric muscle contraction alone, the results aligned with those of the Isolated Muscle Movement Task–the thumb abduction condition exhibited the largest change in average signal amplitude from the relaxed phase. Across the healthy participants, we report an average increase in signal amplitude by a factor of 23.4 for the thumb abduction condition, compared to a factor of 2.5 and 2.1 increase from relaxed during the finger extension and flexion conditions, respectively.

During the thumb abduction condition, a visible and sustained peak in signal during both Isolated Muscle Movement and Isometric Muscle Contraction indicated its sensitivity to thumb activity, whether from movement or muscle engagement (Fig 4). While muscle shape changes during contraction could affect the contact surface with the sensors, the sustained peak during isometric muscle contraction—where no thumb movement occurred—indicated that the signal was likely due to muscle activation rather than motion artifacts.

C. Classification Performance

Using the simultaneously collected fabric sensor and commercial sEMG armband data, we trained three machine learning models (LDA, RF, MLP) with the fabric sensor and the commercial armband separately to assess their classification accuracy. The results are shown in Table II, with the highest classification accuracy per sensing modality marked in bold. For the fabric sensor, the highest classification accuracy of 92.6% was achieved with the LDA model. The commercial sEMG armband achieved a maximum classification accuracy of 91.1% with the RF model.

The classification accuracy of the fabric sensing sleeve highlighted its potential as a viable sensor for intent inferral. For half of the participants, the 3-channel fabric sensing sleeve achieved a maximum classification accuracy within 5% of the commercial armband. This comparison is not intended to suggest the fabric sensing sleeve could replace the commercial forearm sEMG sensor. Rather, this suggests that sEMG signals from TE activity alone captured sufficient signal information for intent inferral. These results suggest the fabric sensing sleeve could augment a forearm sEMG sensing setup to improve intent inferral in future work.

TABLE II
CLASSIFICATION ACCURACY OF FABRIC SENSING SLEEVE AND MYO ARMBAND ACROSS 3 CANDIDATE MODELS

Hx	**Fabric Sensor**			**Myo Armband**		
	LDA	**RF**	**MLP**	**LDA**	**RF**	**MLP**
H1	**70.1%**	68.6%	65.1%	84.6%	**84.7%**	80.4%

Std	24.9%	13.6%	14.5%	4.3%	3.4%	5.2%

D. Preliminary Testing with Stroke Participant

We performed a modified version of this protocol with one stroke survivor who had limited active thumb movement. We performed only the thumb movement of the Isolated Muscle Movement and the Isometric Muscle Contraction Tasks and an abbreviated Hand Gesture Classification data collection set due to stroke participant fatigue.

For the thumb-only Isolated Muscle Movement and Isometric Muscle Contractions, we observed a 0.8 change in signal amplitude from resting for both tasks. Unlike the healthy participants, we did not observe increased signal amplitude with the fabric sleeve during thumb engagement. However, the participant had a 3.9 factor increase in signal amplitude measured by the commercial sEMG armband during isolated thumb movement, and a 2.6 factor increase in signal amplitude during isometric thumb muscle contraction. The lack of signal activity measured by the fabric sleeve could be because the stroke survivor had difficulty isolating fine-motor movement of the thumb from overall hand engagement.

During overall hand engagement, however, the fabric sleeve captured some signals from the stroke participant. The fabric sensor had a maximum classification accuracy of 74.5% with the RF model, and the commercial sEMG armband had a maximum classification accuracy of 86.7% with the MLP model. While the fabric sleeve may not distinguish isolated thumb movement in stroke survivors, this result shows potential for its use with a commercial armband for intent inferral.

E. Future Work & Limitations

The modularity of the textile sensor design presents an opportunity to integrate additional, targeted sEMG sensors on the body for improved intent inferral. A future direction of this work would be integrating additional textile sensors to create an entirely fabric-based sensing sleeve to measure intrinsic and extrinsic muscle activity. Developing a multimodal machine learning model to leverage both intrinsic and extrinsic muscles would be a logical next step toward improving classification accuracy for intent inferral.

Limitations of this work include the small sample size of stroke participants. For the stroke participant, we could not rule out that the activation may have been from *flexor pollicis brevis* rather than APB, as stroke survivors may have difficulty distinguishing between these motions. Expanding the number of stroke participants in the work would allow us to draw more conclusions on using intrinsic hand muscle activity for intent inferral and the use of textile sensors to detect abnormal muscle signals from impaired individuals.

Further research will focus on characterizing the textile sensors, including a comparison of its performance to commercial sEMG systems on the TE, evaluating the sensors' dynamic response, and skin-electrode contact quality. As seen with participant H6, two factors—hand size and skin condition—motivates multiple fabric sleeve sizes and testing sEMG preparation gel to improve skin-electrode contact. Exploring different skin conditions and methods could help address the fluctuations in signal quality observed among healthy participants to ensure better sensor performance.

VI. Conclusion

In this work, we present a textile sEMG sensing array to measure muscle activity of intrinsic hand muscles in the TE. To the best of our knowledge, this is the first fabric sensing sleeve that uses textile sensors to measure intrinsic hand muscle sEMG activity. With a 3-channel sensing array on the thenar eminence, we demonstrate that the textile sensors can effectively discriminate intrinsic thumb movements from extrinsic finger movements during both Isolated Muscle Movement and Isometric Muscle Contraction Tasks. Furthermore, we show that the fabric sleeve alone can achieve promising classification accuracy in classifying hand poses for intent inferral. For assistive robotics, where wearability and comfort are key aspects of device design, textile sensors offer a non-obtrusive interface for muscle sensing.

***Abstract*—The demand for neurorehabilitation is projected to increase drastically over the next decades, creating a need to automate and enhance the efficiency of clinical processes. Clinical assessments are important to track treatment effectiveness and to tailor therapy approaches. We here develop a scoring prediction system for the Action Research Arm Test (ARAT), a common clinical assessment for upper limb function in stroke. To predict each of the 19 movement items individually, we use a raw time series of 5 wearable movement sensors. A general classification model was trained on 100 ARAT tests from various neurological disorders and achieved a mean balanced accuracy across all closely related movement items of 80% (range: 59%-91%). Training disorder-specific models for stroke and Parkinson's disease did not improve accuracy but yielded specific feature maps that can inform future research. This study demonstrates the feasibility of predicting ARAT scores at the item level, preparing the ground for clinical decision support systems or even automated ARAT scoring.**

***Index Terms*—Wearable Sensing, Clinical Assessments**

I. Introduction

Stroke and Parkinson's Disease (PD) are among the most common and fastest-growing neurological disorders. Between 1990 and 2015, deaths from neurological disorders rose by 36.7%, showing their growing impact despite medical progress [1]. Both disorders lead to impaired motor function, negatively affecting quality of life. Despite rehabilitation leading to improvements in function, upper limb impairments persist in 55% to 75% of stroke survivors, and many persons with Parkinson's [2], [3]. Concurrently, health systems have enormous pressure to develop more cost-efficient and scalable pathways for providing rehabilitation [4], [5]. Precision rehabilitation, which relies on granular quantification of individual patients' health status, is an emerging approach to improve treatment outcomes [6]. To make precision rehabilitation more accessible, health assessments need to be rapid and highly automated.

Standardized clinical assessments such as the Action Research Arm Test (ARAT) and Fugl-Meyer Assessment (FMA) are regularly used to evaluate motor recovery and upper limb function. While the FMA measures impairment, the ARAT focuses on functional movement items such as grasping and pinching, aligning with the International Classification of Functioning (ICF) [7]. These assessments are resource-intensive, requiring trained personnel and manual observational scoring, limiting their usefulness for frequent or remote use [8]. Wearable inertial measurement units (IMUs) combined with machine learning provide a promising approach to automate clinical assessments like the ARAT. [9] demonstrated that kinematic features derived from motion sensors could reliably capture movement quality and correlate with clinical outcomes. Similarly, recent studies leveraging kinematic data from IMUs achieved approximately 80% accuracy in predicting ARAT subscale scores, aggregations of multiple movement item scores, with strong correlations to clinical ratings (R^2 = 93%) [10]. Other studies have explored IMU-based predictions of upper-limb function, achieving comparable accuracies. For example, [11] used motion capture to estimate ARAT scores with an R^2 of 67%, highlighting the potential of kinematic metrics such as smoothness and trunk displacement. [12] and [13] also used IMUs to predict motor function scores, achieving R^2 values up to 97%, however, these were limited to subscales of broader assessments such as the Wolf Motor Function Test or CAHAI. Score prediction systems can be useful tools to reduce inter-rater variability, enhance objectivity, and enable scalable, location-independent tracking of impairments, addressing key challenges in neurorehabilitation.

Despite these advances, there is need for further improvement when using wearable sensors to predict ARAT scores in clinical routine. Firstly, current work only enables scoring prediction at a domain level, leading to a functional score prediction that subsumes multiple movement items. In the clinical assessment workflow, however, scores are allocated by an assessor on a single item level sequentially per item. Hence, for a decision support to be useful, a prediction would need to take place on an item level. Secondly, it is unclear whether models specific to neurological disorders are necessary to accurately distinguish adjacent ARAT scores (e.g., scores of 2 and 3) at an item level. Differences in movement patterns, severity of impairments, and compensatory strategies between populations, such as stroke and PD, pose challenges to developing generalizable models, particularly for subtle distinctions critical to optimize therapy content. This paper directly addresses these possible improvements, resulting in two research questions.

- **RQ 1:** How accurately can we predict closely related ARAT scores at an item level?
- **RQ 2:** Do disorder-specific models result in higher classi-

fication accuracy compared to a general model?

II. Methods

A. Study Design and Procedure

This investigation is a retrospective analysis of ARAT assessments collected as part of clinical routine at Cereneo - Center for Neurology & Rehabilitation between 2020 - 2024 and was approved by the Ethics Committees of Northwest and Central Switzerland (EKNZ 2024-00196). All participants had previously provided written informed consent for data reuse per general consent (EKNZ 2017-00730).

B. Participants

To be included in this retrospective analysis, participants had to be at least 18 years old. Participants were excluded if they had: (1) neurological conditions linked to dementia, cognitive impairment, or central motor dysfunction, (2) severe sensory aphasia, (3) a history of arm paresis prior to the current condition, (4) were taking sedatives or neuroleptics, or (5) had significant hearing loss. The analysis included 37 participants (8 females, 29 males) undergoing neurorehabilitation, with a mean age of 63 ± 16 years and an average weight of 83 ± 23 kg. Of these, 14 were diagnosed with stroke, 11 with Parkinson's disease, and 12 with other neurological conditions. 26 of the participants had a left paretic side, while 13 had a right paretic side. The dataset comprised a total of 100 ARAT tests, as some participants performed multiple tests.

C. Action Research Arm Test (ARAT)

The Action Research Arm Test (ARAT) is a widely recognized clinical assessment to assess motor function in individuals with stroke that has strong inter-rater and test-retest reliabilities [14]. Its simplicity and robust psychometric properties make it a popular instrument for assessing motor recovery in clinical settings [15]. The ARAT is composed of 19 movement items categorized into four domains: grasp, grip, pinch, and gross motor movements. Each item is scored by a trained human assessor on a 4-point ordinal scale, ranging from 0 ("no movement") to 3 ("movement performed normally"), leading to a total possible score of 57. The differentiation between score 2 ("adapted movement") and score 3 ("normal movement") is made based on two criteria: Item completion time under 5s, and "normal movement quality". In standard clinical use, the ARAT employs a hierarchical scoring method, allowing assessors to assess the most challenging item within a subscale first. If the item is performed at full points, all simpler items in that subscale are scored accordingly; otherwise, additional items are evaluated to determine the appropriate score [16]. The assessments that constitute the data set were conducted using standardized ARAT materials (as shown in Figure 1) and procedures, with each movement item scored by trained professionals with over 5 years of experience to ensure consistent and reliable ratings. Assessor scores were entered into a digital ARAT application on a tablet, and exported as *.csv for further analysis. Wearable sensor data was streamed at 60Hz to the tablet from 5 synced sensors, respectively mounted at the sternum, on both upper arms, and each wrist (Dot, Xsens, NL). Assessments were typically performed at patient intake and discharge, and in some cases during the rehabilitation period if clinically indicated.

Fig. 1: (A) A depiction of the ARAT setup, including item objects arranged on a standardized table. (B) Screenshot of the scoring interface on a tablet, allowing the therapist to connect wearable sensors and rate movement item performance.

The dataset was unbalanced due to the uncontrolled nature of the data acquisition. Scores 0 and 1 were strongly underrepresented (10%), and were hence removed from this analysis. All classifications are therefore binary, predicting only score 2 or score 3. Scores 2 & 3 were also unbalanced (1113 observations vs 2096 observations over all items). To address class imbalances, the Synthetic Minority Oversampling Technique (SMOTE) was applied to balance the sample distribution across classes 2 & 3 on an item level, ensuring more robust and equitable metric calculations [17]. SMOTE generates synthetic data points for minority classes rather than simply duplicating existing samples, thereby improving model training and reducing bias.

D. Feature Extraction

Accurate movement item classification relies on features that are able to encode differences between movement patterns. Analysis was performed using data from IMU sensors and demographic data. From the IMU, raw acceleration (m/s^2) and raw gyroscope (°/s) time series in three axes were used to extract a wide range of time and frequency domain features. Key time-domain metrics such as mean, standard deviation, skewness, kurtosis, median absolute deviation, inter-quartile range, and root mean square were used to represent movement stability and variability, while features like range represented motion extremes [15]. Frequency-domain features, including dominant frequency, spectral power, peak power, signal-to-noise ratio, and spectral entropy encapsulated aspects of signal complexity [14], [16]. Additionally, jerk magnitude (mean and root-mean-square) and sample entropy represented aspects of motion smoothness and irregularity. Together, these features offered a multifaceted representation of motion patterns, providing rich substance

for the model to learn differentiation between ability levels.

E. Classification

To predict ARAT scores from IMU time-series data, we used traditional machine learning models with 5-fold cross-validation on a participant level and grid search for hyper-parameter optimization. By removing a complete participant from the fold, we ensure that no data from the same individual - also over multiple assessments - is used in the training of this fold. All features across the dataset were included for each analysis, with min-max normalization performed within each fold separately.

- **Random Forest (RF)** [18]: An ensemble method combining decision trees to capture non-linear relationships.
- **AdaBoost** [19]: A boosting algorithm that iteratively improves weak classifiers.
- **Gradient Boosting** [20]: An ensemble method minimizing residuals to reduce prediction errors.
- **K-Nearest Neighbors (KNN)** [21]: A distance-based algorithm assigning class labels from nearest neighbors.
- **Logistic Regression** [22]: A linear model offering interpretable results but limited for complex patterns.
- **Neural Network (NN)** [23]: Interconnected layers of neurons capturing complex, non-linear patterns.
- **Support Vector Classifier (SVC)** [24]: A kernel-based classifier handling non-linearities in the feature space.

To address **RQ2**, we used the same classification approach on subsets of the overall data. One model was trained only on the stroke data, and one model was only trained on the Parkinson's data.

F. Evaluation

Performance was evaluated using balanced accuracy, precision, recall, F1 score, and ROC AUC, calculated from the difference between human-assigned ARAT item scores and the corresponding estimated scores. Balanced accuracy accounts for class imbalance, while precision and recall measure the correctness and completeness of positive predictions. The F1 score balances these two metrics, and ROC AUC assesses the model's ability to distinguish between classes.

To evaluate the error distribution, item-level ARAT scores for each arm were summed per measurement.

III. Results

A. Predict Action Research Arm Test Item Score

All 7 models were trained on each of the 19 movement items across all neurological disorders. Of all trained models, the Random Forest (RF) demonstrated the highest mean performance across all movement items, achieving a balanced accuracy of 80%, ROC AUC of 89%, precision of 77%, and recall of 87% (Table I). Concerning the individual movement items, (Figure 2A) indicates robust performance in fine motor items such as GRASP Ball 7.5, GRASP Cube 7.5, and PINCH Cube 0.6 Middle Finger, with all evaluation metrics

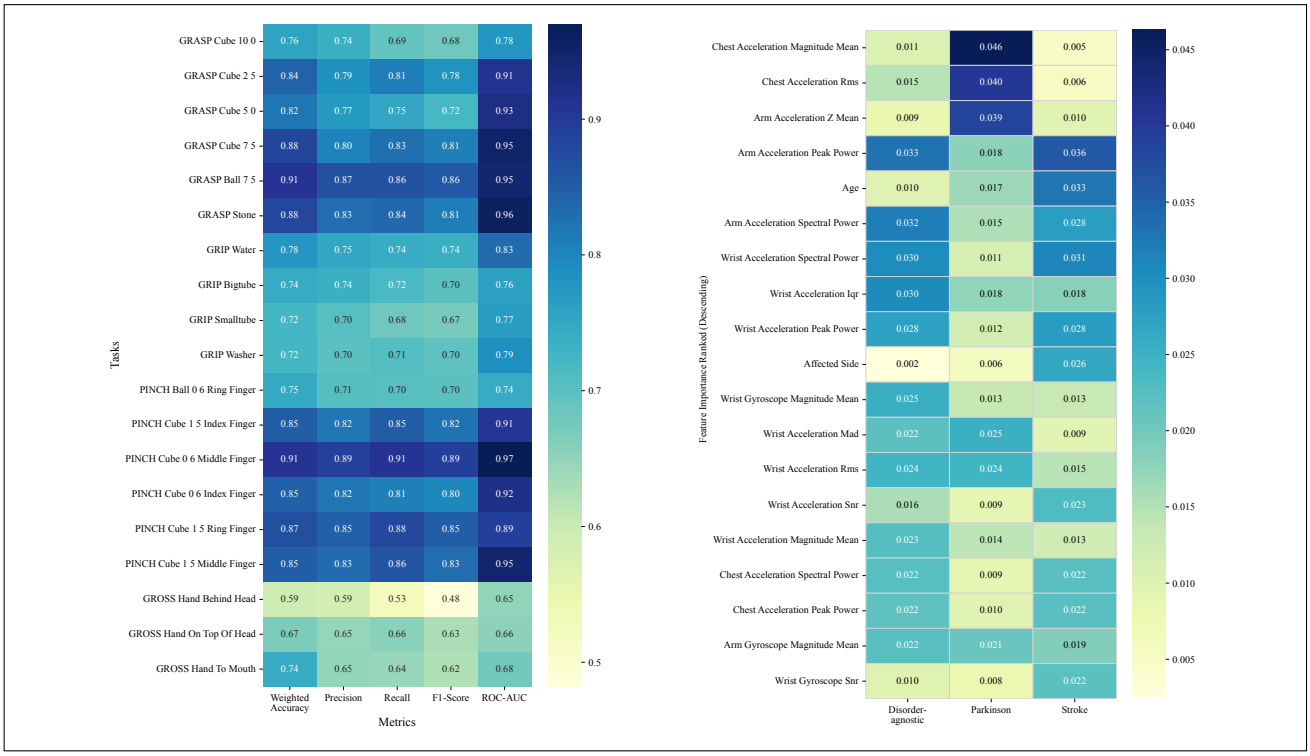

Fig. 2: (A) Performance metrics across movement items: Weighted accuracy, Precision, Recall, F1-Score, and ROC-AUC of the highest performing disorder-agnostic model for each movement item. (B) Feature importance for disorder-agnostic and disorder-specific models: Note that feature maps are quite different between models, indicating that there are disorder-specific patterns underlying the change between scores 2 & 3.

Seven different model architectures were evaluated for classification performance over all 19 movement items of the ARAT. Reported values are means over all movement items. This process was performed once on the combined dataset, that contains data from multiple neurological disorders, and on two subsets of data, containing only stroke patients or only Parkinson's patients. The highest performing metrics are highlighted in bold.

exceeding 85%. These items involve grasping or pinching objects of varying sizes and shapes (e.g. grasping a ball of the size 7.5 cm), assessing controlled hand movements and dexterity. Movement items such as the GRIP Washer demonstrated moderate performance, with metrics ranging from 68% to 79%, whereas gross motor items, including GROSS Hand Behind Head, exhibited the lowest performance, with metrics falling below 60%.

B. Impact of Neurological Disorders on Classification Accuracy

To investigate the robustness of a general classification model over different disorders, we trained disorder-specific models for Parkinson's and stroke, and compared the overall accuracy to the general, random forest classification model. An SVC model trained only on the Parkinson's dataset achieved a balanced accuracy of 76%. A Random Forest classifier trained only on the stroke dataset resulted in a balanced accuracy of 77%. For the combined dataset, as reported above, the model attained a balanced accuracy of 80% (Figure 3). Despite slightly different model architectures performing best in the different populations, there was only around 5% difference in accuracy between architectures. The error distribution reveals a narrower spread for the Parkinson's dataset compared to the combined and stroke datasets, indicating more consistency in the prediction. To understand differences between the models, we ranked the importance of individual features for each model by maximum importance contribution (Figure 2). In the Parkinson's-specific model, the highest ranked features were *chest acceleration magnitude mean* and *chest acceleration root-mean-square*. In the stroke-specific model, *arm acceleration peak power and wrist acceleration peak power* were the highest ranked time-series features. The *affected side* and *age* were observed as distinguishing features for stroke, whilst these played little role for Parkinson's or the combined dataset. Notably, *arm* and *wrist acceleration spectral power* consistently emerged as a key feature across all models, underscoring its relevance in predicting ARAT scores irrespective of the underlying neurological disorder.

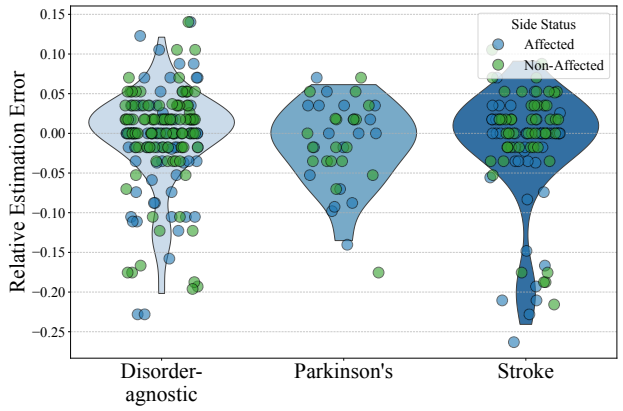

Fig. 3: Violin plots showing the distribution of the estimation error of ARAT score prediction for a disorder-agnostic, Parkinson's-specific, and stroke-specific model. Each point represents a single ARAT measurement with both the affected and non-affected sides.

IV. Discussion

The objective of this work was to evaluate to what extent data captured from wearable sensors during an ARAT assessment can be used to predict clinical ARAT scores. In contrast to previous work [10], we aimed to predict ARAT scores at the item level (**RQ1**) and to investigate the impact of neurological disorders on classification accuracy (**RQ2**). For this, we used raw acceleration and gyroscope data from wrist, arm, and chest sensors in combination with a machine-learning-based classification. Over the complete dataset of 100 ARAT assessments, our disorder-agnostic classifier achieved a mean balanced accuracy over all items of almost 80%. Models trained specifically for stroke or Parkinson's did not demonstrate a major improvement in classification accuracy. In summary, we demonstrate the feasibility of a generalizable classifier for ARAT score prediction at an item level and

identify areas for future improvement

To investigate how accurately ARAT scores can be predicted in neurological disorders using wearable sensors at an item level (**RQ1**), we trained and evaluated seven popular machine learning model architectures for each of the 19 ARAT movement items. Of the evaluated architectures, the RF classifier achieved the highest mean balanced accuracy of 80%. The RF classifier is an ensemble learning method that constructs multiple decision trees on bootstrapped subsets of the data, randomly selecting a subset of features at each split to reduce impurity and find the best decision boundary. It aggregates predictions from all trees to optimize for balanced accuracy, reduce overfitting, and improve generalization. RF works well here because it effectively captures complex, nonlinear feature interactions and is robust to noise and imbalanced datasets. Nonetheless, as shown in Table I, the maximum spread between architectures is 8%, indicating that all models effectively capture the underlying feature contributions. At the level of a single movement item, the accuracies achieved by the RF classifier ranged between 59% and 91%. The classifier achieved the greatest accuracies on items within the subscales GRASP and PINCH, ranging from 76% to 91%. These movement items are quite similar in execution - the main difference being the size and shape of an object that is picked up and moved to a predefined target location. Despite the most distal sensor being mounted at the wrist and hence not capturing finger motion, these signals seem to capture sufficient aspects of the movement pattern to predict scores quite well. Classifier performance on items from the GRIP subscale was slightly lower, with accuracies ranging from 72% to 78%. Movement items of the GRIP subscale include highly skilled movements, such as removing hollow tubes from one support and threading them onto a second support, or pouring water from one cup into another. The classifier achieves the lowest accuracies of 59% to 74% on the GROSS subscale, which entails macro movements such as touching the back of the head with the hand. These very global movements are variable in execution even in a healthy population, which leads to a larger variation in both the visual scoring and in the movement features that are considered healthy. Notably, the classifier is less accurate for larger, more difficult movements (ie. hand behind head) and accuracy increases in smaller, easier movement items (ie. hand to mouth).

Another key factor contributing to performance variation is the imbalance in the distribution of observations across score classes, particularly in movement items such as those in the GRASP subscale, where higher scores were disproportionately represented. While oversampling techniques like SMOTE were applied to address this imbalance, the generated synthetic data may not fully replicate the complexity of real-world observations, leading to reduced classification performance.

Compared to previous work, our mean balanced accuracy of around 80% at a single item level is comparable to estimations made by [10] at a subscale level. As there are no universally accepted minimal clinically important differences (MCIDs) for individual ARAT items, we cannot make any claims about our accuracy in terms of clinically meaningful values. However, we have demonstrated the feasibility of predicting individual item scores between 2 and 3 with a relatively small and heterogeneous dataset.

Our disorder-agnostic classifier trained on data across multiple neurological disorders achieved a mean balanced accuracy of 80%. Disorder-specific classifiers achieved comparable accuracies (stroke: 76%; Parkinson's: 77%), despite using much smaller datasets (stroke: n=14; Parkinson's: n=11). The trade-off between data volume and variability is not clear, hence we cannot answer RQ2 conclusively at this time. However, there are some indications that disorder-specific models will outperform a general model. First, despite the smaller data volume, accuracies are comparable to the overall dataset. Second, error distribution is more constrained in the disorder-specific models, indicating that these models may perform better when trained on larger datasets. Third: The ranking of feature importance is quite different between the disorder-specific models, indicating that individual disorders may result in degradation of disorder-specific movement features. This is something already well-described in clinical perspective, with certain movement patterns being stereotypically associated with disorders. Specifically, for Parkinson's disease, features reflecting movement variability and wrist control, such as *wrist acceleration mean absolute deviation* and *chest acceleration inter-quartile range*, were the most predictive. In contrast, for stroke patients, features that captured arm stability and compensatory strategies, like *chest acceleration signal-to-noise ratio* and *mean arm angular acceleration* in frontal plane, played a larger role. Furthermore, side-specific features were more prominent in stroke datasets, aligning with the typically asymmetric impairments observed in stroke patients.

This study demonstrates that using only statistical features of raw acceleration and angular velocity data in time and frequency domains, which are provided by most inertial sensors, encapsulates sufficient movement information to classify item scores. This approach is more accessible and potentially less biased than methods requiring pre-selection and computation of specific kinematic features, such as endpoint smoothness or joint angles [25], [26]. However, the constrained feature space may limit classification performance. Adding further features, such as joint angle trajectories and spatial information may result in increased performance. Furthermore, inherent limitations arise from using clinical scores as reference data for training machine learning models, as these models are constrained to reproduce the information encoded in the clinical scores. These observational scores may not fully capture all aspects of function at a granular level, which may cause divergent score predictions from the more sensitive sensor system.

With larger and more homogeneous datasets, we expect improved automated predictions of ARAT scores from wearable sensors. This may lead to a clinical decision support

system to support less experienced assessors, perhaps accelerating training times and reducing variability between raters. In the future, automated scoring may be sufficiently accurate for patients to perform self-assessment of upper limb function also at home using ARAT or ARAT-like movements. To support this, future research should investigate the interaction between impairment and function, and strive to determine a minimal set of movements that can inform on both constructs. Secondly, alternative technologies to wearable sensors should be considered that create more feature-rich datasets, such as markerless motion capture. Finally, sensor-based metrics need to be placed within the clinical reasoning framework in a meaningful manner, as to enable a more fine-grained distinction between assessment scores and the allocation of tailored interventions.

V. Conclusion

This study aimed to predict clinical scores for closely related individual ARAT movement items using wearable sensors. We demonstrated that item-level ARAT score predictions can be achieved across disorders with almost 80% accuracy. Disorder-specific models did not improve prediction accuracy, however, differences in the feature maps indicate that accuracy could be improved with larger datasets. By combining raw sensor data with machine learning algorithms, we aim to develop clinical decision support systems for ARAT scoring, ultimately leading to sensitive, objective, automated self-assessment tools in clinics and at home. These tools are a necessary part of the framework needed for precision rehabilitation, enabling fine-grained monitoring of motor recovery across the continuum of care.

Validating predictive simulation-derived electrical stimulation cycling in a person with spinal cord injury

Alexandre B. Peres, Gabriel G. Carmona, Carlos Gonçalves,
Ana Carolina C. de Sousa and Roberto de S. Baptista

***Abstract*— Functional electrical stimulation (FES) is commonly used in rehabilitation for its ability to activate muscle groups and functionally apply them. One of the most popular applications of FES is cycling for its safety and proven increase in users' health and quality of life. However, some challenges are intrinsic to the cycling application, among them, finding the best parameters of electrical stimulation to optimize the benefits for each user. While studies have focused on determining the optimal timing for stimulation with a bang-bang control strategy, there has been comparatively less research on its stimulation profile. This study develops and tests a predictive simulation-derived stimulation profile for FES cycling. We applied fully predictive simulations of FES cycling models following a straightforward framework consisting of (1) building torque-driven and muscle-driven models, (2) defining and solving an optimal control problem, (3) converting the optimal solution result to applicable FES control signal, (4) implementing the signal in an experimental setting, and lastly, (5) validating the control signal on a volunteer with spinal cord injury. The results, when compared to a bang-bang control strategy, increased in power output, cadence, and balance in all trials. As far as we know, this is the first study to successfully implement such a strategy. Our results show the potential of predictive simulations to improve the effectiveness of FES cycling rehabilitation.**

I. INTRODUCTION

Electrical stimulation is a rehabilitation technique that invokes muscles' contraction through electrical current resembling physiological activation [1]. By providing functionality to the generated joint movement, such as for cycling, we can refer to it as functional electrical stimulation (FES). FES significantly improves the quality of life for users with spinal cord injury (SCI) by increasing bone density and muscle mass, and improving cardiovascular health [2].

Nevertheless, many factors should be considered when implementing the exercise with patients, such as finding the optimal muscle stimulation timing [3], and its stimulation profile for each individual. Previous studies developed techniques to determine optimal electrical stimulation timing, meaning when to turn it on and off, including PID control [4], fuzzy logic [5], neural network [6], or a combination of methods [7], being it mostly focused on a bang-bang (BB) control and dependent of constant feedback or a previously collected dataset.

There is great potential in digital twins studies through musculoskeletal (MSK) modeling and simulation [8], [9], allowing for a deeper and non-invasive understanding of human motion biomechanics [10]. MSK modeling can also be integrated with optimal control theory and direct collocation. The optimal control theory is a mathematical framework for determining the control inputs to a system that minimize or maximize a cost function while satisfying dynamic and operational constraints. Meanwhile, in the context of simulations, direct collocation solves optimal control problems by discretizing time, approximating states and controls with polynomials, and enforcing system dynamics at specific collocation points, transforming the problem into a unified optimization framework [11]. A recent cycling study [12] has implemented this combination and developed a framework for optimal control simulation. Another study [13] validated the use of direct colocation by comparing its results with experimental electromyography data. These mentioned studies had as limitations their need for previously collected data from able-bodied subjects, which is not possible for people with SCI.

The integration of MSK modeling, optimal control theory, and direct colocation also enables fully predictive simulations [14]. These simulations provide insights and predictions without requiring prior experimental datasets, focusing on controlling and optimizing a specific objective function problem. For instance, previous studies [15] evaluated the effects of posture and cadence while cycling in the leg muscle activation patterns, showing the versatility and practicality of predictive simulations, but did not implement its findings in an experimental setting, and [16] introduced an electrical stimulation profile with varied intensities throughout the cycle, but was still limited due to its model simplicity, composed by only two ideal actuators in the leg, not taking into consideration the characteristics and complexities of MSK models.

Therefore, the objectives of this study are to (1) determine an optimal stimulation timing, along with its profile, suitable for experimental implementation through a simulation pipeline, and (2) evaluate the movement in an experimental FES cycling setup with a participant with SCI, comparing it to a previously used trial and error BB stimulation pattern

[17]. This framework may shed new light on the application of simulations, while also paving the way for future work that can improve the comprehension of FES cycling muscle activation.

II. METHODS

This study followed a multi-step methodology to develop, implement, and validate predictive simulation-derived stimulation profiles for FES cycling in a participant with SCI. The process (Fig. 1) involved (1) creating cycling models in an MSK simulation environment, (2) solving an optimal control problem to derive stimulation profiles, (3) extracting and processing the stimulation profile, and (4) implementing and testing these signals in an experimental setup.

A. Cycling models creation

We used OpenSim [18], an open-source tool for simulating MSK structures, for modeling and neuromusculoskeletal analysis. The human model used is one of the human default models within OpenSim's library, the *Gait10dof18musc*[1], which has ten degrees of freedom and eighteen muscles in the lower limbs. The *rectus femoris* (RF) and *vastus intermedius* (VI) in the model are a simplified generalization of the quadriceps muscle group. The cycling model is the human model positioned for recumbent cycling in relation to a crank model based on a crank-pelvis relation seen in Fig. 1(a). In addition, there are pedals with the same dimensions as the experimental setup, to which the model's ankles are attached and immobilized to represent the use of orthopedic boots, ensuring the safety of the user during sagittal cycling movement. The cycling model's design was based on our previous studies [19], [20], where it was developed and is publicly available[2], with adaptations to better fit this study's predictive simulations context. A recent update in OpenSim Moco required replacing locked joints in the cycling model with weld joints to improve computation efficiency. Therefore, we modified the upper body joints accordingly, ensuring the model's compatibility with the updated framework while maintaining its biomechanical accuracy.

Two different versions of the base cycling model were created: a torque-driven and a muscle-driven. In the torque-driven model, all muscles were removed and replaced with ideal torques at the hip and knee joints, capable of generating up to 40 Nm, which is enough for the desired simulated cycling intensity based on [13]. For the muscle-driven model, all muscles but the RF and VI were deactivated. This selection was chosen to better represent a previous FES cycling control system [17], where a possible setup is to have only the quadriceps muscle group experience direct activation. Nevertheless, the passive forces and tendon compliance of all other muscles are preserved in the model.

B. Optimal control problem definition and solution

We used OpenSim Moco [21], a toolkit within OpenSim to optimize motion and control of the simulations, and OpenSim Moco, which initiates *CasADI* [22] within *(MocoCasADI)*, converting the problem into a nonlinear programming problem. Then, Moco uses IPOPT [23] to find an optimal solution to the problem.

Similarly to [20], we defined an optimal control problem to be solved (Fig.1(b)). The problem was formulated to simulate a range of cycling data and represent the gear resistance present in the experimental setup. The torque-driven model was required to complete four full revolutions within 7 seconds, encountering a crank resistance moment of 8 Nm. The revolutions requirement was made to obtain cycling data from a steady state regime, while the crank resistance was slightly exaggerated aiming for more expressive muscle activations in the simulations. To prevent the crank from spinning backward and simulate an average performance from the volunteer, its speed must remain within the range of 0°/sec to 240°/sec. The initial position of the crank is fixed at 0°, meaning the left crank arm is at the top dead center (Fig. 1(a)). The model is free to assume initial speeds for the crank, hips, and knee joints as long as they are maintained within the set crank speed. The simulation will be deemed successful if it meets these conditions, along with a convergence tolerance of 10^{-2} and constraint tolerances set at 10^{-4}, while also aiming to minimize the cost function in Eq. (2). The cost function weights were set by balancing the time to execute the movement and its use of torque and are represented by $w_{time} = 6$ and $w_{actu} = 2$ respectively. The eq. (1) minimizes the duration of the movement (t_{sim}) and the sum of each actuator's (x) total energy (J_{actu}) during the torque-driven movement.

$$J_{actu} = \int_0^{t_{sim}} \sum_{i \in actu} |x_i(t)|^2 \, dt \tag{1}$$

$$J_{total} = w_{time}\, t_{sim} + w_{actu}\, J_{actu} \tag{2}$$

Next, we addressed the muscle redundancy problem [24] using the muscle-driven model. To solve this problem, we employed the *MocoInverse* function, which utilized the kinematics from the torque-driven simulation as a reference. This approach helped us determine a combination of muscle activations that could reproduce the kinematics with the available actuators, i.e., the RF and VI muscles. The *MocoInverse* function was beneficial not only for identifying the desired sequence of muscle activations but also for its ease of implementation and computational efficiency, allowing for quick verification of results throughout the development process.

C. Optimal control signal extraction

Once the simulations were finished, the final product was a muscle-driven file containing a time stamped list of all the RF and VI muscle activations ranging from 0 to 1, where the latter represents maximum muscle activation, that contributed to the cycling motion described in Section II-B. To enhance the overall quality of the data, the first revolution was discarded because its motion was not yet stable.

[1]The model can be found at: Gait10dof18musc.

[2]Currently being developed and maintained at: FES-cycling project.

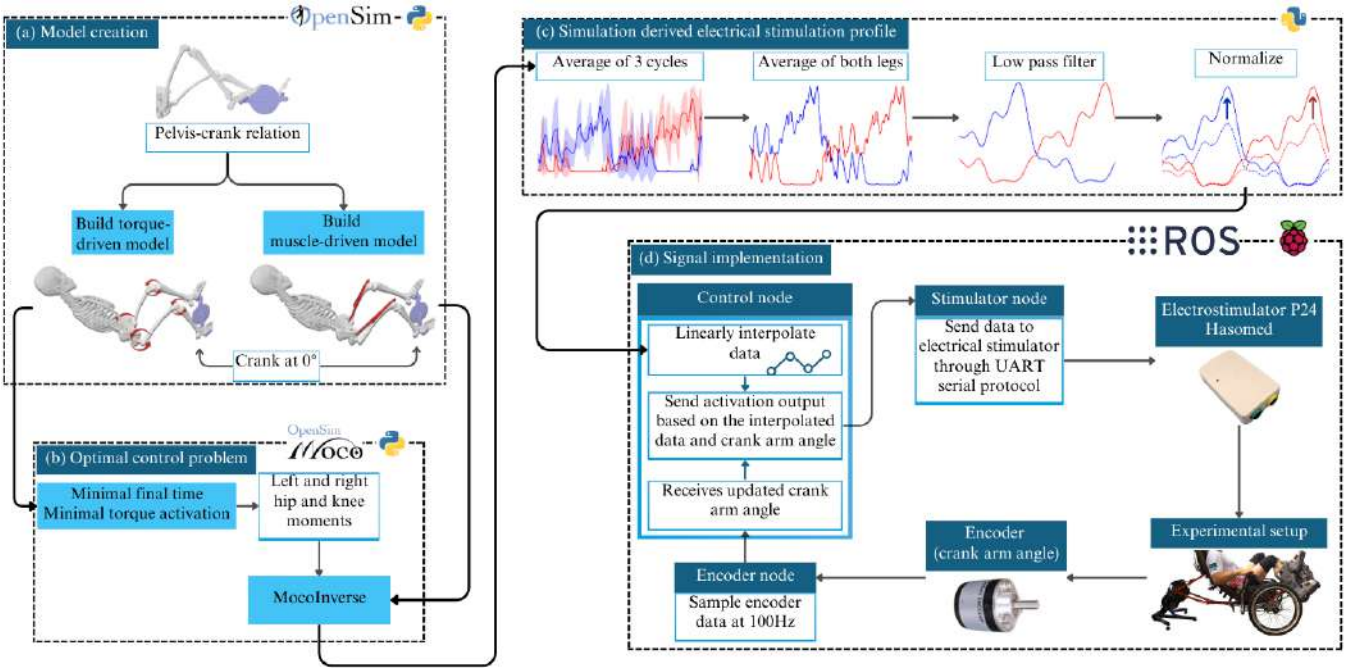

Fig. 1: Framework for generating muscle activation from predictive simulations. (a) Model creation: torque-driven and muscle-driven models were developed using the pelvis-crank relationship from the physical setup. (b) Optimal control problem: simulations that minimize movement time and joint effort using predictive algorithms. (c) Simulation-derived electrical stimulation profile: the necessary steps to obtain the stimulation profile from the simulated data. (d) Signal implementation: the control node receives the stimulation profile and data from the encoder, where angle values are processed and interpolated to generate the stimulation signal, which is then sent to the stimulation topic for delivery via the electrical stimulator.

Therefore, the three remaining revolutions were organized into separate files, where the data was interpolated to ensure consistent resolution. This process allowed for the extraction of an average stimulation pattern for each leg over the three cycles (Fig. 1(c)). Next, to ensure a symmetrical stimulation signal, we calculated the average stimulation from both legs. Furthermore, the signal was filtered using a 5^{th} order Butterworth low-pass filter to achieve a smoother signal and more easily implement it in an experimental setting. Lastly, we normalized the signal, as the simulation results assumed direct muscle fiber activation, which is not replicable through superficial stimulation. All the torque-driven and muscle-drive simulations and data processing were performed on a Ryzen 9 5950X CPU with 64GB of RAM.

D. Optimal control signal implementation

The Fig.1(d) illustrates the setup used in [17] and to validate the study, which is an embedded system consisting of a Raspberry Pi 4 Single Board Computer utilizing the ROS2 (Robot Operating System) framework, an encoder model E38S6G5-600B-G24N from SHARVi Electronics, and an electrical-stimulator model Rehastim P24 from Hasomed. ROS2 facilitates code modularization, creating modules named nodes, which separate input angle data, control logic, and stimulation output into topics that can be subscribed to and published by the respective nodes [25].

We modulated the current according to the interpolation of the simulated result while having the pulse width fixed at 450μs. The stimulation signal was interpolated using a linear model, allowing angle values to have different frequencies from the simulation ones. The control node receives the encoder's angle at a sample rate of 100 Hz. After interpolating, the output is multiplied by the desired current and then published to the stimulation topic, which sends the stimulation pattern current value in a fixed pulse width. The final stimulation signal follows the encoder's sample rate, therefore a control signal sample is generated for every encoder sample.

E. Experimental protocol

We followed a protocol consisting of three non-consecutive days of data collection. Each day of data collection started with 20 minutes of stretching, followed by 20 minutes of electrical stimulation warm-up. Two $8cm$ x $13cm$ electrodes were positioned in each leg over the quadriceps muscle group with the supervision of a physiotherapist similarly to [26]. On the first day, we implemented the unnormalized control signal (uCS) obtained after the filtering step. This signal assumes that the simulated signal is directly applied to the muscles. The normalized simulated control signal (CS) was used on the subsequent data collection days. On the second and third days, four sets of data were collected, with 5 minutes of rest between each set, alternating between the new proposed CS and the BB. The pulse width was set at 450 μs and the current, starting from 30mA, was increased manually in steps of 2mA every 10 seconds

TABLE I: Summary of data collection protocols, including the type of control signal (uCS or CS) and the sequence of trials conducted over three non-consecutive days

day 1	1 set of data	uCS
day 2	4 sets of data	CS_1, BB_1, CS_2, BB_2
day 3	4 sets of data	BB_3, CS_3, BB_4, CS_4

for a safe and cautious approach until a maximum value of 100mA, which is the maximum current the volunteer is used to. From this point on no assistance was given and one minute of data was collected (Table I).

For later data analysis, we collected power (P), crank arm angular velocity (V), and the symmetry of the left and right legs during the motion (B). Two sensors were used for the data collection: (1) instrumented pedals (WAHOO POWRLINK ZERO) to measure P, V, and B at a sample rate of 1Hz, and (2) an instrumented bike trainer WAHOO Kickr V6 that can control resistance to simulate different cycling conditions. Furthermore, during the data collection we connected to *Indievelo*, a virtual cycling environment to better replicate the volunteer's weight and a flat cycling surface and assist with data collection.

F. Compliance with ethical requirements

The volunteer is a 46-year-old male, 170cm tall, 78kg, with a complete SCI (T9 AIS A), meaning no voluntary lower limb muscle contraction, agreed to participate in the study via written consent. The experiments were performed under the ethics committee from the University of Brasília code CAAE: 75441323.4.0000.8093.

III. Results

A. Fully predictive simulations

The problem (Section II-B) was implemented and solved with fully predictive simulations and MSK modeling taking approximately 6 minutes for each simulation. The torque-driven motion was then tracked for the muscle-driven problem and we generated the muscle activations for RF and VI, resulting in the sequence of muscle activation capable of performing the optimal solution to the problem. However, it was noticed that the RF activation patterns are a lot more expressive when compared to the VI, which only activates simultaneously with its correspondent RF but with less intensity. As the VI activations were much lower than the RF, the used signals were the predicted RF activations. but as mentioned in section II-C, only the RF contributions were considered (Fig. 2).

B. Control signal implementation

The predictive simulation-based pattern implementation of the CS was successful. The uCS was used on the first day, and the volunteer could not perform the cycling motion unassisted due to an insufficient current magnitude. Therefore, P, V, and B were not measured (Table II - day 1). On the second and third days (Table II - days 2 and 3), the normalized signal (CS) was used and the cycling motion was performed.

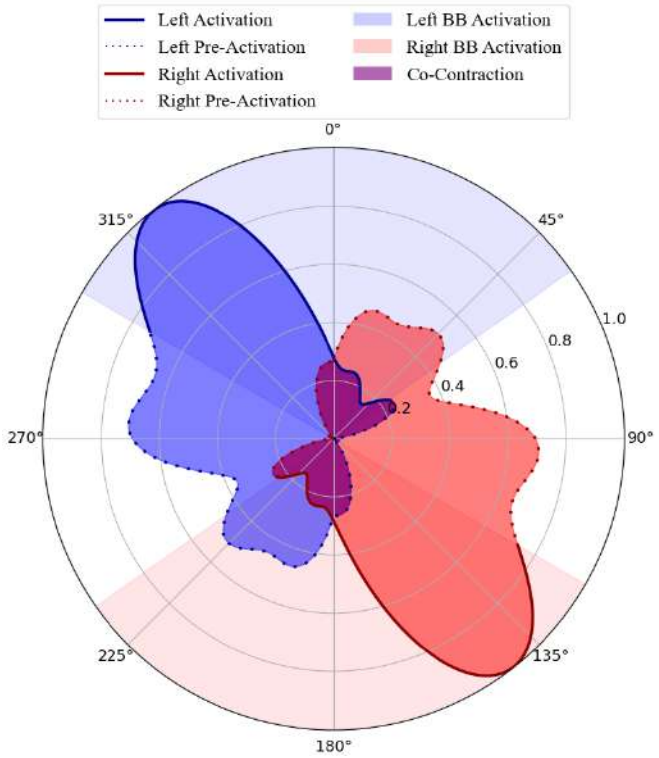

Fig. 2: Rectus femoris (RF) activations for the left (blue) and right (red) legs. The blue and red graphs indicate normalized muscle activation, with the perimeter corresponding to the crank position. The dark blue and red graphs indicate de simulation-derived stimulation profile. The background shades follow the same color code and scale and represent the bang-bang (BB) stimulation pattern used by Project EMA. The dotted lines are outside what is considered mechanically advantageous muscle activation, hence, referred to as pre-activation. The purple area indicates muscle co-contraction, where both RF muscles are activated simultaneously, even during the opposite leg's high activation moments.

There was an increase in all three observed variables when compared to the BB signal. For instance, during the second trial of Day 2 (CS_2 vs BB_2), the power output increased from 11.9 W to 15.2 W (27% higher), the speed rose from 41.3 RPM to 49.0 RPM (18% higher), and the balance improved from 27.1% to 44.0% (62% higher). A high improvement in balance, especially for rehabilitation in SCI patients, could indicate better muscle coordination and safety during cycling. In Fig. 3 is possible to see the 1 minute of non-assisted cycling performed in sequence (CS_4 and BB_4).

IV. Discussion

We successfully created and implemented a framework to predict muscle activations required for FES cycling using fully predictive simulations. We also successfully implemented the simulated-derived CS in an experimental setting, not only working but achieving better results (Table II). This type of conclusion was only achievable by considering

TABLE II: Results of cycling performance metrics collected during experimental trials. Variables include average power output in W, crank angular velocity in RPM, and left-right balance in %, organized by trial and day of collection.

	$\overline{Power}$	$\overline{Velocity}$	$\overline{Balance}$
Day 1 of data collection			
uCS	—	—	—
Day 2 of data collection			
CS_1	13.7	44.1	44.1
BB_1	12.7	42.3	34.6
CS_2	15.2	49.0	44.0
BB_2	11.9	41.3	27.1
Day 3 of data collection			
BB_3	13.2	39.4	35.6
CS_3	14.2	40.9	54.7
BB_4	13.4	40.5	40.1
CS_4	16.3	43.7	48.8

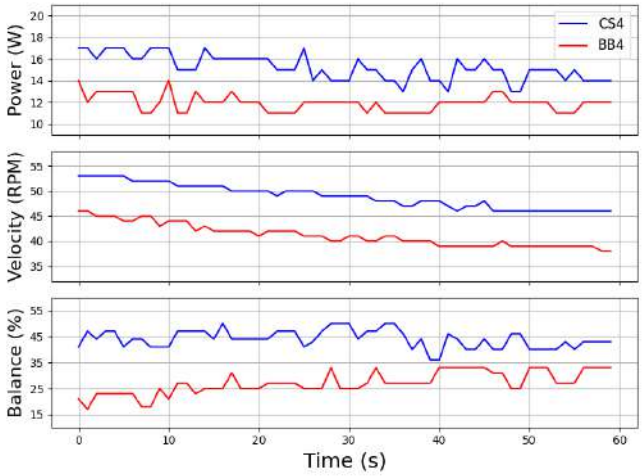

Fig. 3: Comparison of cycling performance during one minute of unassisted cycling between CS_4 and BB_4 trials. Variables shown include power (top), cadence (middle), and left-right balance (bottom), based on data from Table II.

the complete analysis of the dynamics of movement, made possible through the use of fully predictive simulations.

It can be seen in Fig. 2 that the control signal indicated by the simulation overlaps the stimulation pattern utilized by Project EMA in its peak point, but for the most part, it keeps the RF pre-activated with considerably less intensity. Pre-activation, although it may initially seem counterproductive, is commonly observed in high-performance athletes and has been shown to reduce force loss during less energy-efficient stages of cycling [27]. The improved equilibrium between the legs observed during the experiment could be attributed to the decreased muscle reaction time facilitated by RF pre-activation (Fig. 2), which likely contributed to a more balanced and synchronized cycling motion [28].

A second phenomenon present in the simulated FES pattern (CS) is the co-contraction of both RF (Fig. 2). Co-contraction of antagonist muscles is well described [29]–[31], and has an important role in movement stabilization and consequently protection of the joints from elevated stress [32]. In the context of simulations, it is also a result of excessive passive forces from the hip and knee extensors [33]. However, since this is not a factor in the cost function, the co-contraction can be understood as a product of the bi-articulated properties of the RF [34], being not only responsible for knee extension but also the sole responsible for hip flexion throughout the model's movement. Additionally, it is also a mechanism to prevent the crank from exceeding its maximum speed.

We believe a collective of pre-activation, co-contraction, and the optimized control signal is responsible for the increase in average power, cadence, and balance seen in the results. In the rehabilitation context, power is directly related to the user's mass and strength gains, making it the most commonly used metric for evaluating performance and motor recovery when applicable [35]. The crank angular velocity indicates the intensity of cardiovascular exercise as well as work efficiency [36]. Finally, balance is an important indicator of lower limb symmetry [37]. However, further studies need to validate the control signal over longer trials evaluating the effects on fatigue development caused by the longer stimulation periods. Additionally, we recognize that the modeling and simulations presented can be improved to more accurately represent FES cycling conditions, since the validity of the methods relies on the assumption that the models accurately represent SCI conditions. Future work involves grouping muscles within the quadriceps. This is important because superficial non-invasive electrical stimulation can not selectively target specific muscle fibers such as the *rectus femoris* and *vastus intermedius*. When this is implemented in simulations, it's expected to observe a decrease in the overall activation signal, due to the improved use of VI contributions to the movement.

V. Conclusion

As far as we know, this is the first study to successfully implement the results of a fully predictive simulation pipeline in an individual with a complete spinal cord injury. The predictive simulation-derived stimulation patterns outperformed the traditional bang-bang control strategy in terms of power output, cadence, and balance. This was achieved through the integration of musculoskeletal modeling, optimal control theory, and direct collocation techniques, which enabled a comprehensive analysis of movement dynamics and muscle activation. These findings highlight the potential of predictive simulations to enhance FES cycling rehabilitation and provide a solid foundation for future research aimed at further optimizing stimulation strategies and improving clinical outcomes.

***Abstract*—Observational gait analysis and categorical ratings are commonly used by clinicians to assess pathologies. The purpose of this study was to determine the capacity of novice observers to characterize the gait behavior underlying biomechanical performance objectives using stylistic labels. We hypothesized that visual characterization of physics-based musculoskeletal predictive simulations of walking would be sensitive to the biomechanical objective employed by individuals, as well as the visual perspective. We developed 75 full-body muscle-driven predictive gait simulation videos, corresponding to five subject models, five biomechanical objectives, and three visual perspectives. Subject models were constructed for five individuals performing straight line walking, with optimal tracking simulations generated for each using computed muscle control. Direct collocation was used to apply five different objectives to each individual's nominal behavior including metabolic cost, summed and squared muscle activations, time-integrated whole-body angular momentum, time-integrated bilateral ground reaction forces, and an equally weighted multi-objective cost function summing the individual objectives. 100 crowd workers characterized each simulation on a 1-5 scale using stylistic labels corresponding to each objective. Multinomial logistic regression analysis revealed that loading and activation ratings were significant predictors of muscle activation-optimized movements, while activation ratings were significant predictors of movement perspective. Balance ratings were significant for the frontal view alone, suggesting that balance indicators are more easily distinguished in the frontal plane. Collectively, the wisdom of crowds could distinguish motion associated with some biomechanical objectives, but due to the redundancy of motor control strategies used by individuals, the resolution of this observational approach is limited.**

Keywords— gait analysis, predictive simulation, crowdsourcing

I. Introduction

Determining accurate assessments of gait performance is key in preventing falls among individuals with limb loss, neurologic conditions, and the elderly [1]. However, current laboratory and clinically based assessment methods can be expensive, lengthy and suboptimally diagnose comorbidities or subclinical presentations [2]. Pathological gaits are difficult to assess due to the overlapping symptoms underlying multiple gait disorders [1] as well as high gait pattern variability both within and across individuals [3]. These factors make it difficult to determine appropriate interventions from single metrics or clinical assessments, and instead suggest that assessment based on a variety of multi-modal metrics by multiple assessors is needed.

Qualitative, semiquantitative, and quantitative metrics are all used as modes of gait assessment. Qualitative assessments rely on clinical observation, which can be subjective [4, 5], and while useful for assessing severity and risk do not provide much information on specific gait mechanics [2, 6]. Quantitative sensors can be costly and less practical, and while some diagnoses correlate with factors such as self-selected gait speed, these quantitative metrics are often less applicable to geriatric individuals [3], individuals with neurologic gait patterns [7], or those with nonspecific gait abnormalities [4]. Semiquantitative techniques often involve rating scales, such as the Tinetti Mobility Test (TMT) and the Gait Abnormality Rating Scale (GARS) [7, 8], and require extensive gait observation by an experienced clinician [6]. Subjectivity of clinician judgement, gait variability, and gait comorbidities can make it difficult to identify objective quantitative evidence for gait disorders or provide accurate diagnoses [1]. The prevalence of these methods supports the existence of visible indicators of kinematic and postural factors in a patient's motion that are implicitly used to diagnose underlying ailments [9], and suggests that assessment techniques based around these visible indicators provides viable quantitative data. In addition, multifactorial analyses that include both kinematic and postural factors may improve the overall accuracy of diagnosis for those with comorbid or subclinical presentations [10].

Prior work has demonstrated the feasibility of simulation-based and videotaped observational gait analysis (VOGA) to diagnose and assess the severity of gait disorders including multiple sclerosis [11], post-stroke hemiplegia [12], rheumatoid arthritis [4], and Parkinson's disease [13]. These studies were each performed at a small scale, with concerns about the inter-rater reliability of untrained individuals [4, 12]. The inter-rater reliability of VOGA has been shown to vary across studies [14, 15], but also exceeds that of real-time observational assessments [16]. The intra-rater reliability of VOGA also varies, with cases of worse reliability than in-

person assessments [17], as well as moderate reliability regarding the presence of gait characteristics, but a lower reliability when making judgements about their severity [18]. A study on post-stroke gait found a negligible difference in observations made by novice and experienced physical therapists, with visual observations equally reliably made by less experienced individuals [5]. Another study in surgical robotics found a positive correlation between biometric data and both clinician and crowd estimations of the experience level of surgeons based on their performance [19], suggesting crowd workers were able to distinguish surgical skill levels and indicate this via a lexicon of contrasting adjective pairs.

The purpose of this study was to determine the capacity of novice observers (i.e., crowd workers) to characterize gait behavior corresponding with the biomechanical performance objectives underlying an individual's motor control strategy using a lexicon of contrasting adjective pairs. We test the hypothesis that visual characterization of physics-based musculoskeletal predictive simulations of walking would be sensitive to the biomechanical objective (i.e., cost function optimization) used by individuals, as well as the visual perspective (sagittal, frontal, or 3D views).

II. Methods

A. Crowd Worker Video Assessment

Simulated gait videos [20] were generated of a full-body musculoskeletal model completing one full gait cycle. Gait patterns were constructed using subject-specific tracking and ground reaction force (GRF) data from an IRB-approved experiment [21, 22]. Scaled musculoskeletal models of each subject were developed in Visual3D (C-Motion, Inc.) and OpenSim with 21 degrees of freedom, a locked MTP joint, and 92 Hill-type musculotendon actuators [23]. Predicted gait patterns were optimized for each of five biomechanical objectives (metabolic cost, summed and squared muscle activations, time-integrated whole-body angular momentum, time-integrated bilateral ground reaction forces, equal weight multi-objective) [20] in MATLAB (MathWorks, Inc.) as an optimal control problem using direct collocation [20, 24]. Videos presented each unique motion from each of three different views (frontal, 3D, and sagittal) for all five subjects, for a total of 75 videos. Images of the activation-optimized gait model from all three views are shown in Fig. 1.

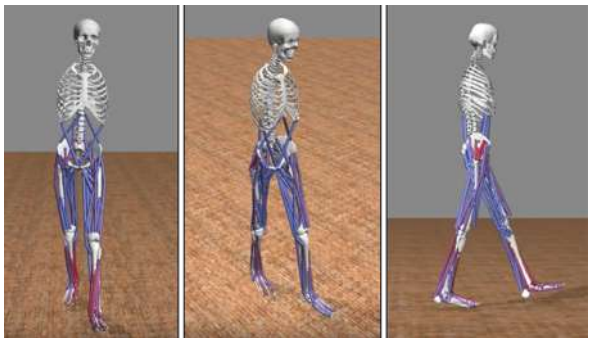

Fig. 1. Visualized time steps of a subject simulation walking with an activation optimized controlled gait from frontal, 3D, and sagittal views.

TABLE I. Lexicon of Gait Objective Adjective Pairs

Category	Qualitative Ratings	
	Low Rating (1)	***High Rating (5)***
Energy	Lethargic	Swift
Activation	Stiff	Casual
Balance	Unstable	Controlled
Loading	Heavy	Light
Normal	Unrealistic	Realistic

This gait assessment technique was evaluated by comparing crowd worker assessments of perceived gait characteristics to underlying gait mechanics. The 75 simulated gait videos were posted on Amazon Mechanical Turk and rated by 100 untrained crowd workers on five objectives (energy, muscle activation, balance, loading, and normal appearance) on a 1-5 semantic differential rating scale using a lexicon of contrasting adjective pairs (Table I), with a rating of "1" corresponding to "negative" terms, and "5" with "positive" ones.

B. Average Crowd Worker Responses and Normalization

The mean and standard deviation of the 100 crowd worker ratings were determined for each objective and simulation view combination, resulting in 15 unique groups. Mean ratings for the characteristics corresponding to biomechanical objectives were Z-score normalized by the "Normal" ratings to discern variations between each simulated gait by their perceived viability as a realistic gait pattern. The mean ratings for each objective were compared with associated quantitative metrics provided by these physics-based simulations [20], including normalized metabolic energy, sum of muscle activations, lower-limb loading, and whole-body angular momentum.

C. Multinomial Logistic Regression Models

Multinomial logistic regression (MLR) was used to determine statistically significant predictors of each gait objective and simulation view from crowd worker ratings, with each gait objective and view representing separate unordered dependent variables. The individual objective probabilities were compared to the multi-objective probability (π_multi) and the views probabilities were compared to the sagittal probability ($\pi_sagittal$), as shown in (1-a) and (1-b). In the equations, a is the intercept and b is the logistic coefficient of each objective and view respectively, where i denotes gait characteristics including: metabolic energy, muscle activation, balance, limb-loading, and normal appearance, respectively. P-values under 0.05 were considered statistically significant.

$$\ln\left(\frac{\pi_objective}{\pi_multi}\right) = a + \sum_{i=1}^{n} b_i x_i \qquad \text{(1-a)}$$

$$\ln\left(\frac{\pi_view}{\pi_sagittal}\right) = a + \sum_{i=1}^{n} b_i x_i \qquad \text{(1-b)}$$

Additional multinomial logistic regression curves were used to predict biomechanical gait objectives (1-a) using the

crowd worker ratings for each individual view to determine which simulation view(s) provided statistically significant results. All data analyses were conducted in MATLAB.

III. Results

A. Crowd Worker Video Assessment

The responses of 100 crowd workers to 75 simulated gait videos resulted in 7500 total ratings for each gait characteristic (Fig. 2). The loading and metabolic energy characteristics received the lowest mean ratings across all simulations, at 2.49±0.05 and 3.26±0.04 respectively, regardless of the optimization or view utilized in the video. The balance characteristic received the highest mean ratings, at 3.62±0.05, for all simulations regardless of biomechanical objective or simulation view shown. These results are also reflected in the normalized values, where the balance Z-scores were positive, and the limb-loading and metabolic energy scores negative, suggesting that crowd workers found the gaits to be mildly controlled, slightly swift, and mildly heavy (Table I) regardless of their optimized objective.

The "normal" metric was also similar across all simulations, at a mean rating of 3.48±0.04. The overall mean rating across all assessments was 3.28±1.03, with few "1" ratings. Maximum (5) and minimum (1) scale values made up only 5.1% and 9.1% of the total ratings respectively. Non-extreme response styles have been observed for semantic differential rating scales [25], with respondents tending towards non-extreme responses when the scale labels are more ambiguous [26]. This infrequency of extreme rating responses could be due to the crowd workers' lack of familiarity with the survey, VOGA or the lexicon of gait characteristics.

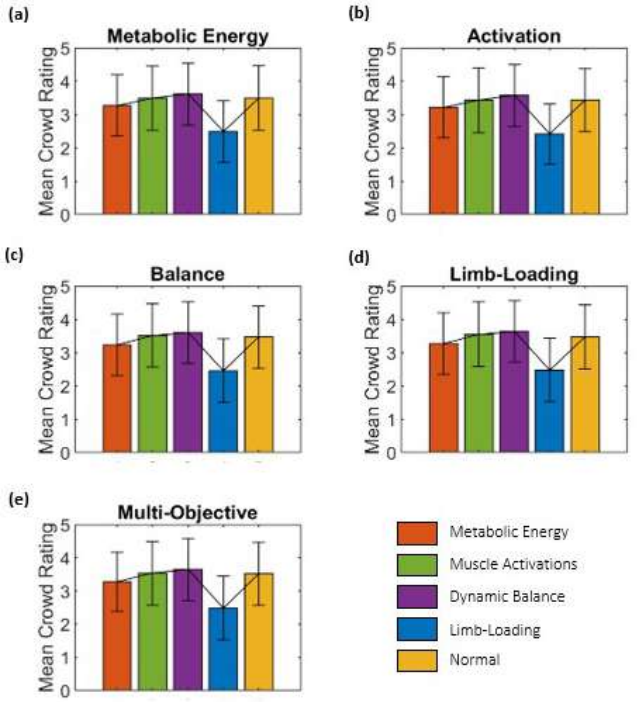

Fig. 2. Mean and standard deviations of raw crowd worker ratings for each simulation optimized for (a) metabolic energy, (b) activation, (c) balance, (d) limb-loading, and (e) multi-objective biomechanical objectives.

B. Comparisons with Biomechanical Simulation Data

Results from the previous simulation study [20] showed that the simulations minimizing muscle activations also had lower normalized metabolic energies [20]. This is reflected in the energy ratings for the muscle activations-optimized simulation, which was rated as the most lethargic on average (3.22±0.05). The activation optimized simulations were also rated as appearing the most unstable (3.58±0.05), stiff (3.43±0.05), heavy (2.42±0.02), and unrealistic (3.44±0.01). Crowd workers rated the multi-objective simulation as appearing to have the greatest metabolic energy (3.29±0.01), the swiftest on average across all three views, followed by the metabolic energy and limb-loading optimized simulations. These gait patterns were also rated as the most controlled (3.65±0.04), and realistic (3.53±0.004). The metabolic energy optimized gait was rated as the lightest (2.49±0.03), and the loading optimized gait as appearing the most casual (3.55±0.06).

The whole-body angular momentum in the transverse plane is significantly lower across all gaits than in the other planes [20]. The wisdom of crowds rated that the 3D view, activation-optimized gait appeared the least balanced, or most unstable, with the 3D view rated as the most unstable view for the balance and loading-optimized gaits as well. Interestingly, the multi-objective optimized gait was rated as the most unstable from the frontal view, and the metabolic energy optimized gait rated as the most unstable from the sagittal view (Fig. 3).

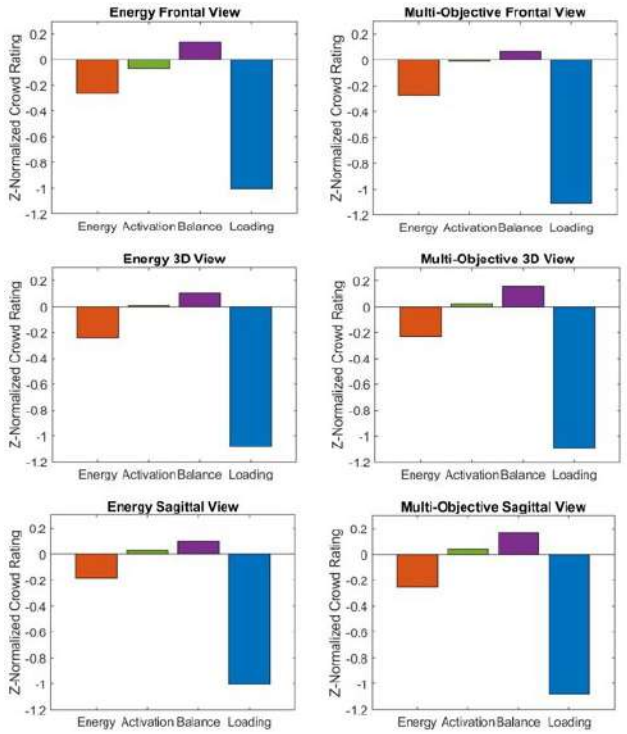

Fig. 3. Comparison of the Z-normalized mean ratings for the metabolic energy and multi-objective optimized gaits.

C. Multinomial Logistic Regression Models

The biomechanical objective MLR model predicts (p=0.002) the logistic probability of each objective compared to the multi-objective probability from all 7500 crowd worker ratings (Fig. 4). The crowd worker ratings for activation (p=0.003) and loading (p=0.001) provided statistically significant indicators for predicting if a simulation was optimized for muscle activation levels. This suggests that crowd worker perceptions of how "casual" vs. "stiff" and "light" vs. "heavy" a gait appeared were statistically relevant in determining if the gait modeled minimized the summed muscle activations as opposed to the multi-objective cost function. MLR analysis also revealed that the crowd worker ratings for normal gait appearance (p=0.016) were a significant indicator of simulations optimized for lower-limb loading.

The simulation views multinomial logistic regression model (p=0.01) determined the logistic probability of each view compared to the sagittal view probability. This model found that activation ratings were a significant predictor of a simulation having a 3D or frontal view rather than a sagittal one. Loading ratings were also identified as a significant predictor for the frontal view.

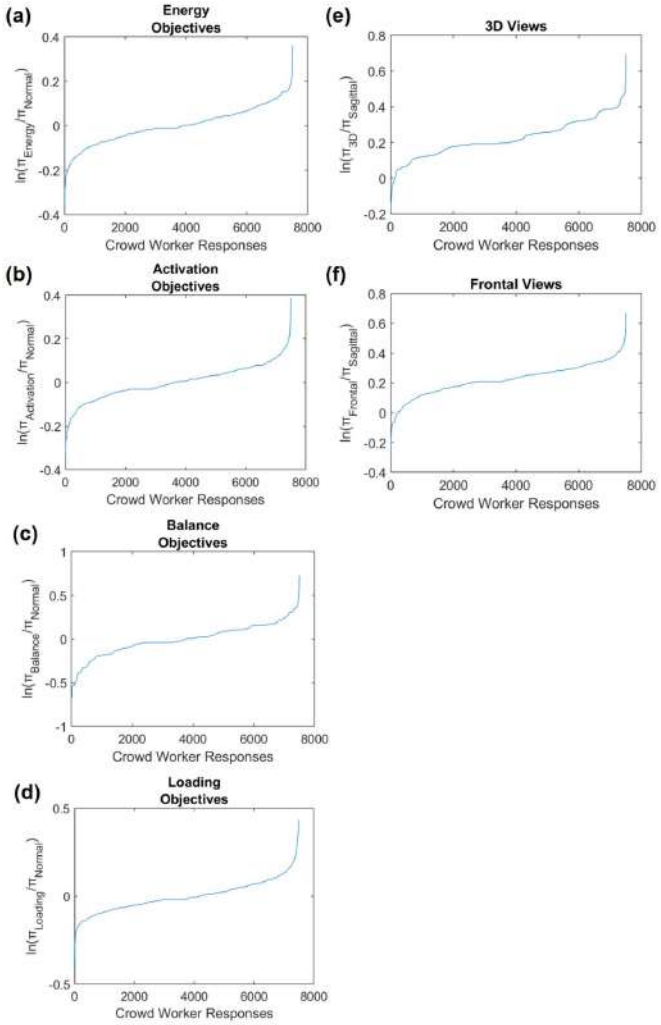

Fig. 4. Multinomial logistic regression models of crowd worker ratings predicting each gait simulation's biomechanical objective (a-d) and simulation perspective view (e-f).

Separate multinomial logistic regression models were constructed for the frontal, 3D, and sagittal views, with 2500 observations for each view. The most statistically significant gait characteristic predictors of biomechanical objectives were found in simulation videos from the frontal view (p=0.049). The results for the frontal view MLR analysis conducted to identify significant predictors for each biomechanical objective cost function can be found in Table II, including the logistic intercept (a) and coefficients (b) used in Equation (1-a) for each objective. Significant predictors are highlighted. Two significant gait characteristics were identified for predicting that a gait simulation was optimized for muscle activations: the balance ratings and limb-loading

ratings. Limb-loading was found to be the single significant gait characteristic for predicting a dynamic balance-optimized simulation. For videos from the 3D view (p=0.020), balance ratings were found to be a significant indicator in predicting whether a simulation was optimized for lower-limb loading. The logistic model for the sagittal view did not yield statistically significant results (p=0.287).

IV. Discussion

In this study, simulated musculoskeletal gait simulations optimized for five different biomechanical objectives and shot from three different views were rated by the wisdom of crowds based on the quality of five gait characteristics: energy, muscle activation, balance, loading, and normal appearance using a provided lexicon of contrasting adjective pairs given in Table I. The purpose of this study was to determine the capacity of novice observers to characterize the gait behavior underlying biomechanical performance objectives using stylistic labels. We hypothesized that visual characterization of physics-based musculoskeletal predictive simulations of walking would be sensitive to the biomechanical objective (i.e., cost function optimization) used by individuals, as well as the visual perspective. In general, we accept these hypotheses. The wisdom of crowds found that the multi-objective gait simulation appeared the most realistic, or "normal" in appearance. This suggests that from a strictly visual perspective, gait patterns optimized for multiple objectives were recognized as more realistic than those optimizing any one biomechanical objective. The gait simulations used in this study are of straight-line walking with no perturbations, differing from previous studies where multi-objective gaits were prioritized in performing perturbed or lateral movements [27], [28], but crowd workers still identified a multi-objective gait optimization as more realistic to the appearance of self-selected walking patterns than that of a metabolically optimal gait.

The muscle activation optimized simulations were rated on average as the least controlled, energetic, and realistic, and the most heavy and stiff, which is supported by the MLR findings that limb-loading and activation ratings were significant predictors of an activation-optimized gait. Balance ratings were not significant predictors overall but were significant when predicting from the frontal view simulations alone, suggesting the visual indicators of balance between the activation and multi-objective simulations were more easily distinguished in the frontal plane. Crowd workers rated the activation characteristic lower for the sagittal view across all simulations except the metabolic energy optimization, where the mean rating was slightly greater than that of the frontal view. The activation ratings were also found to be the sole significant predictor of a 3D or frontal view rather than a sagittal one in MLR analysis. Whole-body angular momentum is greater in the sagittal plane than the frontal plane across biomechanical objectives, but with the greatest disparity in muscle activation and metabolic energy optimizations [20]. This suggests that crowd workers were able to identify the shift in perspective and associate it with the "casual" and "swift" stylistic labels. Conversely, frontal view simulations were rated as appearing the most activated, or "stiff", and low energy, or "lethargic", well as the most normal, or "realistic". This may be due to the frontal view's omission of sagittal information, where joint excursions are greatest during normal walking.

The observed crowd worker response style indicates that the design of the videotaped observational gait analysis (VOGA) survey provided insufficient clarity for the tasks to be accurately completed by untrained crowd workers, and that clarification of the task and semantic rating scale may provide more significant rating deviations between biomechanical objective optimizations [29, 30]. The crowd worker ratings were indicative of a non-extreme response bias typical of surveys with unclear or ambiguous instructions or rating scales. A second potential bias was the wisdom of crowds' limb-loading ratings where a higher, or "lighter" rating was attributed to gait simulations with lower GRFs. The loading ratings were inverted in post analysis to align with the other gait characteristics due to the lower rating of "heavy" carrying a "negative" connotation. The wisdom of crowds demonstrated the capacity to distinguish motion associated with some biomechanical objectives, but we expect that for novice observers, unfamiliarity with this assessment format and the redundancy of motor control strategies used by individuals limit the resolution of this observational approach. Future VOGA assessment methods using the wisdom of crowds should assign clear and comprehensive stylistic labels, use intermediate rating scale labels, and standardize high vs. low ratings across scales.

Future VOGA of gaits shown from the transverse view could be used to determine if the balance characteristic ratings are lower for this perspective across biomechanical objective optimizations, as suggested by the lower whole-body angular momentum observed in the transverse plane [20]. This hypothesis would further the conclusion that visual characterization of walking is sensitive to the perspective view used. These results stem from crowd worker VOGA of simulated, optimized gait patterns, and future work is needed to verify if the wisdom of crowds can accurately characterize these same biomechanical objectives in real healthy and pathological gaits. This method of gait analysis may also be applied in the visual characterization of experimental human gait patterns representing a multi-objective cost function with unknown and uneven biomechanical objective weights [31], which can be used to determine an individual's biomechanical objective strategy. In-clinic, crowd worker trained classification of specific, visually identifiable gait patterns may be used alongside clinician observation to validate diagnoses and suitable interventions in rehabilitative therapy settings [32].

V. Conclusions

This study demonstrates the feasibility of using the wisdom of crowds to characterize some underlying biomechanical objectives. It suggests that specific adjectives are better for distinguishing certain biomechanical objectives, and that specific viewing perspectives are better for visually assessing muscle activation changes within a person. Collectively, this work supports the idea that due to a redundancy of muscle and motor control strategies, visually

assessing the underlying biomechanical objective strategy used by individuals is very difficult. We expect that for this reason, how and why specific individuals respond favorably to specific interventions (e.g., control strategies or design characteristics of wearable devices) is also difficult to predict using standard analysis and movement science techniques.

Face Validity and Usability Evaluation of a Wearable Upper-Limb Motion Sensing System for Home Use

Jaspreet Kalsi, Yue Zhou, *Member, IEEE*, Mary E. Jenkins, Lorie Donelle, Ana Luisa Trejos, *Senior Member, IEEE*, Michael D. Naish, *Member, IEEE*

***Abstract*— Comprehensive, real-world data are required to inform the design of more effective rehabilitation strategies and assistive devices for individuals with Parkinson's disease (PD). Parkinsonian tremor, a common symptom affecting the upper limbs, significantly impairs daily activities and quality of life. Traditional clinical assessments of tremor are limited in frequency and scope, often failing to capture the full variability of tremor experienced in daily life. To address this gap, this paper presents a robust, user-friendly wearable upper-limb motion sensing system designed for home use. It incorporates 23 six-axis inertial measurement units to monitor the motion of 21 joints in the hand and upper limb continuously over extended periods. By enabling continuous home-based monitoring, the system can provide valuable insights into the daily impact of tremor and other upper limb pathologies, facilitating personalized treatment plans. The device was tested on seven healthy participants over 48 hours. To complement the quantitative data, participants maintained an activity log and provided qualitative feedback on the device. The results demonstrate that meaningful data can be collected outside a laboratory or clinic. They further inform several recommendations to improve the design of wearable devices for the upper limb. These findings underscore the potential of wearable technology in rehabilitation robotics for long-term monitoring and management of motor symptoms in PD.**

I. Introduction

Parkinson's disease (PD) is the second most common neurodegenerative disease, with over 10 million diagnosed individuals worldwide [1]. The most common symptom, experienced by 80% of individuals with PD, is tremor [2]. The involuntary oscillatory motion of parkinsonian tremor predominantly occurs in the upper limb, specifically in the hand and wrist [3]. It can have a large impact on an individual's ability to perform activities of daily living (ADL), particularly those that require fine motor skills.

The standard method of assessing tremor uses Part 3 of the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS). It can only be conducted by a neurologist [2] and relies on visual observation in the clinic rather than quantitative evaluation [4]. The motor exam is done in 15 minutes or less and is typically performed 1–4 times a year. This limited assessment does not allow for full characterization of the variation in an individual's tremor and the impact that it may have on their ADL. Further, individuals may be nervous in the clinic and show varied motor skills and tremor patterns compared to what they experience in their daily lives.

The development of new treatments and devices to manage parkinsonian tremor requires a more complete understanding of the general nature of tremor over time, how it can vary between and within individuals, and how it is influenced by activity, sleep, medication, and stress. The first step in improving understanding is the ability to capture quantitative tremor data throughout the day.

The voluntary or intentional motions of people with PD are often superimposed with tremor. Voluntary motion typically has a frequency of around 1–2 Hz [5]. Resting tremor occurs when a body part is at rest against gravity and usually has a frequency of 3–7 Hz [6]. Postural tremor occurs when an individual holds a position against gravity and has a frequency between 5–12 Hz [6].

Inertial Measurement Unit (IMU) sensors are an effective way to measure movement data related to voluntary motion and tremor. These typically use a combination of MEMS-based accelerometers, gyroscopes, and/or magnetometers to measure multiple degrees of freedom (DOF).

A variety of IMU-based wearable motion sensing devices have been developed by researchers to help understand the nature of voluntary motion and tremor. Lin et al. [7] and Fang et al. [8] placed 18 9-DOF IMU sensors on a thin glove. Connolly et al. [9] developed a device with 16 9-DOF IMU sensors that were placed inside a glove. Zhou et al. [10] and Kortier et al. [11] taped IMUs (5 9-DOF IMUs and 16 6-DOF IMUs and 3 magnetometers, respectively) directly to the skin. All of these devices were designed to operate in the controlled environment of a lab for a short time. The sensors and electronics were not covered for protection.

Das et al. [12] developed a simple system to track PD motor symptoms during ADL in a home setting. The system consisted of 5 3-DOF accelerometers that were strapped to the wrists, ankles, and waist. The device batteries were charged at night, allowing data to be collected over several

days. Participants were also asked to log their symptoms and times when medication was taken for PD within a 20-minute range. While able to operate outside of a lab environment, the system only measured wrist motion, which is inadequate to properly characterize tremor and other upper-limb motions.

To date, no devices have been designed that are able to measure the motion of all of the upper limb joints throughout the day. Most have been designed for supervised lab or clinic use. They are not easy to put on and take off, do not protect the electronics and wires, and are not intended for data collection over extended periods. Further, while many measure the joints of the fingers and thumb, the wrist and elbow are often excluded.

This paper presents a wearable motion sensing device that is suitable for home use. It collects data from the elbow and all joints of the hand and wrist to capture a complete picture of upper-limb motion. It adopts a modular design for robustness to failure of one or more IMUs. All wiring and electronics are covered for protection and to prevent them from snagging. The device can operate for at least two days without any intervention from the user, i.e., there is no need to recharge the battery or transfer data from it. Beyond providing a platform that can collect the data necessary to understand the nature of tremor and other upper-limb pathologies better, the data collected by this device is expected to provide insights into the design and use of wearable devices. Specifically, it can help to identify which joints are the most important to measure for particular symptoms or activities, and how long they should be measured for. With this information, future devices can be designed with a minimum number of sensors and power sources optimized for the required operating time.

II. Device Design

To operate within a home setting, the device must be portable, comfortable, and be easy enough for participants to don and doff. It should be able to measure the motion of all joints of the upper limb from the elbow to the fingertips and be able to operate over a two-day period. The proposed device consists of custom-designed and commercially-available electronics that are attached to a glove and sleeve system.

The device hardware consists of a LPC1768 microcontroller unit (MCU) (NXP Semiconductors) that is interfaced with 23 LSM6DS1 IMU sensors (ST Microelectronics) soldered onto 23 custom printed circuit boards (PCBs), with six different variations; a DS1307 real-time clock (RTC) module (Maxim Integrated); a micro-SD card module (Geekstory); and a 10000 mAh 5V battery pack (EAFU). The PCBs are connected with 32-gauge wires. The connected components are shown in Fig. 1.

The IMUs are placed on both sides of the following joints: the interphalangeal (IP), metacarpophalangeal (MCP), and trapeziometacarpal (TMC) joints of the thumb; the distal interphalangeal (DIP), proximal interphalangeal (PIP), and carpometacarpal (CMC) joints of the index, middle, ring, and pinky fingers; the radiocarpal joint (wrist), and the elbow joint.

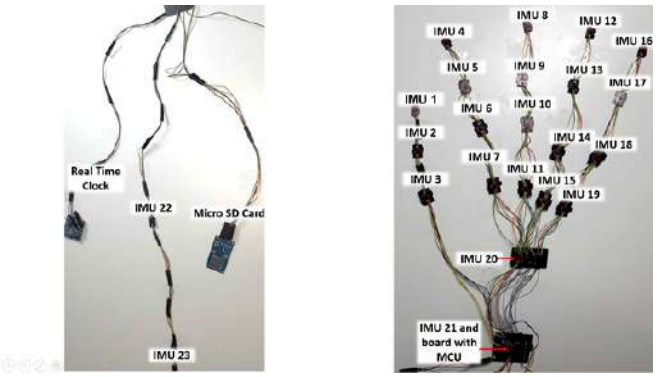

Fig. 1. The connected hardware of the device.

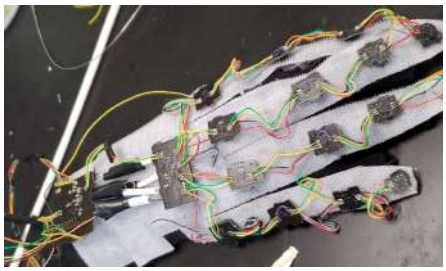

Fig. 2. The hardware attached to the base layer of the glove.

The device has a glove component that consists of a fingerless compression glove and two-way stretch polyester blend fabric. The compression glove has hook-and-loop fastening strips (Velcro) to connect the hand/wrist IMUs (21 total), as shown in Fig. 2. For this initial evaluation, two gloves were developed: one for small hands and one for large hands. Both gloves are right-handed. The hardware is covered by a polyester blend fabric with fingertips that easily lift and attach to hook-and-loop fastening strips on the compression glove. This layer of fabric helps to keep the sensors and wires in place and adds protection.

The sleeve component of the device extends from the biceps to the wrist, where it connects with the glove. It consists of a thin, breathable, nonslip compression sleeve with hook-and-loop fastening strips to attach the two elbow IMU sensors and other electronics. These are covered by the same polyester blend fabric used for the glove to protect the hardware. In addition, an adjustable armband (GoZone) is placed over the compression sleeve on the biceps to hold the battery pack in place. The complete device with the glove, sleeve, and armband on a participant is shown in Fig. 3. The device without the battery pack has a mass of 260 g and the battery pack used for testing weighs 185 g.

III. Experimental Design

The device was evaluated by collecting motion data from healthy participants with the same experimental procedure that is intended for individuals with PD. The experimental procedure was approved by the Health Sciences Research Ethics Board (HSREB) at Western University, Project 118552. Prior to the trial, each participant reviewed a Letter

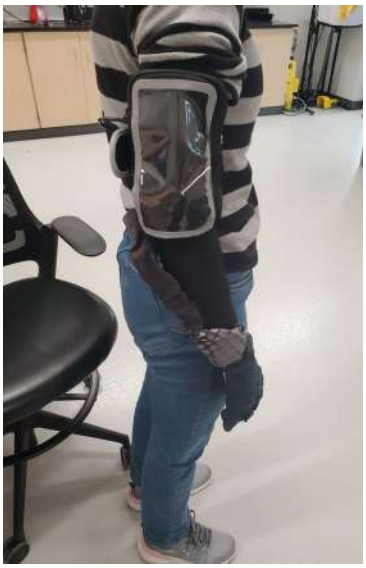

Fig. 3. The complete device on a participant.

of Information. Following consent, participants visited the Wearable Biomechatronics Laboratory at Western University, where the study details were explained in person, measurements of the hand and arm were obtained, the dominant hand was noted, device care instructions were given, and an ADL Log and a Participant Feedback Questionnaire were provided and explained.

Prior to fitting, the IMU sensors were individually validated to ensure that they were performing as expected. For each participant, the 21 IMU sensors on the glove and two IMU sensors around the elbow were positioned according to anatomical landmarks on either side of the target joints. The battery pack was placed over the sleeve, and the participant was shown how to put on the device and take it off.

Data collection took place over a 48 hour period within the home of each participant. Participants were asked to wear the device while performing their typical ADL. For wet tasks, participants could put a rubber/nitrile glove over the device when feasible; otherwise (e.g., showering or submersion), participants were told to remove the device to prevent damage to the electronics. The device was also expected to be removed during sleep.

IMU data were sampled and saved to a micro-SD card every 35 ms as a human-readable comma-separated values (CSV) file. Each data entry included the time, IMU number, and a 16-bit decimal value for each axis—angular velocity about the x, y, and z axes, and linear acceleration along the x, y and z axes. A new CSV file was created every 15 minutes to minimize data loss in the event of power disruption. Since the maximum frequency of typical voluntary motion is 4 Hz [5] and tremor is generally less than 12 Hz [6], the sampling frequency (28.6 Hz) is sufficient to capture both types of motion [13].

Entries in the ADL Log were completed by each participant a minimum of once every two hours. The log serves to record the activity that the participant is performing, the time of occurrence, and the approximate duration. A Participant Feedback Questionnaire was filled out after one hour, at the midpoint (24 hours), and after the trial had finished (48 hours). The Participant Feedback Questionnaire used an 11-point Likert scale to assess the comfort and the ability to perform ADL throughout the trial. At the end of the trial, participants were also asked to rate their overall impression of the device, its ease of donning and doffing, and convenience. Space for additional written feedback was also provided.

A total of 7 healthy subjects (3 male and 4 female, with ages ranging from 23–52) participated in this study. When each trial was complete, the device, ADL Log, and the Participant Feedback Questionnaire were collected from each participant. The remaining battery life was noted and the recorded data were transferred from the micro-SD card to secure cloud-based storage. The IMU data were processed using a 2nd-order low-pass Butterworth filter with a 10 Hz cutoff frequency to extract voluntary motion. Note that studies with individuals exhibiting tremor would use a higher cutoff frequency to extract tremor motion.

IV. Results and Discussion

The performance of the device is reported in this section, along with the qualitative feedback that was received from the participants.

A. Face Validity

The device was able to reliably record data from all 23 IMUs. Clear differences were evident in the IMU data when an individual was engaged in different ADL. Tasks that were associated with rest include sitting, phone calls, laying down, and watching television. In comparison, tasks that were associated with movement include typing on a computer, walking, eating, writing, cooking, and driving. Example angular velocities of the index finger DIP joint for one participant engaged in different tasks are shown in Figs. 4–6. Figs. 7–9 show the angular velocities of the wrist. Similar motion profiles were observed for all joints, with differences resulting from different joints and activities.

The capacity of the selected battery pack was sufficient for every trial. The average battery life remaining after 48 hours for the seven trials was 59%. This indicates that a battery pack with lower capacity could be used to supply power to the device, allowing the device to be smaller, lighter, and more comfortable to wear.

B. ADL Log

The ADL Log documents the tasks that the participants performed during their trials. The participants were asked to log their ADL a minimum of once every two hours, but ideally as often as possible. The ADL Log can be used to correlate the IMU data to specific tasks. Some participants did not fill out the ADL Log for every activity performed, or they estimated the times at which activities took place. The most common ADL performed during the 7 individual trials were using a computer or typing, resting or sitting,

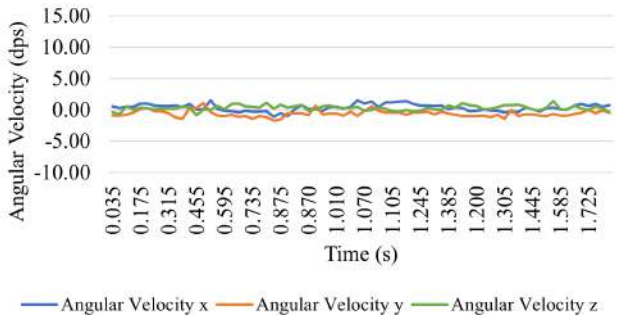

Fig. 4. Example index finger DIP joint angular velocity during rest.

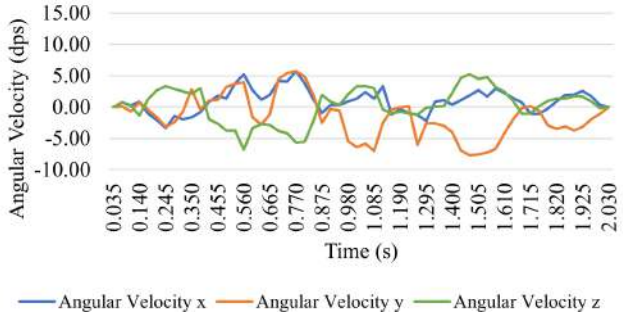

Fig. 5. Example index finger DIP joint angular velocity when using a computer.

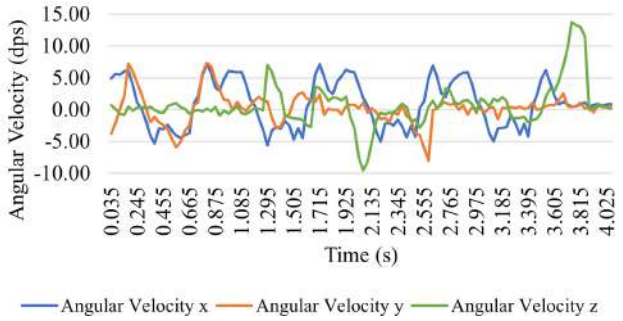

Fig. 6. Example index finger DIP joint angular velocity when walking.

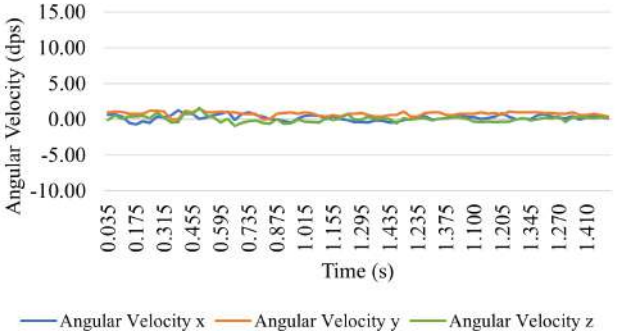

Fig. 7. Example angular velocities of the wrist during rest.

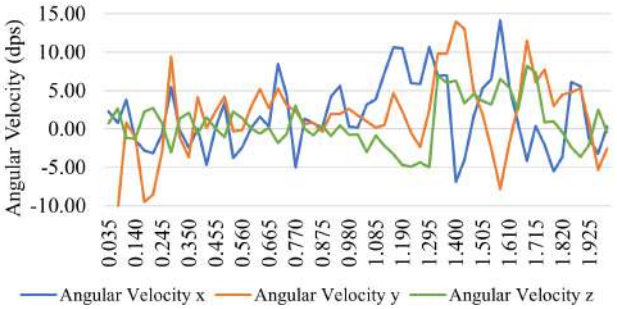

Fig. 8. Example angular velocities of the wrist when using a computer.

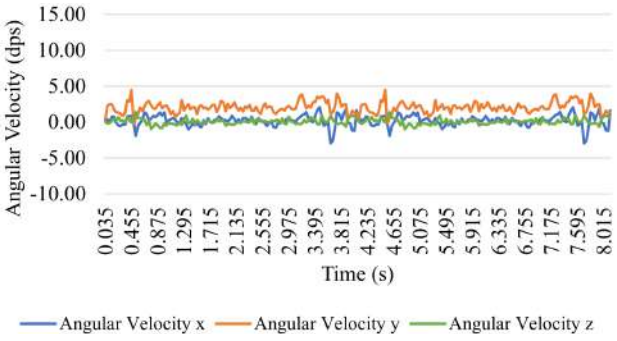

Fig. 9. Example angular velocities of the wrist when walking.

walking, talking on the phone, and eating or drinking. The task breakdown during the trials can be seen in Table I.

Note that ADL were not logged an average of 13.93% of the time. Some participants struggled to update the ADL log for different ADL performed. In addition to providing a timed prompt to users to record their activity, programmable interrupts in the IMUs could be used to detect motion and provide a prompt. Additionally, it may be more convenient for some users to record an audio log on their smartphone than to write their activities on a log sheet.

C. Participant Feedback Questionnaire

The Participant Feedback Questionnaire was filled out by the participants after 1 hour, 24 hours, and at the end of the trial. The mean comfort rating was 6.00 $\pm$ 1.63 after one hour (range: 3–8), 6.14 $\pm$ 1.57 after 24 hours (range: 4–8), and 7.43 $\pm$ 1.27 after 48 hours (range: 5–9), as shown in Fig. 10. Based on the feedback provided, it appears that

TABLE I

THE AVERAGE TIME SPENT ON ADL SORTED BY PREVALENCE.

ADL	Average ADL Time (%)
Using a computer or typing	46.99
Time where ADL not logged	13.93
Resting or sitting	12.42
Walking	7.38
Talking on the phone	4.46
Eating and drinking	4.24
Other	2.55
Driving	1.73
Cooking or food preparation	1.59
Doing laundry	1.41
Texting or scrolling on a mobile phone	1.09
Using the washroom	0.96
Cleaning	0.66
Laying down	0.48
Standing up	0.06
Outdoor work	0.04

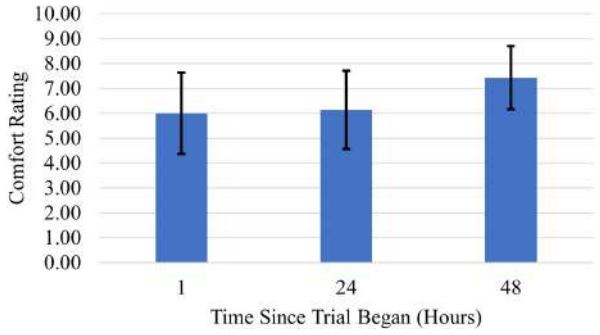

Fig. 10. Mean participant comfort ratings after 1, 24, and 48 hours. The bars show standard deviation.

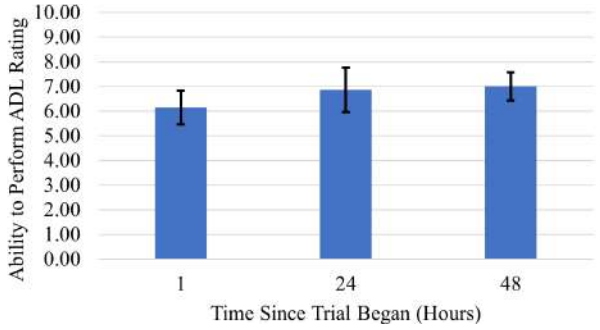

Fig. 11. Mean participant ratings of ability to perform ADL ratings after 1, 24, and 48 hours. The bars show standard deviation.

the participants found the device to be more comfortable the longer it was worn.

Participants scored the ability to perform ADL while wearing the device, with an average rating of 6.14 $\pm$ 0.69 after one hour (range: 5–7), 6.86 $\pm$ 0.9 after 24 hours (range: 5–8), and 7.00 $\pm$ 0.58 after 48 hours (range: 7–8), as shown in Fig. 11. Similar to comfort, the participants found that they were able to perform ADL better as they gained experience with the device.

At the end of the trial, participants were asked to indicate how they felt about the trial, the device, and their overall experience. The average rating for the participants' feelings about wearing the device was 6.43 $\pm$ 2.07 (range: 2–8). The average rating for ease of donning and doffing was 8.60 $\pm$ 0.89 (range: 7–9). The average rating for the convenience of wearing the device was 6.57 $\pm$ 1.90 (range: 3–9). These ratings are summarized in Fig. 12. Overall, the results show that most participants did not dislike the device and felt better than indifferent about wearing the device, but most did not enjoy wearing the device during their trial.

In addition to the ratings, participants provided written comments that provide further insights into how the device performed and highlight areas that would benefit from refinement. These are summarized below:

- In general, participants found the device to be more comfortable on the second day of the trial.
- Most found it difficult to perform ADL at first, but learned to adapt over time.
- The battery became noticeably heavy after 3–4 hours for everyone. Some had a feeling of their arm falling asleep, even when the band holding it to the biceps was loose, and developed a sore arm after 24 hours. In addition, the size of the battery was cumbersome for some tasks.
- The device negatively affected delicate tasks such as writing, typing (seeing a 50% reduction in productivity for some), and tying shoes. It also affected cooking and rummaging though a bag to find an object.
- Drinking and eating were affected by the stiffness of the hook-and-loop fastening strips.
- Driving and other ADL could be performed easily.
- The fabric in contact with the skin was drying for some and caused minor irritation.
- The multiple layers of fabric were very warm, reducing comfort.

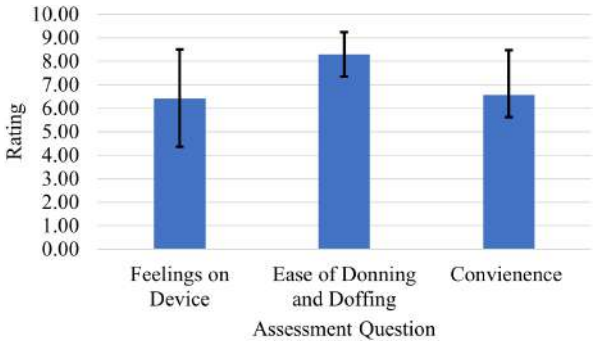

Fig. 12. Mean ratings for the assessment questions. The bars show standard deviation.

V. Recommendations

As this work has demonstrated, designing devices for the upper limb that are worn for extended periods of time presents many challenges. Future designs may benefit by considering the following recommendations:

1) Reduce bulk: The overall size of the device has a significant impact on whether ADLs can be performed normally or not. This is particularly important at the distal end of the fingers, where the sensors, wires, and fabrics must be as small and thin as possible. Consider the use of flexible printed circuit boards and use the smallest components available.
2) Fabric choices: Select materials that are thin and conform to individual anatomy. Thicker fabrics, in addition to adding bulk, tend to impede motion and reduce sensation. Consider biased materials that stretch for comfort while maintaining sensor position over anatomy. Instead of multiple full layers, use pockets and channels to minimize the amount of fabric required for protection and enhance breathability. Cooling fabrics may also be used. Ideally, fabrics in contact with the skin should not cause irritation or drying. Beyond comfort, the materials should provide a degree of water resistance, resist staining, and be easily washed should they become soiled.

3) Free fingertips: Delicate tasks that rely on subtle tactile cues or that require direct interaction with the finger will be impaired less if the fingertips are exposed. Glove should adopt a "fingerless" design.
4) Customize to individuals: While hook-and-loop fastening strips (i.e., Velcro) allows the fit of a device and the placement of sensors to be easily adjusted, it can significantly reduce the comfort of the device, particularly when worn for extended periods of time. Instead, devices should be designed as garments that are sewn to fit the anatomy of a specific user.
5) Power supply location: For portability a battery is necessary; however, it is typically the largest and heaviest part of an unactuated wearable device. If worn on the arm, a battery should closely match the overall power consumption of the device, so that it is not larger than necessary. If a larger battery is necessary, consider locating it on an area of the body that can bear more weight, such as the legs or hips, although the power cable may become cumbersome.

Overall, these recommendations aim to make the device as transparent to the user as possible, with the ultimate goal of feeling like ordinary clothing. Since this may not be achievable, it may be worthwhile to design systems that are as balanced and symmetrical as possible. As the size and weight of the device increases, it may be necessary to add bilateral components to limit imbalances to the overall musculoskeletal system of the wearer.

VI. Conclusion

The device presented in this paper is the first portable device that can collect motion data from 21 upper-limb joints in a home setting over a two-day period. The ability to operate at home is significant because it allows extensive ADL data to be collected. By capturing the full rhythm of the day, it is possible to observe activities and nuances that are not possible in a lab or clinic. Further, the device underscores the potential of wearable technology in rehabilitation robotics, offering a scalable solution for long-term monitoring and management of motor symptoms in PD.

Since the device has now been validated on healthy participants, the next steps are to improve the device and then conduct trials on individuals with PD to capture tremor data. This will lead to a better understanding of how tremor impacts the daily life of people living with PD and their ability to perform ADL. By studying tremor in a home setting, data on individual tremor behavior, how tremor impacts ADL, and how often an individual's tremor occurs in a typical day can be determined. The collected tremor data can also be used to improve our understanding of the characteristics of tremor, such as frequency patterns and power spectral density, leading to better modelling, estimation, and control. The data could be used by a neurologist to better manage PD. It can also be used to design customized wearable assistive devices and adapt their performance to the peculiarities of each person and the changes that their tremor may undergo over time. Further, the data may be used to identify which joints are most important to monitor, allowing the size, weight, and complexity of future devices to be reduced.

Acknowledgment

Technical support from Eugen Porter and the commitment of the study participants, as well as all members of the WearME Lab who supported this work, is greatly appreciated.

An exoskeleton 'teacher-student' gait rehabilitation control system using real-time joint posture acquisition: A feasibility study.

Robert E. Trott, *Member, IEEE,* Jonathan T. Wheare, *Member, IEEE,* Michael P. Russo, Timothy J. Kleinig, Susan L. Hillier, Karen J. Reynolds, David A. Hobbs

***Abstract*—Recovering the ability to walk following the events of a stroke is important for community participation. For patients that are unable to weight bear, rehabilitation is difficult, for both themselves and for therapists that must manipulate their lower limbs. Exoskeletons can reduce the reliance on a patient's capability and reduce the exertion that therapists must provide to deliver manual rehabilitation. Providing intuitive methods of control is important to ensure that users have the inputs they need. We have implemented a simple joint acquisition system to be used in a 'teacher-student' paradigm, that can attach to a therapist's leg (teacher) to measure their hip and knee posture to then control the equivalent joints of an exoskeleton worn by a patient (student). This would provide a therapist with direct control of their patient's leg, which they can manipulate under supervision, to guide a patient through trajectories they would otherwise provide manual support to achieve. The feasibility of the system is demonstrated with one subject as the teacher and the exoskeleton (without a user) as the student. Using motion capture we assess the reference tracking error and the phase delay in the system through single leg standing gait using three different gains. With high proportional gain the mean (SD) phase delay was 11.1 (0.7) ms and 8.4 (4.9) ms for the hip and knee, respectively. Using the same gain the joints were tracked through normal gait ROM with a mean (SD) error of 7.7 (6.1) degrees and 7.6 (5.4) degrees for the hip and knee, respectively. This early-stage feasibility study demonstrated that a low cost 'teacher-student' control system could control a lower limb exoskeleton.**

I. Introduction

Gait is central to mobility and enhances community participation [1]. Hence, in a world where we are often faced with complex mobility scenarios, restoring or improving a person's mobility post-injury is a critical effort and recovery of a person's gait, where possible, is often cited as a high priority [1]. There are few activities that can easily be completed without having a period of gait in between. Gait is often accompanied by activities such as sit-to-stand and stair ascent/descent, reflecting the complexity of the environments we live in [2].

A variety of therapies that aim to restore gait exist, ranging from manual therapies that manipulate a patient's limbs, treadmill training, Body Weight Support (BWS) overground walking and their combinations, through to robotic assisted therapy using exoskeletons. The goal of these therapies is to improve conditioning of the limb and to stimulate the neuroplasticity that is inherent in learning [3], [4], [5], [6]. Across these therapies there is a common theme of kinetic support, where the demands of gait are supported to promote training.

Therapy must focus on the fundamental principles of motor learning [3]; among these principles patients should receive adequate controlled repetitions and intensity delivered across multiple sessions that are relevant to the task, collectively known as dosage [7], [8], [9]. The same principles that promote recovery can also apply maladaptively and it is important to practice good quality movements, and discourage movement strategies that may initially be beneficial, but detrimental in the long term [10].

Therapy is a taxing and repetitious endeavor for both the person and therapist [11], [12], [13], requiring hours of physical work and learning. Within the dosage of rehabilitation, there is a threshold to what an individual can tolerate that needs to be carefully managed so that therapies are sufficiently challenging without being detrimental. Conventional and treadmill training type rehabilitation techniques have a high degree of manual input from up to three therapists, placing a strain on the therapists [14], [15]. Prolonged strain and excessive overwork can limit the amount of therapy they themselves can deliver, and increase the risk of developing musculoskeletal disorders [11], [12], [13]. Variations within and between therapists can also limit the treatment consistency a patient receives [16].

Exoskeleton technology, that was initially intended for industrial applications, has been quickly adapted for the rehabilitation setting. Exoskeletons offer the promise of high rehabilitation dosage with improved consistency, by increasing the number of repetitions and the intensity a patient receives [12], [17], while simultaneously reducing therapist burden as the manual work is applied by the machine. Despite these advantages, exoskeletons have never been considered a substitute for conventional therapies [11], [18]. They have only recently been recognised as complementary to conventional therapy [19], [20].

Therapists and exoskeleton wearers have different methods that they can use to control an exoskeleton. These methods often focus on the initiation of a movement profile that is then completed with or without input from the exoskeleton wearer. For example, buttons can be used to

trigger a step that is completed without user intention [21]. Such strategies are good for general mobility but lack critical engagement from the wearer and may not maximally stimulate intended rehabilitation outcomes [22].

Upper limb pairing between two devices, one as a student and the other as a teacher, has been demonstrated a number of times and may help boost engagement [23]. Despite the critical need to restore gait, this paradigm has been sparsely applied in the lower limbs [24], [25]. The former [24], demonstrated haptic coupling between two users wearing exoskeletons and the ability of their system to control the strength of that coupling and feedback torque between the wearers. The latter [25] used motion capture to measure hip angles from oner person (teacher) and apply these to another person (student) wearing an artificial pneumatic muscle. Coupling a teacher to a student may leverage the advantages of conventional and exoskeleton mediated gait rehabilitation. An exoskeleton guided by the therapist in a consistent manner may be used to recreate a gait cycle and provide the manual input otherwise provided by a therapist, reducing their burden. An initial barrier for such a configuration is the cost of entry, as motion capture technology [25], or two exoskeletons are needed, along with technical challenges to integrate the systems. There are, however, a variety of options that can be used to affordably and simply capture the basic kinematics of a therapist (teacher) for application on an exoskeleton, which in most cases are sagittally constrained.

Here we aim to demonstrate the basic feasibility of a lower limb exoskeleton coupling using a 'teacher-student' paradigm. Sagittal kinematics are captured from the teacher device using readily available sensors to capture hip and knee flexion and extension, and these kinematics are applied to a powered lower limb exoskeleton without an occupant (the student). Our system lacks the haptic coupling offered by dual exoskeleton paradigms [24], but reduces the complexity and cost, and doesn't rely on motion capture [25]. We assess the accuracy of capturing the kinematics from the teacher and their application on the student, and the phase delay between the two.

II. Methods

A. System description

A lower limb exoskeleton (Fourier Intelligence, ExoMotus-X2 exoskeleton) with minor modifications (student) was paired with a joint acquisition system (henceforth, teacher system) composed of a microcontroller (Seeed, Seeeduino Xiao) [26] and two rotary potentiometers (Panasonic EVW-AE4001B14) (Figure 1). The exoskeleton has 4 total active degrees of freedom for the left and right hip and knee, respectively, and 2 passive degrees of freedom at the ankles. The teacher system potentiometers were fixed to custom 3D printed brackets with a bearing to isolate axial and transverse forces from the potentiometer and allow free rotation. Acrylic arms with slots were fixed to the brackets (Figure 1). The potentiometers were located over the center of rotation of the right hip and knee, respectively.

Communication within the exoskeleton components is managed using the open-source software CANOpen Robot Controller (CORC) [27], which uses the Robot Operating System (ROS1) [28], CANbus, and C++. The CORC controller updates the system at 333 Hz. The teacher system uses a Seeeduino Xiao (clock speed 48 MHz), sampled by an ADC at 350 ksps and an effective resolution of 16-bits per channel for both the hip and the knee sensors [26].

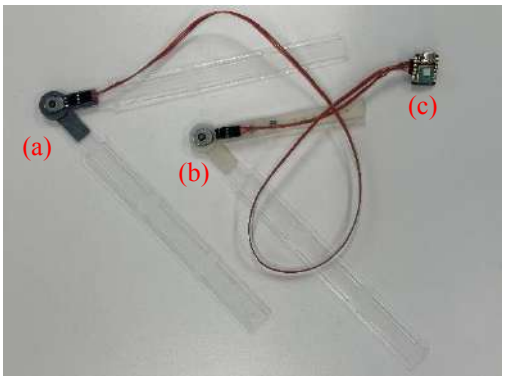

Figure 1. The teacher system with: (a) knee joint, (b) hip joint with waist bracket, and (c) Seeeduino Xiao Microcontroller.

These hip and knee angles were published to the CORC interface as ROS topics using the rosserial [29] Arduino library. CORC also received joint angle information from the exoskeleton via CANbus, and this information was used by both the controller and published via ROS topics. A custom feedback controller in CORC generated the motor velocity targets by multiplying the difference between the teacher and student joint positions by a proportional gain that is varied based on the trial condition as expressed in eq 1. The CORC node then sent these velocity targets to the exoskeleton via CANbus.

$$\dot{X} = k_p \cdot (X_{teacher} - X_{student}) \quad \text{- (1)}$$

Figure 2. The Fourier Intelligence ExoMotus X2 used in this study (left) and the teacher system worn on the subject during piloting (right).

B. Experimental Set-Up

The system was set up in the Rehabilitation and Motion Analysis Laboratory of Flinders University. Ten Vicon 3D motion capture cameras (Vicon Motion Systems, Oxford, United Kingdom) were used to acquire 3D kinematics at 100 Hz. Motion capture was used to determine the phase delay between the teacher and when that motion was applied on the exoskeleton. The exoskeleton was suspended from a BWS system in a neutral standing position above the ground in the center of the room and connected to a PC running CORC and

the teacher system. Retro-reflective markers (Ø10 mm) were placed on both the left and right sides of the exoskeleton over the center of rotation of the ankle, knee, and hip, with two additional markers on the hip motor cover (Figure 2, left).

Retro-reflective markers (Ø10 mm) were also placed on a single subject from the research team (teacher) using the Vicon plug-in-gait pipeline to obtain hip and knee joint angles (Figure 3). Medial knee markers were added to better define the knee axis. The hip joint sensor of the teacher system was approximately placed over the center of rotation of the hip, and the knee joint was placed under the lateral plug-in gait knee marker. The teacher system was fixed to the user using strapping and further fixed using adhesive tape. The top of the hip system slipped over the subject's waist band and was fixed to the user using strong adhesive tape to reduce relative motion between the system and the wearer.

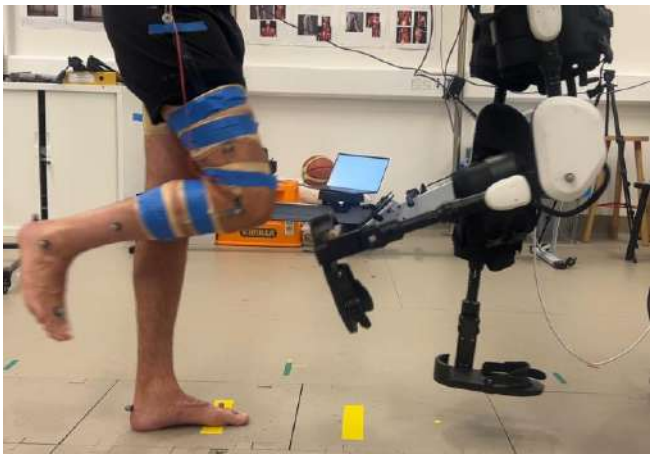

Figure 3. Video image taken during data collecton with both the subject/teacher (left) and the exoskeleton/student (right) with retro-reflective markers. The subject is wearing the teacher system, and the exoskeleton responds to the subject's posture.

C. Data Acquisition

The motion capture system was calibrated on the day, immediately prior to data collection. The subject and exoskeleton were marked up as described in the experimental set-up. The teacher system was fitted to the subject and the system started. The exoskeleton used a hand controller configured as a dead-man switch to enable motion of the system. The state of this controller as well as the internal communications between the exoskeleton and joint capture were captured using the rosbag [30] system, which provided time-stamped recordings of all published ROS messages. Information captured in these recordings included the hand controller status, the target angles of the teacher system, the reported angles of the student exoskeleton, and the reported effort of the exoskeleton motors. The session was broken into three trials of single leg standing gait using both the hip and knee, with three different proportional gains. The gain controlled how aggressively the system attempted to track the reference provided by the teacher system. The three proportional gains, k_p, are referred to as low, medium, and high and correspond to values of 3, 5, and 10.

The three cyclic gait activities were intended to characterise the ability of the system to track both joints and to model the assistance that a therapist would otherwise provide in an assisted walking rehabilitation task. In all activities the subject remained in the center of the room and gripped the exoskeleton for stability and to prevent it from rotating and swinging the BWS. Locating the subject behind the exoskeleton allowed the teacher to supervise both the exoskeleton and a live terminal output of the angles reported by the teacher system. Observation of the exoskeleton is similar to how a therapist responds to a patient's posture during rehabilitation. Between trials the user adjusted the teacher system if necessary. Generally, each trail used the following structure:

1. Subject/teacher was positioned in the middle of the room behind the exoskeleton in neutral stance;
2. Exoskeleton/student was positioned in a neutral stance and held by subject/teacher;
3. Motion recording was started;
4. ROS data collection was started;
5. Exoskeleton/student enabled using dead-man switch;
6. Subject/teacher conducted prescribed movements; and
7. All recordings were stopped in reverse order.

D. Analysis

All motion capture data was processed in Vicon Nexus 2.12 and imported into MATLAB (R2022b The MathWorks Inc, Natick, MA, USA). Teacher sagittal angles were outputted from the Vicon plug-in gait model. Data were trimmed close to the beginning and cessation of a trial. Exoskeleton knee flexion-extension was calculated using vectors made from the ankle, knee, and hip markers. While hip flexion-extension was calculated using vectors made from the knee, hip and one of the additional markers on the hip motor cover. An exoskeleton referred normal vector was produced from two opposing markers at the left and right hip motor cover. Sagittal joint angles were calculated by taking the vector projection on the sagittal normal plane using first principles. Peak angles were automatically detected and erroneous values manually excluded. Both the tracking error and the phase delay were calculated from the teacher to student for like joints. The tracking error was defined as mean absolute joint angle difference, and the phase delay was defined as the timing difference between when a peak value occurred.

III. Results

Figures 4 and 5 show the hip and knee angles for both the subject and the exoskeleton during cyclic gait at low and high gain, respectively. Considering low gain first, the hip performs well around neutral stance and in extension, however, cannot track the joint accurately into flexion. The system is better at tracking the knee, though less so toward extension. Across 10 cycles the mean (SD) tracking error was 12.7° (9.6°) for the hip and 17.4° (11.9°) for the knee. The mean (SD) hip and knee phase delay of the system was 32.0 (3.4) ms and 27.1 (6.3) ms, respectively. There is an offset between the exoskeleton and subject hip joint at stance and this persists and is amplified at the peak flexion. An offset was apparent between the respective knee joints at the beginning of the trial, however, at this time the exoskeleton was prohibited from moving.

For both the hip and knee, compared to the low gain, medium gain improved the mean (SD) phase delay, 19.3 (0.9) ms and 17.1 (5.1) ms, and reduced the tracking error, 9.4° (6.5°) and

13.2 ° (10.2°), respectively. Using a high gain, the mean (SD) tracking error for the hip and knee was 7.7° (6.1°) and 7.6° (5.4°), respectively, and the phase delay was 11.1 (0.7) ms and 8.4 (4.9) ms, respectively. The high gain resulted in much better performance (see Figure 5). The exoskeleton gait profile was able to closely follow the subject at the knee and capture the slight knee flexion that typically occurs through the stance phase of gait despite the unconstrained nature of this task. The exoskeleton hip again closely followed the subject into extension, though still had difficulty tracking the peaks in subject hip flexion. Again, the offset between the respective hip joints persists with high gain. The results for all joint tracking errors and phase lags are summarised in Table I.

TABLE I – Summary of the gait cycle phase delay and tracking errors.

	Phase delay (ms, peak to peak)			Mean Absolute Joint Error (degrees)		
Gain	Low	Medium	High	Low	Medium	High
Hip (Mean, (sd))	32 (3.4)	19.3 (0.9)	11.1 (0.7)	12.7 (9.6)	9.4 (6.5)	7.7 (6.1)
Knee (Mean (sd))	27.1 (6.3)	17.1 (5.1)	8.4 (4.9)	17.4 (11.9)	13.2 (10.2)	7.6 (5.4)

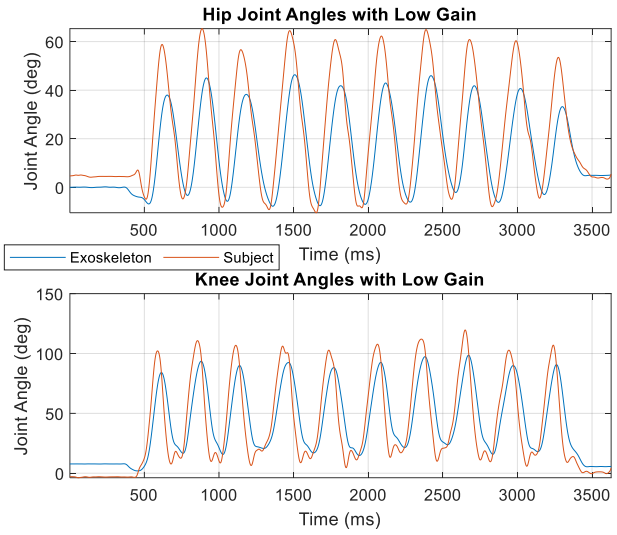

Figure 4. Subject/Teacher (orange) and exoskeleton/student (blue) motion capture angles with low gain.

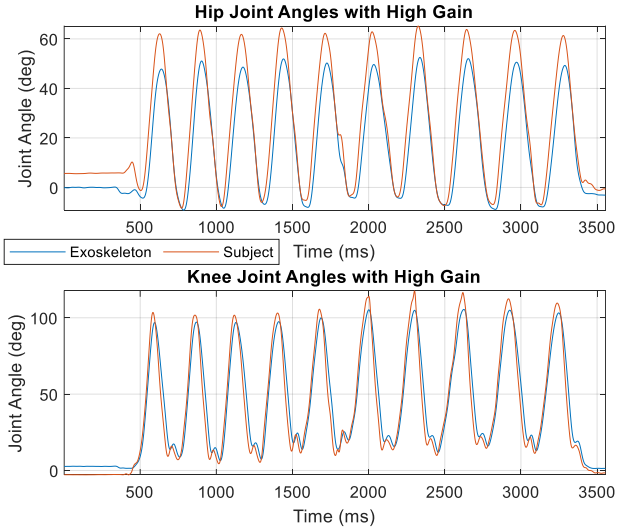

Figure 5. Subject/Teacher (orange) and exoskeleton/student (blue) motion capture angles with high gain.

To better understand the source of the error, the joint values captured from the teacher system, as opposed to motion capture, and those of the exoskeleton in the high gain scenario were compared (Figure 6). The CORC system updates at 333Hz and data was captured after motion capture had commenced, but before the subject began the task. Figure 6 shows close alignment between the acquired joint angles and those of the exoskeleton and the mean (SD) tracking error for the hip and knee were 4.1° (2.6°) and 6.8° (4.4°) respectively.

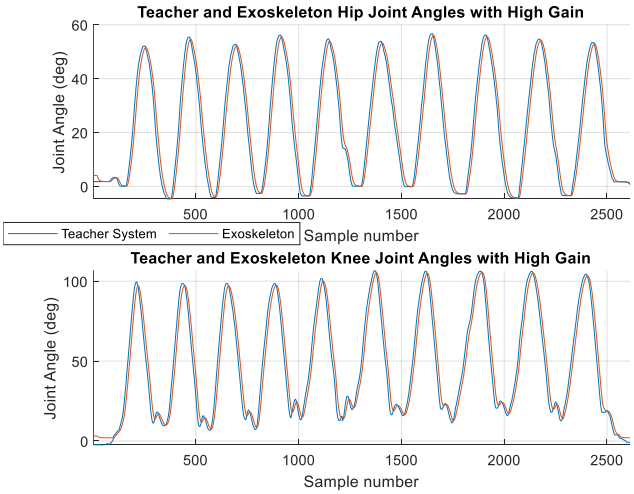

Figure 6. Subject/Teacher (orange) and exoskeleton/student (blue) system angles when using high gain. Angles are aquired from the system, not motion capture.

IV. Discussion

In this proof-of-concept pilot study we developed a system to capture the hip and knee posture of a single subject (teacher) and used that posture to provide a control reference to the same joints on a lower limb exoskeleton (student). We used motion capture, using the plug-in gait protocol as a validation tool, to acquire the subject's lower limb posture while simultaneously capturing the joint postures of the exoskeleton (angles calculated using first principles). From this we were able to characterise the error between the posture of the teacher and the exoskeleton (student) tracking the reference and the phase delay between capture and reproduction between the two. Others have used motion capture to acquire subject posture and apply that posture to an exoskeleton [25], or have used two of the same exoskeletons with differing strengths of feedback between their two postures [24].

Using soft pneumatic actuators the system in [25] achieved a hip angle error of approximately 5° with a phase delay of 400ms, and with joint angle prediction were able to reduce the phase delay to 100ms [25]. In comparison our system experienced higher error (7.7° at the hip), between the motion capture and the subsequent exoskeleton motion, with a lower phase delay (11.1 ms), though their exoskeleton was worn by a person. The system in [24] passed haptic feedback between able bodied users so that one user could feel the intention of the other and try to follow. With a hard stiffness between the two exoskeletons, they were able to achieve 3° mean absolute joint angle difference at the hip and knee, compared to our 7.7° and 7.6°, and did not characterize phase delay, though it appeared to be minimal [24]. The error we report is between

the human state captured through motion capture, not that the teacher system sensors, and the exoskeleton. The system in [25] uses motion capture as the input to their control system and reports the error as the difference, and [24] reports the error between two sets of exoskeleton joints. But importantly no system, including ours, characterizes the error between the two humans. Subsequent analysis showed our teacher system captured angles were faithfully reproduced on the exoskeleton (4.1° and 6.8° tracking error, for the hip and knee, respectively), implying the source of our error came from the teacher system configuration and its fit on the wearer. Generally, this means that while there were errors between the angles measured using plug-in gait and the exoskeleton, there was good agreement between the system driving the exoskeleton (teacher system) and the exoskeleton, indicating reliability in the teacher system).

The error between the respective joints on the subject and the exoskeleton might not be as important as it seems. Minimal clinically important differences (or MCIDs) in hip and knee flexion/extension measurement have been reported as 5.8° [31] and 6.4° [32], respectively, in osteoarthritis patients. Exoskeletons do not align perfectly with the user. The revolute joint at the knee is incapable of recreating the sliding hinge mechanism of the human knee and there will always be a need for some compliance between an exoskeleton and it's wearer. Our system uses supervised control, that is, the teacher is able to alter the state of the exoskeleton according to their posture, but can use visual feedback to alter the student posture to a desired state. Similar to how a therapist guides a patient's limb in overground walking treadmill training, the teacher can alter their posture to induce a change in the student, irrespective of the error between the two.

Our system differentiates from [24] and [25] in its accessibility and affordability, and the use of motion capture to validate performance of the system. We found that when the exoskeleton was set with a high gain there was good agreement between the exoskeleton posture and the subject through motion capture, and the phase delay between the two was low, demonstrating the viability of the joint capture system. As expected, when using a low gain, the exoskeleton was not able to track the subject's posture as well. There was apparent relative motion between the subject and the hip joint of the teacher system. The teacher system was strapped to the thigh and shank using acrylic arms, however, at the hip joint the superior arm was slipped over the shorts of the wearer and secured using tape. There was no mechanism to prevent the shorts from moving relative to the subject and this likely contributed to the error in peak flexion between the subject and the exoskeleton.

Therapist burden is a problem in rehabilitation [11], [12], [13] and can be limiting of the therapy time a patient receives when there is increased emphasis on delivering adequate dosage [7], [8], [9]. Exoskeletons can be difficult to access in a rehabilitation setting, and their efficacy and status as being complimentary to and not a substitute for conventional rehabilitation may be limiting their adoption [19]. Using exoskeletons differently by providing therapists and patients with more intuitive control may boost engagement, and rehabilitation outcomes. Using an exoskeleton to unburden a therapist by providing the therapist with intuitive and direct control may be helpful in these instances.

Our study is limited in that it was applied with a single user, and the exoskeleton was used without an operator. In practice an exoskeleton wearer must adopt a degree of passivity and move with the device, and this may be difficult in instances where the user has motor deficits or experiences spasticity [33]. An exoskeleton with a user will have more mass and this will likely affect the ability of the exoskeleton to track a reference and add further phase delay between the teacher and the student coupling. The joint tracking system used rotary potentiometers, and these were applied in this system without addressing linearity and this may have affected the ability of the system to track joint angles at the extremes, and may have contributed further to tracking the error near peak hip flexion.

An issue this system does not address is feedback to the person controlling the exoskeleton, which can be dangerous for the exoskeleton wearer [24]. The method that we have demonstrated has no impedance between the teacher system and how the exoskeleton responds, an idea that has been addressed by others [24]. Communication between patient and clinician is an important part of rehabilitation and is essential in this model where the clinician is in control of their patient. Exoskeletons are expensive and paradigms that use two exoskeletons, one as teacher and the other as a student, doubly so. Our teacher system is economical (material cost, AUD$30), uses a straightforward implementation, and may reduce the financial barriers to exoskeleton adoption, and increase utility.

The error in hip posture was likely a result of relative motion between the shorts, where the sensor arm was adhered, and the subject. Future iterations of the design and fixation method should focus on this as it was likely the largest source of error in the system. The knee posture obtained through plug-in gait also needs to be considered cautiously. The skin site for the lateral right retroreflective marker was identified, and the potentiometer was placed over this site, but left floating. The reflective motion capture marker was then placed over this site and would have been able to move relative to the site marked. This doesn't seem to have affected the results significantly and at high gain the knee was the better performing joint. The knee has a sliding center of rotation, which a stationary marker on the skin also cannot track. Future iterations of the design will benefit from having a reusable fixation method and instructions that don't rely on expert positioning of the system elements.

V. Conclusion

In this paper we present a low-cost system for capturing hip and knee joint posture of a subject (teacher) and used those postures as the tracking reference for the same limb of a powered lower limb exoskeleton (student). The premise for this type of control is to give therapists an intuitive mechanism for manipulating a person's limbs in rehabilitation settings, to gain precise control and reduce the physical exertion required to deliver gait rehabilitation therapy. Our proof-of-concept system used a single subject and an unworn exoskeleton to characterise the tracking error and the phase delay between the subject (teacher) and the exoskeleton (student). The phase delay was low when a high gain was applied. In the future, we intend on replicating this work with the exoskeleton worn on

a person(s) as the student, and the teacher system applied to both lateralities of the teacher to control both limbs. Furthermore, we aim to investigate and characterise the exoskeleton/user interface.

ACKNOWLEDGMENT

From Lab to Life: Correlating Lab-based Motion Capture and Field-based Wearable Sensor Metrics to Assess Motor Impairments in people with Multiple Sclerosis

Paula Villa Fulton[1], Valerie Thorbecke[1], Benedikt Becker[2], Philipp Gulde[1], Joachim Hermsdörfer[1]

***Abstract*— Understanding the relationship between lab-based kinematic metrics and real-world wearable sensor data offers valuable insights into motor dysfunction in multiple sclerosis (MS). This study explores the correlations between task specific metrics derived from motion capture systems during Tea Making and Drinking tasks and wrist-worn inertial measurement units (IMU). Path length hand differences (PL_Diff) in lab tasks exhibited strong correlations with the Expanded Disability Status Scale (EDSS)(r = 0.64, adjusted p = 0.02), indicating their potential as markers of disease severity. Consistent correlations between lab-based kinematics and wearable sensor metrics across different activities of daily living highlight the potential of IMU data for real-world motor impairment monitoring. This emphasizes the role of wearable assessments in improving the sensitivity and scalability of MS progression tracking.**

I. INTRODUCTION

Multiple Sclerosis (MS) is a chronic and progressive autoimmune disease affecting the central nervous system, with peak onset typically occurring in early adulthood [1]. Even when symptoms appear mild, maximum performance tests can detect underlying impairments [2]. However, commonly used clinical tools such as the Expanded Disability Status Scale (EDSS) [3] primarily assess static or isolated functional deficits, failing to capture the dynamic motor challenges people with MS (pwMS) face in real-world environments.

Motor impairments often manifest in subtle, task-specific ways. Submaximal tasks, performed at less than maximal effort, are particularly relevant because many real-world activities do not require peak performance but instead demand sustained coordination, precision, and adaptability. Submaximal behaviors, such as Activities of Daily Living (ADL), may reveal latent motor dysfunctions, making them crucial for real-world monitoring.

Despite the importance of ADLs, their relationship with MS-related motor impairments remains poorly understood [4]. While EDSS effectively quantifies neurological deficits, it does not fully capture how these impairments impact daily task performance. In contrast, wearable sensors and kinematic analyses provide a more comprehensive assessment by continuously monitoring movement dynamics in both structured and spontaneous activities. These technologies have demonstrated sensitivity to subtle motor changes that standard clinical tests may overlook [5]. Prior studies have shown their efficacy in detecting motor differences in populations such as young adults, the elderly, and stroke survivors [6], [7], yet their application to ADL performance in pwMS remains largely unexplored.

Fig. 1. Living laboratory setup with 9 Qualisys motion capture cameras.

This study bridges the gap between traditional clinical assessments and real-world functionality by integrating lab-based kinematic data with real-world inertial measurement unit (IMU) metrics. Laboratory-based ADL kinematics, obtained via state-of-the-art motion capture systems, provide high-resolution insights into motor performance under controlled conditions, while IMU-derived metrics offer scalable, continuous monitoring in free-living environments. Together, these approaches allow for the identification of both task-specific movement patterns and task-independent biomarkers of disease severity, complementing clinical scores such as EDSS.

Since kinematic parameters, such as movement smoothness, are highly task-dependent [8], we examine two ADLs with differing complexities: Tea Making task, a multi-step task requiring coordination and planning, and drinking from a glass, a simpler motor action. By identifying robust kinematic markers across these tasks, we aim to enhance the sensitivity of motor assessments, ultimately improving real-world disease monitoring and MS management.

This study was funded by the Federal Ministry of Education and Research and the Free State of Bavaria under the Federal Government's Excellence Strategy.

Ethical approval: All procedures performed in studies involving human participants were in accordance with the ethical standards of the Ethics Committee of the Technical University of Munich (reference number: 2023-212-S-KH).

II. Materials & Methods

A. Participants

This study involved 21 pwMS and 21 age-matched healthy controls. The pwMS group had a mean age of 46.2 ± 11.4 years (22-62 years), while the control group averaged 44.7 ± 10.6 years (24-60 years). Both groups included 61.9% females. MS participants exhibited mild to moderate disability, with an average EDSS score of 2.3 ± 1.7 (0-6).

The study is part of the TUM Innovation Network, eXprt, and received ethical approval from the Ethics Committee of the Technical University of Munich (reference: 2023-212-S-KH). Written informed consent was obtained from all participants prior to their participation.

B. Clinical Assessments

Participants completed clinical assessments to evaluate motor and functional abilities:

- **Nine-Hole Peg Test (PEG):** Trial duration [s].
- **Box and Blocks Test (BB):** Blocks transported per minute [1/min].
- **Grip Strength (GRIP):** sex-specific z-scores based on kilogram force [kg].
- **Tapping Tasks (TAP):** Finger tapping speed [Hz].
- **Reaction Task (REACT):** Average reaction speed [ms].
- **Two-Point Discrimination (DISCR):** Minimal detectable distance [mm] on the index finger.

Higher values generally indicate better performance, except for PEG, DISCR and REACT. Results for dominant and non-dominant upper limbs were averaged, and a laterality index was calculated to reflect performance asymmetry, with higher values indicating greater lateralization of impairments.

The Normalized Difference quantifies the performance asymmetry between the dominant (DL) and non-dominant (NDL) limbs:

$$\text{Normalized Difference} = \frac{|\text{DL} - \text{NDL}|}{(\text{DL} + \text{NDL})/2}$$

C. Lab-Based Kinematics

Motor performance was assessed through two everyday activities: preparing a cup of tea [6], [7] and drinking from a glass [9]. These tasks mimic real-world demands while enabling precise kinematic measurements. Hand movements were recorded using an optoelectronic motion capture system with nine Miqus cameras (Qualisys Inc., Gothenburg, Sweden), tracking reflective markers at 120 Hz. Extracted kinematic parameters included:

- **Trial Duration (TD):** Time to complete the task, excluding the water boiling wait [s].
- **Path Length (PL):** Length of hand trajectories [m].
- **Relative Activity (RA):** Time one hand exceeds a velocity of 0.05 m/s [s].
- **Mean Peak Velocity (MP):** Average velocity peaks over 0.05 m/s [m/s].
- **Number of Peaks per Meter (NP):** Velocity peaks per meter [1/m].
- **Bimanual Quotient (BQ):** Ratio of non-dominant to dominant hand path lengths.
- **Bimanual Cooperation (BC):** Time both hands exceed a velocity of 0.05 m/s [s].

The absolute difference and normalized difference (laterality) of hand-specific measures was computed for PL, RA and NP, respectively (PL_Diff, RA_lat and NP_lat).

D. Real-World Wearable Sensor Metrics

Participants wore inertial measurement units (IMUs) on both hands for seven days following the lab assessments. IMUs captured kinematic data at a sampling rate of 64 Hz, with features categorized as:

- **Time-Domain Features:** Task duration (TD), maximum and mean acceleration and gyroscopic values (A_Max, G_Max, A_Mean, G_Mean).
- **Smoothness Features:** Spectral Arc Length from acceleration and gyroscopic signals (A_SPARC and G_SPARC).
- **Variability Features:** Standard deviation (STD) of acceleration, gyroscopic values, and derived metrics.
- **Laterality:** The normalized difference of hand-specific measures was also computed.

E. IMU Data Processing

IMU data was processed using the 2MPAC algorithm [10], with analysis restricted to a four-hour segment of sensor data collected from wrist-worn IMUs between 12:00 and 16:00 on the second day of wear. The algorithm identifies activity onset and offset by detecting acceleration and angular velocity thresholds, thus segmenting independent of activity duration. Movements exceeding a minimum acceleration (0.5 m/s²), angular velocity (60°/s), and duration (400 ms) are classified as valid activities, with pauses within activities limited to 1 second. This approach aims to capture both short and fragmented movements while filtering out noise and inactivity.

F. Statistical Analysis

Differences between MS and control groups were assessed using ANOVA, with sex interaction included for GRIP. Linear associations between kinematic features and EDSS scores for MS participants were examined using Pearson correlation. Statistical significance was set at $\alpha = 0.05$, with Benjamini-Hochberg corrections applied to account for multiple comparisons and control the false discovery rate.

III. Results

A. Group Differences and Laterality

Group differences were analyzed for absolute values and symmetry measures, including laterality (normalized differences) and absolute differences (e.g., Path Length). As illustrated in Fig. 2, significant group-level differences were observed in laterality measures for the Nine-Hole Peg Test (PEG_lat) (p = 0.01, η^2 = 0.76) and Two-Point Discrimination (DISCR_lat) (p = 0.02, η^2 = 0.71), emphasizing the sensitivity of these assessments in detecting motor asymmetry.

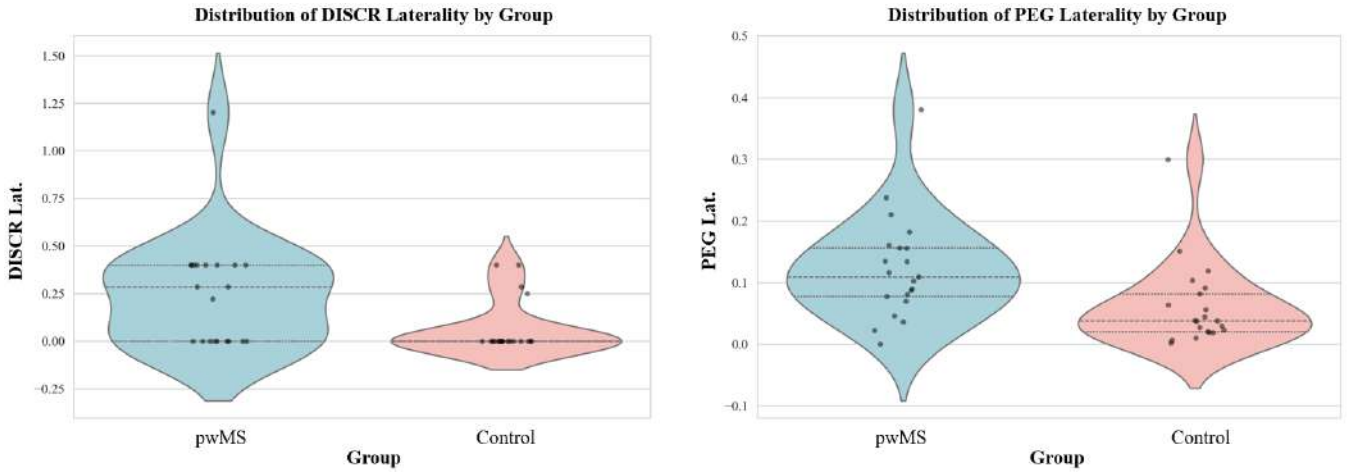

Fig. 2. Statistically significant differences between groups.

However, other metrics did not reach statistical significance (Table I), suggesting that gross motor speed and force-based measures may be less sensitive to mild impairments compared to assessments requiring fine motor control and sensory processing.

Despite these significant group differences in clinical assessments, no significant group differences were observed in field-based IMU-derived metrics or lab-based kinematic parameters from Tea Making and Drinking tasks. This indicates that while traditional clinical assessments can detect motor impairments, IMU and motion capture metrics may require more refined analytical approaches or complementary measures to better reflect functional deficits observed in clinical assessments.

TABLE I
CORRECTED P-VALUES, EFFECT SIZES, AND BENJAMINI–HOCHBERG (BH) SIGNIFICANCE FOR CLINICAL FEATURES

Feature	Corr. P-Value	Effect Size (η^2)	BH Significant
PEG_lat	0.01	0.76	True
DISCR_lat	0.02	0.71	True
REACT	0.05	0.21	False
GRIP_lat	0.09	0.67	False
BB_lat	0.44	0.58	False
TAP_lat	0.91	0.001	False

[a]Group differences were significant for a subset of clinical measures.

B. Correlations with Disease Severity

To evaluate the sensitivity of kinematic lab-based and IMU field-based features to disease severity, Pearson correlations with EDSS scores were analyzed. The difference between hand path lengths (PL_Diff) showed a strong positive correlation with EDSS in the Tea Making task, with a Pearson correlation coefficient of r=0.64 (p=0.002, adjusted p=0.02), as seen in Fig. 3.

C. Relationships Between Lab and Real-World Data

We conducted an exploratory analysis to examine the relationships between kinematic features measured in lab-based motion capture tasks and field-based IMU data. The aim was to uncover consistent patterns and correlations that could inform the development of hypothesis-driven studies in the future. By comparing features across two distinct ADL, Tea Making and Drinking tasks, we sought to identify task-specific and task-independent markers of motor impairment.

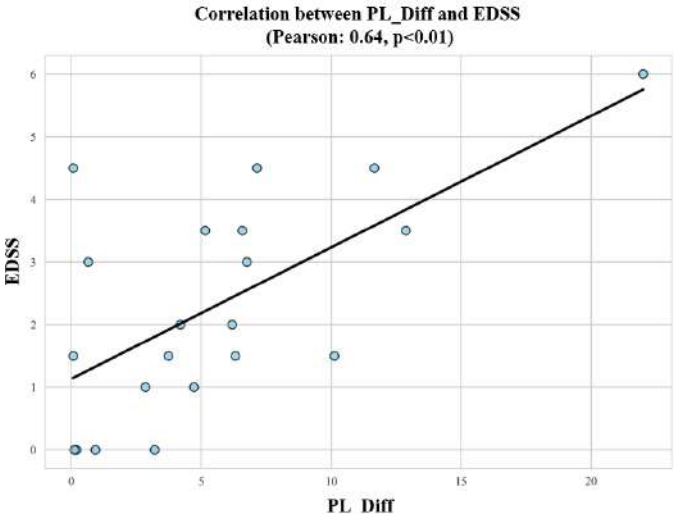

Fig. 3. Observed correlation between the absolute path length difference between hands (PL_Diff) and EDSS scores.

Absolute values (e.g., path length, velocity) and their symmetry metrics (e.g., laterality or absolute differences) were evaluated for correlations between lab-based kinematics and field-based IMU-derived measures.

Rather than examining single-task correlations, we specifically identified features that were significantly correlated between lab and IMU metrics across both the Tea Making and Drinking tasks. This approach was designed to pinpoint robust, task-independent relationships.

While individual task correlations varied, only two feature pairs consistently correlated across both Tea Making and Drinking tasks (Table II, as seen in Fig 4). Lab-based Path

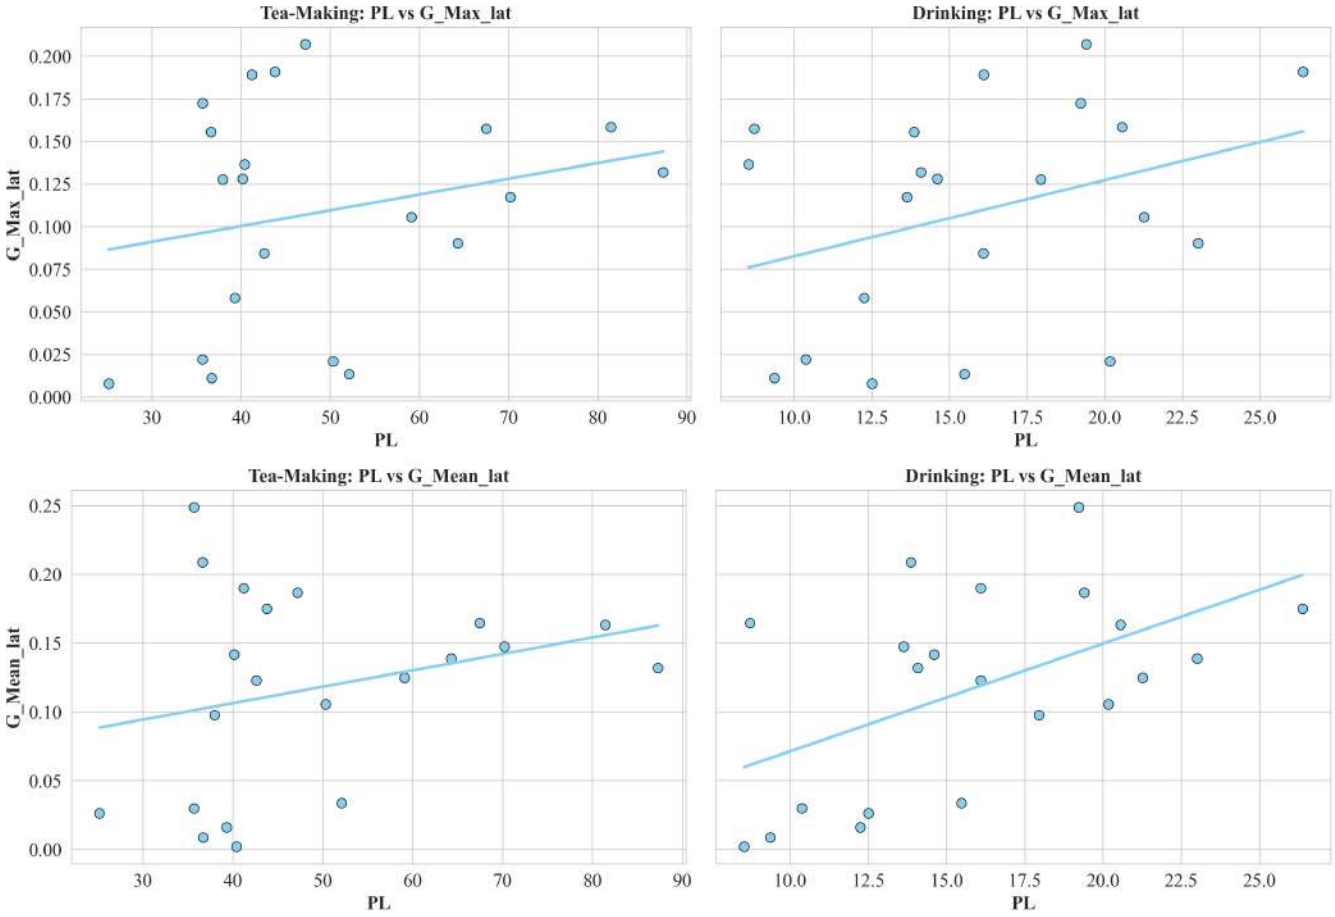

Fig. 4. Consistent relationships were observed between lab-based kinematics and field-based IMU metrics across Tea Making and Drinking tasks. Regarding the laterality of the mean angular velocity signal (G_Mean_lat), significant correlations were found for Tea Making task (r = 0.41, p< 0.001) and drinking (r = 0.52, p< 0.001). Similarly, the laterality of the maximum angular velocity signal (G_Max_lat) showed correlations for Tea Making task (r = 0.39, p = 0.011) and drinking (r = 0.36, p = 0.018).

Length (PL) correlated significantly with the laterality of the mean angular velocity signal (G_Mean_lat: Tea Making task r=0.41, p< 0.001, drinking r=0.52, p< 0.001), and laterality of the maximum angular velocity signal (G_Max_lat: Tea Making task r=0.39,p=0.011, drinking r=0.36,p=0.018). The consistency of these correlations highlights their potential as task-independent biomarkers for assessing motor impairments in free-living environments.

TABLE II
CORRELATIONS BETWEEN ADL AND IMU FEATURES ACROSS TASKS

ADL Feature	IMU Feature	Correlation	P-Value	Task
PL	G_Mean_lat	0.41	< 0.001	Tea
PL	G_Mean_lat	0.52	< 0.001	Drink
PL	G_Max_lat	0.39	0.01	Tea
PL	G_Max_lat	0.39	0.02	Drink

IV. DISCUSSION

This study highlights the importance of assessing submaximal behaviors in ADL using IMU and motion capture data. Submaximal tasks may not always detect functional limitations when impairments are mild. This is reflected in the lack of significant group differences and the weak associations with EDSS. These findings emphasize the need for task-independent metrics capable of capturing subtle motor impairments in real-world settings.

We explored the potential of combining lab-based kinematics with field-based IMU-derived metrics to assess motor impairments in pwMS. Correlations between lab-based path length (PL) and IMU-derived angular velocity metrics across tasks suggest these features may serve as robust, task-independent markers of motor behavior (Table II). Path length differences between hands have been shown to distinguish pwMS from controls [11], likely due to MS-related demyelination, even in mild cases [12]. Meanwhile, gyroscopic metrics capture rotational hand dynamics, offering complementary insights into motor performance. Their strong correlations across tasks suggest they are sensitive and robust for real-world disease monitoring (Fig. 4).

Prior studies have shown that kinematic markers detect early motor impairment in stroke and Parkinson's disease, but their use in upper limb analysis for MS remains limited. Our findings align with recent research emphasizing move-

ment asymmetry as an indicator of disease severity in MS [13]. The strong correlation between EDSS and PL_Diff in the Tea Making task (Fig. 3) supports prior evidence that unilateral deficits are an early hallmark of MS-related motor dysfunction and may reflect compensatory or pathological strategies in MS. However, its clinical implications require further validation, as PL_Diff alone may not fully encapsulate the nuances of daily motor deficits, reinforcing the need for more granular kinematic analyses.

The consistency of path length correlations with IMU features across tasks (Table II) highlights their potential as task-independent biomarkers, allowing for scalable assessments in home settings. This correlation likely arises because both Tea Making and Drinking require coordinated wrist rotations for object manipulation, which increase the total angular displacement captured by gyroscopes; correspondingly, the wrist travels a greater distance in space, thereby elevating the measured path length in lab-based tasks. IMU-based tracking could complement clinical evaluations and reduce the need for frequent hospital visits. However, a key question remains: Do these markers provide insights beyond traditional clinical assessments? Addressing this will be crucial for integrating IMU-based monitoring into clinical practice.

Despite strong correlations with disease severity, the lack of significant group-level differences suggests some individuals with MS retain near-normal task performance, likely due to the mild symptoms of this cohort. While features like PL_Diff showed high sensitivity to disease severity, they lacked discriminative power between groups. This highlights the need to select kinematic features based on specific research or clinical goals—whether for tracking disease progression or detecting early impairments.

Although correlations with EDSS suggest that IMU metrics reflect disease severity, they do not inherently establish their added clinical value. Given EDSS's broad, ordinal nature, IMU-based assessments should ideally provide more refined functional insights. Without a well-established clinical parallel, standalone interpretation of these metrics remains challenging, reinforcing the need for further validation.

Future research should prioritize validating IMU-derived features against more detailed functional assessments. Longitudinal studies could determine whether these metrics serve as early indicators of motor or cognitive decline. Refining data segmentation algorithms and task-specific movement analyses may also enhance IMU-based sensitivity to subtle impairments.

While IMU metrics showed limitations in cross-sectional analysis due to the lack of group-level differences, their potential for continuous, remote disease monitoring remains promising. With further refinement, IMU-based tracking could become a valuable tool for personalized rehabilitation and real-world disease management.

V. Conclusion

This study explored the integration of lab-based kinematic analyses and field-based IMU metrics to assess motor impairments in pwMS. Correlations between path length and gyroscopic measures across tasks of different complexities suggest the potential utility of these features as task-independent markers of motor behavior. While the findings highlight the promise of combining lab precision with wearable sensor scalability, further research is necessary to validate these relationships and assess their broader applicability in monitoring disease progression and real-world motor performance.

Skeleton-Based Transformer for Classification of Errors and Better Feedback in Low Back Pain Physical Rehabilitation Exercises

Aleksa Marusic[1], Sao Mai Nguyen[1] and Adriana Tapus[1]

***Abstract*— Physical rehabilitation exercises suggested by healthcare professionals can help recovery from various musculoskeletal disorders and prevent re-injury. However, patients' engagement tends to decrease over time without direct supervision, which is why there is a need for an automated monitoring system. In recent years, there has been great progress in quality assessment of physical rehabilitation exercises. Most of them only provide a binary classification if the performance is correct or incorrect, and a few provide a continuous score. This information is not sufficient for patients to improve their performance. In this work, we propose an algorithm for error classification of rehabilitation exercises, thus making the first step toward more detailed feedback to patients. We focus on skeleton-based exercise assessment, which utilizes human pose estimation to evaluate motion. Inspired by recent algorithms for quality assessment during rehabilitation exercises, we propose a Transformer-based model for the described classification. Our model is inspired by the HyperFormer method for human action recognition, and adapted to our problem and dataset. The evaluation is done on the KERAAL dataset, as it is the only medical dataset with clear error labels for the exercises, and our model significantly surpasses state-of-the-art methods. Furthermore, we bridge the gap towards better feedback to the patients by presenting a way to calculate the importance of joints for each exercise.**

I. INTRODUCTION

Physical rehabilitation plays a crucial role in helping patients recover from injuries, surgeries, and various medical conditions that affect their movement and functional abilities. Low back pain (LBP), which is the focus of our research, is a leading cause of disability globally, affecting over 50% of the population at some point in their lives. Consequently, healthcare providers face substantial challenges in managing the increasing number of LBP patients [1]. The success of rehabilitation exercises depends significantly on how accurately and consistently they are performed. Throughout the weeks or even months of a rehabilitation program, patients often have to carry out exercises at home without direct oversight from healthcare professionals. The absence of supervision and timely feedback from healthcare providers diminishes patient engagement in rehabilitation. Additionally, incorrect movements can not only delay the rehabilitation process but also increase the risk of further injuries [2]. Thus, there is a critical need for accurate and automated movement analysis methods to support patients and clinicians in monitoring rehabilitation exercises.

*This work was supported by ENSTA Paris

[1]Autonomous Systems and Robotics Lab, Computer Science and System Engineering (U2IS), ENSTA Paris, Institut Polytechnique de Paris, 828 Blvd des Maréchaux, 91120 Palaiseau, France, name.surname@ensta-paris.fr

The primary objective of automated monitoring systems for physical rehabilitation is to identify the activity being performed, evaluate its quality, and offer detailed information on errors and potential improvements. Current movement analysis methods in rehabilitation typically provide a general quality score that reflects how well an exercise is executed [3], [4], [5] While these scoring systems provide useful feedback, they represent only the initial step toward a fully automated and practical monitoring system.

A more detailed analysis, which not only evaluates the overall quality of movement but also identifies and localizes specific errors, would be highly beneficial for both patients and clinicians. This detailed feedback can help patients adjust their movements more precisely, keep them motivated throughout the rehabilitation sessions, and allow clinicians to more accurately monitor patients' progress while in-home rehabilitation [6], [7].

Human activity analysis is an evolving field that tackles the complex challenge of interpreting body movements based on data collected from various sources such as videos, images, or wearable sensors. While using data from wearable sensors directly as input is the dominant approach, recently, human pose estimation to estimate joint coordinates from videos has become a promising approach to analyze human movement. Given that skeletons can be naturally modeled as graphs, it is not surprising that Graph Convolutional Networks (GCNs) have become a leading method for skeleton-based action recognition. By representing the body as a graph of joints and their spatial-temporal relationships, skeleton-based methods effectively capture movement dynamics and remain resilient to changes in appearance and environmental conditions, while capturing spatial and temporal relationships during exercise performance [8], [9].

Furthermore, Transformer models, originally developed for natural language processing tasks, have shown remarkable success in various applications, such as recognition of daily activities in smart homes [10]. Their ability to model long-range dependencies and capture contextual information makes them well-suited for analyzing sequential data, such as skeleton sequences in rehabilitation exercises [11].

For automated feedback allowing physical rehabilitation patients to improve their performance, this paper offers two key innovations: error classification and movement analysis. Unlike previous methods that focus solely on providing a quality score, our approach requires a more precise model, thus we utilize a skeleton-based transformer model. Through self-attention mechanism, our model is able to better learn spatial and temporal relations between skeleton

joints. Specifically, our model is designed to:

- Classify errors: Identify and categorize different types of errors that may occur during the performance of rehabilitation exercises.
- Biomechanical attention: Identify the most important joints in human body skeleton for a specific movement, thus providing better feedback to the patient.

The remainder of this paper is organized as follows: Section II reviews related work on movement analysis in rehabilitation and skeleton-based action recognition models. After outlining the data we used in Section III, Section **??** describes the architecture of our skeleton-based transformer model and the methods for error classification and localization. Section V details our experimental setup and results, and discusses the implications of our findings. Finally, Section VI summarizes our main contributions, acknowledges the limitations of our approach, and suggests potential directions for future research..

II. RELATED WORK

A. Skeleton-based Action Recognition

Skeleton-based action recognition is a dynamic and rapidly evolving research area. Early studies depended on handcrafted features that utilized relative 3D rotations and translations between joints [12], [13]. However, the field has experienced significant advancements in recent years, largely driven by Deep Learning algorithms [8]. These Deep Learning methods for skeleton-based action recognition can be categorized into three primary groups, based on their approaches to extracting features from skeleton data for classification:

- Recurrent Neural Networks (RNNs), which consider skeleton data primarily as a temporal sequence of continuous features. Some of the examples are [14] that introduced a hierarchical recurrent neural network, and [15] that proposed Context-Aware Attention LSTM Networks.
- Convolutional Neural Networks (CNNs), [16], [17] apply CNNs on pseudo-images obtained from skeleton data [16], [17]. In this way, they capture spatial relations between joints in a frame.
- Graph Neural Networks (GNNs): Skeleton data naturally corresponds to a graph structure, with joints as vertices and bones as edges. As a result, Graph Convolutional Networks have become increasingly popular as they can extract both spatial relationships and be combined with temporal data [18], [19].

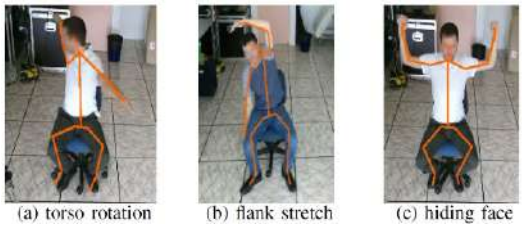
B. Physical Rehabilitation Assessment

Qualitative exercise assessment is essential for effective home-based rehabilitation systems, aiming to provide patients with informative feedback and enhance their performance. Early research on exercise evaluation applied traditional machine learning methods for classification, such as Adaboost, K-Nearest Neighbors (KNN), or Bayesian classifiers. Some approaches also utilized distance function-based models [20], [21]. Later studies adopted probabilistic models like Hidden Markov Models (HMMs) and Gaussian Mixture Models (GMMs) [6], [22]. While these models capture the stochastic nature of human motion and provide a quality score for movement accuracy, they do not fully exploit given information, such as joint or spatial connections between body parts.

Liao et al. [23] introduced a deep neural network model that generates quality scores for movements. They proposed a deep learning architecture for hierarchical spatio-temporal modeling, combining GMMs, CNNs, and LSTMs to compute a quality score. With the advent of Graph Neural Networks (GNNs), it is now possible to exploit spatial information through the skeletal graph structure. The authors in [24] and [25] applied Graph Convolutional Networks (GCNs) to assess physical rehabilitation, achieving state-of-the-art results on popular datasets such as KIMORE and UI-PRMD. Additionally, Yu et al. [26] employed an ensemble of two GCNs, one for position and one for orientation features of the skeletal joints, to further improve performance.

While existing methods primarily focus on quality scoring, a few studies have explored error classification and localization. For example, dynamic time warping (DTW) was used in [27] to compare patient movements with reference movements and identify phases with significant deviations. Devanne et al. [7] added on top of DTW, a GMM model to analyse the likelihood per body part and per time segment to localize the error. However, its accuracy remains modest. On the other hand, our approach leverages the power of Deep Learning and Transformer models to capture the spatial-temporal dynamics of movements and provide actionable feedback with error classification and localization.

In the following sections, we describe our methodology in detail, including the architecture of our skeleton-based transformer model and the approaches for error classification and movement analysis.



III. DATA PROCESSED

A. Dataset

We evaluate our model on the Keraal dataset [28], as it is the only one of the available rehabilitation datasets that fits into our problem setting and has error labels. TRSP [29] is the only other rehabilitation dataset, to our knowledge, with error labels, but they only use two types of simple reaching motions.

In the Keraal dataset, participants performed each of 3 predefined exercises, and the movements were recorded with Microsoft Kinect V2 and Vicon Recordings are annotated by physiotherapists in detail, with assessment of correctness, recognition of errors, and spatio-temporal localization of errors. In our model we used Kinect data as input, since it is a non-invasive system we would like to focus on.

The three exercises, chosen in agreement with medical experts, are namely torso rotation, flank stretch, and hiding face, which are illustrated in Figure 1. For each exercise therapists identified three most common errors, and each labeled recording was classified either as correct or as one of these 3 errors. As can be seen on Figure 2, the common

(a) torso rotation (b) flank stretch (c) hiding face

Fig. 1: The three rehabilitation exercises in the Keraal dataset. Image sourced from [28].

Fig. 2: Errors descriptions for all three exercises in the Keraal dataset. Image sourced from [28].

mistakes for exercise (a) torso rotation are: 1) Arms are not raised enough, 2) The torso's rotation is not sufficient, 3) The body is leaned on the side; for exercise (b) flank stretch: 1) Opposite arm is not along the body, 2) Body is not tilted, 3) The above arm is not bent; and for exercise (c) hiding face: 1) Arms are not raised enough, 2) Arms are not outspread enough, 3) Arms are not raised enough.

The Keraal dataset was recorded during a clinical rehabilitation study that included Low Back Pain patients, aged 18 to 70 years. The dataset includes recordings from both healthy subjects and 12 rehabilitation patients, from three groups of participants:

- Group 1 where patients performed exercises
- Group 2 where healthy participants performed exercises without specific intructions
- Group 3 where trained healthy participants performed exercises while simulating errors.

Groups 1 and 2 were labeled by physiotherapists, while Group 3 was implicitly labeled as participants simulated errors.

B. Data representation

The data of the Keraal dataset recorded exercises at a fixed frame rate, capturing the spatial information of key skeletal joints in the human body, either in two or three dimensions. The data include joint positions and sometimes their orientations (in our case we use only 3D joint positions).

Consider a tracking system that monitors V key points (joints) on a person's body. When someone performs one repetition of an exercise, the system records data across a certain number of time frames. Since that number can vary from recording to recording even for the same exercise type, we interpolate each recording to T timeframes. For each frame, we collect the positions of all V joints in a vector $x(i), i \in [1 \dots T]$. This vector has the dimension $D = V \times C$, where C equals either 2 or 3, depending on whether we are working with 2D or 3D data. When we combine these vectors from all frames, we create a three-dimensional tensor $X \in \mathbb{R}^{T \times V \times C}$, which represents the complete movement data from a single repetition.

C. Evaluation scenarios

Our goal is to classify a performed movement into one of four categories: correct, error1, error2, or error3. To achieve this, we train a separate model for each exercise. The primary metrics used for evaluation are the F1 score and accuracy.

We consider three cases:

- Scenario 1: Initial scenario where we train the models on trained professionals simulating errors (group 3), and evaluate on healthy subjects and patients (groups 2A and 1A). This setup is critical as it demonstrates the model's performance on unseen data, closely simulating real-life application conditions.
- Scenario 2: In the second scenario, data from all three groups are combined and split into training and testing sets, in proportion 80:20. Also, it is important to note that the split is stratified, meaning the proportion of class labels is approximately the same in both training and test splits. This second scenario highlights the model's full potential by showing the level of performance achievable with sufficient data for both training and validation.
- Scenario 3: The scarcity of labels for certain exercises in the first scenario prompted us to design a third scenario. We still wanted to have unseen patient data in the test set to simulate real-life conditions, but we added a portion of healthy participants in the test set as well, so that we better evaluate our model. In this setup, the test set is made from patient data (group 1) and 15% of the combined data from groups 2 and 3, while the training set consists of the remaining 85% of the healthy participants' data (split is stratified in this case as well).

IV. Algorithm

A. Self-attention

Self-attention in Transformers was originally developed to identify and map relationships between words in a text, whether they are close together or far apart in a sentence. This mechanism helps the network prioritize important parts of the input data [30], [31].

We can adapt this same concept to analyze human movement patterns captured through skeletal tracking. Just as Transformers process relationships between words in a text, we can process relationships between body joints in motion. Individual joint positions can be seen as words and each

frame of movement as a sentence. By applying the self-attention mechanism, we can more effectively learn both local (between nearby joints or sequential frames) and distant relationships (between far-apart joints or temporally distant frames) in the motion sequence.

Consider a given input sequence $X = (x_1, x_2, \ldots, x_n)$ where each x_i represents an input token. Each token x_i is transformed into three vectors: Query vector q_i, Key vector k_i, and Value vector v_i. These vectors are obtained by applying learned projection matrices to each token, transforming them into new representations suited for computing attention. Essentially, these projections allow the model to learn more complex spatial relations of the input data.

For each token x_i, its attention score is computed relative to every other token in the sequence x_j, including itself. The attention score is calculated by applying a softmax function on the dot product A_{ij} between the query vector q_i of token i and the key vector k_j of token j:

$$A_{ij} = q_i \cdot k_j^{\top} \tag{1}$$

To capture more complex relationships, an extension called Multi-Head Self-Attention (MHSA) is added [31]. With multiple attention heads, the model learns different kinds of spatial relations between the joints, in parallel.

B. Model architecture

The main processing idea is inspired by a novel algorithm - Hyperformer [32]. It has achieved state-of-the-art results on well-known human action recognition (HAR) benchmarks, proving it can learn complex relations between joints in the movement. However, unlike HAR datasets, we are not interested in distinguishing different types of actions, but different types of errors in one specific action. Thus, we are looking for much more subtle differences in motions during the same actions and trying to classify each motion accordingly. We train one model per exercise (action), compared to HAR algorithms which train one model in total to classify actions.

Furthermore, we have only a few classes (for errors), and even more importantly, very limited medical data to train the model, which emphasizes the need for a better understanding of spatio-temporal relations between the joints. That was another reason to choose Hyperformer as our basis, since it is one of the smallest HAR algorithms available (by number of trainable parameters).

One of the key novelties of Hyperformer is utilizing hypergraphs - dividing the initial skeleton graph into subgraphs in order to obtain more precise relations between the joints. In our paper we propose a different split of the skeleton graph, more tailored to our problem setting. We split 25 joints into 6 different groups: left and right forearm and hand (with wrists and fingers), legs and spine with head, as can be seen on the left part of Figure 3. We give particular importance to arms as they are one of the key parts in all exercises from the dataset used, as opposed to legs which do not move much during the exercises.

The overall model architecture can be seen on the right part of Figure 3 The input data is passed through a certain

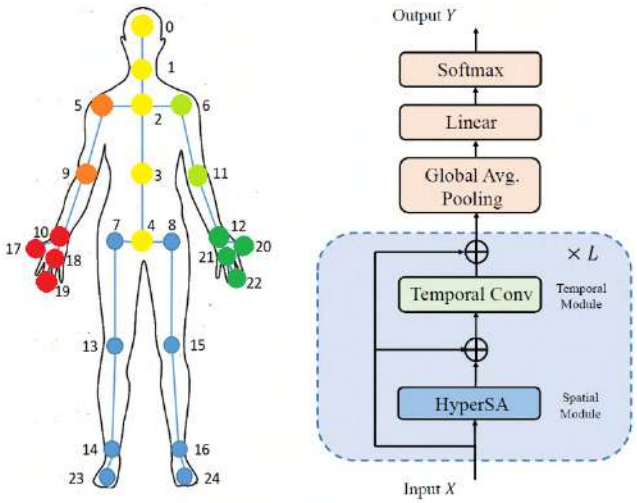


Fig. 3: Groups of skeletal joints (hypergraphs) on the left and model overview on the right. Right part taken from [32]

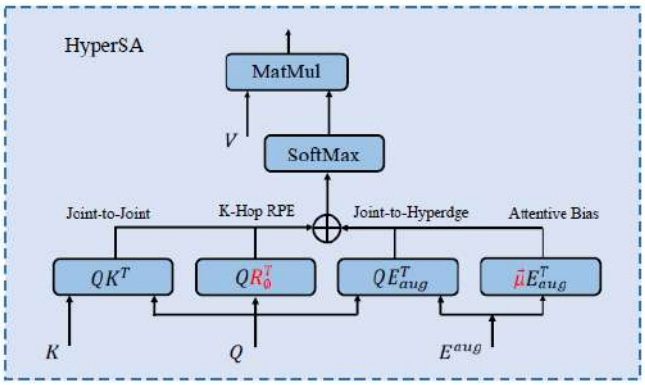

Fig. 4: Overview of the hyper self-attention module [32].

number of layers (10 in our case). Each layer consists of a custom self-attention layer followed by Multi-Scale Temporal Convolution. Global pooling, a linear activation and softmax functions are added at the end. The model is trained via backpropagation through a cross-entropy loss function by comparing $\hat{\mathbf{y}}$ with the true label $\mathbf{y}$ - a class labeled by the physiotherapists.

The main part of the layer is a custom self-attention module, as depicted in Figure 4. It consists of 4 parts :

- Joint-to-joint attention. Projection matrices used to get q, k, v vectors are obtained with 2D convolutions. Attention is calculated as described in IV-A.
- Joint-to-subgraph attention. Learns relations between joints and subgraphs, calculated the same way
- Relative positional embedding. Incorporates structural information of the skeleton, obtained with the Shortest Path Distance between the joints
- Attentive bias. Assigns the same amount of attention to each joint that belongs to a certain subgraph, enforcing independence of the query position.

V. RESULTS & DISCUSSION

In this section, we present the results of comprehensive comparative experiments conducted to assess the perfor-

mance of our model. We provide a comparison between our proposed approach and the current state-of-the-art, as well as some guidelines for further improvement.

A. Implementation details

Python 3.10 and the PyTorch 2.3 + CUDA 12.1 framework were used to develop the model. The system is equipped with an Intel Core i9-9900KF Silver 4215R CPU, 32GB of RAM, and an Nvidia RTX 2080 Ti 11GB. The model was trained with the Adam optimizer for 600 epochs, with a learning rate set to 25×10^{-4}, and using a batch size of 10. Performance measures were recorded for each run and averaged to ensure accuracy. Our code is based on the Hyperformer code repository and is available at `https://github.com/aleksamarusic/hyperphysio/`

B. Comparison with state-of-the-art

Table I shows that out model reaches higher accuracies in Scenario 1, outperforming the models benchmarked in [28].

TABLE I: Accuracies of our model and benchmark from [28]

Exercise	Ours	LSTM best	LSTM mean	GMM
Torso rotation	**73.17 %**	64.44 %	53.89 %	27.78 %
Flank stretch	**64.10 %**	43.04 %	31.64 %	25.32 %
Hiding face	**74.28 %**	56.19 %	49.1 %	33.33 %

Additionally, we present confusion matrices for the classification of rehabilitation movements, comparing three described scenarios

The confusion matrices for the first case are presented in Figure 5, with true labels on the left and predicted labels on the bottom. The values in the matrices represent the percentage of exercises classified as a certain class. For instance, in Figure 5a, the first row indicates that 71% of "Correct" exercises are classified as correct, 28% as error2, and 1% as error3. Consequently, the sum of any row in these matrices should be 1. Exceptionally, rows with all zeros mean that the corresponding error is not present in the test set. The value in brackets next to the left-side labels denote the frequency of the corresponding class in the test set.

For the torso rotation exercise, it is very hard to evaluate the model performance as we have 72 "correct" labels, only 4 of error1 and 6 of error2, while error3 is not present in the test set.

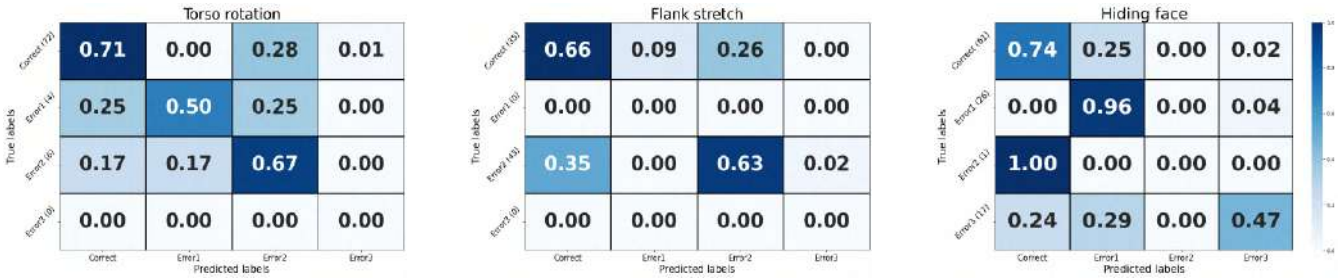
Similarly, the scarcity of labels for errors 1 and 3 in the flank stretch exercise poses significant challenges for accurately evaluating the model's performance. Error2 exhibits some confusion with correct exercises, which can be explained by the general challenge to determine that the body is not tilted enough solely based on joint positions.

For hiding face, error2 has only 1 example in the test set, and we need more to properly evaluate. Also, it can be noticed that error3 shows misclassification with both correct and error1 categories. These can be also attributed to a general challenge as errors 1 and 3 are quite similar, and both are hard to distinguish from the correct performance as it is only a matter of a few pixels on the image whether they would be classified as one or the other. These issues could potentially be mitigated with the inclusion of additional training and validation data, and with more precise data.

Confusion matrices for the second case can be seen in Figure 6. As explained, we randomly sample 20% of the dataset for testing, keeping the proportion of the labels in the test set. This scenario obtained better performance, which confirms the model's potential to perform significantly better when having more training data.

The confusion matrices for the third case are shown in Figure 7. While the majority of movements are correctly classified, some confusion can be observed between "correct" and "error3" in the flank stretch exercise . This may be attributed to the limited number of sequences labeled as correct by the medical expert and the subtle differences between correct movements and error2. The latter occurs when the body is not sufficiently tilted, a distinction that can be challenging to detect solely through skeleton joint data.

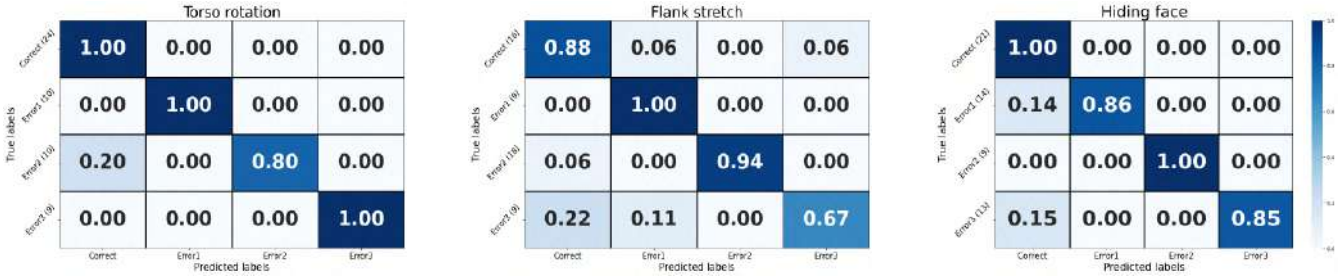
C. Visualization of joints' importance



The described visualization aims to analyze and compare the attention weights learned during the training and evaluation phase. By analyzing attention matrices, we can identify important joints in each exercise.

From our model, we can obtain the self-attention weights, which are quite comprehensive as we have weights for every layer, frame, and head (of multi-head attention) from every batch and input sequence. However, by averaging across these dimensions, we can obtain self-attention map that shows the attention weights for each body joint to every other body joint (since we have 25 joints, it is represented as $25 * 25$ matrix). Further, the joint role can be computed by the column-wise summation over that map. Additionally, we also notice that is important to look at differences in self-attention maps obtained from correct and incorrect exercises. This way we can more easily obtain information on which joints play an important role in the exercise.

Looking at Figure 8, we can notice that arm joints play an important role in all exercises, contrarily to the legs, as the exercises relate to the upper body. Additionally, Torso rotation and Hiding face give more importance to the angles of the shoulders and elbows, contrarily to Flank stretch. This is expected as the two former exercises require keeping the upper arm horizontal, while Flank stretch leaves the arm free, focusing more on the flank. These observations align with key joint patterns seen in the exercises (Figure 1), confirming the ability of the model to provide accurate and useful feedback to patients.



VI. CONCLUSION

In this paper, we present a Transformer-based model for classifying errors in physical rehabilitation exercises. The model takes skeleton joint positions as input and classifies movement as either correct or one of the predefined errors. Inspired by the Hyperformer algorithm, our approach divides

the skeleton graph into subgraphs to enhance the learning of complex spatial joint relations using the self-attention mechanism. We evaluate our model on the Keraal dataset, focusing on low back pain rehabilitation, which is the only dataset suitable for this error classification task. We can draw several conclusions:

- Our model achieves significant improvements over benchmark algorithms and sets new state-of-the-art re-

sults. This proves the ability to better capture spatial and temporal relations with the self-attention module, and sets a new direction for automated rehabilitation assessment

- We also calculate the importance of specific joints in performed exercises. This information can be used to detect which joints are wrongly moved, leading to enhanced feedback provided to the patients.
- Since we were interested in subtle differences in motions during the same exercise, it was necessary to train one model for each exercise type. In a scenario in which patients are trained by a coach, the system knows which exercise is being performed and the focus was on the assessment method. A more comprehensive model integrating exercise detection, can be a future research direction.
- One of the key limitations lies in the limited data available. While the Keraal dataset has detailed annotations, medical datasets are unfortunately limited in number.
- The imbalance of the dataset makes it harder to evaluate the model for underrepresented classes. Exploring data augmentation methods could lead to better classification and is a potential research direction for further studies.
- Some of the further research directions are temporal localization of errors, as well as more precise instructions on how to fix errors. These are essential for qualitative feedback to a patient.

Effects of Visual and Verbal Feedback on Active Patient Participation during Robot-Assisted Gait Training

F. Di Tommaso[1,*], M. Ferrara[1], F. Patarini[2,3], S. Mohebban[2,3], A. Bigioni[5], G. Serratore[5], M. Lorusso[5], F. Cincotti[2], G. Scivoletto[5], D. Mattia[3], F. Tamburella[4,5], J. Toppi[2,3], F. Pichiorri[3], N. L. Tagliamonte[1,5]

***Abstract*—Robot-Assisted Gait Training (RAGT) is a widely adopted neurorehabilitation approach for individuals with Spinal Cord Injury (SCI). In this context, active patient participation is a key factor to improve the success of the therapy. Previous works with the robotic trainer Lokomat have shown that real-time visual feedback and verbal instructions from a physical therapist effectively enhance active participation. However, the optimal type of visual feedback and its potential synergy with verbal indications remain unclear. This study investigates how different visual feedback types influence active participation when combined with therapist verbal instructions. Nine participants with SCI underwent RAGT sessions with three types of visual feedback (*chart*, *emoticon*, *game*) and two levels of patient-therapist verbal interaction (*high*, *low*). Active participation was quantified from a biomechanical point of view through the human-robot interaction work in four joints (left/right hip and knee) during the stance and swing phases of the gait cycle. Results showed that feedback *chart* was the most effective in promoting positive, symmetric performance, as opposed to feedback *game* and *emoticon* which, though probably more engaging, exhibited heterogeneous results. *High* therapist interaction significantly improved the performance of the limb with the highest muscular strength for the hip during the swing phase, whereas the effects on the limb with the lowest muscular strength were less clear.**

***Index Terms*—Robot-assisted gait training, visual feedback, patient-therapist verbal interaction, spinal cord injury.**

I. Introduction

Gait rehabilitation for individuals with neurological disorders, such as stroke, Spinal Cord Injury (SCI), and traumatic brain injury, has evolved significantly over the past decades. In particular, Robot-Assisted Gait Training (RAGT) has transformed traditional therapeutic approaches [1] based on the manual assistance from physical therapists or the use of a treadmill with a weight-unloading system. Although effective [2], conventional methods required significant physical effort from both therapists and patients [3]. The introduction of lower-limb robotic systems has overcome these limitations by offering intensive, repetitive, task-specific, and goal-oriented rehabilitation sessions, reducing the physical burden on therapists while preserving patient engagement and therapeutic effectiveness [3], [4]. The adoption of RAGT has gained prominence in neurorehabilitation due to the possibility of providing controlled assistance and collecting objective performance metrics [5]. Furthermore, consistent, biomechanically accurate and meaningful movements of the limbs can contribute to providing the useful sensory input required to stimulate spinal neural circuits, promoting brain plasticity [6] and allowing activation of lower limb muscles that cannot be voluntarily controlled [7].

A widely adopted device for RAGT is the Lokomat (Hocoma AG, Switzerland), which consists of a treadmill, a Body Weight Support (BWS) that modulates weight-bearing effects and a bilateral robotic orthosis that assists the hip and knee joints in flexion/extension [8]. Several studies have highlighted the therapeutic efficacy of the system when integrated with traditional gait rehabilitation approaches, for pathologies affecting the central nervous system [9], [10]. A relevant contribution to successful clinical outcomes lies in the ability to ensure active patient participation during the movement, which has been widely shown to be crucial for motor learning and rehabilitation [11], [12]. In this context, providing visual feedback on real-time task-related metrics is a fundamental aspect, as it compensates for the loss of information on the patient's contribution to the task due to the lack of physical interaction with the therapist. Hence, visual feedback represents both an assessment and motivational tool for the therapist and the patient, respectively [13]. Specifically, it supports patients' intrinsic feedback mechanisms, which may be compromised due to impaired somatosensory pathways [14], and complements the extrinsic feedback provided by the therapist. This combination facilitates a better understanding of the task and encourages movement corrections aligned with the therapeutic goals [13], [15]. Additionally, the effectiveness and enjoyment of the functional training can be enhanced by incorporating gamification strategies, such as virtual environments [16], [17].

The Lokomat can provide visual feedback based on human-robot joint interaction torques measured via force sensors embedded in its linear actuators. Specifically, interaction torques are multiplied by corresponding weighting functions for each joint to provide positive feedback values when the patient is performing therapeutically desired movements, and negative values in case of passive or resistive contributions, depending on the specific phase of the gait cycle [13]–[15]. Despite the robot-mediated physical guidance, the role of therapists remains indispensable in bridging the gap between the visual feedback and the patient's comprehension. By interpreting robot-generated feedback, offering verbal support and empa-

thetic encouragement, therapists ensure the correct execution of the movements and promote active participation [16]. Nevertheless, determining the optimal balance between robotic feedback and therapist intervention remains a significant challenge, as patients often rely on the therapists' expertise to fully comprehend their performance, properly exploit the robotic assistance and translate it into meaningful movements.

This study explores how the combination of different types of visual feedback and verbal interactions influences the active participation of SCI patients during RAGT with the Lokomat. To the best of our knowledge, these two factors have always been considered separately in previous relevant studies on Lokomat-assisted training, despite their synergy representing an essential ingredient to implement effective and engaging rehabilitation protocols. In a recent study, we have already investigated the effects of visual and verbal feedback on attention and emotional engagement by using eye-tracking and EEG metrics [18]. In this paper, we shift the focus to the biomechanical quantification of patient participation by analyzing physical metrics based on human-robot joint interaction data.

II. Materials and Methods

A. Recruitment of Participants

Nine participants (6 females, age 62.9 ± 14.7 y.o.) were recruited from the Spinal Cord Injury Unit of the Neurorehabilitation 1 Department at Fondazione Santa Lucia (Rome, Italy). The study was approved by the local Ethics Committee (protocol number: PROT.CE/PROG.883). Inclusion criteria were defined as: *i)* incomplete spinal cord injury classified as AIS C or D according to the American Spinal Injury Association Impairment Scale (ASIA); *ii)* lesion level at or above D12; *iii)* traumatic or non-traumatic aetiology; *iv)* subacute or chronic phase; *v)* age between 18 and 85 years; *vi)* absence of severe cognitive impairments, assessed with the Montreal Cognitive Assessment (MoCA, cut-off > 26) [19]; *vii)* absence of severe psychiatric conditions, assessed with the Beck Depression Inventory (BDI-II, cut-off < 30, severe depression) [20] and the State-Trait Anxiety Inventory (STAI, cut-off < 40) [21]. All participants underwent RAGT in addition to conventional therapy. Epidemiological data and neurological features of recruited participants are reported in Tab. I. The lower limbs of each participant were evaluated using the Lower Extremity Motor Score (LEMS) from the International Standards for Neurological Classification of SCI [22], [23], whose values account for the strength of five key lower limb muscles. Hereafter, we will refer to the limb with the highest and lowest LEMS as *High Strength Limb* (HSL) and *Low Strength Limb* (LSL), respectively.

The RAGT sessions were carried out by 3 different research physical therapists (2 females, age 32.66 ± 5.50 y.o.) with at least 6 years of experience in neurorehabilitation and fully trained on the use of the Lokomat, including the visual feedback types, from at least 1 year.

B. Experimental Setup

1) Robotic Device: The study was carried out with the robotic gait trainer Lokomat. The device assists the movements of the hip and knee in the sagittal plane and the pelvis rotation, whereas passive spring-based foot lifters support ankle dorsiflexion. The user's limbs are fixed to the orthosis by cuffs with Velcro straps and their motion is assisted by a stiffness controller, whose reference trajectory is defined by the physical therapist together with the Gait Speed (GS). The level of assistance, (Guidance Force, GF), is typically decided according to the user's needs in a range from 0% (no robotic assistance) to 100% (full robotic assistance).

2) Visual Feedback: Three types of visual feedback were selected among those available from the manufacturer [14], referred to in this paper as *chart*, *emoticon* and *game* (Fig. 1). Despite their different visual formats, they are all derived from human-robot interaction torques, with positive and negative torques corresponding to the user flexing or extending a joint, respectively [15]. The interaction torques are processed with joint-specific weighting functions, defined following two principles: *i*) to reward distinctive intervals of the gait cycle and neglect the possible detrimental effects of transitory phases that might not capture the real patient's intention of movement [13] and *ii*) to account for the assumption that meaningful joint interaction torques are expected to have the same sign as the joint angular velocity (*i.e.* they should point in the same direction of the desired movement), except the knee during stance, in which extensive action counteracting weight loading is desired [24]. Additional details regarding the weighting functions are reported in [13]–[15], [24], [25]. The weighted torques are then averaged over each gait cycle, separately for the stance and swing phases, yielding eight values per stride: right and left values for the hip and knee joints during the stance and swing phases. In summary, positive feedback values indicate active participation, whereas negative values suggest passive behaviour or resistance to robot assistance.

Feedback *chart* displays the eight feedback values in four time-series graphs for the left and right hip and knee joints, with separate lines for stance and swing phases. Each data point corresponds to the value from a single stride, and participants are instructed to walk actively to produce positive values. Feedback *game* provides a virtual environment where the patient's movements are mapped onto an avatar: the hip and knee values are averaged for the left and right limbs and used to control the avatar, allowing it to navigate along a walking path to collect coins as rewards. Finally, in the *emoticon* modality, the average of the eight feedback values represents the overall performance and is visually depicted by a cartoon face, whose degree of smiling or frowning corresponds to the patient's performance relative to a threshold set during a calibration phase. The goal is to achieve a full smile, reflecting positive and consistent engagement.

3) Data Acquisition: The Lokomat was configured in *Research Mode* to export, through the *Research Output* module, real-time analogue data, specifically joint angles and

interaction torques. Data were collected with a National Instruments USB-6218 acquisition board (National Instruments, Austin, TX, USA) and recorded with MATLAB Analog Input Recorder tool at 500 Hz.

C. Experimental Protocol

1) Experimental Manipulation: Two experimental factors, visual feedback (*feedback*) and patient-therapist verbal interaction (*interaction*), were randomly varied to create different training conditions (Fig. 1). Factor *feedback* included three levels (*chart*, *emoticon*, *game*), as detailed in Sec. II-B2, whereas factor *interaction* consisted of three levels (*high*, *medium*, *low*). At the *high* interaction level, the physical therapist provided continuous verbal support, enhancing the information conveyed by the visual feedback, such as translating it into specific instructions when incorrect movements were observed, assigning focused tasks to targeted joints during specific gait phases, and maintaining motivation to encourage active participation throughout the exercise. At the *medium* interaction level, the therapist set a predefined task for the participant, *e.g.* focusing on a specific joint, while relying on the visual feedback, but only intervened upon request for clarification or assistance. At the *low* level, verbal communication between the therapist and the participant was limited to non-technical aspects, such as inquiring on perceived comfort, leaving the participant to rely solely on the visual feedback.

2) Training Sessions: All participants completed an initial familiarization session (SS0) to adjust the device parameters according to their needs, such as the robot dimensions, based on anthropometric measurements, and the values of BWS, GS and GF. Once configured, these settings remained unaltered throughout the subsequent training sessions. For the entire cohort of participants, the average selected parameters were BWS = $60.1 \pm 15.0\%$, GS = 1.24 ± 0.30 km/h, GF = $89.70 \pm 9.96\%$. The study involved six training sessions (SS1-SS6), each lasting approximately 45 minutes and covering an average of two weeks as part of the rehabilitation plan defined by the medical team. Each visual feedback type was used for two consecutive sessions, during which the therapist alternated the three interaction levels every 5 minutes. In odd-numbered sessions, the sequence of interaction levels followed a predefined order (*high–medium–low*), while in even-numbered sessions, the order was randomized. This approach ensured that participants experienced all the combinations of feedback modalities and interaction levels in a balanced manner. Data from Lokomat were not recorded during these sessions.

3) Assessment Session: After the last training session, participants' performance was evaluated in a final assessment session (SS7). First, participants completed a 5-minute warm-up walking with the Lokomat without any specific task or feedback. Then, all three visual feedback types were administered in a randomized order, with only *high* and *low* levels of patient-therapist verbal interaction adopted for each visual feedback type. We excluded the *medium* interaction level during this phase because its characteristics might not have been clearly different from those of the other levels and easily standardized among therapists and sessions. Nonetheless, the reason for its inclusion in the training sessions lies in the need to provide patients with a gradual and smooth transition from a continuous technical interaction (*high*) to none (*low*), avoiding the risk of generating possible confusion. The session followed a block design, where each visual feedback type was presented in a 5-minute block. Each block was evenly divided into two halves, corresponding to *high* and *low* interaction. The sequence of blocks was randomized across participants to minimize order effects. During this session, we collected Lokomat data to evaluate the effects of visual feedback and verbal interaction on participants' performance after six RAGT sessions, as described in Sec. II-B3.

D. Data Analysis

Data processing and statistical analysis were performed in MATLAB (Mathworks, Natick, MA, USA).

1) Biomechanical Quantification of Participation: Joint angles data were differentiated to obtain angular velocity profiles and human-robot interaction torques were normalized to the body mass to account for inter-participant variability. Then, data were smoothed by using a third-order, zero-lag Butterworth low-pass filter with a cutoff frequency of 5 Hz. The dataset for each trial was segmented based on heel strike events and time-normalized to express all variables as a function of the percentage of the gait cycle. For each gait cycle, joint interaction torques were multiplied by the corresponding angular velocities to compute the interaction power. The angular velocity was used directly for the knee, while for the hip it was quenched during mid-swing by using a cosine function. This approach, motivated by the need to mitigate the potential contribution from passive factors, such

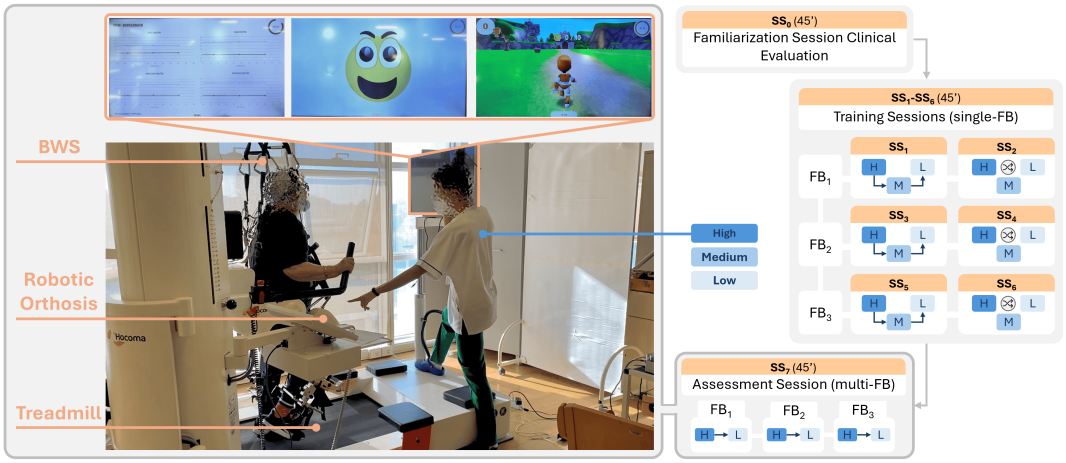

Fig. 1: Experimental setup and protocol for RAGT sessions with three visual feedback types (*chart*, *emoticon*, *game*). A representative participant is depicted during the assessment session with *high* patient-therapist verbal interaction.

as gravity, that could otherwise have inflated the interaction power, was suggested in [14], [15]. The interaction power was then integrated over specific windows of the gait cycle to calculate the work for the stance and swing phases. In accordance with [15], the window for the stance phase was defined as 0-50% of the gait cycle for both joints; the window for the swing phase was defined as 55-82% for the hip and 51-90% for the knee. By definition, positive work values indicate active contribution while negative values represent passive or even resistive behaviour. This process yielded eight values for each stride: hip and knee stance and swing for both sides.

2) Statistical Analysis: The distribution of the data was assessed for normality by using the Shapiro-Wilk test (significance level $\alpha = 0.05$). Results indicated a non-normal distribution, thus non-parametric statistical tests were employed to analyze the differences in the work values with respect to three factors: *feedback* (3 levels: *chart*, *emoticon*, *game*), *interaction* (2 levels: *high*, *low*), and *impairment* (2 levels: HSL, LSL).

For factor *feedback*, Friedman tests were employed to detect differences in the dependent variables across the three levels ($\alpha = 0.05$). In case of significant results, post-hoc pairwise comparisons were conducted by using Tukey's test to identify specific differences. For factors *interaction* and *impairment*, Wilcoxon signed-rank tests were applied to compare results between the two levels of each factor and Bonferroni correction was used for multiple comparisons.

III. Results

Fig. 2a shows the physical variables (angular velocity $\dot{\theta}$, torque τ and power P) used to compute the work W within the highlighted windows, and Fig. 2b shows the resulting work values for the stance and swing phases of the gait cycle for hip (W_{hip}) and knee (W_{knee}) separately.

The analysis of the aggregated data in Fig. 3a revealed that participants were able to generate positive work across most conditions, except for knee during the swing, for which median negative values were observed regardless of feedback type, interaction, or more impaired side.

1) Effects of Impairment: Participants delivered significantly more positive, or less negative, work with the joints of the HSL compared to the LSL (hip stance: $\Delta W = 1.38$ J/kg, $+65\%$, $p = 0.003$; hip swing: $\Delta W = 1.13$ J/kg, $+72\%$, $p < 0.001$; knee stance: $\Delta W = 0.56$ J/kg, $+45\%$, $p < 0.001$; knee swing: $\Delta W = 2.15$ J/kg, $+122\%$, $p < 0.001$). This trend was especially pronounced under specific conditions. For instance, during hip stance with feedback *game*, the average work for the HSL was 1.73 J/kg, compared to -1.03 J/kg for the LSL ($\Delta W = 2.76$ J/kg, $+788\%$), highlighting a marked performance discrepancy. Similarly, during hip swing with feedback *emoticon*, the work for the HSL was 1.79 J/kg, compared to 0.58 J/kg for the LSL ($\Delta W = 1.22$ J/kg, $+102\%$). For the knee joint, the differences were generally smaller though exceptions were noted, such as for knee swing with feedback *emoticon* ($\Delta W = 1.93$ J/kg, $+98\%$). In contrast, conditions that minimized discrepancies between HSL and LSL were predominantly associated with feedback *chart*: hip stance ($\Delta W = 0.63$ J/kg, $+25\%$), hip swing ($\Delta W = 0.28$ J/kg, $+21\%$), and knee stance ($\Delta W = 0.27$ J/kg, $+20\%$). A similar effect was observed in knee swing with feedback *game* ($\Delta W = 0.17$ J/kg, -6%).

2) Effects of Verbal Feedback: When patient-therapist verbal interaction was set to *high*, participants generally produced more positive work with the HSL compared to conditions with interaction *low*, significantly for hip swing ($\Delta W = 0.48$ J/kg, $+23\%$, $p = 0.008$). Other examples include hip stance with feedback *chart* ($\Delta W = 0.86$ J/kg, $+30\%$) and knee swing with feedback *emoticon* ($\Delta W = 1.15$ J/kg, $+350\%$). The only exceptions, where interaction *low* yielded slightly better performance, were hip stance ($\Delta W = 0.32$ J/kg, $+18\%$) and hip swing ($\Delta W = 0.29$ J/kg, $+16\%$) with feedback *emoticon*, though these differences were minor. For the LSL, factor interaction yielded heterogeneous results. Even if higher work was generally observed with interaction *high* for feedback

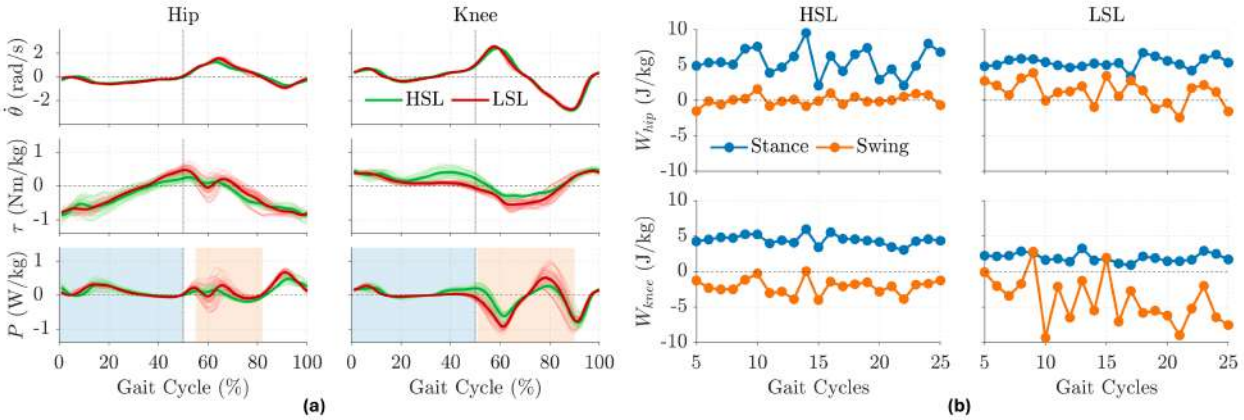

Fig. 2: Data from a representative participant (P7 in Tab. I). (a) Angular velocity $\dot{\theta}$, interaction torque τ and power P, time-normalized to the gait cycle duration, for the High Strength Limb (HSL) and Low Strength Limb (LSL). Blue and orange shaded areas represent the windows of integration for the stance and swing phases, respectively. (b) Stride-by-stride work for hip (W_{hip}) and knee (W_{knee}) calculated for stance and swing phases.

chart (hip stance: $\Delta W = 1.75$ J/kg, $+78\%$; hip swing: $\Delta W = 0.17$ J/kg, $+19\%$; knee stance: $\Delta W = 0.34$ J/kg, $+27\%$; knee swing: $\Delta W = 0.83$ J/kg, $+40\%$), under feedback *emoticon* and *game* participants sometimes produced comparable or higher work with interaction *low*. The most remarkable example of this result was found for hip stance with feedback *emoticon* ($\Delta W = 2$ J/kg, $+164\%$).

3) Effects of Visual Feedback: Overall, the results indicated that feedback *chart* was the most effective in promoting positive work, followed by feedback *emoticon* and *game*. This trend was consistent across all joints and phases, but statistically significant only for hip swing ($p = 0.032$), for which post-hoc analysis confirmed that feedback *chart* was significantly more effective than feedback *game* ($\Delta W = 1.22$ J/kg, $+63\%$, $p = 0.026$) in eliciting positive work.

Regarding the variability of the work (Fig. 3b), the hip and the knee during the stance phase exhibited the highest and lowest variability across all conditions, respectively (average median values around 2 J/kg for the hip and 0.5 J/kg for the knee). Although no statistically significant differences were observed with factors interaction or impairment during the stance phase, a significant effect of factor feedback was identified for both the hip ($p = 0.008$) and knee ($p = 0.013$), for which post-hoc analysis revealed that variability was significantly higher for feedback *game* compared to *emoticon* (hip: $\Delta W = 1.44$ J/kg, $+74\%$, $p = 0.006$; knee: $\Delta W = 1.33$ J/kg, $+71\%$, $p = 0.013$). During the swing phase, the variability was more comparable between the hip and knee, with median values around 1 J/kg. For both joints, the HSL demonstrated higher variability with interaction *high* compared to *low*, but significantly for knee only (hip: $\Delta W = 0.28$ J/kg, $+23\%$; knee: $\Delta W = 0.28$ J/kg, $+23\%$, $p = 0.002$). Additionally, the hip during swing showed significantly higher variability for the HSL compared to the LSL, regardless of the level of interaction ($\Delta W = 0.27$ J/kg, $+25\%$, $p < 0.001$).

IV. Discussion

This study examined the effects of visual feedback and patient-therapist interaction on the active participation of individuals with SCI during RAGT with the Lokomat. Previous research has demonstrated that Lokomat-assisted training with visual feedback produces similar performance as verbal instructions from a therapist for healthy participants and SCI patients [13]–[15], [25]. Building on these findings, we focused on identifying the most effective type of visual feedback for eliciting active patient participation and investigated whether combining visual feedback with an empathetic and supporting human component would enhance performance. From a biomechanical perspective, active participation during RAGT with Lokomat has been described with different, yet rather similar, approaches [13]–[15], [17], [24], [25]. In our work we referred to the interaction energy between participants and the robot, calculated as the integral of the pointwise multiplication between the weight-normalized interaction torques and angular velocities or, in other words, the normalized interaction power.

A. Role of visual and verbal feedback

One relevant result is the efficacy of feedback *chart* in promoting positive work. Across nearly all conditions and joints, it yielded smaller discrepancies between the HSL and the LSL, suggesting its capacity to promote symmetric performance. Moreover, it elicited higher median values with respect to the other feedback types, even if only significantly better than feedback *game* during hip swing. This suggests that the structured and detailed nature of feedback *chart* may provide patients with a clearer, more practical understanding of their performance, enabling them to focus on generating positive work. In contrast, feedback types like *game* and *emoticon* displayed heterogeneous results. Even though they likely foster engagement and motivation, their qualitative and abstract

nature may have introduced ambiguities in how patients interpreted and responded to the task, despite the dedicated training sessions before the assessment. For example, with feedback *game*, discrepancies in work between HSL and LSL were high during hip stance, and for feedback *emoticon*, the LSL sometimes performed better with interaction *low* compared to *high*. These inconsistencies suggest that while these feedback types may promote enthusiasm and playfulness, their lack of specificity might limit their effectiveness in supporting targeted performance improvements. This hypothesis is consistent with our previous findings, which suggested that feedback *game* elicits lower mental and physical demands [18].

As for patient-therapist verbal interaction, the level *high* was generally associated with better performance of the HSL, particularly during hip swing. This suggests that verbal cues and a closer engagement may have provided support and motivation for the participants, encouraging them to focus on specific goals. However, the impact of interaction level was less clear for the LSL, with level *low* resulting in higher work in some cases, such as hip stance with feedback *emoticon*.

B. Limitations and future works

A critical consideration in interpreting these results is the generic nature of the instructions given to participants during the experiment. Participants were encouraged to enhance their performance across all joints and phases rather than focusing separately on specific sub-tasks. This approach, even if realistic for clinical training scenarios, may have diluted the measurable differences among conditions specifically for the LSL. Indeed, in the absence of specific instructions, patients likely directed their efforts more consistently toward the HSL, given that it is the limb with greater muscular strength. This broad approach could have partially masked the full impact of the interventions, especially for the LSL in which we expect higher inter- and intra-subject variability. To address this limitation, future studies should explore a more task-specific approach: by isolating individual sub-tasks, for example, the knee of the LSL during the stance phase, patients could be given clearer, more focused goals. This might enhance their ability to respond to visual feedback and better highlight the benefits of different modalities and interaction levels. Additionally, this approach could allow for a more detailed evaluation of how feedback and interaction strategies influence specific impairments, ultimately leading to more effective rehabilitation protocols. In the envisioned scenario, feedback *chart* is likely the most useful among the

investigated options, as it provides information on all joints and gait phases separately, as opposed to feedback *game*, which only discriminates between left and right limbs, and feedback *emoticon*, which cumulatively considers all joints and gait phases, thus providing very generic feedback. On the other hand, our previous work hypothesized that feedback *chart* likely elicited a higher mental demand due to the concurrent amount of displayed information, but a frustration level comparable to the other types [18]. In this context, we believe that the role of the therapist's verbal instructions can be determinant in facilitating the conveyance of information.

Overall, these results suggest the need for feedback mechanisms that balance motivational benefits with clear, consistent guidance to maximize performance. At the same time, besides the type of visual feedback and therapist's verbal instructions, the nature of the task seems likewise important. A generic task with broad, non-specific instructions may only partially highlight the therapist's contribution. In contrast, a more specific task with clearly targeted requests and instructions could better boost the benefits of therapist's role, potentially enhancing the rehabilitation outcomes.

V. Conclusions

The study highlights the role of patient-therapist verbal interaction combined with different types of visual feedback, to enhance the active participation of individuals with SCI during RAGT. Specifically, it shows that providing patients with a quantitative measure of their performance while verbally interacting with the physical therapist results in more evident participation. We also argue that the type of visual feedback and the level of verbal interaction with the therapist are not the only factors influencing the active patient participation. Indeed, the role of the selected task and the specific requests deserve further investigation in dedicated experiments.

Development of a Real-Time Neural Controller using an EMG-Driven Musculoskeletal Model

Joel Biju Thomas and Brokoslaw Laschowski

Abstract – **Here we present the development of a novel real-time neural controller based on an EMG-driven musculoskeletal model, designed for volitional control of robots and computers. Our controller uniquely enables motion control during both isometric and non-isometric muscle contractions. We address several key challenges in EMG control system design, including accuracy, latency, and robustness. Our approach combines EMG signal processing, neural activation dynamics, and Hill-type muscle modeling to translate neural commands into muscle forces, which can enhance robustness against electrode variability and signal noise. Additionally, we integrate muscle activation dynamics with impedance control, inspired by the human motor control system, for smooth and adaptive interactions. As a proof of concept, we demonstrate that our system can control a robotic actuator across a range of lower-limb movements, both static and dynamic, and at different operating speeds, achieving high reference tracking performance and state-of-the-art processing time of 2.9 ms, important for real-time embedded computing. This research helps lay the groundwork for next-generation neural-machine interfaces that are fast, accurate, and adaptable to diverse users and control applications.**

I. Introduction

Surface electromyography (EMG) is a non-invasive neural interface that can be used to volitionally control robots and computers by translating feedforward neural commands from the brain (i.e., that encode information about motor intent) into actionable control signals. Despite this potential, the development of reliable EMG neural controllers faces significant challenges, particularly in terms of system accuracy, latency, and adaptability to diverse users [1]. Applications in patients with amputation require precise control during isometric muscle contractions, while controllers for able-bodied persons need to also support dynamic, non-isometric contractions for natural, functional movements. High accuracy and low latency, which are critical to optimal user experience, remains an open problem for these neural controllers [2]-[5].

Two of the main paradigms used for EMG neural control are data-driven classification models and neuromusculoskeletal models. Data-driven methods typically use machine learning algorithms to classify, or decode, the joint movement from EMG signals [6]-[7] such as quadratic discriminant analysis used by [6] for patients with amputation. While these models have shown success, they often make simplifying assumptions about the underlying data distributions, which can limit their robustness given the inherent non-Gaussian nature of EMG data. Factors such as noise, muscle fatigue, and inter-subject variability also pose significant challenges to these classification models for long-term operation [7]-[8], including requiring long user training times. More complex models such as convolutional or recurrent neural networks could help eliminate these assumptions but could compromise real-time inference with low latency.

In contrast, neuromusculoskeletal modelling approaches model muscle forces and joint dynamics more directly, thus allowing for improved accuracy in muscle force prediction and system adaptability. Previous research [5] has used these computational models to simulate muscle-generated forces from EMG signals. However, they tend to lack an EMG-to-activation model, which can limit their robustness to variations in sensor placement and EMG signal-to-force mapping accuracy, constraining their practical utility. Despite progress in both machine learning and neuromusculoskeletal modelling EMG controllers, the focus has been on isometric control for amputees, with less attention given to the general population (i.e., able-bodied users) and to dynamic, non-isometric movements [5]-[7], which can be more technically challenging.

To address these gaps, here we present the development of a novel EMG neural controller driven by a musculoskeletal model. We include an EMG-to-activation model to improve robustness and to more accurately map EMG signals to muscle forces. Our controller uniquely handles both isometric and non-isometric muscle contractions, expanding functionality over previous work [5]-[7]. By combining the strengths of neuromusculoskeletal modeling with a more accurate EMG signal-to-force mapping model, our research helps lay the foundation for next-generation neural-machine interfaces that can support diverse users and control applications. While the focus of this study was on the control system design, as a proof-of-concept, we demonstrate that our EMG neural controller can be used to accurately and in real-time control a robotic actuator across a range of operating speeds using neural commands to leg muscles (see Fig. 1).

II. Methods

A. Signal Processing

We used standard EMG processing to enhance our signal quality and to reduce unwanted artifacts [9], including a 200x gain amplifier, hardware bandpass filter between 20-498 Hz, signal rectification, and offset removal. We also performed envelope detection using a linear, passive first-order filter with a cutoff frequency of 3.6 Hz. This filter has a frequency response characterized by a -20 dB/decade attenuation, capturing the slow-varying envelope of the rectified EMG signal [9]. To further enhance clarity, we amplified the envelope using a secondary gain amplifier and digitized the signal with an Arduino

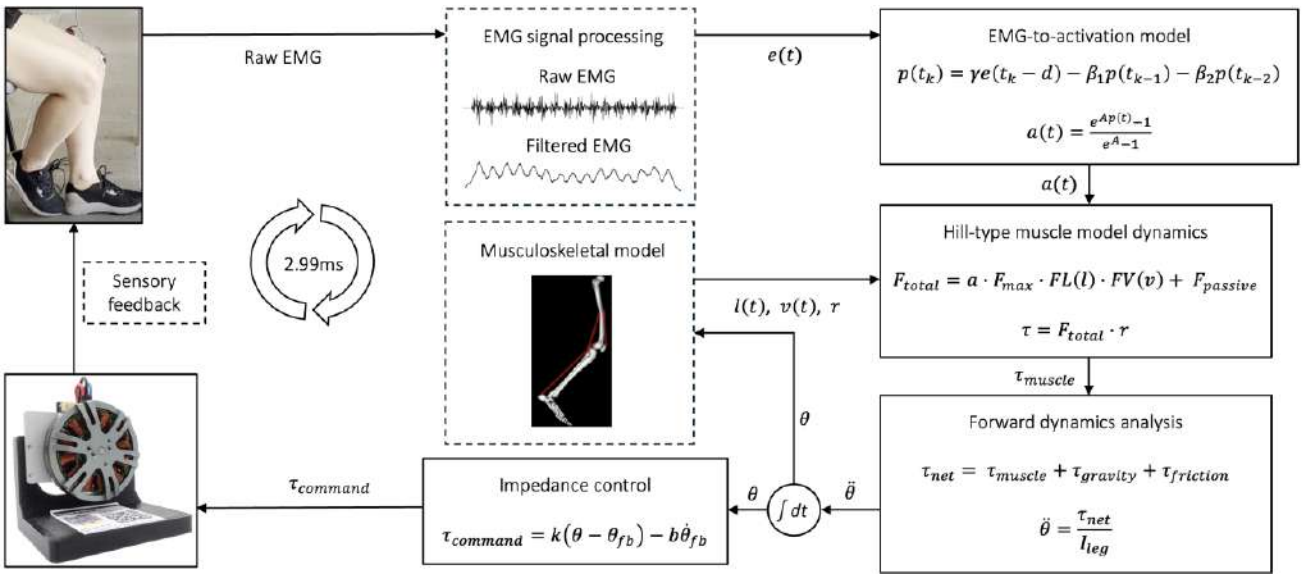

Fig. 1 System diagram of our real-time neural controller using an EMG-driven musculoskeletal model. We process and convert raw EMG signals into neural activations, which drive our muscle and musculoskeletal dynamics models to produce joint torques and movement. We also developed an impedance controller to generate torque commands for our motor actuator, which takes as input the simulated joint kinematics. The control loop is closed by the user receiving visual feedback of the rotating motor.

Uno R3 as an ADC, sampling at 1400 Hz with a baud rate of 115,200. The digitized EMG signals were sent to Raspberry Pi using USB UART for further processing. We normalized the signal to a 0–1 range to enable consistency across subjects using maximal voluntary contraction (MVC) and minimum EMG amplitude during full muscle flexion and relaxation. This minimizes variations in amplitude due to individual physiology, which allow for more accurate cross-subject and experimental comparisons [10].

B. Neural Activation Model

The biological tissue between the EMG electrode and muscle filters the neural signals produced by the muscles before they are recorded. This can pose an issue where factors such as the positioning of the electrodes, ambient temperature, skin condition, and electrical impedance can influence filtering [11]. To reduce this effect of tissue filtering, we developed an EMG-to-activation model to interpret the EMG signals and estimate muscle forces, accounting for physiological delays and nonlinearities in muscle activations, thus enhancing precision.

The EMG-to-activation model begins with activation dynamics, which transforms the processed EMG signals $e(t)$ into neural activations $p(t)$ [12]. This process addresses the time delay between EMG onset and muscle force generation, as well as the longer durations of muscle forces compared to EMG signals [11]. Unlike previous work [5], our controller includes this EMG-to-activation model for a more reliable muscle force estimation by taking into account biological delays and nonlinearities. We used a critically-damped linear second-order differential system to model the delayed muscle twitch response, which occurs when a single action potential stimulates an individual muscle fiber [12]. In its discrete form, see Equation 1, the second-order system can be expressed recursively to compute $p(t)$, providing a more accurate representation of the muscle's force generation based on the input EMG neural signal.

$$p(t_k) = \gamma e(t_k - d) - \beta_1 p(t_{k-1}) - \beta_2 p(t_{k-2}) \quad (1)$$

$$a(t) = \frac{e^{Ap(t)}-1}{e^{A}-1} \quad (2)$$

where $e(t)$ is the filtered EMG signal, d is the electromechanical delay, and γ, β_1, and β_2 are coefficients governing the second-order system dynamics. To ensure a positive and stable outcome, we enforced specific constraints: $\beta_1 = C_1 + C_2$ and $\beta_2 = C_1 C_2$, with the conditions $|C_1| < 1$ and $|C_2| < 1$. Furthermore, to preserve the filter's gain, we must satisfy $\gamma - \beta_1 - \beta_2 = 1$. We used a nonlinear conversion between the neural activations $p(t)$ and muscle activations $a(t)$, see Equation 2, to address the non-linear relationship between the EMG signal and muscle force generation at low-force and high twitch frequencies [12].

C. Muscle Model

We developed a Hill-type muscle model to mathematically model the muscle force generation based on the relationships between muscle length, contraction speed, and activation dynamics. Our Hill-type muscle model combines active forces from neural activations with the passive forces from muscle stretching for a more biofidelic representation of biological muscle dynamics. We used the force-length factor to model how the muscle force generation depends on its length relative to optimal length, with maximum force at the optimal length and an exponential decrease as the muscle length deviates.

$$FL(l) = e^{-\left(\frac{l - l_{opt}}{0.5 \cdot l_{opt}}\right)^2} \quad (3)$$

where $FL(l)$ is the muscle force-length factor, l is the current muscle length, and l_{opt} is the optimal muscle length [13]. For concentric muscle contractions, where velocity is greater than

or equal to 0, we used a linear force-velocity relationship. For eccentric muscle contractions, where the velocity is less than zero, we used a nonlinear force-velocity relationship.

$$FV(v) = \begin{cases} 1 - \frac{v}{v_{max}} & if\ v \geq 0 \\ N - (N-1) \cdot e^{\frac{v}{v_{ecc} \cdot l_{opt}}} & if\ v < 0 \end{cases} \quad (4)$$

where $FV(v)$ is the muscle force-velocity factor, v is the muscle velocity, v_{max} is the maximum shortening velocity, N is the eccentric muscle force factor, and V_{ecc} is the characteristic velocity of eccentric muscle contractions [13]. Active force (F_{active}) is defined as the product of the muscle activation, maximum isometric force, force-length factor, and the force-velocity factor, and is represented by:

$$F_{active} = a \cdot F_{max} \cdot FL(l) \cdot FV(v) \quad (5)$$

where a is the muscle activation level, ranging from 0 to 1, and F_{max} is the maximum isometric force. We derived muscle length and velocity from the joint angle and angular velocity using our musculoskeletal model. We calculated the muscle length by converting the joint angle into radians, adjusting for deviations from the reference angle, and scaling by moment arm. We calculated muscle velocity by converting the joint angular velocity into radians and scaling using the moment arm. Passive forces $(F_{passive})$ are generated when the muscle stretches beyond its optimal length, increasing quadratically with stretch. We assume no passive muscle force is produced below the optimal length, but beyond that, the force grows exponentially and is defined by the maximum isometric force and a passive stiffness coefficient $(C_{passive})$ [13].

$$F_{passive} = F_{max} \cdot C_{passive} \cdot \left(\frac{l - l_{opt}}{l_{opt}}\right)^2 \quad if\ l > l_{opt} \quad (6)$$

We calculated the total force F_{total} generated by the muscle using the sum of the active F_{active} and passive $F_{passive}$ muscle forces. The resultant joint torque τ generated by the muscle was calculated using the product of the total force F_{total} and the moment arm r.

D. Forward Dynamics

We used forward dynamics analysis to calculate the joint motion from the applied muscle torques, gravitational forces, and joint friction in our musculoskeletal system model.

$$\tau_{muscle} = \tau_{quad} - \tau_{ham} \quad (7)$$

where τ_{muscle} is the net joint torque, which is the difference between the joint torques generated by the quadricep muscles τ_{quad} and the hamstring muscles τ_{ham}. We estimated the joint torque generated from gravity acting on the leg $\tau_{gravity}$ using Equation 8:

$$\tau_{gravity} = m_{leg} \cdot g \cdot \frac{l_{leg}}{2} \cdot sin\left(\theta_{joint} + 90°\right) \quad (8)$$

where m_{leg} is the estimated mass of the leg, g is acceleration due to gravity, l_{leg} is the length of the leg, and θ_{joint} is the instantaneous joint angle. We estimated the frictional torque in the joint using $\tau_{friction} = -b \cdot \dot{\theta}$, where b is the biological damping coefficient and $\dot{\theta}$ is the angular velocity of the joint. The net joint torque τ_{net} is the sum of τ_{muscle}, $\tau_{gravity}$ and $\tau_{friction}$, and the resulting angular acceleration $\ddot{\theta}$ is calculated as $\ddot{\theta} = \frac{\tau_{net}}{I_{leg}}$, where I_{leg} is the estimated moment of inertia of the leg derived from anthropometric measurements. When calculating τ_{net} for isometric contractions, we set $\tau_{gravity}$ and the muscle velocity to 0. We did this so that the EMG signal is used to generate an angular velocity, which means that the motor will only actuate when the muscles are contracting and is stationary when the muscles are relaxed. This is important for downstream applications in patients with amputation, for example, to minimize fatigue while operating our controller. We assume a constant muscle length.

E. Kinematics

We used kinematic analysis to continuously track the joint angular velocity and position over time based on the initial conditions and integrals. We calculated joint angular velocity $\dot{\theta}(t) = \dot{\theta}(t_0) + \int_{t_0}^{t} \ddot{\theta}(t')\ dt'$ using the initial velocity $\dot{\theta}(t_0)$ and the cumulative angular acceleration $\ddot{\theta}(t')$. We calculated the joint angular position $\theta(t) = \theta(t_0) + \int_{t_0}^{t} \dot{\theta}(t')\ dt'$using the initial position $\theta(t_0)$ and the integrated velocity.

F. Impedance Control

We developed an impedance controller for our low-level controller to convert joint motion (input) to torque (output). Impedance control is widely used in robotics to control the interaction between force and motion by adjusting mechanical impedance. This control paradigm is inspired by human motor control, where the nervous system regulates muscle stiffness and compliance for smooth and adaptive physical interactions with the environment. Research has consistently shown that myoelectric impedance control outperforms conventional velocity-based controllers in constrained motion tasks [4]. Our impedance controller is expressed as:

$$\tau_{command} = k\left(\theta - \theta_{fb}\right) - b\dot{\theta}_{fb} \quad (9)$$

where $\tau_{command}$ is the torque command to the field-oriented controller of our motor actuator, θ is the joint position of our musculoskeletal model, θ_{fb} is the motor position, $\dot{\theta}_{fb}$ is motor velocity, and k and b are stiffness and damping, respectively. Here we assumed that k and b are fixed constants that do not change based on muscular co-contraction.

G. Experiments

As a proof of concept to evaluate the performance of our EMG neural controller, we tested the ability of a single user to volitionally control a robotic actuator, specifically a brushless DC electric motor, during isometric (static) and non-isometric (dynamic) muscle contractions. We determined accuracy of our controller based on the root mean square error (RMSE) with reference joint angle trajectories, and we measured latency to assess responsiveness and real-time control.

For EMG acquisition, we used EMG sensors in bipolar configuration with the help of surface Ag/AgCl electrodes. We prepared the EMG recording sites similar to [2]. To locate the

Table 1. Comparison of our EMG neural controller with the previous state-of-the-art [6]. We evaluated performance based on the RMSE in joint angles for isometric and non-isometric muscle contractions across different movement frequencies.

	0.50Hz	**0.33Hz**	**0.25Hz**	**0.20Hz**	**Avg.**
Previous SOTA (isometric)	-	5.6°	-	7.9°	6.8
Our controller (isometric)	9.4°	9.7°	8.2°	9.5°	9.2°
Our controller (non-isometric)	9.3°	9.7°	7.9°	9.7°	9.2°

best electrode position, we had the user fully extend their leg and perform maximum quadricep contractions while we palpated the muscle. Two electrodes, ~25 mm apart, were placed on the quadricep muscle. We used a similar procedure for the hamstrings when the knee was flexed. We had the user perform maximum voluntary contraction and relaxation of their quadricep and hamstring muscles and we recorded the maximum and minimum EMG signals for normalization. In a seated posture, we instructed the user to flex and extend their instrumented leg with the goal of controlling the motor angle to follow a reference video displayed on a computer. The user practiced with our controller for ~10 minutes before results were recorded. The user performed non-isometric, sinusoidal knee flexion and extension, followed by isometric contractions with a fixed knee joint angle.

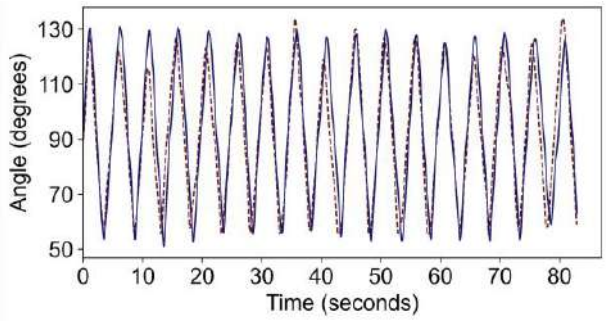

Fig. 2 Trajectory tracking of our EMG neural controller for isometric, sinusoidal movements at 0.2 Hz frequency. The red dashed signal is the reference joint angle, and the blue dashed signal is the motor angle of our neural-controlled actuator.

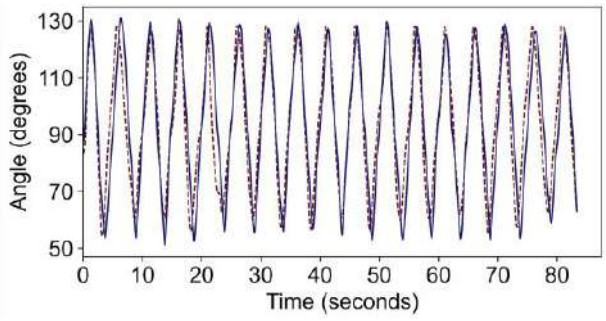

Fig. 3 Trajectory tracking of our EMG-driven neural controller for non-isometric, sinusoidal movements at 0.2 Hz frequency. The red dashed signal is the reference joint angle, and the blue dashed signal is the motor angle of our neural-controlled actuator.

We evaluated accuracy of our EMG neural controller by calculating the RMSE between the neural-controlled motor angles as measured by the motor controller (moteus r4.11 controller connected to mj5208 brushless motor) and the calculated knee joint angles from the reference video displayed on the computer. We conducted 80-second trials to test different movement frequencies at 0.2 Hz, 0.25 Hz, 0.33 Hz, and 0.5 Hz, with RMSE selected for direct comparisons with the previous state-of-the-art [6]. We developed the reference video by recording the user flex and extent their leg at the specified frequencies, guided by a metronome. We calculated the joint angles using Vicon motion tracker with 16 passive markers on the leg sampled at 100 Hz and the Vicon ProCalc software. Lastly, we measured our controller's latency by combining the processing times from the Arduino and Raspberry Pi during a motor controller update.

III. Results

Table 1 shows the accuracy of our EMG neural controller across different movement frequencies, ranging from 0.50 Hz (2 seconds) to 0.20 Hz (5 seconds). For isometric muscle contractions, our controller achieved the lowest RMSE of 8.2° at 0.25 Hz and the highest RMSE of 9.7° at 0.33 Hz (Fig. 2). Non-isometric muscle contractions followed a similar trend, with the lowest RMSE of 7.9° at 0.25 Hz and highest RMSE of 9.7° at both 0.33 Hz and 0.20 Hz (Fig. 3). Our controller achieved an average RMSE of 9.2° across all conditions, demonstrating a relatively consistent accuracy for a diverse set of motion control. Moreover, our controller achieved a state-of-the-art end-to-end processing time of 2.9 ms, showcasing its responsiveness and real-time control.

IV. Discussion

In this study, we developed a new real-time neural controller using an EMG-driven musculoskeletal model. Our system enables intuitive and responsive control for both isometric and non-isometric movements. Using processed EMG signals, we dynamically drive a muscle model to translate the user's intent into precise motor control with minimal latency. As a proof-of-concept, we demonstrate that our system can use feedforward neural commands to leg muscles for accurate real-time control of a robotic actuator across a range of different movements and operating speeds. This performance is partially due to our incorporation of muscle activation dynamics and a Hill-type muscle model with impedance control. Motivated by these promising results, our controller could be used to support the development of next-generation neural-machine interfaces for diverse users and control applications.

Our EMG neural controller achieved an average RMSE of 9.2° over 80-second experiments for both isometric and non-isometric movements. In comparison, [6] achieved 6.2° RMSE in patients with leg amputation. For 3- and 5-second isometric movement frequencies, our controller achieved an RMSE of 9.7° and 9.5°, whereas [6] achieved an RMSE of 5.6° and 7.9°, respectively. Although we achieved slightly lower accuracy, our controller can uniquely support both isometric and non-isometric motion control, whereas [6] focused on patients with amputation, and thus limited to isometric movements. Given that joint proprioception accuracy in healthy adults is ~2.5° [14], our controller's instantaneous error difference is arguably imperceptible, especially as RMSE reflects cumulative error.

Our study is one of few to develop an EMG neural controller for both isometric and non-isometric movements. Moreover, our use of a neuromusculoskeletal model can enhance our system's robustness compared to [6], which used a data-driven model. Our controller also requires significantly less training time, achieving intuitive control with only 10 minutes of user familiarization, whereas [6] required one-hour of training per session, repeated three times a week. Most notably, our controller achieved state-of-the-art processing speed of 2.9 ms, compared to 10 ms times for other two-channel EMG systems [3].

Despite these advantages, our controller has limitations. It cannot not seamlessly transition between isometric and non-isometric states as it lacks a learning algorithm for movement classification, operating in discrete controllers rather than continuously. Moreover, while our neuromusculoskeletal model offers flexibility via tunable parameters, this can lead to inconsistent accuracy across users such that optimizing our model for one user may yield suboptimal results for another unless calibrated. While muscle co-contractions are common in patients with amputation [6], our controller does not include signal processing to account for this, which would otherwise benefit our controller. Although our EMG-to-activation model can theoretically improve system robustness to uncertainty in electrode placement, we did not explicitly test this. Another limitation of our study was that the experiments were based on one user. However, the focus of this research was on the engineering control system design, while the user testing was to demonstrate an initial proof-of-concept.

Future research could expand our control system design to also include a classification algorithm to detect isometric and non-isometric movements, advancing toward a more universal EMG neural controller. Incorporating additional processing to manage muscle co-contraction—such as principal component analysis used by [6], or unsupervised learning algorithms like k-means clustering—could improve accuracy. Other neural sensors such as electroencephalography (EEG) could also be used to decode different movements and tasks [15]-[16]. Adding sensors like accelerometers or computer vision could help supplement our neuromusculoskeletal model by providing data on gravitational directionality for better control in variable orientations [17]-[20]. Overall, future research is needed to explore generalizability of our control system to novel users and tasks.

In conclusion, we developed a new EMG neural controller driven by neuromusculoskeletal model. As a proof-of-concept, we showed that our controller could achieve accurate and consistent motion control of a robotic actuator across a range of different movements and operating speeds, in addition to state-of-the-art processing speed, important for real-time embedded computing. With further development, our controller could be used to interact with and control robots and computers, providing an intuitive neural-machine interface.

ACKNOWLEDGMENT

This research study is dedicated to the people of Ukraine in response to Russia's ongoing invasion. We thank Stephen Yang and Yume Yamamoto for their assistance.

Lower Limb Muscle Activities and Contractility during Stepping Response to Unexpected Waist-Pull Perturbations

Oluwasegun Akinniyi[1], *Graduate Student Member, IEEE*, Maxwell Gainey[1], Dario Martelli[2], Qiang Zhang[1*], *Member, IEEE*

***Abstract*— Reactive balance responses, which involve corrective and protective strategies, are highly dependent on rapid muscle activation to restore postural stability. Although electromyography (EMG) is commonly used to measure muscle activity, it has limitations such as signal interference, particularly during fast responses to external disturbances. Ultrasound imaging (US), in contrast, provides visualization of both superficial and deep muscles. Combining EMG and US imaging offers complementary insight into muscle behavior during reactive balance tasks. In this study, we investigated muscle activation and fascicle length changes in the medial gastrocnemius (MGS), lateral gastrocnemius (LGS), and soleus (SOL) muscles of the dominant (stepping) leg during stepping responses to unexpected low-amplitude (57.6 ± 5.8 N) and high-amplitude (123.4 ± 11.1 N) waist-pull perturbations in the anterior and posterior directions. Five young male adults (age: 25.2 ± 5.5 years) participated in the study. Results showed that perturbation amplitude significantly affected the EMG activation of both the MGS and SOL muscles in both directions, consistent with previous studies. Similarly, perturbation amplitude impacted fascicle length shortening in the LGS and SOL muscles. Significant differences in MGS and SOL activation were observed between high-amplitude and low-amplitude perturbations in both directions. Fascicle shortening in the LGS also differed significantly between perturbation amplitudes, whereas SOL fascicle shortening did not. By combining EMG and US imaging within the same participants, this study provides new insights into the neuromuscular mechanisms underlying balance control. These findings may inform the development of improved control strategies for neurorehabilitation devices and fall-prevention systems.**

I. Introduction

Falls and fall-related injuries are a growing medical concern among older adults [1]. Most falls result from internally generated errors or external disturbances that cause undesired movement of the center of mass (CoM), often occurring when an individual cannot recover from a loss of balance due to missteps, slips (backward falls), or trips (forward falls) [2], [3]. While physical injuries are the most noticeable outcome of falls, the fear of falling may also cause individuals to reduce their activity levels, leading to a decline in function and potentially increasing their risk of future falls [4].

[2]D. Martelli is with the Orthopedics/Sports Medicine Department, MedStar Health Research Institute, Baltimore, MD 21218, USA.

Timely and appropriate postural adjustments are crucial to preventing falls, such as keeping the CoM within the base of support (BoS). Reactive balance response describes how individuals respond to unexpected external disturbances (perturbations), this involves the selection of the most appropriate strategy based on the magnitude of the disturbance [5], [6]. For small disturbances, corrective strategies, such as the ankle strategy, help maintain the BoS, while for larger or limited BoS disturbances, the hip strategy is more effective [7]. Protective strategies, including stepping, are considered last resort responses, used when the CoM moves outside the BoS, requiring active movements to restore balance [8]. These reactive strategies depend on muscle activation to maintain postural stability following the detection of a disturbance by the central nervous system. Hence, studying how lower limb muscles rapidly respond to external perturbations to help maintain balance is important to preventing falls.

To study the human response to perturbations, researchers simulate fall conditions (slips, trips, and missteps) in the laboratory, applying perturbations to various parts of the body, such as the foot [9], pelvis / waist [10] and shoulder [11] to alter the original postural balance of individuals in static or dynamic positions. These perturbations are applied using robotic devices/platforms like waist-pull perturbation systems and instrumented treadmills. Waist-pull perturbation systems are mostly cable-driven devices used to apply a pull force to the pelvis in different directions (forward, backward, and sideways). Their application includes perturbation training [6], locomotor adaptation studies [12], prediction of protective stepping response [13], and stability. In such studies, reactive balance strategies are examined by assessing metrics such as whole-body sway, lower limb kinematics and kinetics, and muscle activation and contraction.

Surface electromyography (EMG) is used to measure muscle electrical activities, it provides information about the timing and magnitude of muscles activities. However, its signals suffer from interference from adjacent muscles, particularly during rapid unexpected external disturbances. Another challenge with EMG is its inability to measure activations of deep-layer muscles [14], [15]. In contrast, ultrasound (US) imaging enables non-invasive visualization of the targeted muscle's musculature. For instance, a two-dimensional brightness mode (B-mode) ultrasound imaging device allows us to see both superficial and deep muscle layers simultaneously. Common architectural features derived from US images include muscle thickness [16], pennation angle [17], fascicle length [18], and cross-sectional area [19].

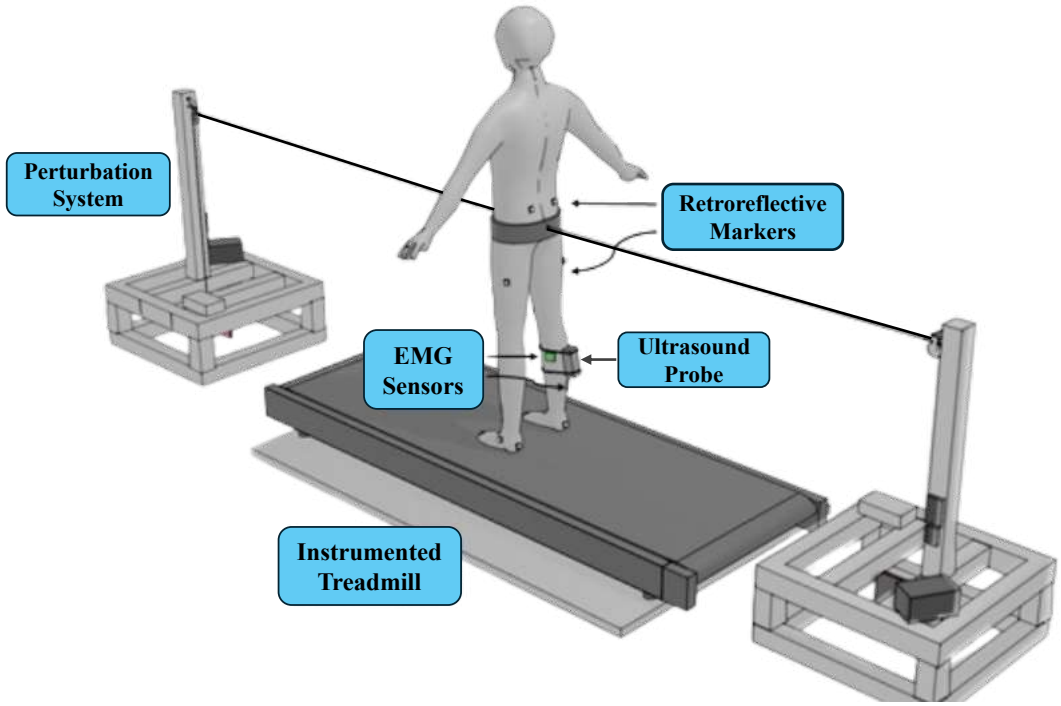

Fig. 1: Experimental setup showing the perturbation system and measurement sensors attached to a participant.

These features have been associated with joint kinematics and kinetics during various static and dynamic tasks [20]. To overcome the shortcomings of both EMG and US imaging, several studies have proposed multi-modal fusion of both technologies to estimate human hand force [21], develop control framework for ankle exoskeleton assistance [22], predict ankle moment [23], and predict plantarflexion force during dynamic cycling tasks [24]. EMG signals and US imaging may offer complementary information, and their combination could reduce interference effects from neighboring EMG signals, and minimize image drift in US imaging caused by cumulative errors from misaligned probes during limb movement [25]. Several studies have investigated lower limb muscle activity during reactive balance, using EMG [26]–[29], however, the use of US imaging to study lower limb muscle architecture during reactive balance is less explored. To the best of the authors' knowledge, no study has investigated the lower limb muscles using both EMG and US imaging during waist-pull human balance perturbation. This study investigated the relationship between the electrical activity (muscle activation) and architectural feature (fascicle length changes) of the calf muscles during protective stepping responses to bidirectional waist-pull perturbations of varying amplitudes delivered while standing. The findings from this study may contribute to improved control mechanisms for neurorehabilitation devices, and enhanced fall-prevention strategies.

II. Materials and Method

A. Participants and Protocol

Five male participants with no record of musculoskeletal or neurological deficits (age: 25.2 ± 5.5 years; height: 174.7 ± 4.9 cm; weight: 83.9 ± 8.4 kg) volunteered for the study. Table I shows the demography of the participants. All participants provided written informed consent according to the guidelines approved by the Institutional Review Board of the University of Alabama (21-06-4695-R2).

A cable-driven perturbation system was used in this study to induce waist-pull disturbances (perturbations), as illustrated in Fig. 1. The system comprises a modular aluminum frame (80/20, IN, USA), an actuation unit with a brushless EC motor (EC 90, Maxon Group, Switzerland), a pulling cable, a waist belt, and additional hardware components. Designed for compactness and versatility, the system can be easily mounted to a wall using screws and adjusted for various experimental setups. A lightweight force sensor connects the waist belt to the pulling cable, which is guided through a pulley to the motor, ensuring precise force application. For participants' safety, a breakaway cable is incorporated to automatically disconnect the system in the event of excessive force. An adaptive closed-loop controller implemented in a MATLAB-Simulink (MathWorks, Natick, MA, USA) program controls the actuation unit of the perturbation system. The program sends force commands to the perturbation system which translates into a pulling force applied to the participants. The perturbation system has been previously validated and detailed in [30].

TABLE I: Participant demographics and perturbation levels

LF = Low Perturbation (7 %BW), HP = High Perturbation (15 %BW)					
Participant	Mass (kg)	Height (cm)	BMI	LP (N)	HP (N)
S01	90.7	177.8	28.7	62.3	133.4
S02	81.4	167.6	29.0	55.9	119.8
S03	81.6	172.7	27.4	56.0	120.1
S04	93.4	180.3	28.7	64.1	137.4
S05	72.3	175.2	23.6	49.6	106.3

B. Experimental procedure

Participants stood on an instrumented treadmill (Bertec Corp., Columbus, OH, USA) embedded with two force plates, with their feet positioned approximately hip-width apart, each foot placed on a separate force plate. The positions of their feet were marked on the platform surface to ensure consistent foot placement across all sessions. Participants were asked to maintain a normal, relaxed stance while standing and to respond naturally to the perturbations. They were instructed to take a step with their dominant leg if they lose their balance to avoid falling. We recommended that after taking a step, they remain in that position for about 5 seconds to regain stability before returning to the initial position. Horizontal waist-pull perturbations were induced using an adaptive-controlled, cable-driven waist-pull perturbation system described in detail previously. During the experiment, all participants wore a commercially available harness system attached to the ceiling to prevent falls during the experiment. Additionally, an emergency stop switch, accessible to both the experimenter and participant, was available to stop the system in case of malfunction. Force-impulse perturbations [31] were applied anteriorly and posteriorly to participants' pelvis region while they stood on the treadmill. Two levels of perturbation were administered: low-amplitude perturbation (7% body weight (BW)) (57.6 ± 5.8 N) and high-amplitude perturbation (15% BW) (123.4 ± 11.1 N) levels, with 10 repetitions for each level [32]. The interval time between successive perturbations (10–16 seconds) was pseudo-randomized for each participant, while the order of perturbation level was also randomized. Participants were blinded from the sequence of perturbation throughout the experiment. We ensured that all participants regained their stability and returned to the initial position before applying the next perturbation. A rest time of 5 minutes was observed between each perturbation level to prevent fatigue. Data collection began once the participant was prepared and the measurement equipment setup, as described below, was completed.

C. Experimental Measurement and Analyses

Throughout the experiment, we recorded muscle activities from the medial gastrocnemius (MGS) and soleus (SOL) muscles of each participant's dominant leg using the Trigno wireless biofeedback system (Trigno, Delsys Inc., Natick, MA, USA) at 1000 Hz. EMG wireless sensors were placed longitudinally over the muscles following skin preparation using published recommendations [33]. Eight cameras (Vicon Motion Systems Ltd., Yarnton, UK) were used to capture lower limb kinematics at 100 Hz. The Plug-in Gait Lower-body Model was used, with 16 retroreflective markers affixed to anatomical landmarks on both legs, including the anterior superior iliac spine, posterior superior iliac spine, thigh, knee, tibia, ankle, heel, and the second metatarsal head of the feet. After data collection, each trial's EMG data was bandpass filtered (20 Hz - 400 Hz), rectified (full-wave), low-pass filtered at 6 Hz, and normalized to each subject's maximum peak value across all trials. The variable of interest is the peak muscle activation amplitude during stepping response. For EMG processing, the perturbation onset (time point when a pull-force is applied to a participant) was defined as the point when the signal exceeded three times the resting activity level for at least 50 ms.

To measure individual muscle fascicles, a B-mode ultrasound diagnostic system (ArtUs EXT-2H, Telemed, Lithuania) was used to capture cine B-mode images of individual muscle fascicles through LGS and SOL muscles of the dominant leg of participants at 60 frames per second, with an imaging depth of 40 mm (Fig. 2). The start and stop times of the perturbation system, VICON motion capture, EMG recording, and ultrasound image recording were synchronized using a custom MATLAB Simulink multi-system controller running on a computer system with a data acquisition system (Quanser Q8-USB, ON, Canada). To minimize inter-investigator variability, the same investigator processed all ultrasound data, the same for all data processing. In the case of fascicle length processing, the perturbation onset was defined as the point when the fascicle length shortens below three times the resting activity level for at least 50 ms. After the definition of a resting activity level before perturbation onset, a region of interest was defined around the muscle bellies and aponeuroses of the lateral gastrocnemius (LGS) and SOL muscles. An affine optical flow algorithm (Ultratrack) [34] was used to quantify the time series of LGS and SOL fascicle lengths from the perturbation onset to stepping. The tracking results were filtered using a 4th-order low-pass Butterworth filter with a 6 Hz cutoff frequency.

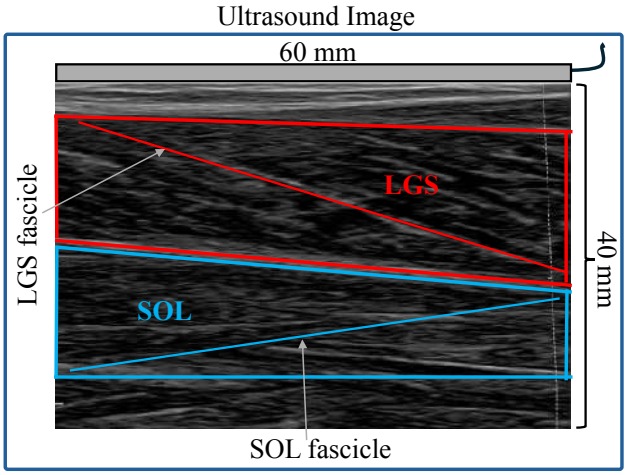

Fig. 2: Ultrasound image recorded from the LGS and SOL muscles during the experiment

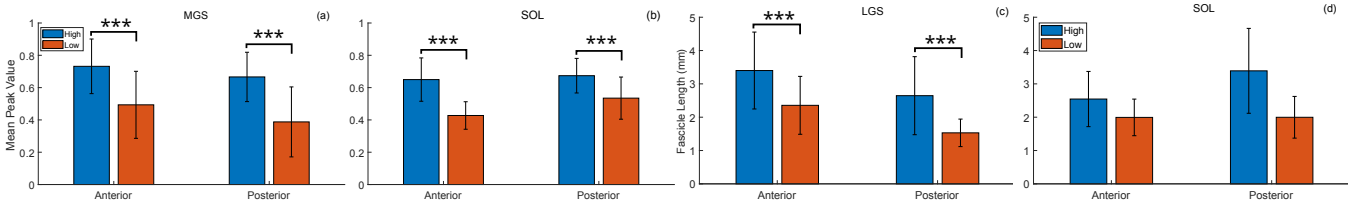

Fig. 3: Mean and standard deviation of peak EMG activation and fascicle length shortening following perturbation onset across all perturbation conditions and trials. (a) Mean and standard deviation of MGS peak values across all subjects (b) Mean and standard deviation of SOL peak values across all subjects (c) Mean and standard deviation of LGS fascicle shortening across all subjects (d) Mean and standard deviation of SOL fascicle shortening across all subjects. Error bars represent the standard deviation of the mean. "High" represents high-amplitude perturbation, and "Low" represents low-amplitude perturbation. Asterisks (*) indicate significant differences $P < 0.05$

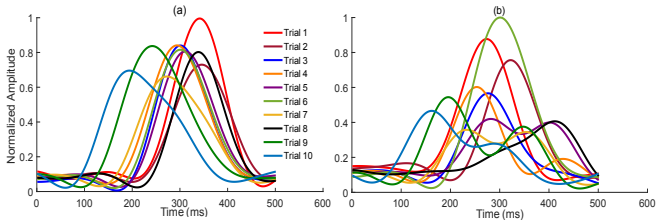

Fig. 4: EMG activity for a representative participant during low-amplitude anterior perturbation across ten perturbation trials. (a) MGS muscle activity (b) SOL muscle activity, each plot represents the muscle activity following perturbation onset

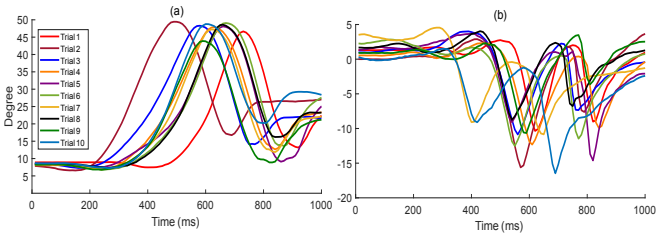

Fig. 5: Joint angles of the dominant leg of a representative participant during low-level anterior perturbation across ten trials. Each plot represents the joint angle trajectory during a step response: (a) Knee joint angles, (b) Ankle joint angles

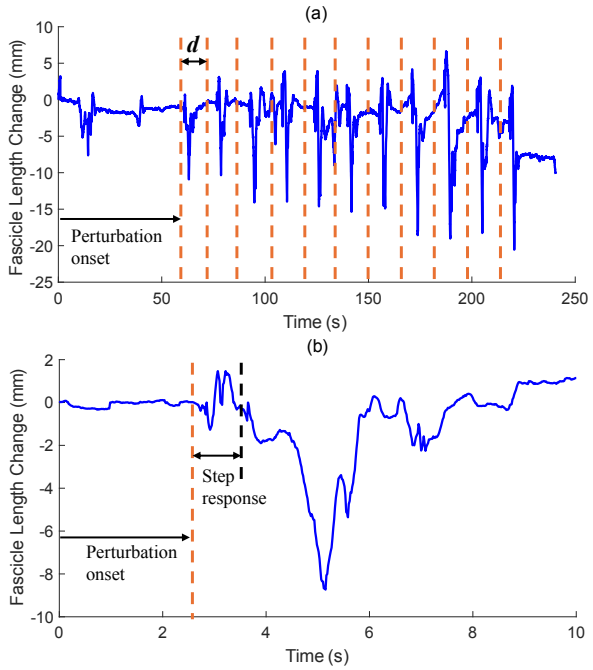

Fig. 6: US Imaging for a representative participant during low-amplitude anterior perturbation showing the (a) relative fascicle length change of the LGS muscle across ten perturbation trials, d represents the delay between each perturbation (10-14 s) (b) relative fascicle length change of the LGS muscle during a perturbation

Paired t-tests were conducted to examine differences in MGS and SOL muscle activation, as well as LGS and SOL fascicle length changes, between low-amplitude and high-amplitude perturbations in both anterior and posterior directions. A significance level of $P < 0.05$ was used.

III. Result and Discussion

A. Experimental Outcomes

Paired t-tests revealed a significant difference in MGS activation between high-amplitude and low-amplitude perturbations in both the anterior direction ($p < 0.0001$), and posterior direction ($p < 0.0001$) (Fig. 3a). Similarly, SOL activation showed a significant difference between high-amplitude and low-amplitude perturbations in the anterior direction ($p < 0.0001$), and the posterior direction ($p < 0.001$) (Fig. 3b). For fascicle length changes, a significant difference was observed in LGS length shortening between high-amplitude and low-amplitude perturbations in both anterior direction ($p < 0.001$), and posterior directions ($p < 0.0001$). However, SOL length shortening did not differ significantly between high-amplitude and low-amplitude perturbations in either the anterior or posterior directions (Fig. 3c,d).

B. Discussion

The main goal of this study is to investigate the relationship between muscle activity (muscle activation) and

architecture (fascicle length change) across both the gastrocnemius and soleus muscles during a stepping response to waist-pull perturbations in different directions (anterior and posterior) and amplitudes (high and low). Several studies have investigated how the lower limb muscles respond to unexpected balance perturbation, with all aiming at several goals including the effect of perturbation profile, perturbation magnitude, varying time intervals in perturbation, and motor adaption. These studies use only EMG for analyzing the lower limb muscle activity. We combined EMG and US imaging to analyze the gastrocnemius and soleus muscles during stepping response to an unexpected waist-pull perturbation under different perturbation conditions. In this study, MGS and SOL muscle electrical activities were recorded with EMG sensors while an ultrasound probe recorded the architecture of the LGS and SOL muscles [35].

We observed a notable increase in EMG activation in the MGS and SOL muscles during high-amplitude perturbations in both anterior and posterior directions. This increased activation reflects the contribution of these muscles in maintaining postural stability under substantial external disturbances. The increased muscle activity likely reflects the recruitment of additional motor units to generate the necessary force to counteract the destabilizing effect of the perturbation. In response to anterior perturbations, the MGS and SOL muscles act to decelerate forward motion and restore balance by producing greater plantarflexion forces. Conversely, during posterior perturbations, the increased muscle activation is essential for preventing backward falls by resisting the posterior shift of the CoM. Notably, a relatively high activation was observed in the SOL muscle during posterior perturbations, emphasizing its specific contribution to stabilizing the ankle joint during backward stepping. These findings are consistent with previous studies, which have demonstrated that enhanced activation of the ankle plantarflexors (gastrocnemius and soleus muscles) serves as a compensatory mechanism to maintain stability during balance recovery tasks involving external perturbations [36], [37]. Furthermore, evidence of motor adaptation was observed during perturbation trials [38], as reflected in EMG activation. The activation levels varied with repeated perturbation, leading to an adaptation trend across trials. As shown in Fig. 4(a,b), the EMG activation during the initial trials was notably higher, while subsequent trials showed more consistent and reduced amplitudes. This pattern suggests that participants adapted to the repeated perturbations, likely through improved neuromuscular control and optimized motor responses over time. Similar trend was observed in the knee and ankle joint angle trajectories of participants (Fig. 5 a,b).

Our US imaging results showed fascicle length shortening following perturbation onset (Fig. 6 a,b) indicative of muscle contraction during stepping responses to unexpected external disturbances. We observed greater shortening of LGS and SOL fascicle lengths during high-amplitude perturbations in both anterior and posterior directions, reflecting increased muscle contractions in response to higher perturbations. These findings on muscle architecture align with the observed EMG activity patterns. However, Hodges et al. [39] reported a nonlinear relationship between EMG activity and muscle architecture. In contrast, Narici et al. [40] found a linear relationship between muscle activity and architecture in certain muscles such as MGS. Results from these studies suggest that the relationship between muscle activity and architecture varies across different muscles, and is influenced by muscle-specific factors such as innervation [41], [42].

This study has several limitations. First, only the calf muscles were investigated; the tibialis anterior (TA), a key contributor to ankle dorsiflexion and foot stability during protective stepping, may be included in future studies to provide a more comprehensive analysis of muscle activity and contractility during reactive balance. Second, in ultrasound imaging, we examined only the lateral region of the soleus muscle, which may differ significantly from other compartments of the muscle. Investigating additional architectural features and muscle geometry, such as muscle thickness, pennation angle, and cross-sectional area, could offer deeper insights into muscle architectural properties during stepping. Furthermore, we did not analyze the EMG activity or muscle architecture of the non-dominant leg. Future studies could explore muscle responses in the non-dominant leg to better understand its role during the stepping response.

IV. Conclusion

We investigated both muscle electrical activation and fascicle length changes in MGS, LGS, and SOL muscles of the dominant (stepping) leg during stepping responses to unexpected low-amplitude and high-amplitude waist-pull perturbations in the anterior and posterior directions. By combining EMG and US imaging, we provided complementary insights into muscle activation and fascicle length changes of the calf muscles. Our findings show that waist-pull perturbation amplitude has significant effect on the EMG activation of both MGS and SOL muscle, and fascicle length shortening of both LGS and SOL muscle. Our next study will investigate the neuromuscular responses of the lower limb using EMG and US imaging during combined perturbation methods, such as platform translations and waist-pull perturbations.

Aknowledgement

The authors extend their gratitude to Yun Chen, Zhiyu Zhang, and Johnnie Reed for assisting with data collection preparations.

A Task-Agnostic Hip Exoskeleton for Osteoarthritis Pain Relief: Energetic Control Across Activities of Daily Life

Jiefu Zhang, Nikhil V. Divekar, Ernesto Hernandez Hinojosa, and Robert D. Gregg

***Abstract*— Hip osteoarthritis (OA) affects millions worldwide, yet effective conservative (non-surgical) treatments are still limited. Conventional hip braces cannot reduce painful joint loads associated with contractile forces from flexors and extensors during locomotion. Powered hip exoskeletons could potentially reduce biological hip moments by applying flexion/extension torques, thus attenuating muscle forces that contribute to OA pain. Here, we present a novel task-agnostic controller for a backdrivable hip exoskeleton that relieves hip OA pain across the primary activities of daily life. Inspired by the energy shaping method, this controller utilizes biomechanics-based components to assist with level walking, ramp and stairs ascent/descent, and sit-to-stand transitions, which can be customized to different populations, like hip OA. In a pilot study with three hip OA participants, the hip exoskeleton holistically reduced pain and perceived difficulty during a multi-activity test (except difficulty of level walking). The exoskeleton also increased hip range of motion during walking, with subject-specific improvements in walking speed. This pilot study suggests that hip exoskeletons may offer a promising new intervention for managing hip OA.**

I. Introduction

Hip osteoarthritis (OA) is a degenerative joint disease that affects millions worldwide, yet effective conservative treatments are still limited. While total hip arthroplasty (THA) is considered the gold standard for late-stage hip OA patients, it is economically unjustifiable for less severe cases [1]. Pharmacologic treatments such as non-steroidal anti-inflammatory drugs (NSAIDs) [2] and intra-articular injection [3] are common treatments for mild OA. However, prolonged use of NSAIDS can have adverse effects [2], and masking pain without addressing root causes can result in further joint damage [4]. Exercise is typically recommended to counter muscle atrophy/dysfunction [5] that contributes to abnormal joint loading and pain [6]–[8]. However, pain often forces patients to avoid strenuous activities like stair climbing and limit themselves to low-impact exercises like walking. Restricted mobility can perpetuate a detrimental cycle where muscle weakness and physical inactivity contribute to the worsening of OA symptoms [9].

Hip unloading braces can reduce pain caused by hip OA by restricting frontal plane motions and thus reducing hip joint load [10], [11], but their effectiveness was subject-dependent. This can be potentially attributed to the bulkiness and rigidity of current braces, which are essential for motion restriction but negatively affect their usability [12]. Moreover, they neglect flexion/extension moments that also cause OA pain [13], since unloading forces by restricting motion in the sagittal plane is not an option, given the necessary range of motion (RoM) for locomotion.

Powered exoskeletons, which apply external torque to joints, offer a promising approach to reduce joint compression forces [14] and associated pain in lower-limb OA. These devices have been shown to effectively decrease joint moments [15] and muscle effort [16] during various activities. Since joint compression forces during dynamic movements are primarily caused by muscle contractions generating internal joint moments [17], powered exoskeletons can potentially benefit OA patients by providing external torques that partially reduce the requisite muscle activation. Simulation studies [14] have suggested that knee exoskeletons applying pure torque can decrease joint loading across different walking speeds. However, the effects of hip exoskeletons on OA patients remain to be investigated.

In order for hip exoskeletons to help manage OA pain on a daily basis, they must be sufficiently versatile to support the various activities of daily life (ADLs). However, existing commercial hip exoskeletons like Samsung GEMS [18], [19] typically use task-specific controllers that must first identify the activity being performed before applying pre-programmed torque profiles. This approach proves problematic in real-world applications due to the unpredictable and varied nature of daily activities. For instance, studies with the highly-geared Keeogo knee exoskeleton [20] failed to show immediate improvements for knee OA patients, likely due to the lengthy user adaptation needed to effectively use the task recognition-based controller. While neural networks trained with unimpaired human data can enhance task adaptability by estimating normative biological hip moments across various activities [15] (referred to as a *task-agnostic* controller), the lack of tunability limits customization for specific patient populations like hip OA. Moreover, the "black box" nature of neural networks raises safety concerns when used with impaired populations due to the possibility of unpredictable behavior outside training scenarios.

Our previous research on energy shaping-based controllers has shown promise in providing task-agnostic, biomimetic torque assistance with improved safety and stability guarantees [21]–[24]. However, the optimization over hundreds of non-intuitive torque bases made these methods susceptible to over-fitting the training data and impractical to tune for more effective assistance, resulting in limited interpretability

and customizability. In [25], an energy shaping controller was designed using physically-meaningful components like virtual springs and dampers, which are inherently passive and intuitive but not necessarily biomimetic. This idea was extended in [16] by optimizing physically-meaningful energetic components to match human data followed by manual tuning to maximize quadriceps assistance during lifting, lowering, and carrying tasks. By moving away from purely data-driven optimization of abstract torque bases, this approach has demonstrated superior effectiveness in improving physical performance and reducing muscle effort across various activities while maintaining customizability. The use of intuitive parameters also makes the controller more practical to tune and adapt for individual needs. While the results in [16] are promising for healthy individuals, this technology may also have impact for people with hip OA.

In this paper, we designed and implemented an energy shaping-inspired hip exoskeleton controller based on the approach in [16] for individuals with hip OA. Fig. 1 provides a high-level overview of our controller, which utilizes virtual springs modulated by kinematic variables such as joint angles and velocities, featuring physically-meaningful parameters that can be customized. This design represents our first key contribution, offering task-agnostic assistance for common ADLs with improved interpretability and customizability. Our second major contribution lies in investigating the effects of powered hip exoskeleton assistance on the hip OA population, hypothesizing that it could reduce pain and decrease the difficulty of performing ADLs. To validate this, three participants with hip OA performed various activities both with and without our hip exoskeleton at different assistance levels. Results demonstrated significant pain and difficulty reductions during hip-intensive tasks across all subjects, along with subject-specific improvements in walking speed accompanied by increased hip RoM. These promising outcomes reveal the potential of powered hip exoskeletons as an effective treatment option for individuals with hip OA.

II. Controller Design and Implementation

In our previous hip exoskeleton controller design [23], assistive torque was formulated as a linear combination of trigonometric basis functions, whose coefficients were determined through off-line optimization using normative human data. This approach presents challenges for impaired populations like hip OA patients, primarily due to its heavy dependence on data and the use of non-intuitive basis functions. Designing controllers for impaired populations is complicated by the scarcity of rich population-specific datasets, leading to the use of datasets with less subjects and activities, thus increasing the risk of overfitting. Furthermore, patient datasets often consist of pathological movement patterns, which will be reproduced by a purely data-driven controller, leading to suboptimal assistance. For example, hip OA patients typically exhibit reduced range of motion during walking, partly stemming from insufficient hip extension moment [8]. A controller developed using such patient data would reproduce these limited movement

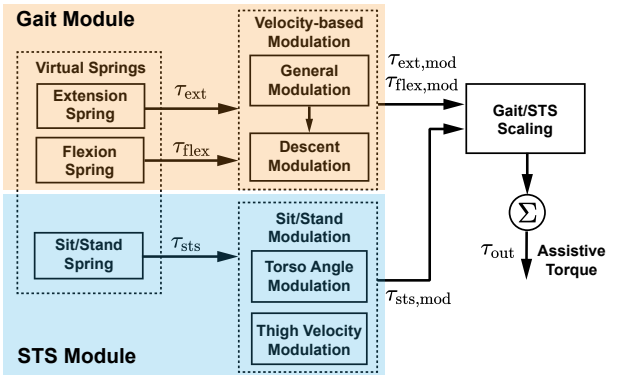

Fig. 1. High-level overview of the controller. Torque generated by virtual springs is modulated based on joint kinematics, and then scaled and summed to obtain the output assistive torque.

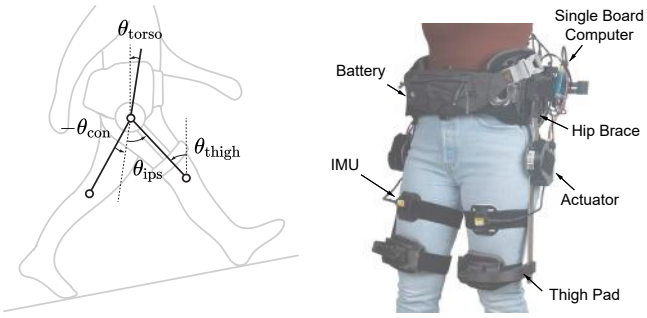

Fig. 2. **Left:** Definitions of angles used in the controller. Black-outlined circles represent the centers of hip and knee joints. $\theta_{\mathrm{torso}}, \theta_{\mathrm{thigh}}, \theta_{\mathrm{ips}}$, and θ_{con} denote torso angle, thigh angle, ipsilateral hip angle, and contralateral hip angle respectively. **Right:** Picture of the modified M-BLUE hip module. For clarity only one of the inertia measurement units (IMUs), actuators, and thigh pads are labeled.

patterns, resulting in insufficient torque. Unintuitive control parameters would also prevent heuristic fine-tuning based on user feedback, often essential in clinical settings. To address these limitations, in this paper we propose a biomechanics-informed controller, which incorporates virtual springs modulated by human kinematics. This new design can provide task-agnostic assistance for hip OA patients, while remaining tunable.

A. Physical Component-based Controller Design

The physical component-based controller comprises two modules: the gait module that generates torque for gait activities (level walking, ramp and stairs ascent/descent), and the sitting/standing (STS) module that generates torque for sit-to-stand transitions. The gait module includes two unidirectional virtual torsion springs—the extension spring and the flexion spring, modulated by joint velocity. The STS module consists of one unidirectional virtual torsion spring—the STS spring, modulated by the torso angle and thigh velocity. The torque from the two modules is scaled and combined to provide the output assistive torque. The definition of joint angles used in the controller is shown in Fig. 2 (left). The counterclockwise (flexion) direction is defined as positive.

1) Gait Module: In the gait module, the extension spring and flexion spring provide extension and flexion torque

during gait activities. The torques generated by the two springs are given by

$$\begin{aligned}\tau_{\text{ext}} &= \min\left(0,\ k_{\text{ext}} \cdot (\theta_{\text{ips}} - \theta_{\text{ext,eq}})\right) \\ \tau_{\text{flex}} &= \max\left(0,\ k_{\text{flex}} \cdot (\theta_{\text{flex,eq}} - \theta_{\text{ips}})\right),\end{aligned} \tag{1}$$

where $k_{\text{ext}},\ k_{\text{flex}}$ are the constant spring stiffness values of the extension and flexion springs, θ_{ips} is the ipsilateral hip angle, and $\theta_{\text{ext,eq}}$, $\theta_{\text{flex,eq}}$ are the equilibrium angles of extension and flexion springs respectively. The $\min(\cdot)$ and $\max(\cdot)$ functions ensure that springs are unidirectional and only provide torque in the intended direction.

We want to predict biomimetic torques using measurable input kinematics (e.g., angles and velocities) across multiple ADLs, which is not feasible with virtual springs alone, since similar hip angles may correspond to dissimilar biological hip moments in different activities and gait phases. For example, a vertical thigh orientation during mid-stance and mid-swing corresponds to conflicting extension and flexion biological moments, respectively. Prediction power can be substantially improved by modulating the torque from two springs using joint velocity (the general modulation block in Fig. 1). In early-to-mid stance, the flexion spring torque is attenuated due to large negative hip velocity, providing extension torque aligned with leg movement. This attenuation continues until late stance, when hip velocity is slightly negative, signaling the need for overall negative power for braking. Similarly, in early-to-mid swing, the extension spring torque is attenuated based on large positive hip velocity until late swing. This velocity-based modulation strategy for general gait activities enables precise control of torque application timing across gait phases. Due to the smoothness and boundedness of sigmoid function, we chose it as the nonlinear modulation function:

$$\sigma(x, w, \phi) = \frac{1}{1 + e^{-w \cdot x + \phi}}\ , \tag{2}$$

where x is the input argument, and w, ϕ are parameters that determine the slope and horizontal shifts of the sigmoid function. Let x be the angular velocity $\dot{\theta}$, then (2) maps $\dot{\theta} \in \mathbb{R}$ to $[0, 1]$, ensuring the boundedness of the modulation. By adjusting w and ϕ, the timing of assistive torque and its sensitivity to velocity can be tuned.

The general modulation factors can then be determined by

$$\begin{aligned}\eta_{\text{ext}} &= \sigma(\dot{\theta}_{\text{ips}}, w_{\text{ext}}, \phi_{\text{ext}})\ , \\ \eta_{\text{flex}} &= \sigma(\dot{\theta}_{\text{ips}}, w_{\text{flex}}, \phi_{\text{flex}})\ ,\end{aligned} \tag{3}$$

where $\dot{\theta}_{\text{ips}}$ is the ipsilateral hip angular velocity, and $w_{\text{ext}}, w_{\text{flex}}, \phi_{\text{ext}}, \phi_{\text{flex}}$ are parameters to be determined.

For certain descent tasks, such as stair descent, modulations solely based on velocity direction are insufficient to generate biomimetic assistive torque. During mid-swing, the concentric contraction of the hip flexors swings the leg forward. On the other hand, a hip flexion velocity is also observed during stance in descending tasks, associated with the eccentric contraction of hip extensors, to allow a "controlled lowering" of body center-of-mass. In this case, the exoskeleton needs to provide torque against the leg's motion to brace the user from collapsing, which is challenging with existing modulations since they tend to provide torque that aligns with the leg motion's direction (or sign of the velocity). By analyzing normative kinematics of descending tasks, we observed that during early to mid-stance, the ipsilateral hip flexes for lowering, while the contralateral hip flexes to swing the leg forward. This pattern allows us to further introduce descent modulation for effective assistance during descending tasks, determined by the descent modulation factor

$$\begin{aligned}\eta_{\text{desn}} = \sigma(\dot{\theta}_{\text{ips}}, w_{\text{ips}}, \phi_{\text{ips}}) \cdot \sigma(\dot{\theta}_{\text{con}}, w_{\text{con}}, \phi_{\text{con}}) \\ \cdot \text{step}(\theta_{\text{ips}} - \theta_{\text{con}} - \theta_{\text{th}})\end{aligned} \tag{4}$$

where $\dot{\theta}_{\text{con}}$ is the contralateral hip angular velocity, step$(\cdot)$ is the step function, θ_{con} is the contralateral hip angle, and θ_{th} is the angle difference limit. Parameters $w_{\text{ips}}, \phi_{\text{ips}}, w_{\text{con}}, \phi_{\text{con}}$ are designed such that both sigmoid functions converge to 1 when velocities are positive and to 0 when velocities are negative. The multiplication acts as a proxy of the "AND" logic operation, allowing $\eta_{\text{des}} \to 1$ only when both thighs are flexing, an indicator of descent activities. The step function further restricts the descent modulation to only be applied in a certain range of joint angle.

Combining (1), (3), and (4) gives the extension and flexion torques from the gait module:

$$\begin{aligned}\tau_{\text{ext,mod}} &= \tau_{\text{ext}} \cdot \left[\eta_{\text{desn}} \cdot C_{\text{ext}} + (1 - \eta_{\text{desn}}) \cdot \eta_{\text{ext}}\right]\ , \\ \tau_{\text{flex,mod}} &= \tau_{\text{flex}} \cdot \left[\eta_{\text{desn}} \cdot C_{\text{flex}} + (1 - \eta_{\text{desn}}) \cdot \eta_{\text{flex}}\right]\ ,\end{aligned} \tag{5}$$

where C_{ext} and C_{flex} are constant parameters to be chosen. General modulation and descent modulation together comprise velocity-based modulation, which changes the angle to torque mapping of extension and flexion springs to angle-velocity to torque, improving versatility and allowing more task-adaptive, biomimetic assistance from simple virtual springs.

2) STS Module: Due to the differences between sit-to-stand transitions and other walking tasks, the STS module is designed separately and operates in parallel with the gait module. The core of the STS module is the STS spring, a unidirectional virtual torsion spring with equilibrium angle at $\theta_{\text{thigh}} = 0°$, where θ_{thigh} is the ipsilateral thigh angle, as defined in Fig. 2. An extension restoring torque is generated when the thigh is flexed, determined by

$$\tau_{\text{sts}} = \min(0,\ -k_{\text{sts}} \cdot \theta_{\text{thigh}})\ . \tag{6}$$

Similar to the gait module, solely relying on the thigh angle leads to large extension torque at the end of the stand-to-sit transition and while seated. Therefore, to reduce torque while the user is seated, τ_{sts} is first modulated based on the torso angle θ_{torso}, as defined in Fig. 2 (left). The torso angle is a key differentiator between the sit-to-stand transition and a sitting posture, where the sit-to-stand transition exhibits an anterior torso lean ($\theta_{\text{torso}} > 0$). Furthermore, to reduce bracing during the late stand-to-sit transition, hip velocity is used to taper down extension torque when the thigh is flexing, indicating a stand-to-sit transition. Combining the

two modulations, the modulation factors for STS torque are determined by

$$\begin{aligned} \eta_{\text{sts,torso}} &= \sigma(\max(0, \theta_{\text{torso}}), w_{\text{torso}}, \phi_{\text{torso}}) \ , \\ \eta_{\text{sts,vel}} &= \sigma(\dot{\theta}_{\text{ips}}, w_{\text{vel}}, \phi_{\text{vel}}) \ . \end{aligned} \tag{7}$$

The maximum function $\max(0, \theta_{\text{torso}})$ allows the STS spring to only engage when $\theta_{\text{torso}} > 0$ (forward torso lean). Combing (6) and (7) gives the modulated STS torque:

$$\tau_{\text{sts,mod}} = \tau_{\text{sts}} \cdot \eta_{\text{sts,torso}} \cdot \eta_{\text{sts,vel}} \ .$$

3) Module Integration: To create seamless transitions between the gait module and the STS module, the torque from both modules is scaled based on the symmetry of bilateral kinematics, serving as a strong indicator of walking and STS activities. The scaling factor is determined by

$$\beta = \sigma(|\theta_{\text{ips}} - \theta_{\text{con}}|, w_{\text{sc}}, \phi_{\text{sc}}) \cdot \text{step}(|\dot{\theta}_{\text{ips}} - \dot{\theta}_{\text{con}}| - \omega_{\text{th}}) \ ,$$

where ω_{th} is the velocity difference limit. The step function ensures that β is nonzero only when the bilateral velocity is below the threshold determined by ω_{th}, implying symmetric bilateral velocities. By modifying $w_{\text{sc}}, \phi_{\text{sc}}$, and ω_{th}, one can adjust the sensitivity to asymmetry. Subsequently, the torques from the walking and STS modules are combined as a convex combination to produce the output torque

$$\tau_{\text{out}} = \beta \cdot \tau_{\text{sts,mod}} + (1 - \beta) \cdot (\tau_{\text{ext,mod}} + \tau_{\text{flex,mod}}) \ .$$

B. Parameter Optimization

Our biomechanics-informed design offers enhanced flexibility, enabling parameter adjustments beyond the original data-driven optimization process—a capability our previous design [23] lacked. Similarly to our previous work, we use normative datasets to inform the initial parameters (providing a *warm start*), which were later tuned based on pilot subject feedback. We formulate the parameter design problem as an optimization problem using normative human data from open-source multi-activity datasets [26] [27]. By minimizing the difference between estimated assistive torque (given normative input kinematics) and biological joint moment, we obtain parameters that serve as an improved starting point for further fine-tuning.

The parameters to be optimized are $w_{(\cdot)}, \phi_{(\cdot)}$ in (3), and $C_{\text{ext}}, C_{\text{flex}}$ in (5). The objective function is

$$\begin{aligned} J = \sum_{i \in T} \ & (\gamma_i \cdot \|\tau^i_{\text{out}} - \tau^i_{\text{bio}}\| + \gamma_2 \cdot \|\tau^0_{\text{out}}\| \\ & + \gamma_3 \cdot \|\text{sgn}(\tau^i_{\text{out}}) - \text{sgn}(\tau^i_{\text{bio}})\|) \ , \end{aligned}$$

where T is the set of activities used in the optimization, τ^i_{bio} is the scaled biological hip moment, and τ^i_{out} is the estimated assistive torque for activity i. The biological hip moment is scaled to 35% since the actuators can only provide around 1/3 of normative hip moment. τ^0_{out} denotes the estimated torque when all kinematics are zero, which corresponds to the configuration of standing still. $\text{sgn}(\cdot)$ is the sign function. γ_i is the task-dependent weight, and γ_2, γ_3 are constant weights. The first term of the objective function minimizes the difference between assistive torque and biological moment, with activity-dependent weight to emphasize hip demanding activities. The second term minimizes the static torque to prevent discomfort, and the third term minimizes the sign difference between τ^i_{out} and τ^i_{bio} to penalize assistive torque in the wrong direction.

To cover a range of ADLs, we used data from six subjects performing the following activities as our training set: level walking at 0.85 and 1.15 m/s, ascending and descending ramps at 5.2° and 11°, ascending and descending stairs with step heights of 5 and 7 inches (12.7 and 17.8 cm), and rising from a chair. The optimization problem was solved in MATLAB R2023b using the "`fmincon`" function, with physically reasonable lower and upper bounds. Figure 3 compares the estimated torque from the optimized controller, based on normative kinematics, to the corresponding scaled biological hip moment. Although data from healthy individuals were used, the optimized parameters served only as an initial guess and were further fine-tuned through feedback from pilot tests. Once determined, parameters remained fixed throughout the study.

C. Hardware Implementation

The controller was implemented on a bilateral hip exoskeleton shown in Fig. 2 (right), which is an improved hip module of the M-BLUE system [28]. The hip exoskeleton combines off-the-shelf hip braces (Breg T Scope Hip) with two highly backdrivable actuators (T-motor AK80-9 with Dephy FASTER driver) that provide 25 Nm peak torque with low reflected inertia (92.1 kg $\cdot$ cm^2). During the study, the maximum torque was limited to 20 Nm. Three IMUs (Microstrain 3DM-GX5 AHRS) were directly attached to thighs and torso to acquire: sagittal thigh, torso, and hip angles, and their angular velocities. The real-time controller ran on a Raspberry Pi 5 8 GB at 300 Hz. Hip angular velocity and commanded torque were filtered with second-order Butterworth low-pass filters with cutoff frequencies of 10 Hz and 5 Hz respectively. The system was powered by a 24 V, 2 Ah power tool battery (Kobalt 24-V Lithium Battery) and weighs approximately 4.3 kg. For safety, a remote e-stop switch was implemented to cut power to the motor if needed.

III. Hip Osteoarthritis Pilot Study

A. Experimental Design

To investigate the effect of the exoskeleton/controller on hip OA patients' physical performance and perceived pain and difficulty during different activities, we designed a study consisting of a multi-activity test approved by the Institutional Review Board at University of Michigan (HUM00201957). As a proof of concept, we enrolled three participants diagnosed with hip OA. Participant 1 was diagnosed with bilateral hip OA (S1: female, age-53, weight-52 kg, height-1.65 m), while participant 2 and 3 were diagnosed with unilateral hip OA (S2: male, age-32, weight-70 kg, height-1.71 m; S3: female, age-64, weight-78 kg, height-1.68 m). All participants gave written consent before participation. Participants were required to wear a safety harness to prevent falling during the study.

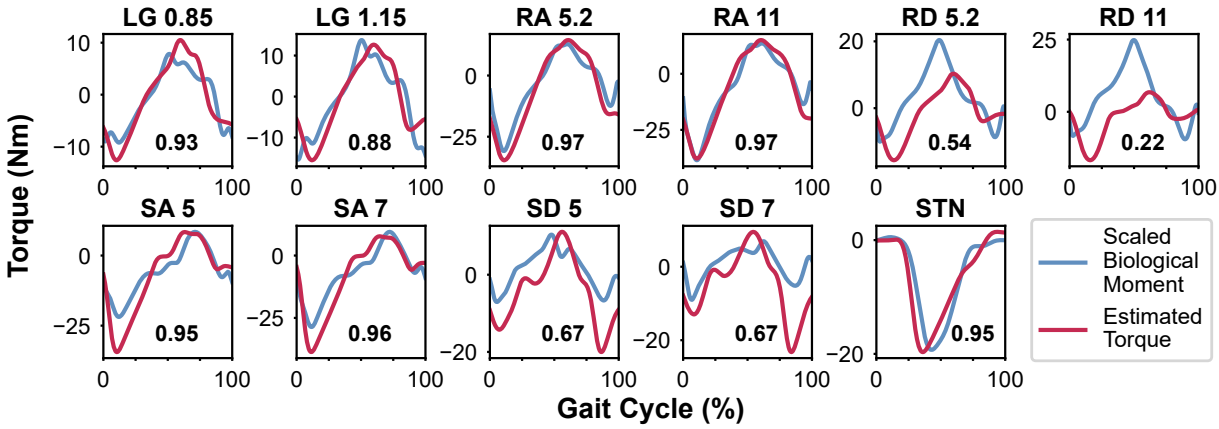

Fig. 3. *In silico* comparison between controller estimated torque and scaled biological hip moment. Estimated torque is computed using across-subject average kinematics with optimized parameters, and biological moment is the average hip moment scaled to 35%. Activities include LG (level-ground walking) at 0.85 and 1.15 m/s, RA (ramp ascent) and RD (ramp descent) on 5.2° and 11° ramps, SA (stairs ascent) and SD (stairs descent) on 5 and 7-inch step height stairs, and standing. Bold numbers in the subfigures denote the cosine similarity between the estimated torque and the scaled hip moment for the corresponding task [23].

Before the tests, participants underwent an acclimation session in which they performed different activities with the exoskeleton under different levels of assistance (LoA) until they were confident with the device. Participants also indicated the maximum LoA that they felt comfortable with across activities, which was used later in the test. To investigate the effect of exoskeleton assistance the test was performed under the following conditions: no exoskeleton (No-Exo), passive exoskeleton (0% Exo), 50% active exoskeleton (50% Exo), and 100% active exoskeleton (100% Exo), where 100% denotes the maximum comfortable LoA indicated during acclimation. Note that in the No-Exo condition, participants wore a low-profile data collection setup, with IMUs attached to body segments using elastic straps to measure kinematics.

In the multi-activity test, participants performed ADLs including level-ground walking (LG), ramp ascent (RA), ramp descent (RD), stairs ascent (SA), stairs descent (SD), sit-to-stand (STN), and stand-to-sit (SIT) on a multi-terrain circuit comprising a 3.7-m ramp inclined at 15°, a short level platform of 2 m, and a 5-step staircase with 7-inch (18 cm) step height. We repeated each activity multiple times until obtaining at least 10 gait/task cycles with average speeds within $\pm 10\%$ of their baseline values measured during the acclimation. Pain and difficulty were assessed using a modified Western Ontario and McMaster Universities Arthritis Index (WOMAC) questionnaire, in which participants rated their perceived pain and difficulty on a scale of 0-4, corresponding to "None", "Slight", "Moderate", "Very", and "Extremely". Additionally, participants performed a 10-meter walk test (10MWT) at their comfort and fast speeds with three repetitions each, and the average of these repetitions was recorded as their comfort or fast 10MWT speed.

B. Results

Each participant's pain and difficulty ratings across activities for each condition are shown in Table I and Table II. Additionally, Fig. 4 compares the effect of the active exoskeleton on pain and difficulty with No-Exo, where the best rating out of 50% and 100% LoA was chosen for the active condition. Compared to No-Exo, the active exoskeleton reduced the across-subject average pain rating for all tasks. Similarly, average difficulty ratings were lower with the active exoskeleton for all tasks except LG.

The average and individual speed changes of 10MWT in the Exo conditions compared to No-Exo condition are shown in Fig. 5. Both average comfort and fast speeds in 100% Exo condition increased compared to No-Exo condition, but with large inter-participant variation.

For comfort speed 10MWT, results from three exoskeleton conditions (0%, 50%, and 100% Exo) were compared to the No-Exo condition. S1's comfort speeds were 1.55, 1.56, and 1.52 m/s in the respective exoskeleton conditions, corresponding to changes of +0.98%, +1.63%, and -0.98% compared to the No-Exo condition (1.54 m/s). S2's comfort speeds were 1.40, 1.32, and 1.79 m/s, representing changes of -0.99%, -7.06%, and +26.46% compared to the No-Exo condition (1.42 m/s). S3's comfort speeds were 1.32, 1.36,

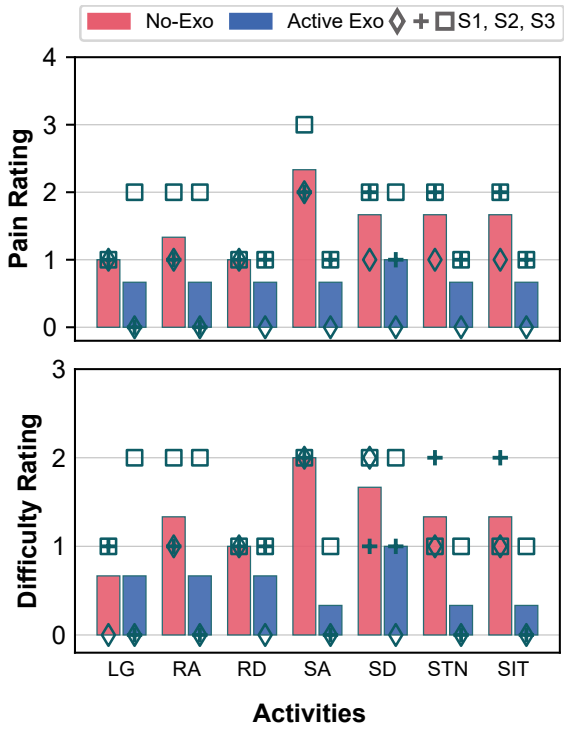

Fig. 4. Across-subject average and individual pain and difficulty ratings of activities under no exoskeleton (No-Exo) and active exoskeleton (Active Exo) conditions. Bar plots and scatter plots show the average and individual ratings.

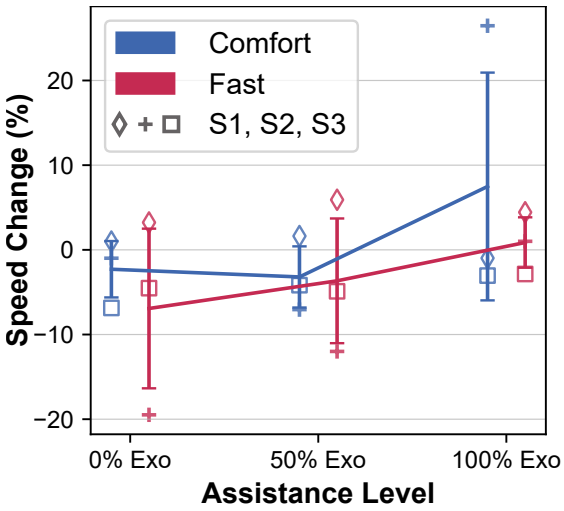

Fig. 5. Across-subject average and individual 10MWT speed changes relative to the No-Exo condition. Points where lines intersect error bars (± 1 standard deviation) indicate the mean values, and scatter plots denote individual data points. Positive numbers indicate faster speeds.

and 1.37 m/s, corresponding to changes of -6.86%, -4.17%, and -2.9% compared to the No-Exo condition (1.41 m/s).

For fast speed 10MWT, results from three exoskeleton conditions were compared to the No-Exo condition. S1's fast speeds were 1.89, 1.93, and 1.91 m/s in the respective exoskeleton conditions, corresponding to changes of +3.23%, +5.91%, and +4.44% compared to the No-Exo condition (1.83 m/s). S2's fast speeds were 1.84, 2.01, and 2.31 m/s, representing changes of -19.48%, -12.00%, and +1.01% compared to the No-Exo condition (2.28 m/s). S3's fast speeds were 1.54, 1.54, and 1.57 m/s, corresponding to changes of -4.52%, -4.89%, and -2.85% compared to the No-Exo condition (1.61 m/s).

As an exploratory result, Fig. 6 shows participants' hip joint angle over a gait cycle during 10MWT at comfort speed under No-Exo, 0% and 100% Exo conditions, overlaid with the commanded torque from the 100% Exo condition. Compared to No-Exo, hip RoM increased in 100% Exo for all participants. Specifically, the hip RoM of S1 was (-11.5°, 42.9°) in No-Exo, (-14.4°, 36.7°) in 0% Exo, and (-16.5°, 41.7°) in 100% Exo. This corresponds to 3.8° RoM increase in 100% Exo compared to No-Exo. The hip RoM of S2 was (-10.5°, 36.7°) in No-Exo, (-17.4°, 35.2°) in 0% Exo, and (-18.8°, 40.2°) in 100% Exo. This corresponds to a 11.8° RoM increase in 100% Exo compared to No-Exo. The hip RoM of S3 was (-12.0°, 40.6°) in No-Exo, (-21.2°, 30.3°) in 0% Exo, and (-22.8°, 39.3°) in 100% Exo. This corresponds to a 9.5° RoM increase in 100% Exo compared to No-Exo.

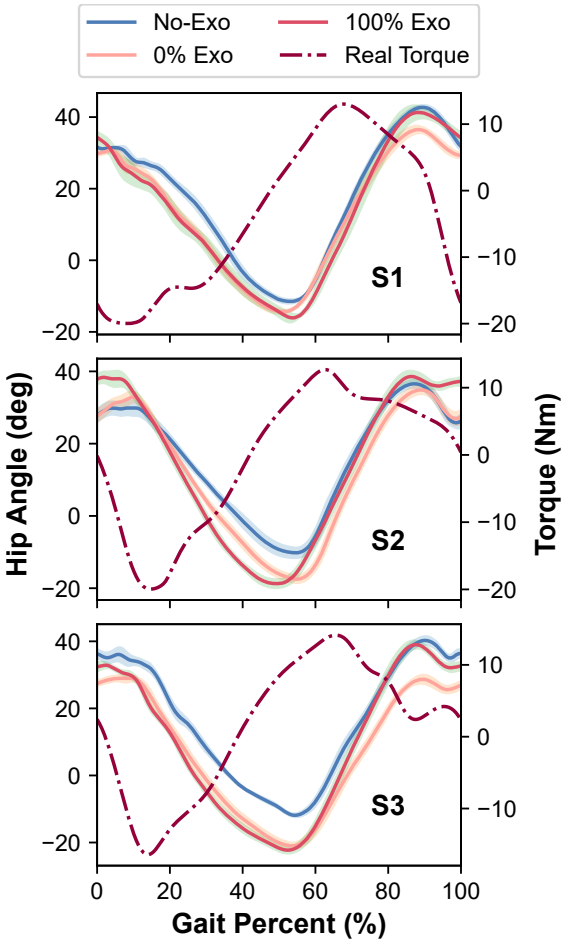

Fig. 6. Participants' hip joint angle over a gait cycle during comfortable speed 10MWT, under No-Exo, 0% Exo, and 100% Exo conditions. Solid lines represent the mean value, and shaded areas represent ±1 standard deviation. Dashed lines represent the commanded actuator torque. Positive values indicate flexion.

IV. Discussion

We hypothesized that our powered hip exoskeleton can reduce pain and difficulty in the hip OA population when performing various activities, due to reduced internal joint moments. The results of this study support our hypothesis. Across-subject pain ratings reduced across all tasks with the active exoskeleton, and the average difficulty ratings decreased for all tasks except LG. Pain and difficulty were most reduced in hip-intensive tasks like SA, STN and SIT. The small reductions in pain and difficulty in RA, an activity that requires large hip extension moment, was unexpected. A possible explanation is that participants adopted an altered gait that requires less hip effort during RA, due to muscle weakness and pain—such gait adaptations have been reported in the knee OA population during stair climbing [29]. This can also explain the lower pain/difficulty ratings in RA compared to SA in No-Exo condition. However, inverse dynamics will be needed to verify this hypothesis, which is outside the scope of this initial study.

The effect of LoA on pain and difficulty was as expected. In general, higher LoA led to the same or reduced pain and difficulty. However, for certain tasks like SD and STN, less reduction in pain or difficulty was reported in 100% Exo condition compared to other LoAs. During SD, the exoskeleton mainly does negative power, which causes resistance to leg motion, potentially leading to more difficulty. During STN, large bilateral assistive torque in the same direction needs to be applied in a short time, which leads to a large rate of torque increase. This might have increased the difficulty in 100% Exo condition, compared to milder and smoother assistive torque rates in the 50% Exo condition. The discrepancies in LoA preferences show the importance of customizability in exoskeleton control. Although we left the controller unchanged across participants in this study, the design of our controller allows user-based customization and task-specific fine-tuning to maximize the benefits of the exoskeleton in managing hip OA.

The passive exoskeleton (the 0% Exo condition) had mixed effects compared to No-Exo. In some tasks like SA, the passive exoskeleton induced benefits, likely because the underlying post-op hip brace provides hip stabilization and restricts frontal plane motions (a common strategy in OA treatment). On the other hand, increased pain and difficulty with the passive exoskeleton can still be observed in other activities, which indicates the potential penalty due to the weight and/or restrictions of the exoskeleton. Note that due to the backdrivable actuators, the penalty caused by the backdrive torque (1-2 Nm) is likely negligible. Overall, the mixed effect of the passive exoskeleton condition reflects the limited benefit of passive braces, further demonstrating the value of powered exoskeletons for OA treatment.

Slower walking speed has been observed in the hip OA population compared to the control group [30]. In this study, we compared the comfort/fast speeds during 10MWT between conditions, observing increases on average for the 100% Exo condition compared to No-Exo condition. However, large inter-subject variation exists: S1 and S2 responded well to active exoskeleton and had increases in both comfort and fast speed, while S3 did not have any speed increase with the exoskeleton. This large variability might be caused by inter-subject differences in sensorimotor factors other than muscle strength and pain; including balance, reaction time, and proprioception [31]. Although the exoskeleton can compensate for muscle strength loss and reduce pain, the assistance can also cause disruption of underlying physiology and negatively affect their gait. Therefore, acclimation is usually required for exoskeleton users to experience the most benefit. However, becoming fully acclimated to exoskeletons takes several hours, and older age further slows motor adaptation to walking with exoskeletons [32]. Therefore, it is possible that the senior most participant in our cohort (S3) did not fully acclimate to the exoskeleton, although they indicated confidence during acclimation. This may have prevented them from benefiting more from assistance compared to the younger participants.

Reduced hip RoM is a typical gait characteristic of the hip OA population during walking. This compromised gait may lead to abnormal joint load patterns at the hip and other lower extremity joints, further causing joint degeneration and chronic pain [33]. In this study, the active exoskeleton condition was associated with notably higher hip RoM compared to No-Exo. The most probable reason is the effect of the assistive extension torque of the active exoskeleton. This likely enabled participants to walk with a high peak hip extension by overcoming the effects of weak hip extensors and possible flexion contractures. On the other hand, pain arising from the higher joint forces associated with a larger step length could lead to a reduced hip RoM. The force and pain reduction capabilities of the active exoskeleton could have offset these effects, thereby encouraging larger steps and RoM. While hip RoM and walking speed are generally correlated, S1 and S3 had larger RoM despite slower speed in the 100% Exo condition. This indicates that the holistic increase in hip RoM is not simply a by-product of changes in walking speed.

The effect of the exoskeleton's assistance is evident in the commanded torque shown in Fig. 6. Across all participants, significant extension torque was provided during early-to-mid stance, which can compensate for the decreased hip extension moment associated with OA. It is important to note that normative extension torque during slow walking is typically small compared to hip-intensive activities such as ramp or stair ascent. As a result, a purely data-driven controller based on normative data would likely generate insufficient extension torque for hip OA populations, who require greater extension assistance than healthy individuals. In contrast, our controller produced large extension torques, with peak values approaching 20 Nm (the maximum allowable torque), demonstrating its ability to assist impaired populations without relying on population-specific data.

V. Conclusion

In this paper, we presented a novel biomechanics-informed, task-agnostic hip exoskeleton controller designed to address hip OA-related mobility challenges. Inspired by energy shaping principles, the controller utilizes virtual springs modulated by joint kinematics, allowing improved customizability. A pilot study with three hip OA patients showed that our hip exoskeleton and controller can reduce pain and difficulty across activities, increase hip RoM during walking, and improve 10MWT speed on an individual basis. These promising results suggest that hip exoskeletons may provide a novel conservative intervention for managing hip OA to improve patient mobility and quality of life.

Identification of Neuromotor Patterns Associated with Hand Rehabilitation Movements from EMG and EEG signals

Michelle Soto-Florido[1], Elkin Garcia-Cifuentes[2], Angela M. Irragorri[2], Ivan F. Mondragon[1], Diego Mendez[1], Julian D. Colorado[1], Catalina Alvarado-Rojas[1]

***Abstract*— Stroke rehabilitation is essential for restoring upper limb function, impaired in nearly 85% of stroke survivors. Accurate classification of movement intention and execution can enhance rehabilitation through improved patient monitoring and robotic assistance. This study explores integrating electroencephalography (EEG) and electromyography (EMG) signals to classify five hand movements commonly used in rehabilitation therapy: four finger pinches and full hand closure. Biological signals were acquired from 22 healthy participants using a synchronized setup of EEG and EMG systems. Signal processing methods were applied to extract frequency and connectivity features from EEG and muscle activity metrics from EMG. These features were used to train machine learning models, including Ensemble Bagged Trees, neural networks, and SVMs, for classifying movement intention and execution. Results demonstrated that the Ensemble Bagged Trees model achieved the highest accuracy classified 5 classes, particularly when employing EEG power spectral density features, with 84.7% and 67.4% accuracy for movement execution and intention, respectively. Correlation analysis identified distinct motor-related brain connectivity patterns, offering insights into neuromotor processes. These findings support the integration of EEG-EMG analysis with machine learning to enhance stroke rehabilitation, improving patient monitoring and robotic-assisted therapy.**

Keywords—Hand rehabilitation, EEG signals, EMG signals, Signal Processing, Machine Learning

I. INTRODUCTION

Stroke is one of the leading causes of death and disability worldwide, placing a significant burden on healthcare systems and patients alike. According to the World Health Organization (WHO), approximately 12.2 million new cases of stroke were reported in 2022, with an estimated 101 million individuals living with its aftermath [1]. Moreover, it is estimated that one in four individuals over the age of 25 will experience a stroke during their lifetime. Stroke typically results from an interruption of blood flow to the brain—either due to an obstruction (ischemic stroke) or a rupture of a blood vessel (hemorrhagic stroke)—leading to cellular death and significant neurological impairment [2]. Notably, up to 85% of stroke survivors experience upper limb dysfunction, highlighting the critical need for effective rehabilitation strategies to restore hand functionality and improve activities of daily living [3].

Since the dominant hand is essential for daily activities. Stroke can severely limit independence and participation in task that requiring precision, coordination an strength. With up to 80% of individuals being right-handed and nearly half of all strokes affecting the left hemisphere, a significant portion of stroke survivors experience right-hand paresis. Studies suggest that the dominant hand benefits from greater motor efficiency, muscle endurance, and refined motor programs due to lifelong use. Therefore, effective rehabilitation strategies must prioritize restoring right-hand function to maximize recovery and maintain quality of life.[4], [5]

Early and intensive rehabilitation is crucial for maximizing recovery, particularly within the first three months following a stroke. Rehabilitation programs are most effective when they are tailored to the individual, often combining initial in-hospital therapy with subsequent outpatient sessions designed to address the specific motor deficits of each patient [6] [7]. Recently, there has been growing interest in incorporating technology-assisted therapies, such as robotic exoskeletons, to complement traditional rehabilitation methods. These devices not only support the restoration of motor function but also offer enhanced patient monitoring and personalized therapeutic interventions [8], [9]

Furthermore, advances in biomedical signal processing have enabled the integration of electroencephalography (EEG) and electromyography (EMG) to monitor both neural and muscular activity during rehabilitation. Several studies have demonstrated the utility of EEG and EMG signals in decoding movement intention and execution, which can significantly improve the control of robotic devices in therapeutic settings [10][11]. By leveraging machine learning algorithms to analyze these signals, it is possible to develop more adaptive and responsive exoskeleton-assisted rehabilitation systems that cater to individual patient needs. This innovative approach enhances the efficacy of rehabilitation but also accelerates the recovery process for stroke survivors.

Soekadar et al.[12] research on brain computer interfaces (BCIs) for motor recovery, showing that EEG-based systems can facilitate functional restoration through neuroplasticity driven mechanisms. In this way other studies have demonstrated the effectiveness of combining EEG and EMG signals for movement classification in rehabilitation applications. Aly et al. [13] utilized deep learning approaches, such as CNNs with 192 layers and 24,576 neurons, achieving 95% accuracy for classifying wrist and hand movements. Similarly, Yang et al. [14] employed Pearson correlation coefficients and graph convolutional networks (GCN) to analyze EEG and EMG data, achieving 80.7% accuracy in distinguishing between hand opening, closing, and wrist movements. These findings underscore the potential of EEG and EMG integration for neuromotor rehabilitation.

In this study, we explore the integration of EEG and EMG signal analysis with machine learning techniques to classify hand movements commonly used in rehabilitation therapy. Our approach aims to provide a robust framework for understanding neuromotor processes and facilitating the development of intelligent robotic systems for stroke rehabilitation, but it also represents the first step toward understanding the evolution of cortical behavior in patients during therapy process.

II. Methods

In this work, we aim to analyze electrophysiological signals, such as electroencephalography and electromyography, during the execution of movements related to hand rehabilitation therapies in healthy subjects. Due to the importance of complex movements of the hand for activities of daily life and the scarce literature in dexterous movements, the exercises selected for this study were 4 individual finger pinches and hand closing. For this purpose, the experimental setup consists of synchronous acquisition of biological signals (EEG, EMG), followed by signal processing to extract features relevant to movements of interest, and intention/execution classification of the 5 movements (Fig. 1).

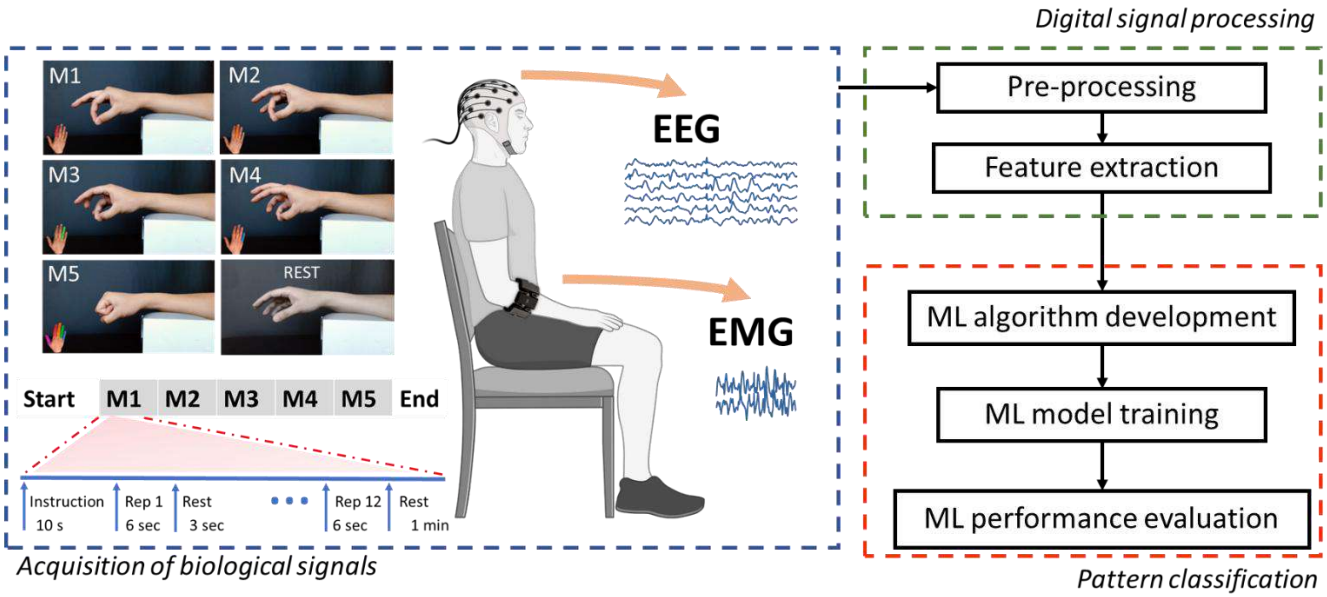

Fig. 1 General methodology diagram. The diagram outlines the sequential steps of the study, beginning with the synchronous acquisition of EEG and EMG signals from healthy subjects performing five hand movements (four individual finger pinches and a full hand closure)

A. Acquisition of Biological Signals

Twenty-two right-handed healthy subjects (12 males - 10 females; age 18 - 30 years) volunteered to participate in the study. From all of them, the informed written consent was obtained, following the approval of the Ethics Committee of the School of Engineering at Pontificia Universidad Javeriana, Bogotá, Colombia. The electroencephalography (EEG) data were collected with the USBAmp system (g.tec medical engineering, GmbH, Austria). A total of 28 electrodes were acquired at a sampling rate of 256Hz. The electrodes covered the frontal (F1-F4, FC1-FC4), motor (FCC3-FCC6, C1-C4), somatosensory (CCP3-CCP6), and parietal (CP1-CP4, P1-P4) cortical areas according to the 10-10 system. The electromyographic (EMG) signals were recorded with the Myo ARMBAND (Thalmic Labs, Canada) device. The 8 electrodes of the sensor were located superficially on the forearm and sampled at 200Hz (Fig. 2).

1) Experimental Procedure

Participants were asked to perform 5 different movements of the hand: 4 finger pinches (index, middle, ring, and little, all with the thumb), and full hand closure. The five distinct hand gestures are frequently used in rehabilitation therapy. To guide the participant along the experiment, the sequence of movements was presented in a video. Each movement was repeated 12 times, with each repetition lasting for 6 seconds followed by 3 seconds of rest between repetitions of the same movement, and 1 minute of rest between movements. Those times are based on previous project work [15].Therefore, we obtained 60 observations of 6 seconds per participant. The segments of 6 seconds were further divided into 2 segments of 3 seconds, one segment before and one segment after the

gesture execution. The signals were segmented into 3-second windows for movement intention classification (60 events), and 3-second windows for movement execution classification (60 events). Finally, the acquisition systems were synchronized using Universal Time Coordinated (UTC) to ensure precise alignment between EEG, EMG and movements.

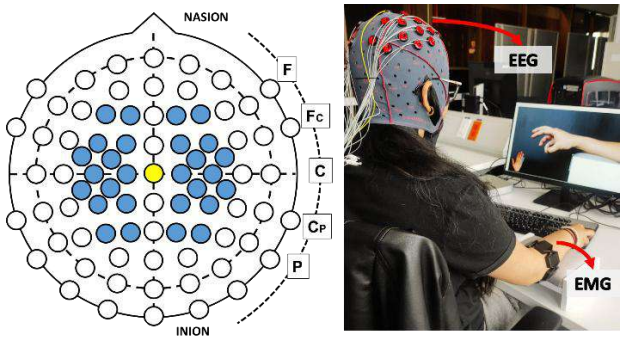

Fig. 2. Montage Acquisition, 28 channels F1-F4, FC1-FC4, FCC3-FCC6, C1-C4, CCP3-CCP6, CP1-CP4, P1-P4. And experimental Procedure set up.

B. Digital Signal Processing

1) EEG Signal Processing

The EEG signals were preprocessed, and features related to frequency and brain connectivity were extracted (TABLE I). To compute the frequency content of the signals, the power spectral density (PSD) was computed using Welch's method for each channel, and the mean power in 5 physiological frequency bands was computed for theta (4-8 Hz), alpha (8-12 Hz), low beta (12-18 Hz), high beta (18-30 Hz) and gamma (30-100 Hz) Fig. 3. Thus, the power for the 3-sec windows was obtained for 28 channels and 5 frequency bands, giving a total of 140 frequency features for classification purposes.

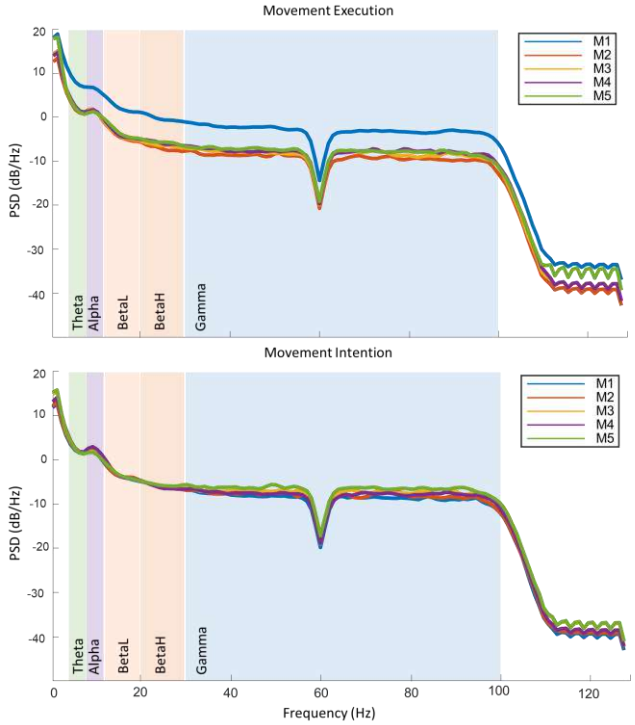

Fig. 3. Mean PSD for C3 channel of all Subjects, to each movement execution an intention.

The EEG signals were then filtered to divide the physiological bands and analyze brain networks, by means of brain connectivity measures. To filter the signals, Butterworth bandpass filters (n=4) were implemented for each physiological band. Moreover, power line interference at 60 Hz was removed using a notch filter. Subsequently, the Pearson's correlation was calculated from the filtered signal to determine the connectivity strength between different pairs of EEG electrodes. The weighted connectivity matrix was constructed, pairing all combinations of channels. (28x28). Then, we reduced the connectivity matrix into predefined regions of interest related to motor control processes, with electrodes grouped according to 3 anatomical locations: premotor, sensorimotor and sensory association cortices for left and right hemispheres (6x6). The values were averaged to obtain regional connectivity measures. Finally, graph theory metrics based on weights, such as clustering coefficient, path length, and node degree, were derived from the connectivity matrices (28x28) with the *Brain Connectivity Toolbox* from MATLAB. We then obtained a total of 420 brain connectivity features for classification purposes.

TABLE I
EEG FEATURES

Features	Equation
PSD	$PSD(f_m) = \frac{1}{N\Delta t}\lvert X_m^2\rvert\,;\ \Delta t = \frac{1}{fs}$
Pearson	$\lVert r_{ij}\rVert = \left\lVert \frac{Cov(X_i X_J)}{\sqrt{varX_i}\sqrt{varX_j}} \right\rVert$
Clustering coefficient	$k^w = \sum_{j\in N} W_{ij}$
Path lengh	$d_{ij}^w = \sum_{a_{uv}\in gi^w \leftrightarrow j} f(w_{uv})$
Node degree	$C^{\rightarrow} = \frac{1}{n}\sum_{i\in N} \frac{2t_i^w}{k_i(k_i-1)}$

2) EMG Signals Processing

On the other hand, the EMG signals were analyzed to extract features focused on measures to known to capture muscle activation dynamics (TABLE II) like mean absolute value (MAV), zero crossing rate (ZC), waveform length (WL), and variance (VAR). those related to the activity and frequency of muscle activation. These measures were computed for each of the 8 electrodes, obtaining a total of 40 features for EMG signals. These measures are highly reported in literature[16], [17], [18] and were previously used by our group[19], [20].

TABLE II
EMG FEATURES

Features	Equation
MAV	$\frac{1}{N}\sum_{i=1}^{N}\lvert x_i\rvert$
WL	$\sum_{i=1}^{N-1}\lvert x_{i+1} - x_i\rvert$
VAR	$\frac{1}{N-1}\sum_{i=1}^{N} x_i^2$
WAMP	$\sum_{i=1}^{N-1} f(\lvert x_i - x_{i+1}\rvert);$ $f(x) = \begin{cases} 1, si\ x \geq Threslhold \\ 0, si\ x < Threslhold \end{cases}$
ZC	$\sum_{i=1}^{N-1} f(x_i - x_{i+1}),$ $f(x_i, x_{i+1}) = \begin{cases} 1, if\ x_{i+1} > 0\ y\ x_i < 0 \\ 1, if\ x_{i+1} < 0\ y\ x_i > 0 \\ 0, in\ other\ case \end{cases}$

C. *Movement Classification*

Initially, the extracted features from both EEG and EMG initially analyzed separately to assess the individual contributions of each modality. Subsequently, these features were merged into a combined Feature matrix to get complementary information from neural and muscular signals. The resulting features matrices were partitioned into 70% for training and 30% for testing. To ensure robustness, k-fold cross-validation (k=5) was applied to the training set.

In the first phase, various machine learning models, such Ensemble Bagged Trees, Neural Networks, and SVMs, were evaluated to identify those with significant performance. The top-performing models from this inial evaluation advanced toi the hyperparameter optimization phase. During optimization, 20 variants of each ensemble tree type were generated using methods such as Bagging, RUSBoost, and AdaBoostM2. For SVMs, hyperparameters including box constraint level (ranging from 0.5 to 930), encoding type (one-vs-one and one-vs-all), and kernel scale (ranging from 150 to 700) were adjusted. For neural networks, the number of hidden layers and of epochs were modified to optimize performance. Finally, the model with the best performance was selected for different combinations of input features, including PSD and connective metrics for EEG and the features extracted for EMG.

III. Results

The preprocessing, feature extraction and classification methods were applied to the dataset collected from 22 healthy volunteers. After segmenting the signals, each subject contributes 60 events for identifying movement intention and 60 executions were obtained per subject. This gives a total of 2640 events. 1320 events for movement intention and 1320 events for movement execution used to train and test the algorithms.

Using Pearson's correlation, 28 x 28 channel feature matrix were obtained for different movements and frequency bands. The results of these matrices are shown in Fig. 4a where some regions exhibit a correlation coefficient of 1. To reduce the dimensionality of the matrix obtained and facilitate the physiological analysis, two strategies were applied: grouping by regions and extracting graph features, as was described in the previous section. Fig. 4b shows the connectivity matrices after grouping electrodes by neuroanatomical functions: premotor, sensorimotor and sensory cortex. The average value of the electrodes corresponding to each section was calculated. The motor region includes electrodes located at F and FC, the sensory-motor region includes the central line and adjacent positions FCC and CCP, and the sensory-association region includes CP and P. This was done for both hemispheres, obtaining 6 regions, as shown in Fig. 4b. The matrices shown are the average for the 12 repetitions of the subject, which shows a consistent network's behavior for some regions, in specific movements and frequency bands.

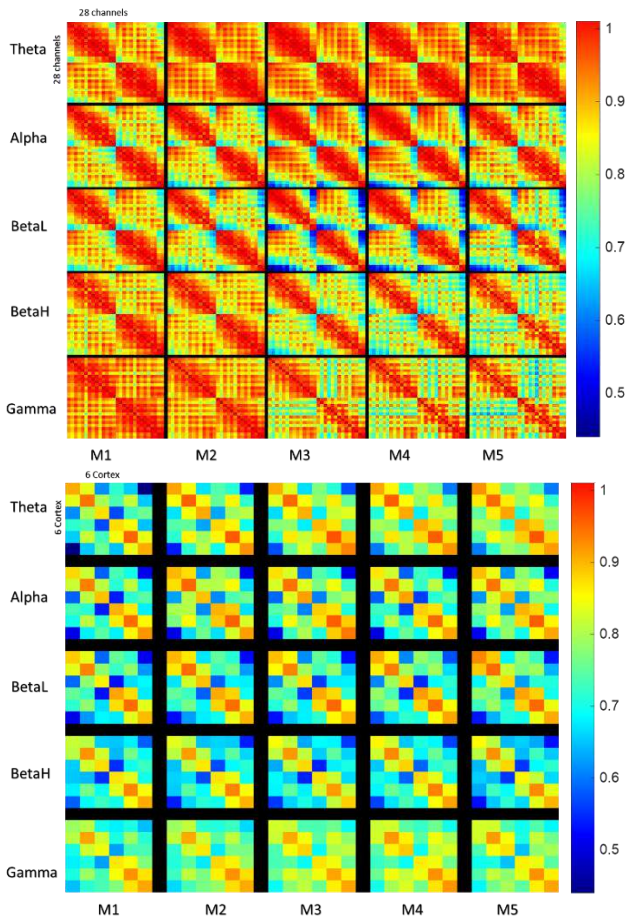

Fig. 4. a. Average Correlation Matrix from volunteer 14. All gestures all Band. b. Grouping Matrix From volunteer 14.

The extracted features were combined to train and test the selected machine learning algorithms. The initial models included Ensemble Bagged Trees, neural networks (medium and wide), and SVM, with accuracy being the primary comparison criterion, as it was a balanced dataset as shown on TABLE III. The Ensemble Bagged Trees model consistently showed better results, especially with brain connectivity and PSD features.

TABLE III
RESULTS FROM CLASSIFICATION LEARNER EXPLORATION

	Model	Movement Intention		Movement Execution	
		Training (%)	*Test (%)*	*Training (%)*	*Test (%)*
PSD	Ensemble Bagged trees	51.7	54.5	52.7	53
	Medium Neural network	38.2	36.4	38.2	39.9
	Wide Neural network	39.1	40.4	39.4	37.9
	SVM	39.4	38.9	38.6	37.6
Regions	Ensemble Bagged trees	38.3	38.4	34.8	39.4
	Medium Neural network	33.2	33.1	31.8	32.3
	Wide Neural network	34.0	37.4	30.7	33.8
	SVM	33.3	38.1	32.1	33.3
Graph	Ensemble Bagged trees	35.0	36.9	35.6	37.6
	Medium Neural network	33.4	31.8	31.2	32.3
	Wide Neural network	31.8	34.3	32.3	29.0
	SVM	31.9	31.3	30.2	36.6
EMG	Ensemble Bagged trees	66.2	65.8	82.1	85.6
	Medium Neural network	59.4	66.1	84.5	90.1
	Wide Neural network	67.4	72.2	85.8	86.3
	SVM	66.2	72.9	86.4	87.6

Subsequently, hyperparameters were optimized for Ensemble Bagged Trees (using methods such as Bagging, RUSBoost, and AdaBoostM2), SVM (adjusting box constraint level, multiclass coding, and kernel scale), and neural networks (varying the number of hidden layers and epochs). The top five optimized models for each approach were selected based on metrics such as accuracy, precision, recall, and F1-score. After the optimization, the best-performing model was Ensemble Bagged Trees with AdaBoostM2, configured with 464 learning cycles, a learning rate of 0.8642, and a minimum leaf size of three. This was the selected model to analyze different sets of features (Fig. 5), implicated in Movement Intention and Movement Classification.

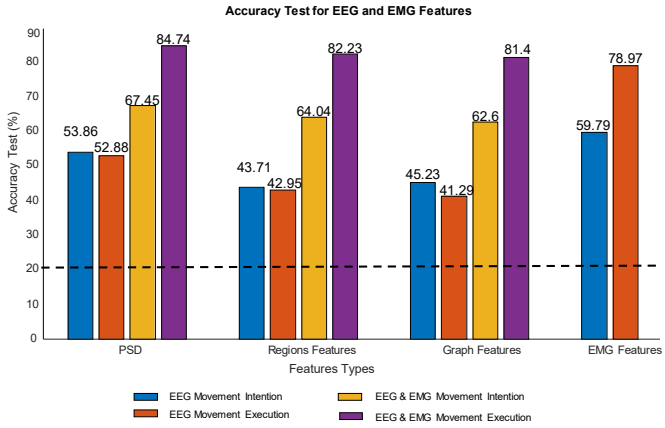

Fig. 5. Comparative accuracy chart of the optimized model using individual and combined EEG and EMG feature matrices.

IV. Discussion

In this work, we developed signal processing and machine learning techniques on EEG and EMG signals, to classify 5 hand gestures commonly used in rehabilitation therapy after stroke that involves global finger extension and flexion [21]. The aim is to advance the study of biological signals that could eventually help to understand neuromotor processes during movement and rehabilitation of the hand function. Moreover, the control of robotic devices to assist during therapies of the patients using biological signals is of great interest in research and clinical contexts. The models trained in this study outperformed the expected random chance level (20%) for 5-class classification. The Ensemble Bagged Trees model achieved the highest accuracy, with 84.74% for movement execution and 67.45% for movement intention. After a feature analysis, the power extracted from the PSD was the most effective for classification purposes.

The EEG analysis revealed significant differences between motor activity and resting states. Volunteers exhibited more random signals during rest and synchronized signals with pronounced peaks during execution, often reporting moments of drowsiness or relaxation. Correlation matrices revealed higher correlation patterns within brain hemispheres, with intra0-hemispheric interactions being more pronounced in the theta band and less pronounced in the low beta range. Furthermore, central EEG electrodes (FC to CP) showed the greatest interaction, highlighting the recruitment of neuronal groups near the motor region, these findings align with previous research indicating that theta and alpha waves play a crucial role in motor control and planning [10]. Theta and alpha waves exhibited more inter-hemispheric interaction, while frontal and parietal electrodes showed the least correlation, suggesting shorter signal transmission pathways.

Regional correlation matrices aligned with theoretical expectations. The left motor and sensory regions exhibited higher correlation values, particularly with alpha waves (mu waves), which diminish during movement execution. Significant interaction was observed between the primary motor-sensory and premotor regions in the left hemisphere for theta and alpha waves, increasing as movements were executed. Gestures involving the ring and pinky fingers consistently showed stronger correlations, which could be due to the increased effort to perform fewer common movements. Finally, comparisons between the classification of movement intention and movement execution patterns showed similar connectivity patterns, but lower values for movement intention. hese results suggest that early neural signatures of movement can be captured before execution, which is critical for rehabilitation strategies involving brain-computer interfaces and assistive robotics.

EMG signals exhibited rapid changes during movement execution, reflecting the action of agonist and antagonist muscles during hand opening and closing. The extracted EMG features, including MAV, WL, and ZC, contributed to the classification accuracy by capturing muscle activation dynamics. The integration of EEG and EMG features provided complementary information, reinforcing the potential of multimodal signal analysis for decoding movement intention and execution in neurorehabilitation contexts.

Our results match previous studies showing that theta and alpha brain waves are important for movement control and planning [10]. Higher theta wave connections between brain hemispheres may help prepare for movement, while lower alpha waves (mu suppression) happen when a movement is actively performed. These findings agree with Seta et al.[22], who used beta-wave brain signals to classify movements with 85% accuracy, highlighting the value of EEG connectivity in understanding and predicting movement.

Overall, these results suggest that classification of hand movements is possible with EEG and EMG signals, in different moments such as movement intention and execution. This approach holds great promise for rehabilitation applications, as it can support patient monitoring after a stroke and enhance the control of robotic exoskeletons during therapy. Future work should extend this analysis to stroke patients to validate its clinical applicability and explore adaptive models that personalize rehabilitation strategies based on individual neurophysiological responses.

Towards an Optimal Model of Post-Stroke Sensorimotor Control

Erica L. Waters[1], Reem Azar[2], Joana Opong-Duah[3], Samuel Gaardsmoe[4], Alwyn Johnson[5], Rochelle J. Mendonca[6], Pamela Z. Cacchione[7], Michelle J. Johnson[8]

***Abstract*— After stroke, motor control deficits are a common cause of disability. An optimal control model could provide insight into how motor and cognitive impairments influence post-stroke sensorimotor control. We present an initial attempt at modeling how post-stroke individuals perform a robot-based preview tracking task. Specifically, we fit a feedback controller with added delay and position bias to the impaired and less-impaired limbs of 11 stroke patients. We use an inverse linear quadratic regulator (LQR) to find the cost function for each participant. We also use linear regression to determine relationships between model parameters and clinical assessments of motor and cognitive impairments. Our main findings are that post-stroke sensorimotor control can be modeled as an optimal feedback controller and adding a delay and bias constant may improve the performance of this model. We also comment on how model parameters may be related to clinical assessments via linear regression. Future work should model more individuals and evaluate kinematic performance.**

I. Introduction

Stroke is a leading cause of disability among older adults [1]. Upper-extremity impairments are a common contributor to post-stroke disability [2]. Motor control deficits can be observed in kinematic performance of tasks [3], and these deficits persist even among stroke patients who demonstrate near or full recovery of sensorimotor function on standard assessments [4]. Despite the pervasive nature of motor control deficits, recovery of motor control is essential for true motor recovery. Deficits in motor control are particularly detrimental to functional task performance [5]. Improvements in motor control typically occur early after stroke incidence but can continue into the chronic phase [6]. A more complete understanding of post-stroke sensorimotor control would better inform post-stroke rehabilitation.

A model of post-stroke upper-extremity movement could provide insight into post-stroke sensorimotor control. Modeling post-stroke impairment, however, is complex. Stroke related sensorimotor impairments are highly heterogeneous, affecting both the contralesional ("impaired") and ipsilesional ("less-impaired") limbs [7]. Furthermore, post-stroke deficits on motor tasks may be influenced by cognitive impairments [8], [9], which are common post-stroke [10]. Modeling post-stroke motor control, therefore, requires a patient-specific approach that considers both limbs and accounts for cognitive deficits.

Optimal control modeling is commonly used to understand motor control. Over two decades ago, Todorov and Jordan proposed that human sensorimotor control is an optimal feedback control process in which goals may be quantified as cost functions that the human seeks to minimize [11]. Since then, researchers have employed optimal control techniques to model healthy human motor control on a variety of movements including posture control [12], reaching movements [13], and saccadic eye gaze [14]. Optimal control models are less studied for individuals with impairments, but a few models exist for impaired movements. For example, an optimal control model that accounts for Parkinson's tremors with a modeled delay [15] and an optimal control model of older adults with mild cognitive impairment in a walking obstacle crossing task [16]. Specific to stroke, Asghari et al. introduced a planar neuro-musculoskeletal arm model based on optimal control with "muscle significance factors" that modify the contribution of each muscle to the movement [17]. This model showed promising results but was only assessed on a simple point-to-point reaching movement. The model was also not assessed in the context of specific motor and cognitive impairments. Another interesting application of optimal control techniques to stroke modeling is to model the pre-stroke optimal behavior that stroke patients would have performed in order to create a biomechanical index that compares the impaired limb to the modeled pre-stroke limb [18]. To our knowledge, there has not been an attempt to model post-stroke individuals' motor control of a complex task featuring motor and cognitive components.

In this study, we propose an optimal control model of post-stroke sensorimotor control. We model the impaired

*Note: MoCA is reported out of 30, MoCA-EF is reported out of 5, FM is reported out of 66; all other metrics are reported as normalized z-scores.

and less-impaired limbs of 11 post-stroke participants and correlate various model parameters with clinical assessments of motor and cognitive function. We seek to (1) verify that an optimal control model is feasible for modeling post-stroke sensorimotor control on a tracking task and (2) understand how model parameters related to post-stroke motor and/or cognitive impairments.

II. Methods

A. Human Data

The data for this study come from the Rehabilitation Using Community-Based Affordable Robotic Exercise Systems (Rehab CARES) clinical trial (phase II), which aims to validate a robotic gym of 1-DOF TheraDrive rehabilitation robots for providing effective, affordable post-stroke upper limb rehabilitation in a community-based setting [19]. This protocol was approved by the Institutional Review Board of the University of Pennsylvania (protocol 853607).

This study is ongoing and plans to recruit 36 post-stroke individuals. Participants will complete therapy either with the robotic gym or standard of care over a period of 4-6 weeks. The study includes several pre- and post-clinical and robot-based assessments. In this paper, we analyze the pre-assessment data of the 11 participants enrolled in the study at the time of publication, including clinical evaluations and a robot-based assessment—trajectory tracking.

1) Participants: To enroll in the study, participants must be 55 or older, a requirement of the clinical location, with an official diagnosis of stroke at least 3 months prior to study start. All participants must have a CT Scan or MRI Scan completed post-stroke onset. All participants must have hemiplegia, with a Fugl-Meyer Upper Extremity (FM) score between 15 and 60. Participants are excluded if they present severe spasticity, greater than moderate language difficulties, or greater than moderate depression.

At the time of this paper, 11 participants are included in the study. This group is used as preliminary data for the development of the proposed optimal control model. These participants completed the pre-assessment phase of the study, including clinical assessments and robot-based assessments.[1] Table I shows participants' demographic information.

[1]Participant 012 did not complete the trajectory tracking task with their impaired limb. All other participants completed the task with both limbs.

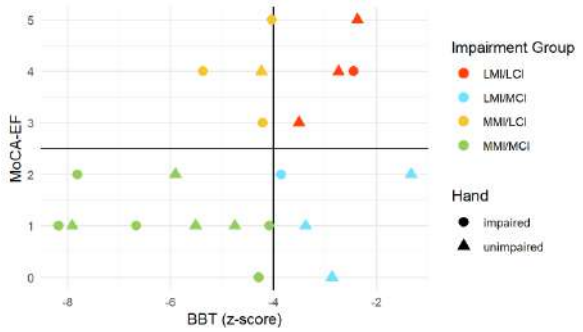

Fig. 1: Participants' impaired and less-impaired limbs sorted into impairment group by normalized BBT and MoCA-EF. A BBT cut-off score of four standard deviations below the norm (BBT z-score = 4) indicates moderate motor impairment; a MoCA-EF cut-off score of 2.5 out of 5 possible points indicates moderate cognitive impairment.

2) Clinical Assessment: A battery of cognitive and motor assessments are used to determine the level of functioning. Figure 1 shows participants sorted according to motor and cognitive impairment levels. Cognitive assessments include the Montreal Cognitive Assessment (MoCA), which targets multiple domains of cognitive function, including visuospatial/executive function, naming, memory, attention, language, abstraction, delayed recall, and orientation [20]. A score of 26 out of 30 indicates normal cognitive functioning across these domains. An executive function subscore—MoCA-EF—is also calculated out of 5 [20]. Participants also complete the Color Trails parts 1 and 2. This pair of tests are used to determine impairment in selective attention, sequencing, visual-spatial skills, mental flexibility, and motor speed. Performance is assessed as the time taken to complete each task; a shorter time indicates better performance [21]. The motor assessments include the Blocks & Box task (BBT), which assesses gross motor function by asking participants to move blocks from one side of a box to the other in one minute [22]. The Grooved Pegboard (GP) task is used to assess fine motor skills with an added cognitive component, and a lower completion time equals a better performance [23]. An occupational therapist administers the FM assessment to the impaired limb. Table I provides the clinical scores for all participants.

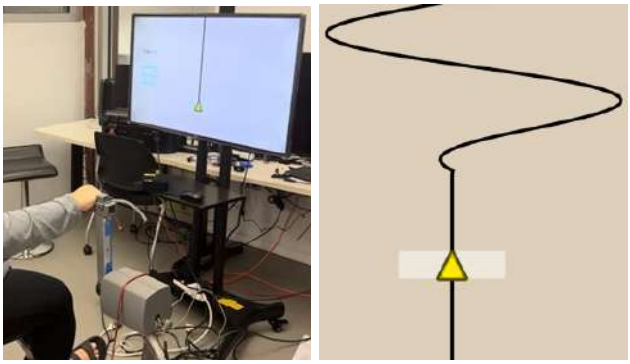

Fig. 2: TheaBot robot and trajectory tracking task

For analysis purposes, participants' hands are sorted into four impairment groups: low motor impairment and low cognitive impairment (LMI/LCI), low motor impairment and moderate cognitive impairment (LMI/MCI), moderate motor impairment and low cognitive impairment (MMI/LCI), and moderate motor impairment and moderate cognitive impairment (MMI/MCI). The motor impairment group is defined by normalized BBT because BBT is a measure of gross motor function and is performed on both hands. The cognitive impairment group is defined by MoCA-EF because MoCA-EF is sensitive to cognitive deficits relevant to the trajectory tracking task [9]. Figure 1 shows the participants' hands sorted into each of these four groups.

3) Robotic Interface: TheaBot, developed by Recupero Robotics, LLC, is based on the Haptic TheraDrive robot [24]. TheaBot is now a standalone robot mounted on a movable base and is interfaced with a custom assessment and therapy gaming suite developed in collaboration with EnAble Games, LLC. The 1-DOF robot is equipped with Picasso Intelligence Gemini motors. The robot is re-configurable and can be placed in 3 positions that cover shoulder, elbow, and wrist range of motion from 135 degrees to -135 degrees. These positions can be adjusted based on participant need. Figure 2 shows the TheaBot robot in position 1.

4) Trajectory Tracking Task: The trajectory tracking motor task is designed to assess motor performance by asking the player to follow a pseudo-sinusoidal wave [9], [24]. In a single trial, the user moves the crank arm forward and backward to follow the path for 15 seconds. Figure 2 shows the trajectory tracking task and a user performing the task. Participants complete 15 trials of this task. The displayed trajectory is the same each time. To account for effects of learning and fatigue, only the middle five trials are used to fit the models described in the next section.

B. Modeling Approach

1) System State Equations: For this initial implementation, we simplify the system dynamics to a point mass in discrete time such that the dynamics may be represented as in Equation 1.

$$x_{k+1} = Ax_k + Bu_k \tag{1}$$

In Equation 1 x_k is the system state and u_k is the control output or torque applied by the human operator to the robot at time step k. We define A and B in Equation 2 and Equation 3 where Δt represents the time step.

$$A = \begin{bmatrix} 1 & \Delta t \\ 0 & 1 \end{bmatrix} \tag{2}$$

$$B = \begin{bmatrix} 0 \\ \Delta t \end{bmatrix} \tag{3}$$

We recognize that this simplified model will not capture the full complexity of human sensorimotor control, but we believe that it may be sufficient to represent the overall behavior in this preview tracking task. Furthermore, a similar simplified representation has been used to model healthy participants in a pursuit tracking task [25].

2) Feedback Control Model: The human model is based on a simple feedback controller with a gains on error in position (K_p) and velocity (K_v), similar to Takagi et al. [25]. We modify the model to better represent post-stroke impairment. Specifically, we adjust the target trajectory with two constants: a delay term (γ) and a bias term (ζ).

The feedback controller is in Equation 4.

$$u_k = -Kx_k = -\begin{bmatrix} K_p & K_v \end{bmatrix} \begin{bmatrix} \theta_{t,k+\gamma} - \theta_{h,k} + \zeta \\ \dot{\theta}_{t,k+\gamma} - \dot{\theta}_{h,k} \end{bmatrix} \tag{4}$$

In Equation 4, $\theta_{h,k}$ and $\dot{\theta}_{h,k}$ represent the angle and angular velocity of the human while $\theta_{t,k}$ and $\dot{\theta}_{t,k}$ represent the desired angle and angular velocity of the target.

TABLE II: Feedback control models

Model	Description	Tuned Parameters
M1	standard model ($\zeta = 0$, $\gamma = 0$)	K_p, K_v
M2	bias model ($\gamma = 0$)	K_p, K_v, ζ
M3	delay model ($\zeta = 0$)	K_p, K_v, γ
M4	bias and delay model	K_p, K_v, ζ, γ

Table II shows the four model variations that we explore. The most basic is M1, which only tunes the feedback control gains. Some participants, however, present with a clear bias to one side such that their trajectory is not centered around zero, and M1 fails to solve (Figure 3B). We propose M2 to account for bias, which is calculated by finding the average of the medians of the participant's trajectories. The displayed trajectory has a median of zero, so a median other than zero may indicate a shifted range of motion—i.e. a "bias" to one side or the other. We likewise observe that some participants follow the trajectory but are delayed in their response (Figure 3C). M3 accounts for delay by finding the average lag corresponding to the maximum cross correlation between the participant's trajectory and the target trajectory. M4 combines M2 and M3 with both bias and delay. Feedback control gains for all models are tuned with least squares to minimize the error in position and velocity. Delay and bias terms are added to the model prior to this optimization for M2, M3, and M4.

3) Inverse Optimal Control: We define the inverse optimal control problem as an inverse linear quadratic regulator (LQR) problem. In LQR, we may seek to minimize the cost function in Equation 5 such that we obtain an optimal set

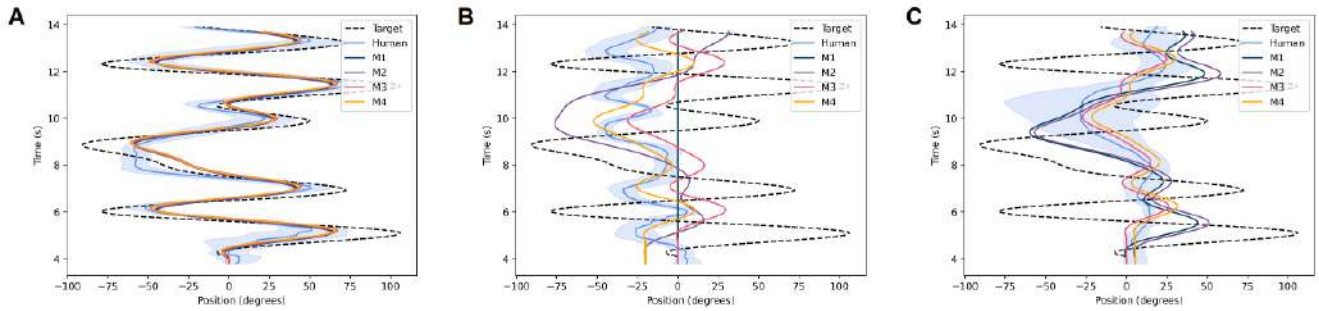

Fig. 3: Exemplar plots of 3 participants' actual and modeled trajectories. The blue line represents the average actual trajectory, and the shaded area represents the standard deviation across all 5 trials. **A:** Participant 011, impaired arm in the LMI/LCI group; all models perform similarly. **B:** Participant 003, less-impaired arm in the LMI/MCI group; M4 performs best. **C:** Participant 002, less-impaired arm in the MMI/MCI group; the M3 and M4 models perform best.

of control gains K for the feedback controller described in Equation 4 with $Q \succeq 0$ and $R \succ 0$, where Q is the state cost matrix and R is the control cost matrix.

$$J = \sum_{k=0}^{\infty} x_k^T Q x_k + u_k^T R u_k \tag{5}$$

This optimal value of K may be computed according to Equation 6.

$$K = (B^T P B + R)^{-1}(B^T P A) \tag{6}$$

We define P as the unique, positive definite solution to the discrete time algebraic Riccati equation in Equation 7.

$$A^T P A - P - (A^T P B)(B^T P B + R)^{-1}(B^T P A) + Q = 0 \tag{7}$$

We may solve the inverse LQR problem according to the linear matrix inequality and gradient descent method employed by Priess et al. [12]. In this method, they describe using linear matrix inequalities to ensure uniqueness of solution. Their problem formulation in discrete time is provided in Equation 8 – Equation 12.

$$(\hat{Q}, \hat{R}, \hat{P}, \hat{\alpha}) = \arg \min_{Q,R,P,'\alpha} \alpha^2 \quad s.t. \tag{8}$$

$$P \succeq 0 \tag{9}$$

$$A^T P A - P - A^T P B K + Q = 0 \tag{10}$$

$$B^T P A - (B^T P B + R) K = 0 \tag{11}$$

$$I \preceq \begin{bmatrix} Q & 0 \\ 0 & R \end{bmatrix} \preceq \alpha I \tag{12}$$

If Equation 8 is infeasible (no exact solution exists for the inverse LQR problem), then they suggest approximating the cost function parameters by using gradient descent to reduce the error between the actual control gains K and the estimated control gains $\hat{K}$ according to the minimization problem in Equation 13 with $\zeta = [Q_{11}, Q_{12}, Q_{22}, R_{11}]$.

$$\hat{\zeta} = \arg\min_{\zeta} \|\hat{K}(\zeta) - K\|_F^2 \tag{13}$$

We then use the analytical gradient of the cost in Equation 13 to minimize the difference between the estimated control gains $\hat{K}$ and the actual control gains K; more information about this problem formulation is available in their original publication [12].

C. Data Analysis

1) Feedback Control Model Selection: Performance of the four feedback models is assessed with root mean square error (RMSE) between the modeled trajectory and the average human trajectory across the five trials, for each participant/hand. The feedback controller (M1, M2, M3, or M4) with the best RMSE is selected for all other analyses.

2) Inverse Optimal Control Analysis: The inverse optimal control approach is analyzed by comparing the feedback controller gains that were initially found with least squares and then approximated with LQR. Specifically, we use a paired Mann-Whitney U test to compare the controller gains (Kp or Kv) between each method of gain fitting.

3) Linear Regression Analysis: The influence of motor and cognitive impairment on various model parameters are assessed with linear regressions. The model parameters include: elements of the state cost matrix (Q_1, Q_2, Q_3), the response cost (R), the delay constant, and the bias constant. The four parameters associated with the optimal controller (Q_1, Q_2, Q_3, R) are cube root transformed to create a more even distribution. Due to a low sample size (impaired limb n = 10 and less-impaired limb n = 11), only one metric is used to predict each parameter for the separate analyses. The independent variable for each model is selected based on which clinical assessment score had the highest correlation with the dependent variable. Prediction strength is set at $r^2 \geq 0.25$ for a mild prediction, $r^2 \geq 0.5$ for a moderate prediction, and $r^2 \geq 0.75$ for a strong prediction.

III. Results

A. Model Performance

Figure 3 shows the actual and modeled trajectories for three exemplar participants/hands (011 impaired, 003 less-impaired, 002 less-impaired). Figure 4 shows the performance of the four models. From the figure, it is clear that although all models perform fairly well for the LMI/LCI participant (011 impaired) but M4 performs better for the LMI/MCI participant (003 less-impaired) and MMI/MCI participant (002 less-impaired). Figure 4 shows that all of the models have fairly similar performance in terms of RMSE with no significant differences, but M4 performs slightly

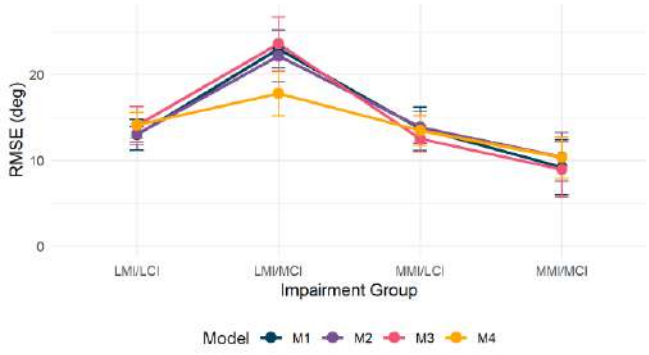

Fig. 4: Median and standard error of model RMSE for all modeled participants/hands separated by impairment groups

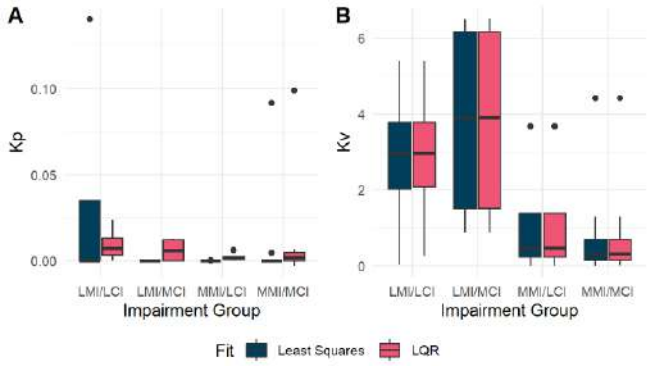

Fig. 5: Box plots comparing the control gains tuned with least squares fit and calculated with LQR. **A**: K_p gains are close to zero for all groups, regardless of fit. **B**: K_v gains are similar for both Least Squares fit and LQR fit. K_v is higher for the LMI groups compared to the MMI groups.

better for the LMI/MCI group. For this reason, M4 is selected to proceed in the analysis.

B. Inverse Optimal Control Analysis

Figure 5 shows the feedback gains for each impairment group. The paired Mann-Whitney U shows no significant differences between the feedback gains (Kp and Kv) fitted with the least squares and inverse LQR approaches. As shown in Figure 5, Kp is overall very low, with the mean for all groups falling very close to zero. Furthermore, Kv tends to be higher for the higher motor function groups (LMI/LCI and LMI/MCI) than the lower motor function groups (MMI/LCI and MMI/MCI).

C. Linear Regression Analysis

Figure 6 shows the Pearson correlation coefficients (r) between all clinical assessments and all model parameters for both the impaired and less-impaired limbs. The clinical assessment score with the highest correlation is chosen as the independent variable in the linear regression model for each model parameter (Q_1, Q_2, Q_3, R, delay, bias). $Q1$'s highest correlation is moderate (CT1, $r = 0.65$) in the impaired limb and mild (BBT, $r = 0.24$) in the less-impaired limb. $Q2$ has moderate correlations with cognitive metrics in both limbs with CT2 ($r = 0.56$) for the less-impaired limb and MoCA-EF for the more impaired limb ($r = -0.52$). $Q3$ likewise has mild correlations with cognitive metrics in the less-impaired limb (MoCA, $r = -0.34$) and impaired limb (MoCA-EF, $r = -0.28$), respectively. R also has mild correlations with cognitive metrics for the less-impaired limb (CT2, $r = 0.31$) and the impaired limb (CT1, $r = -0.35$). Bias is most related to a cognitive metric (MoCA-EF, $r = -0.5$) for the less-impaired limb, but for the impaired limb, it is most related to a motor metric (FM, $r = -0.71$). Delay is most correlated with BBT in both the less-impaired limb ($r = -0.52$) and the impaired limb ($r = -0.74$).

Figure 7 shows the linear regression results for the less-impaired limb. BBT is a poor predictor of Q_1 with the model explaining less than 6% of the variance in Q_1 ($r^2 = 0.0567$). MoCA and CT2 are likewise poor at predicting Q_3 and R, respectively ($r^2 = 0.118$, $r^2 = 0.095$). $CT2$, $MoCA - EF$, and BBT are mildly predictive of $Q2$, bias, and delay, respectively ($r^2 = 0.315$, $r^2 = 0.249$, $r^2 = 0.272$).

Figure 8 shows the linear regression results for the impaired limb. MoCA-EF and CT1 are poor predictors of Q_3 and R, respectively ($r^2 = 0.0774$ and $r^2 = 0.123$). CT1 and MoCA-EF are mild predictors of Q_1 and Q_2, respectively ($r^2 = 0.426$, $r^2 = 0.275$). CT1 explains 43% of the variance in Q_1, and MoCA-EF explains 28% of the variance in Q_2. Bias and delay each have a moderately predictive model. FM-UE explains 50% of the variance in bias ($r^2 = 0.504$), and BBT explains 55% of the variance in delay ($r^2 = 0.548$).

IV. Discussion

We present an inverse optimal control model of post-stroke sensorimotor control on a preview tracking task. Our results indicate that a subset of post-stroke participants can be represented by a simple feedback control model with a delay and bias constant. All four feedback control models perform similarly in this analysis, but M4 shows a modest improvement in RMSE for the LMI/MCI group, Figure 4.

The difference in model performance across groups may be explained by the fact that only some participants exhibit a delay or a bias term. Figure 3A shows that a participant/hand with low motor and cognitive impairment, like 011's impaired limb, may not have a large bias or delay. Because M1 is the same as M4 just with bias and delay set to zero, these values being low in M4 will result in very similar trajectories between M1 and M4. The model, however, shows noticeable improvements for participants with delay or bias. Participant 002's less-impaired limb in Figure 3C displays a pronounced delay. M1 approximates the movement, but M3 and M4 show much better fits with the actual behavior. The addition of a bias term in M2, however, does not improve performance over M1 for this participant due to low bias in the behavior. Conversely, as shown in Figure 3B, 003's less-impaired limb has a pronounced bias to the negative side. This bias seems to prevent M1 from solving at all, resulting in a trajectory with no movement. M2, however, uses the bias to adjust and achieves non-zero movement. Participant 003 also has a clear delay; the addition of a delay term in M3 results in

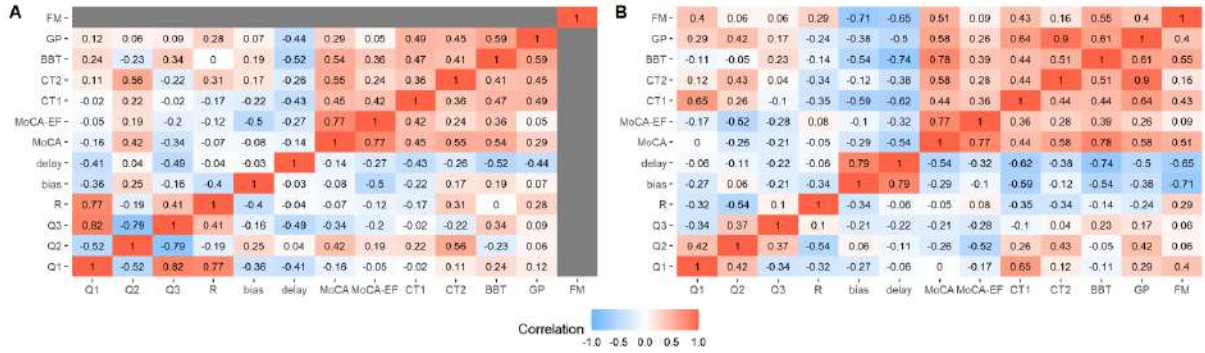

Fig. 6: Heat map of Pearson correlations between model parameters and clinical assessments. (A) Correlations for the less-impaired limb (B) Correlations for the impaired limb

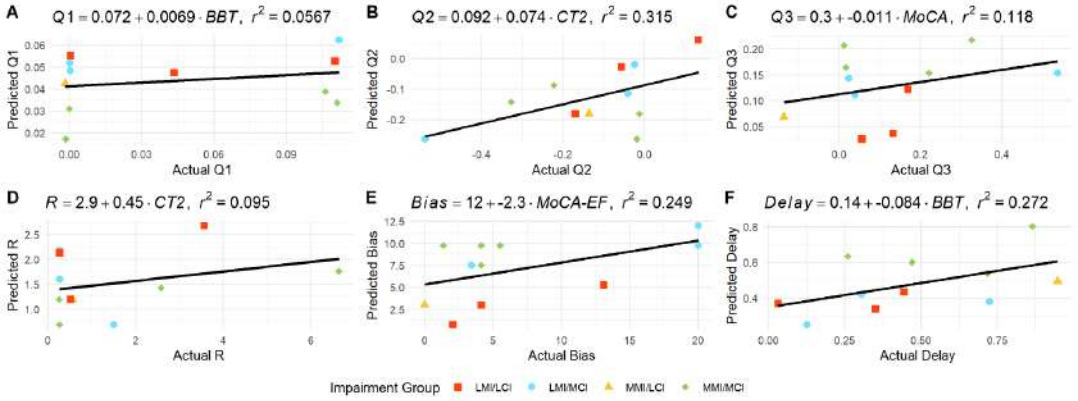

Fig. 7: Linear regression results for less-impaired limb model parameters

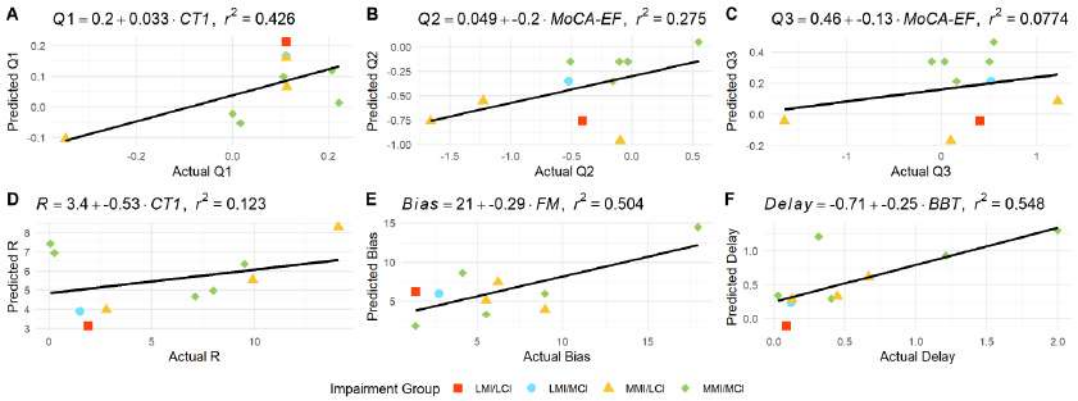

Fig. 8: Linear regression results for impaired limb model parameters

better performance than M1. The combination of both bias and delay terms in M4 allows the best fit. Taken together, these results suggest that the bias and delay terms in M4 may help to account for differences in tracking behavior due to motor and cognitive impairments.

This paper also supports that inverse optimal control can be used to identify a cost function employed by individuals with varying levels of post-stroke motor and cognitive impairment. The inverse optimal control method performs well, producing feedback control gains that are almost identical to the least squares fit feedback controller. The control gains are close to zero for the gain on position K_p, which may indicate that post-stroke participants rely on target velocity more than the position in a preview tracking task.

The linear regression analysis shows mixed results at predicting model parameters. Interestingly, the linear regression analyses perform better for the impaired limb than for the less-impaired limb. This result could be due to less overall spread in the motor assessment data for the less-impaired limb. Another explanation is a learning bias affecting performance in the less-impaired limb influencing model fit. During assessment, participants perform the trajectory tracking task with their less-impaired arm first, meaning they are still familiarizing themselves with the task, which may lead to higher motor variability across trials. By the time they complete the task with the impaired arm, they have

completed fifteen trials with the less-impaired arm and better understand the task, which may reduce motor variability.

The delay model has moderate predictive power for the less-impaired limb and mild predictive power for the impaired limb. Interestingly, delay is correlated with BBT for both limbs. Although BBT is a motor assessment, it is time-based and may involve a cognitive component [8]. The bias model also performs better for the impaired limb than the less-impaired limb with moderate and mild predictive powers, respectively. Interestingly, bias is associated with a motor impairment metric (FM) in the impaired limb but a cognitive metric (MoCA-EF) in the less-impaired limb. Similarly, models for $Q1$ show mild predictive power for the impaired limb but very poor predictive power for the less-impaired limb. The models of $Q2$ are moderately predictive for both limbs. Finally, models for $Q3$ and R are not highly predictive, indicating that a larger sample size and/or expanded set of clinical assessments may be necessary. We note that with the exception of the less-impaired $Q1$ model, all cost function parameters are most highly correlated with cognitive assessment scores. This result highlights the extent to which cognition influences sensorimotor control.

Limitations include a small sample size, exclusion of healthy participants, and a lack of severely motor impaired participants. Future work should investigate the model with a larger population. Likewise, more in-depth system identification, including tasks with higher movement frequency, could increase the complexity and fit of the model. Finally, a more robust and complete analysis of the model, perhaps on a kinematic level that considers limb dominance is necessary.

Manipulation of sensory information in competitive scenarios induces adaptive changes in action selection: insights for neurorehabilitation

***Abstract*—Competitive settings may be promising for neurorehabilitation as they may lead to stronger patient motivation. However, the mechanisms underlying the development of an interaction in competitive settings are not well understood. We use a dyadic haptic interface to investigate the dynamics of competitive interaction. Pairs of participants engaged in a ball game (a penalty kick challenge), with an attacker and a defender. To explore how the participants adapt to each other over game iterations, we manipulated the amount of information available to each one about the location of their opponent. We found that under the different experimental conditions, the participants adjusted their behavior in response to their opponents' strategy change. These observations are consistent with simulations with a computational model assuming that during interaction the participants use optimal (Bayesian) perception and action selection (based on game theory). Taken together, experiments and simulations suggest that the participants develop and update a flexible, adaptive predictor of their opponents next action, which helps them adjust their behavior to optimize performance. These findings provide a foundation for further research into the mechanisms that drive adaptive behavior in competitive scenarios, and provide new insights into how competitive environments can be used in rehabilitation.**

***Index Terms*—competitive games, joint action, optimal control**

I. Introduction

Neuromotor recovery is facilitated by repeated task-oriented movements of the impaired limb. Stroke survivors typically perceive using the impaired limb as more costly than using the intact limb or, more in general, than using compensatory strategies that rely on the spared body movements [1]. Therefore, the exercises used in neuromotor rehabilitation should not only focus on training the impaired limb, but also need to be sufficiently engaging to counteract their perceived greater cost.

Competitive games have high potential in neurorehabilitation due to their ability to maintain motivation and adherence to treatment [2]. Competitive games involving two players have been reported to be more effective than similar tasks in single-player mode in maintaining a high level of engagement and exercise intensity [3], [4]. Likewise, dyadic haptic communication in a competitive scenario may lead to a greater active effort than in a similar cooperative task [5]. Game modality also influences the physiological response. It has been suggested [6] that training through a competitive two-player game modality resulted in higher physiological responses when compared to the single-player and cooperative modes. A study on different forms of therapeutic games with subacute stroke patients underlined that patients preferred competitive modalities to cooperative ones both in terms of engagement and intensive game play [7]. Moreover, the use of serious games that can adapt the difficulty based on the patient strategy could be a valuable approach in the upper limb rehabilitation to improve training outcomes [8], [9]. A review on human-machine-human interaction in motor control and rehabilitation settings [10] revealed that, although the benefits of different interaction modalities and partner characteristics are still unclear, the study of optimal personalized interaction may lead to the development of more effective exercise protocols.

In joint action in general and competitive scenarios in particular, the actions of each participant are determined by the (predicted) reaction of their opponent. The emerging coordination strategy is influenced by the amount of information that each player has available about their partner [11], [12].

Dyadic haptic interfaces are useful tools to study these mechanisms as all aspects of interaction (haptic, visual) can be manipulated. For instance, haptic coupling between two participants can lead to an improvement of the performance of the partner that initially exhibits poorer performance [5]. Likewise, haptic coupling during an ankle tracking task improves the performance of the worst partner [13].

While cooperative dyadic tasks have been extensively studied, competitive interactions remain less understood. In a competitive scenario, humans accumulate sensory evidence to predict the action intentions of their opponents [14]. The behavior of baseball batters, for instance, has been interpreted [15] in terms of Bayesian models, showing that they manage

pitch uncertainty by optimally integrating prior information with real-time observations.

The study of the mechanisms underlying how, in competitive games, each player understands (perceives) and predicts (takes decisions) the opponent's actions may lead to new insights in the developpent of rehabilitation games that can adapt the difficulty on the patient action selection strategy and use principles of optimality in the interaction.

The aim of this study is to understand how two players change their own action selection in a competitive scenario according to the behavior of the partner. In particular, we use a haptic version of a ball game (penalty kick) to study whether and to what extent competitors account for the sensory information (knowledge about partner location) they have available about their partner.

II. Materials and Methods

A. Task and experimental protocol

The task involves two players, an attacker (A) and a defender (D). They cannot see and hear each other. Each player sits in front of a computer screen and grasps the handle of a robot manipulandum (H-MAN, Articares) [16], as in Fig. 1. Both are constrained to move within a horizontal line (implemented as a haptic channel). On the computer screen each participant sees the game state in a subjective view by displaying their location along a horizontal line on the lower portion of the screen and the opponent on the upper portion of the screen; see Fig. 1. An elastic force (virtual spring) pulls each handle toward the center of each player's horizontal line, thus creating a preferred region for both participants. Each competitor is also aware of the position of the opponent's elastic force thanks to a green spring displayed above the opponent's line to provide a prior information about the partner.

At the beginning of each trial, both players are asked to move to a start position right at the center of their horizontal line. At the start of the trial, both the attacker and the defender are free to move along the horizontal line. The attacker's goal is to shoot a ball (yellow circle) in a vertical direction. The ball is fired by exerting a vertical force on the wall of the haptic channel. The defender must try to intercept the ball before it crosses the horizontal line. The attacker may shoot the ball at any time. Once shot, the ball moves at a constant speed of 3 m/s, too high to be trackable by the defender by reactive movements. However, the defender can try to predict where the attacker will shoot the ball and elicit a corrective movement to compensate for its own displacement from the attacker at the time instant when the ball is shot. After the ball is shot each player receives the information about the partner's location at that trial and at the moment of shooting/receiving (depending on the role) the ball, as in Fig. 2. In particular, the attacker sees the receiving defender's position on the upper horizontal line on the screen. The defender sees the ball once it is shot, which is equal to seeing the attacker's position since the ball is fired on a vertical line.

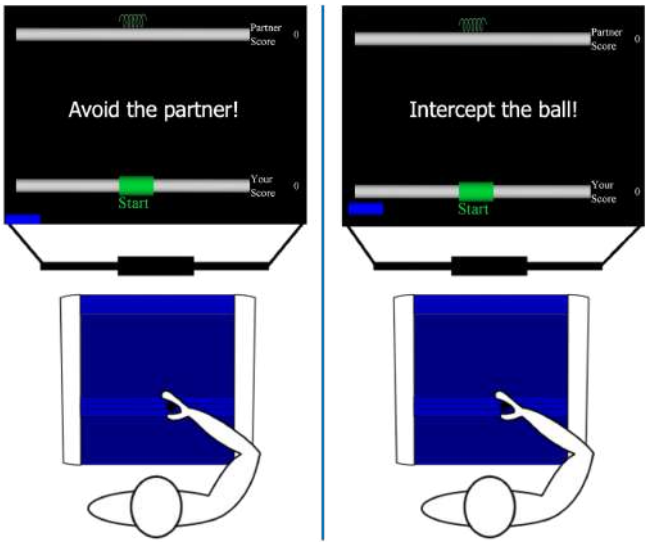

Fig. 1. Experimental apparatus and task. Attacker (left) and defender views (right)

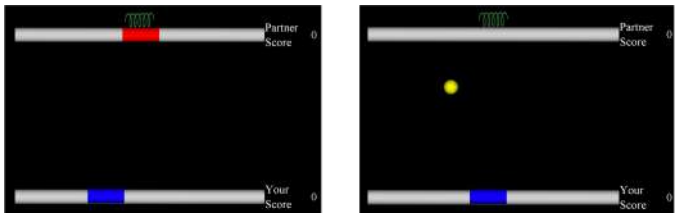

Fig. 2. Attacker (left) and defender (right) views after the ball is shot (Z-Z condition, i.e. each player has a perfect view of their opponent)

To understand if the performance is affected by the uncertainty about partner location (sensory information), in different experimental blocks we varied the uncertainty Σ_y on the visual display of the position of the opponent for player A or the ball for player D: (i) Zero (Z): opponent/ball location is fully visible ($\Sigma_y = 0$); (ii) Low (L): opponent/ball location displayed a cloud of random dots with a Gaussian distribution ($\Sigma_y = 0.08$) on the horizontal axis; (iii) Inf (I): opponent/ball location not visible ($\Sigma_y = \infty$).

We recruited 12 participants (five male and seven female, aged 24-27 yo) and randomly assigned them to each dyad. All participants signed a consent form before starting the experiment. Each participant played one fixed role, either A or D. The experimental protocol was organized into blocks (epochs) of 30 trials each, with a randomized block design. A familiarization block with $\Sigma_y = 0$ of a pass ball game was followed by nine blocks of competitive play (total 300 trials). Within each epoch, we varied the sensory information (Σ_y^A and Σ_y^D) of both players.

B. Computational model

We used a probabilistic computational model [12] to simulate the time series of the attacker and the defender actions under all experimental conditions. The model uses a trial-by-trial development to describe the joint coordination and the

time series of players; in this case, we modeled it as a non-cooperative game.

Specifically, the model assumes that each agent (i) uses Bayesian principles (Kalman filter) to predict the next action of their opponent, and (ii) selects the action minimizing their expected cost, given the expected action of their opponent; see Figure 3. Each player knows their own goals but not their opponent's and has imperfect information about their opponent's actions. On each trial t, the i-th player chooses their action, $u_i(t)$, based on the expected opponent action, $x_i(t) = \hat{u}_{\infty i}(t)$. Both players collect information $y_i(t)$ about their own and their partner's actions through their sensory systems, and use such information to update their prediction of the action of their opponent, which is taken into account when selecting the next action.

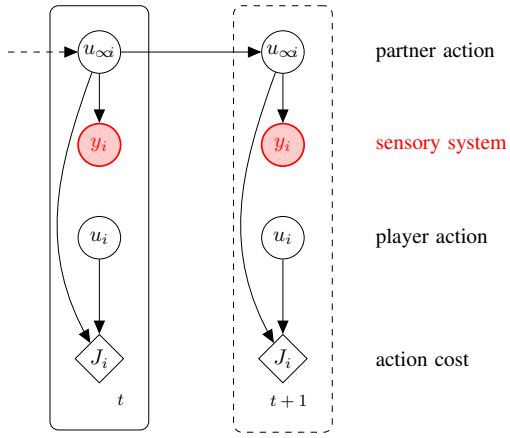

Fig. 3. Probabilistic graphical model (influence diagram) of a player in a generic joint action game. At each time step, Player i receives information about partner action (u_{-i}) through their sensory system (y_i). The player assumes that opponent actions depend on previous actions and combines this prior information with sensory feedback to predict the opponent's next action. Action selection involves minimizing a cost function (J_i) which depends on both own (u_i) and partner's action (u_{-i}). See [12] for details

The model is very general, and a specific task is encoded by the players' cost function. To model the competitive scenario, we assumed that the attacker's goal is to maximize the distance from the defender's position, while the defender's goal is to minimize the distance from the attacker's position. In addition, both players try to minimize their effort (spring force, i.e. the distance from the workspace center). The cost functions are defined as:

$$\begin{aligned} J_A(u_A, u_D) &= -\frac{1}{2} w_A |u_A - u_D|^2 + \frac{1}{2} r_A |u_A|^2 \\ J_D(u_A, u_D) &= \frac{1}{2} w_D |u_A - u_D|^2 + \frac{1}{2} r_D |u_D|^2 \end{aligned} \quad (1)$$

where parameters w_A and w_D control the minimum displacement from the partner to score the goal, whereas r_A and r_D control the weight of each player's effort. The sensory system is defined as:

$$y_i(t) = u_{\infty i} + v_i(t) \quad (2)$$

where

$$v_i(t) \sim N(0, \Sigma_y^i)$$

is the sensory (measurement) noise of the i-th player, with covariance Σ_y^i. In the simulations, we varied the sensory noise of each player among the three conditions: (i) Zero, $\Sigma_y^i \to 0$; (ii) Low, $\Sigma_y^i = 0.08$; (iii) Infinite, $\Sigma_y^i \to \infty$.

Based on the computational model of interaction and the experimental task we expected that each player uses principles of optimality to choose their strategy. The action selection at each trial would be balanced between the minimization of the effort (try not to move so far from the virtual spring that pulls the handle toward the center of the workspace) and the achievment of each competitor's goal.

C. Data analysis

The study aimed to understand how much players account for the differences in the visual display of the partner location (sensory system) giving some prior information about the preferred partner's region in the workspace.

In both experiments and simulations, we focused on the spatial distribution of A and D actions within the workspace. We took the attacker action u_A as the position in the horizontal line when the ball is shot. Likewise, we took the defender's action u_D as the horizontal position when the ball crosses the gate line. For each block, as the players were not informed about the changing conditions, the first five trials were excluded from the analysis.

We used a Gaussian mixture model to describe the joint probability density function of attacker and defender, $p(u_A, u_D)$. For each dyad and each experimental condition, we tested different variants of the model, with a different number of clusters (one, two, three or four) and different covariance structures (diagonal, non-diagonal). We used Akaike's Information Criterion (AIC) and Bayesian Information Criterion (BIC) to select the optimal model.

III. Results

A. Experiments

The scoring probability was similar in all dyads and in all experimental conditions ($87\% \pm 3\%$ for the attacker and $13\% \pm 3\%$ for the defender).

The morphology of the action distribution in the joint workspace is similar in all dyads. The attacker tends to shoot on either the left or the right of the defender, thus resulting in a bimodal distribution. On the contrary, the defender tends to cover the whole workspace, thus resulting in a (approximately central) unimodal distribution. The optimal model for the joint distribution – qualitatively similar in all conditions – is a mixture of two Gaussians, with non-diagonal covariances. However, in most conditions the covariances' principal directions are aligned along the vertical direction; see Fig. 4.

For each dyad, we took the inter-cluster distance $\Delta\mu_A$ and the dispersion σ_D^2 to quantify attacker (A) and defender (D) performance within each experimental condition.

A 2-way ANOVA (factors: Σ_y^A and Σ_y^D) revealed that the reliability of their own sensory information had no significant effects on their performance. However, in the defender behavior alone we observed a significant effect (p=0.025) of the

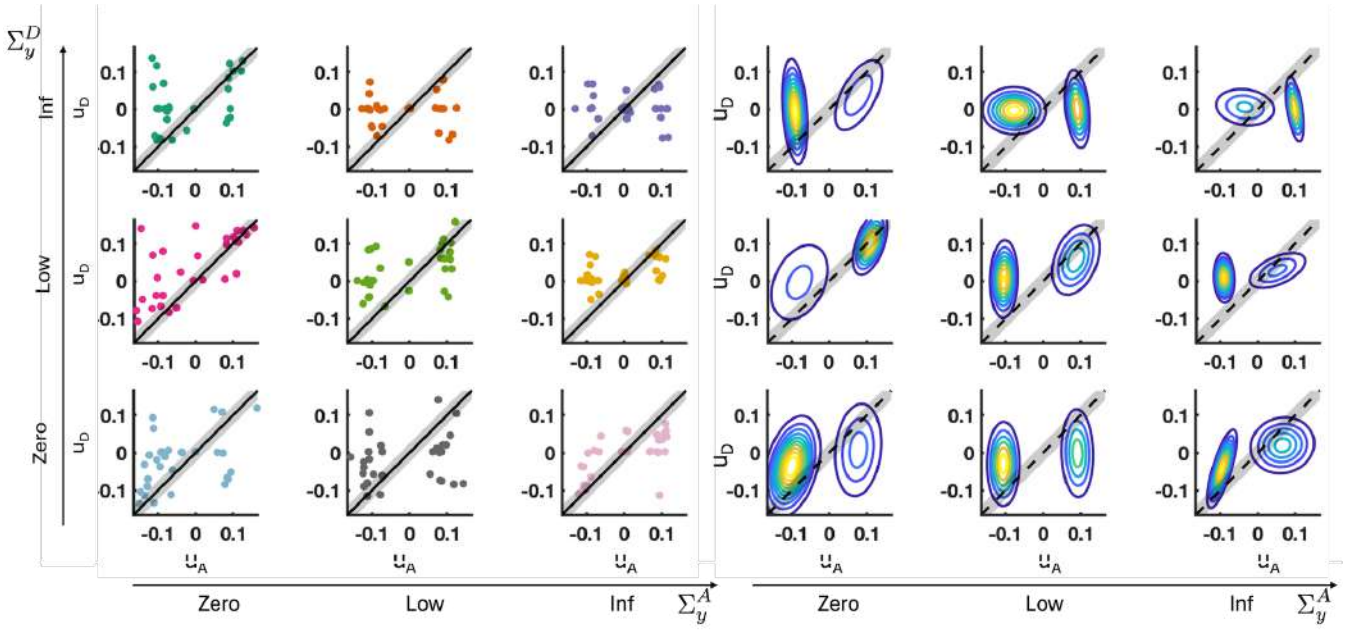

Fig. 4. Joint distribution of the A and D actions in a typical dyad, displayed as a scatter plot (left) and a Gaussian mixture model (right). Each subplot panel corresponds to one of the nine experimental conditions resulting from the manipulation of the sensory noise of both players. The grey area denotes the region where the attacker and the defender are within half the cursor size (5 cm), corresponding to the case when the defender catches the ball

attacker's sensory information. If the latter is more reliable, the defender tends to increase the dispersion of their actions. A similar trend, though not statistically significant, was observed in the attacker. These results are summarised in Fig. 5.

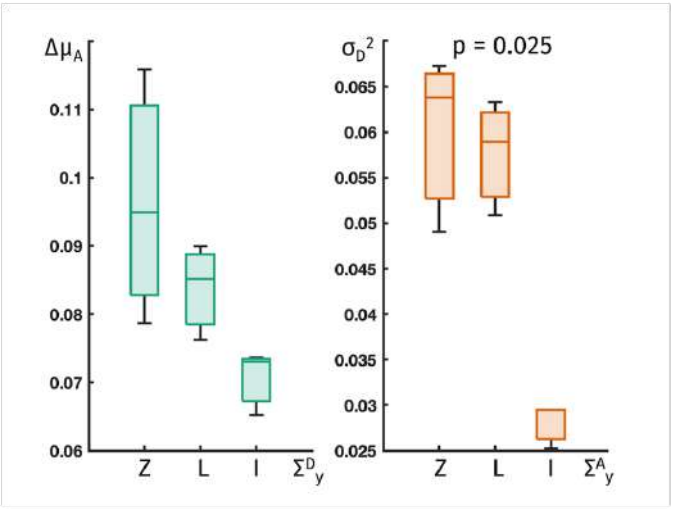

Fig. 5. Attacker ($\Delta\mu_A$, left) and defender performance (σ_D^2, right) as a function of the sensory uncertainty of their respective opponents, i.e. Σ_y^D (left) and Σ_y^A (right)

B. Simulations

Model simulations qualitatively reproduce the observed behavior. In particular, the joint distribution of the actions is qualitatively similar to the experimental results; see Fig. 6. We analyzed the simulated data in the same way as the experimental results using a Gaussian mixture model. We found that $\Delta_{\mu A}$ has greater values when the defender has more reliable information about the position of the attacker, in the same way the σ_D^2 is wider when the attacker has more reliable information about the defender's location. The simulation results are summarized in Fig. 7.

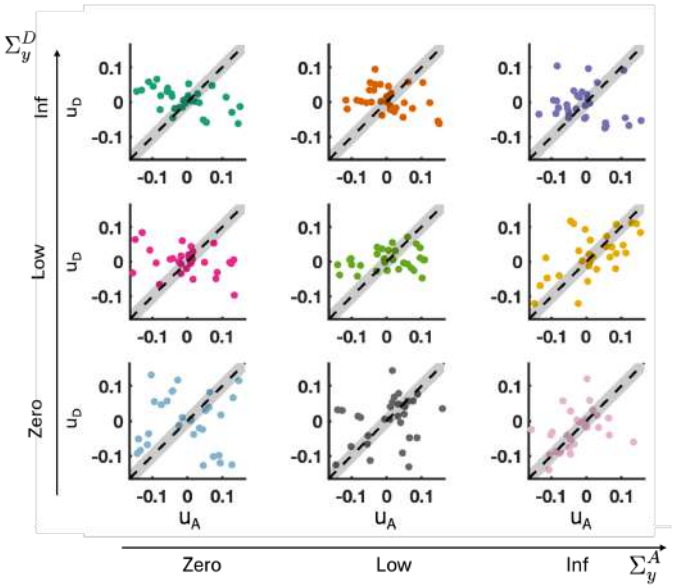

Fig. 6. Joint distribution (scatter) of the simulated players' actions in all experimental conditions (one simulation). Gray area as in Fig. 4

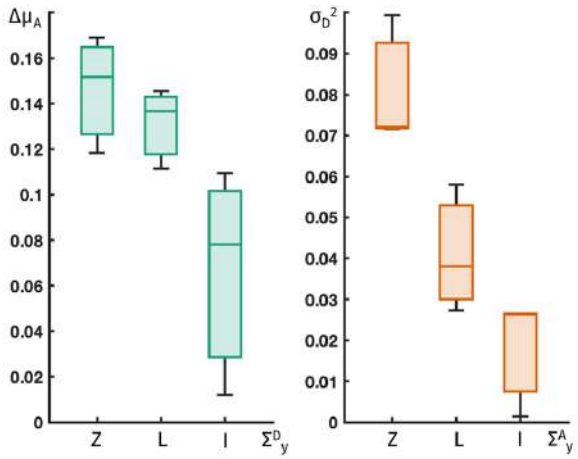

Fig. 7. Attacker ($\Delta\mu_A$, left) and defender performance (σ_D^2, right) as a function of the sensory uncertainty of their respective opponents, i.e. Σ_y^D (left) and Σ_y^A (right). The same model was used to simulate each dyad's randomized block order

IV. Discussion

Overall, these preliminary results suggest that each player strategically uses the information about their opponent's actions to develop a representation of their strategy and this enables them to continuously adapt their own actions accordingly. Players seem to rely on their observations of the opponent's behavior to adjust their strategy and make more informed action selections in the game.

Kucuktabak et al. [10] suggested that a deeper understanding of optimal personalized interaction can play a crucial role in the development of more effective rehabilitation protocols. Simulations conducted using a computational model designed around optimal action selection principles align with the experimental observations. These results suggest that players are using optimal strategies (in the game-theoretic sense) when choosing their next actions.

Our findings suggest that, in a competitive rehabilitation context, a patient can be encouraged to increase their range of motion (action dispersion) by manipulating the information available about their partner's location. For instance, adjusting sensory information could be used to dynamically modify the task's difficulty level, tailored to the patient's specific needs. More specifically, such manipulation could directly influence the patient's action selection strategy, pushing them to increase their action dispersion.

The competitive nature of the game can help patients maintain a high level of engagement and focus throughout their rehabilitation. Additionally, the ability to control and adjust the difficulty level of the task allows for a more personalized approach, attempting that motor improvements are maximized.

In the context of the rehabilitation game, patients may engage in training sessions either with another patient, a therapist, or even a simulated human-like partner. The use of the computational model proposed that can replicate human-like behaviors could be a promising tool. Such a model could be used as a simulated partner that adapts the action selection strategy in response to the patient's behavior by manipulating the sensory noise on the patient's position. By doing so, it allows the task to dynamically adjust to the patient's progress, helping to maintain the necessary level of challenge to promote improvement.

This adaptive approach can be beneficial in maintaining patient engagement and providing a more personalized rehabilitation experience.

***Abstract*— Ankle push-off power generated by the plantar flexor muscles is essential for efficient walking but is often impaired in individuals with cerebral palsy (CP), leading to inefficient walking. Both powered and passive (i.e., motor- and spring-based) wearable resistance devices are being developed for targeted training. This study explored the use of ankle power biofeedback across powered and passive wearable resistive devices to improve muscle recruitment and push-off power in individuals with CP. Seven individuals with CP completed walking sessions under the following conditions: (1) baseline (no device), (2) spring resistance with and without biofeedback, and (3) motor resistance with and without biofeedback. Push-off power and muscle recruitment were compared between biofeedback vs no-biofeedback conditions for both devices, and to baseline. Combined spring resistance and biofeedback increased soleus activity by 40% compared to the spring resistance only ($p = 0.004$) and by 48% compared to baseline ($p = 0.002$). Similarly, spring resistance and biofeedback increased peak ankle power by 32% relative to the spring resistance only ($p = 0.009$) and by 33% compared to baseline ($p = 0.010$). In contrast, motorized resistance and biofeedback did not significantly increase peak soleus activity or peak ankle power relative to motor resistance only ($p = 0.544$; $p = 0.544$). These findings show that ankle power biofeedback can augment spring resistance to elicit increased muscle recruitment and power during push-off in CP.**

***Keywords*— Ankle power, Gait, Rehabilitation Robotics**

I. Introduction

Ankle push-off power plays a significant role in human walking. It is the burst of positive power generated by the ankle plantar flexor muscles at the end of the stance phase of the gait cycle that facilitates the transition into the swing phase, propels the body forward, and initiates the progression from one leg to the other [1]. Impaired ankle plantar flexor muscle recruitment, therefore, can significantly reduce push-off power, and negatively affect walking ability. This diminished push-off power can place a greater demand on the hip joint, resulting in an inefficient walking pattern [2], [3]. Over time, the extra demand on the hip joint can lead to hip pain, especially for individuals with cerebral palsy (CP), the most prevalent lifelong cause of childhood disability [4], [5].

This work was supported in part by the National Science Foundation under Grant 2045966.

Several gait rehabilitation interventions have been implemented to address gait impairments experienced by individuals with CP [6]. Among these, functional resistance training with robotic devices has emerged as a highly effective approach. In recent years, robotic resistance has been shown to significantly improve ankle muscle recruitment and strength for individuals with CP [7], [8], [9]. Robotic devices offer a more effective method of delivering the intensity, duration, and progressive training to targeted joints, facilitating better mobility outcomes when compared to conventional or manual therapy [10], [11], [12].

Robotic devices are available in both powered and passive forms. Powered robotic devices use motors to provide resistance, while passive devices utilize springs. Powered robotic devices for resistance training have typically targeted the ankle joint, and previous research demonstrated that powered ankle resistance can improve soleus muscle recruitment in individuals with CP by 45% [7]. Conversely, passive robotic devices for resistance training have typically focused on the knee rather than the ankle. For example, Washabaugh et al. showed that passive knee resistance improved hamstring and quadriceps muscle recruitment in a healthy individual [13], though the effects in individuals with CP remain uncertain.

Audio-visual biofeedback systems have also been increasingly combined with resistance training to enhance the benefits of rehabilitation. These systems provide real-time feedback on specific gait parameters that align with rehabilitation goals. For instance, audio-visual biofeedback targeting step length, when paired with resistance training has been showed to improve step length in individuals with CP [14]. Similarly, biofeedback using electromyography (EMG) and plantar pressure have demonstrated to increase plantar flexor muscle activation [15]. These improvements are likely to be further amplified when paired with resistance training. Additionally, ankle power biofeedback has also showed to improve ankle push-off power in individuals with CP [16]. Given that plantar flexor muscles are the primary contributors to ankle push-off power, it raises an important question: Could ankle power biofeedback lead to increased muscle

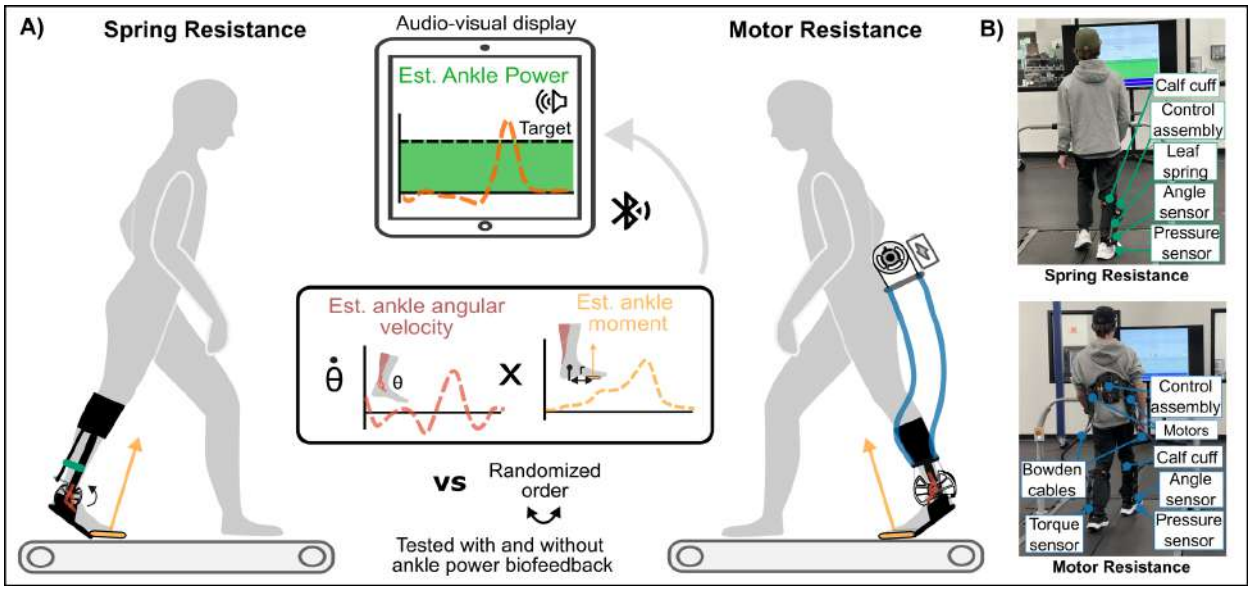

Figure 1: A) Depiction of ankle power biofeedback system and its operation as used in the experimental protocol B) Participant pictured wearing the ankle exoskeleton with motorized resistance and the ankle device with spring resistance.

recruitment and improved ankle power when its benefits are significantly enhanced by pairing it with resistance training?

We previously developed a powered ankle exoskeleton and passive ankle device capable of provide plantar flexor resistance via motors and springs, respectively. This study aimed to explore the use of ankle power biofeedback across powered and passive wearable resistive devices to enhance plantar flexor recruitment and push-off power in individuals with CP. We hypothesized that combining ankle power biofeedback with resistance would result in greater plantar flexor muscle recruitment and increased ankle push-off power compared to resistance alone, for both motor- and spring-based resistive devices. We also hypothesized that both the combination of ankle power biofeedback with resistance and resistance alone during training would increase plantar flexor muscle recruitment and ankle push-off power relative to baseline.

II. METHODS

A. Ankle Power Biofeedback System

We developed a biofeedback system that utilized on-board sensors on our wearable devices to provide feedback on estimated net ankle power (i.e. device and biological ankle power). The biofeedback system leveraged force sensitive resistors (FSRs), and angle sensors embedded in the ankle devices to estimate ankle power in real-time. Ankle power was calculated as the product of ankle angular velocity and the ankle moment estimated from FSR data [17]. Real-time audio-visual biofeedback on ankle power was provided to participants during the biofeedback conditions via a 65-inch television placed in front of them for clear visibility (Figure 1). An iOS application (Biomotum, Portland, US) received, processed, and streamed the ankle power data via Bluetooth, projecting it onto the television. This setup was similar to those described in prior studies [15], [18]. The real-time estimated ankle power displayed on the screen was for the participant's more affected limb only. The television also displayed a horizontal target line, set as a 10% increase of the participant's peak ankle power during walking without resistance or biofeedback. When the estimated peak ankle power exceeded the target line, the system displayed a green background with confetti and played an audible 'ding' as a reward to reinforce the desired performance.

B. Ankle Device with Spring Resistance

We used a simple ankle device that employed a carbon fiber leaf spring to deliver targeted plantarflexion resistance. The device consisted primarily of an ankle assembly, which included the carbon fiber leaf spring, a custom 3D-printed slider with carbon fiber reinforcement (Onyx, Markforged) to adjust the pivot point of the spring and modulate its effective length for varying resistance, a neutral angle adjuster, a footplate with an embedded force-sensitive resistor (FSR), Hall-effect angle sensor (AS5600, AMS OSRAM), a calf cuff, and a pulley. The leaf spring was a 6.35 mm thick 0/90 ply carbon fiber bar (8194K111, McMaster-Carr) with a functional length of 115 mm. It generated a maximum peak resistive torque of 0.073 Nm/kg. The timing for spring

P7	13	56.2	1.70	I	0.85

GMFCS: Gross Motor Function Classification System. PF: Plantarflexion. Participants were all males and had their right side more affected by CP.

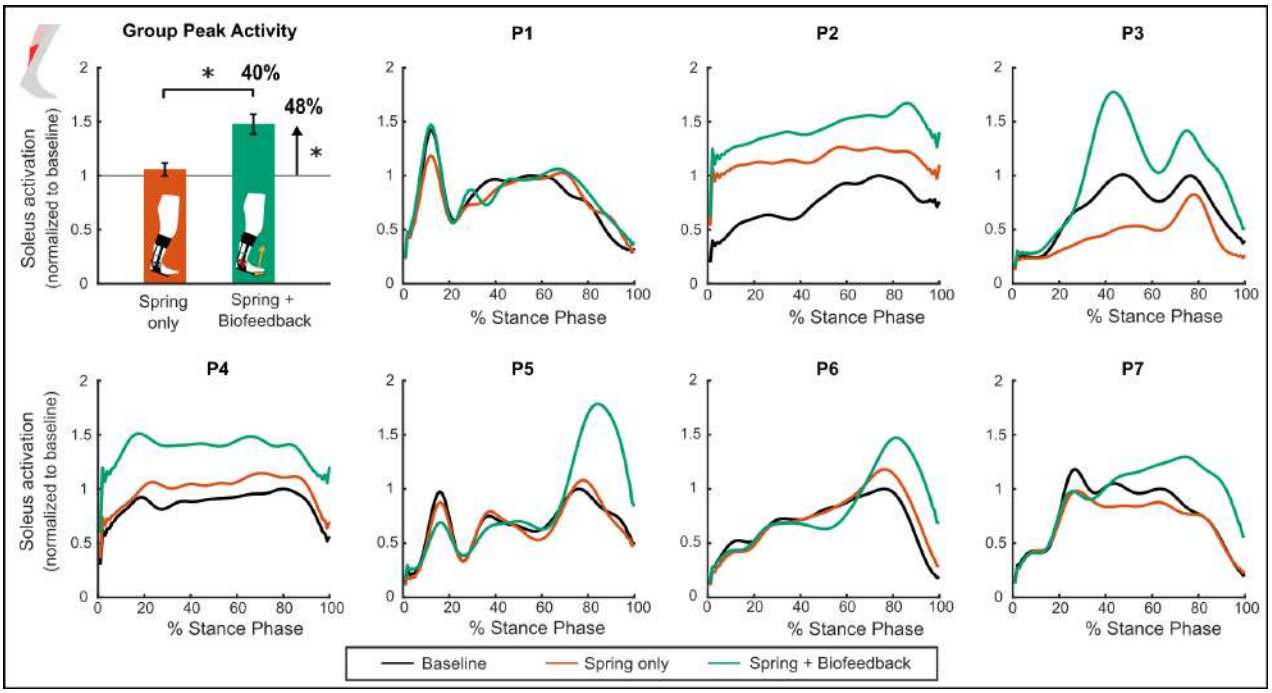

Figure 2: *First plot:* Group level peak propulsive phase soleus activation relative to baseline for walking with spring resistance only (orange) and spring resistance plus biofeedback (green) and *Remaining plots:* Soleus activation curves (average across all gait cycles) for baseline walking (black), walking with spring resistance only (orange) and spring resistance plus biofeedback (green); Error bars represent standard error of the mean, bracket represent pairwise comparison between walking spring resistance only and spring resistance plus biofeedback, upward arrow indicate pairwise comparison between baseline walking and walking with spring resistance plus biofeedback, and * indicates statistical significance (p-value) less than 0.05.

engagement was customized for each participant using the neutral angle adjuster, allowing the spring to engage at the onset of plantarflexion. This adjuster consisted of a barrel adjuster and a steel coupling nut, interfacing with the spring via a steel cable that terminated at an ankle pulley.

C. Ankle Exoskeleton with Motor Resistance

The ankle exoskeleton used in this study was untethered, battery-powered and capable of adaptive control, as previously described in [19], [20] (Figure 1). The device comprised waist and ankle assemblies connected via Bowden cables. The waist assembly housed two DC motors (T-Motor, AK60v1.1), a custom printed circuit board, microcontrollers, and an 1800mAh lithium-ion battery. The ankle assembly included footplates embedded with force sensitive resistors (FSRs; Tekscan, FlexiForce A502), custom torque sensors, angle sensors (Hall-effect; AS5600, AMS OSRAM), a pulley, and calf cuffs. The accuracy and reliability of the custom torque sensor has been shown in our prior work [21]. The exoskeleton applied plantarflexion resistance by using its motors to drive a chain-and-sprocket transmission, which interfaced with a Bowden cable system terminating at the ankle pulley. Its control strategy provided resistive torque proportional to the real-time estimated biological ankle joint moment [7], [19]. Torque sensors in the ankle assembly measured the applied resistive torque, enabling closed-loop torque feedback control. FSRs in the footplates informed a finite state machine to differentiate between stance and swing phases of the gait cycle. The peak torque setpoint was set to 0.08 Nm/kg, providing resistance similar to highest spring resistance.

D. Study Approval and Participants

This study was approved by the Institutional Review Board of Northern Arizona University (#2137266). Seven individuals with CP (ages 13 – 40 years) completed this study (Table I). Inclusion criteria were a diagnosis of CP, Gross Motor Function Classification System (GMFCS) level I, II, or III, and the ability to walk on a treadmill continuously with or without support for at least six minutes. Exclusion criteria included orthopedic surgery within the past six months, any botulinum toxin injections within the past six months, and any other conditions that would prevent safe participation. A licensed physical therapist completed a physical evaluation with each participant to assess function and confirm eligibility. All adult participants and the parents of participants below the age of 18 provided their informed written consent before participation. Minor participants provided verbal assent as well.

E. Experimental Protocol

First, we obtained participants' preferred walking speed while they walked on the treadmill without any devices. Then, participants walked with both motor and spring resistance devices, with ankle power biofeedback to familiarize themselves with the biofeedback system and

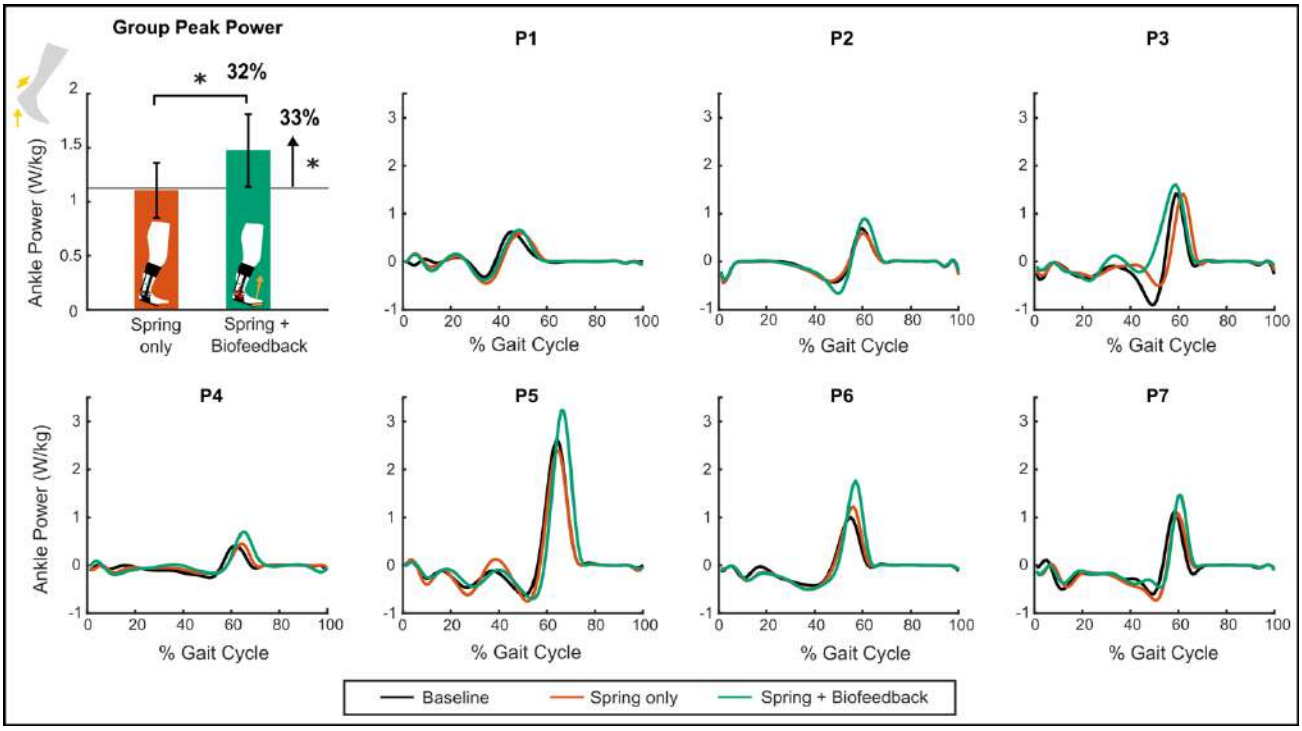

Figure 3: *First plot:* Group level peak ankle power for walking with spring resistance only (orange) and spring resistance plus biofeedback (green) and *Remaining plots:* Ankle power curves (average across all gait cycles) for baseline walking (black), walking with spring resistance only (orange) and spring resistance plus biofeedback (green); Error bars represent standard error of the mean, bracket represent pairwise comparison between walking with spring resistance only and spring resistance plus biofeedback, upward arrow indicate pairwise comparison between baseline walking and walking with spring resistance plus biofeedback, and * indicates statistical significance (p-value) less than 0.05.

acclimate to the devices. Participants walked continuously until they hit the target line for ten consecutive steps and for a minimum of four minutes in each device. Following this acclimation period, each participant had a seated rest for twenty minutes.

We then placed wireless EMG sensor (Trigno, Delsys, Natick, MA) on the soleus and medial gastrocnemius muscles of the more affected limb of participants, and reflective markers on participants' lower legs to define the foot and shank segments. Participants then walked at their preferred speed with no device *(Baseline)* for two minutes and either the ankle device with spring resistance for two minutes first with no biofeedback *(Spring only)* and another two minutes with biofeedback *(Spring + Biofeedback) or* ankle device with motor resistance for two minutes first with no biofeedback *(Motor only)* and another two minutes with biofeedback *(Motor + Biofeedback)* in a randomized order. A four-minute seated resting period was included between each condition. During each condition, we recorded EMG data at 1200 Hz and lower limb kinematic data at 120 Hz using an eight-camera capture system (Vicon, Oxford, UK). A trigger system synchronized with Vicon Nexus system was used to separate between the first and last two minutes of walking conditions with devices. Walking with the ankle device with spring resistance was completed in low, medium and high spring configurations, corresponding to effective spring lengths of 115mm, 65mm, and 15mm, respectively. The motor resistance was matched with the high spring resistance configuration.

F. Data Analysis

To assess our objective of evaluating how ankle power biofeedback affects walking across passive vs powered resistance systems, we analyzed measurable outcomes for conditions with the high spring resistance, motor resistance and baseline. EMG data were bandpass filtered (15 - 380 Hz, 4th order Butterworth), rectified, and lowpass filtered (7 Hz, 4th order Butterworth) to generate the linear envelope. The linear envelope was then normalized by the peak value from the baseline condition. We calculated the peak EMG during the push-off phase of the gait cycle (51-100% of the stance phase [22]). Gait events were identified using Vicon Nexus.

We used OpenSim 4.4 to calculate the sagittal plane joint kinematics and kinetics [23]. A 3D generic musculoskeletal model was first scaled for each participant, and then ankle angles and moments were computed using inverse kinematics and inverse dynamics, respectively. Inertia properties from each device were integrated into their respective OpenSim models by rigidly attaching the ankle assemblies to the tibia and the waist assembly to the pelvis for the ankle device with motor resistance. Ankle power was calculated as the product

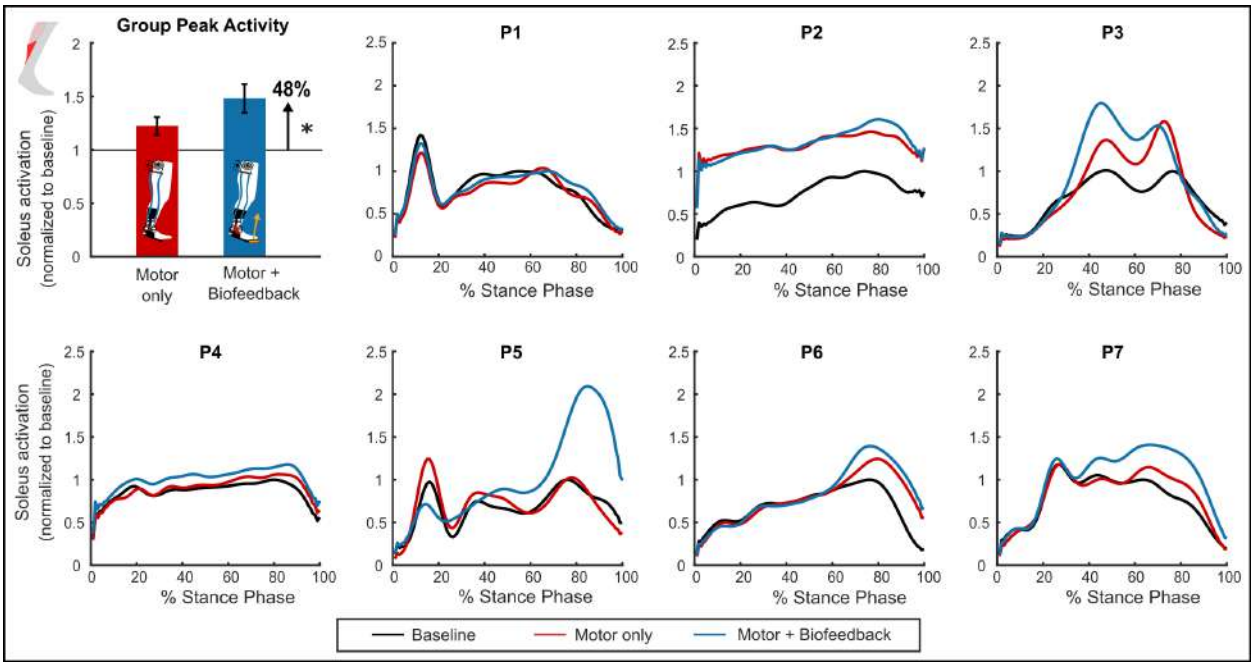

Figure 4: *First plot:* Group level peak propulsive phase soleus activation relative to baseline for walking with motor resistance only (red) and motor resistance plus biofeedback (blue) and *Remaining plots:* Soleus activation curves (average across all gait cycles) for baseline walking (black), walking with motor resistance only (red) and motor resistance plus biofeedback (blue); Error bars represent standard error of the mean, upward arrow indicate pairwise comparison between baseline walking and walking with motor resistance plus biofeedback, and * indicates statistical significance (p-value) less than 0.05.

of the ankle moment (excluding resistive torque from devices) and the respective ankle angular velocity.

G. Statistical Analysis

To validate our first objective of evaluating how ankle power biofeedback affects outcomes during walking with passive resistive devices, we used one-way repeated measures ANOVA to compare measured outcomes between the *Baseline*, *Spring only*, and *Spring + Biofeedback* conditions (p-value set at 0.05). Prior to this, we conducted normality tests on the differences between pairs for measured outcomes using the Shapiro-Wilks test; all data passed normality tests. Pairwise comparisons were made using paired two-tailed t-tests with Holm-Bonferroni correction for multiple comparisons (adjusted significance level set at 0.05).

To validate our second objective of evaluating how ankle power biofeedback affects outcomes during walking with motorized resistive devices, we used Friedman test to compare measured outcomes between the *Baseline, Motor only, and Motor + Biofeedback* conditions (p-value set at 0.05). Prior to this, we conducted normality tests on the differences between pairs for all measured outcomes using the Shapiro-Wilks tests; some data did not pass normality tests. Pairwise comparisons were made using Wilcoxon signed rank test with Holm-Bonferroni correction for multiple comparisons (adjusted significance level set at 0.05).

III. RESULTS

A. Effect of Ankle Power Biofeedback on Spring Resistance

There was a significant effect of walking condition on peak soleus activity ($p < 0.001$, Fig 2). Pairwise comparisons showed that the spring resistance plus biofeedback condition significantly increased peak soleus activity relative to the spring resistance only condition by 40% ($p = 0.004$) and baseline by 48% ($p = 0.002$). There was no difference between baseline and spring resistance only conditions ($p = 0.377$).

There was a significant effect of walking condition on peak ankle power ($p = 0.001$, Fig 3). Pairwise comparisons showed that the spring resistance plus biofeedback condition significantly increased peak ankle power relative to the spring resistance only condition by 32% ($p = 0.009$) and baseline by 33% ($p = 0.010$). There was no difference between baseline and spring resistance only conditions ($p = 0.773$).

B. Effect of Ankle Power Biofeedback on Motor Resistance

There was a significant effect of walking condition on peak soleus activity ($p = 0.002$, Fig 4). Pairwise comparisons showed that the motor resistance plus biofeedback condition significantly increased peak soleus activity relative to baseline by 48% ($p = 0.002$). The motor resistance plus biofeedback condition did not significantly increase peak soleus activity relative to motor resistance only ($p = 0.544$). There was also no difference between baseline and motor resistance only conditions ($p = 0.098$).

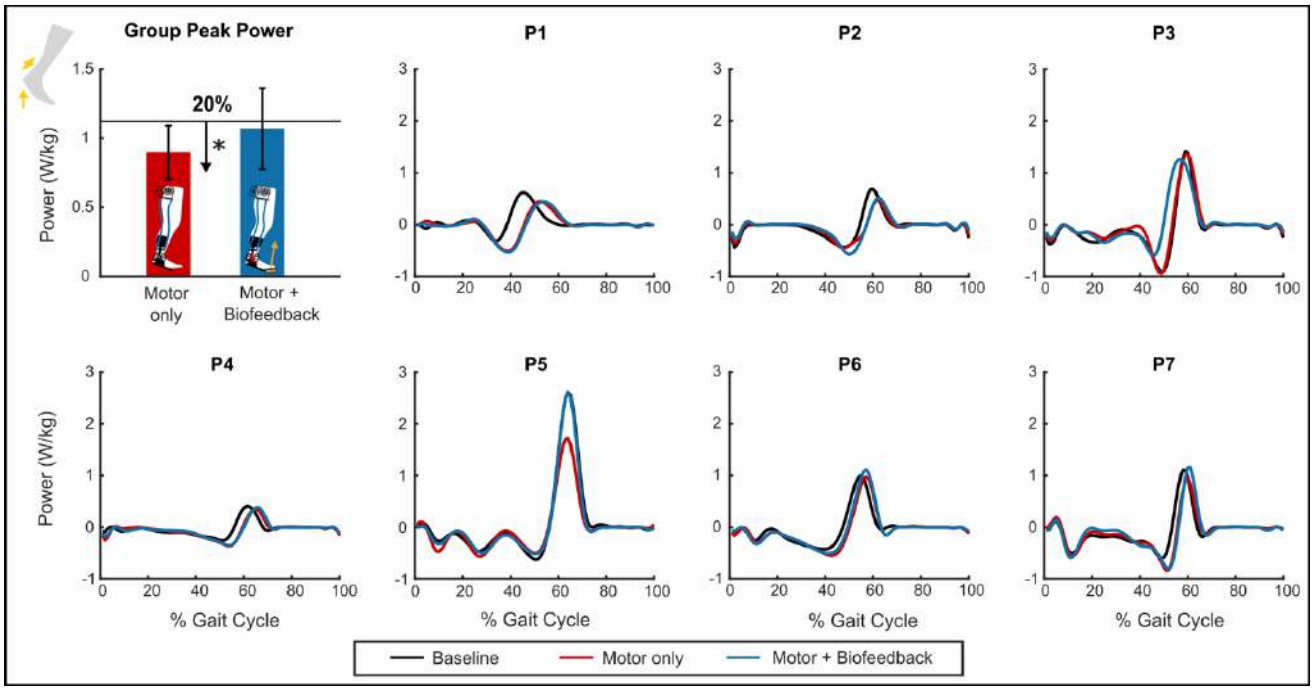

Figure 5: *First plot:* Group level peak ankle power for walking with motor resistance only (red) and motor resistance plus biofeedback (blue) and *Remaining plots:* Ankle power curves (average across all gait cycles) for baseline walking (black), walking with motor resistance only (red) and motor resistance plus biofeedback (blue); Error bars represent standard error of the mean, downward arrow indicate pairwise comparison between baseline walking and walking with motor resistance only, and * indicates statistical significance (p-value) less than 0.05.

There was a significant effect of walking condition on peak ankle power ($p = 0.028$, Fig 5). Pairwise comparisons showed that the motor resistance only condition decreased peak ankle power relative to baseline by 20% ($p = 0.023$). The motor resistance plus biofeedback condition did not significantly increase peak ankle power relative to motor resistance only ($p = 0.544$). There was no difference between baseline and motor resistance plus biofeedback conditions ($p = 0.544$).

IV. DISCUSSION

The purpose of this study was to implement an ankle power biofeedback system paired with motor- and spring-based resistance training modalities to improve plantar flexor muscle engagement push-off power in individuals with cerebral palsy (CP) relative to resistance alone. We partially confirm our hypothesis combining ankle power biofeedback with resistance would result in greater plantar flexor muscle recruitment and increased ankle push-off power compared to resistance alone, for both motor and spring resistance devices – ankle power biofeedback improved plantar flexor muscle engagement and push-off power for the spring device only.

Improvements in peak soleus activity and peak ankle power for walking with resistance plus biofeedback compared to resistance alone were observed, but for only the spring device. It is surprising that no difference was observed between motor resistance only and motor resistance plus biofeedback, as prior research showed that combining plantar pressure biofeedback with motor resistance improved both peak and mean soleus activity relative to resistance alone [18]. For plantar pressure biofeedback, participants typically respond by simply applying plantar pressure into the ground during gait training. However, ankle power biofeedback requires participants not only to apply plantar pressure but also to quickly rotate their ankle. While participants appeared to successfully perform this during acclimation, the added complexity of ankle rotation may have made it more challenging to effectively improve muscle recruitment. Future studies should explore whether additional training can mitigate the complexity associated with ankle power biofeedback and enhance its effectiveness in improving muscle recruitment.

There remains an unmet need for effective gait rehabilitation tools for individuals with CP. In this study, combining ankle power biofeedback with spring resistance led to improved peak push-off soleus activity and power compared to spring resistance alone. A passive spring-based ankle gait rehabilitation system would likely be a simpler and more cost-effective option than its powered alternative. This system can potentially facilitate faster clinical adoption [24] and broader applications, including use in at-home training.

This study has several limitations that need to be considered. First, the sample size was small ($n = 7$). Although this is similar to other exploratory intervention studies in CP [15], [25], our findings cannot be generalized to the broader CP population. Secondly, this study focused on an immediate effect of the intervention following only a brief of acclimation. It is still unclear how additional acclimation may affect our results. Future studies are needed to further investigate how additional training would affect muscle recruitment and power.

V. CONCLUSION

This study demonstrates that ankle power biofeedback can augment spring resistance to elicit both increased plantar flexor muscle recruitment and ankle power during push-off in individuals with CP. This approach offers a promising strategy to improve two key biomechanical outcomes necessary for efficient human walking. Its relatively simpler design also holds promise in facilitating clinical translation and practical at-home training. Future research will explore the long-term effects of functional training with the combined spring resistance and ankle power biofeedback, with focus on sustained improvements.

***Abstract*—Human Activity Recognition (HAR) is a valuable tool for healthcare and rehabilitation, enabling applications like remote patient monitoring and rehabilitation progress assessment. This paper introduces `TIFEX-Py`, a comprehensive Python toolbox designed for time series feature extraction in HAR. `TIFEX-Py` offers a rich set of 195 feature extraction methods across statistical, amplitude, spectral, and time-frequency domains. To evaluate its effectiveness, `TIFEX-Py` was applied to 11 publicly available HAR datasets: *DSADS*, *HHAR*, *MHEALTH*, *MotionSense*, *PAMAP2*, *REALDISP*, *RealWorld*, *UniMiBSHAR*, *USC-HAD*, *WARD*, and *WISDM*. Machine learning pipelines utilizing `TIFEX-Py` features, evaluated under both random and subject-stratified cross-validation settings, consistently achieved performance that is competitive with or superior to state-of-the-art (SOTA) benchmark performances available for the datasets. In 11 out of 11 random split cross-validation scenarios, our pipeline surpassed or matched SOTA performance. For stratified by subject cross-validation, this was the case for more than half of the datasets. These results highlight the power of `TIFEX-Py`'s feature space in representing time series data. `TIFEX-Py` is open-source and publicly available for researchers in rehabilitation and movement analysis fields.**

***Index Terms*—Time Series, Feature Extraction, Classification, Python, Human Activity Recognition**

I. Introduction

Human activity recognition (HAR), the automatic detection of activities through sensor data analysis, is a critical tool in healthcare and rehabilitation [1]–[3]. HAR has various applications, including remote patient monitoring and evaluation of rehabilitation progress [2], [4]. For example, for elderly individuals, HAR systems enable the monitoring of activity patterns, the identification of critical events such as falls, and the promotion of independent living [1], [2]. In the context of e-health, HAR holds immense potential for remote care, tracking rehabilitation outcomes, and monitoring physical and mental health [1], [4].

While automated feature extraction (AutoFE) in deep learning (DL) models, such as convolutional neural networks (CNNs), has significantly advanced HAR, manual feature extraction (ManFE) in statistical learning (SL) and traditional machine learning (ML) approaches remains highly competitive, especially when paired with well-crafted feature representations [5]–[8]. Specifically, studies show that ensemble learners can match or even surpass DL models on specific HAR datasets, particularly in classification performance (e.g., accuracy and precision) [9]–[11]. However, constructing an effective feature space remains challenging, requiring domain expertise and careful feature selection.

This paper presents `TIFEX-Py`, a comprehensive compilation of feature extraction methods from the literature for **Ti**me series **Fe**ature **Ex**traction in **Py**thon, specifically tailored for HAR applications in healthcare and rehabilitation. By incorporating a diverse set of statistical, spectral, and time-frequency feature extraction methods, `TIFEX-Py` provides a rich and structured feature representation of time-series data, facilitating its effective use in ML pipelines. The toolbox is benchmarked on various HAR datasets, offering a robust resource for extracting meaningful features that can enhance classification performance. By enabling accurate activity classification, it supports key rehabilitation tasks such as ADL monitoring, rehab progress assessment, fall detection, and managing secondary medical conditions [3].

II. Materials and Methods

Fig. 1 outlines the experimental workflow, including time-series pre-processing, sliding window segmentation, feature extraction with `TIFEX-Py`, and model evaluation via k-fold cross-validation against SOTA benchmarks. Each step is detailed in the following subsections.

A. *TIFEX-Py*

As walked through in Fig. 1, `TIFEX-Py` is a Python 3 toolbox developed for time series feature extraction across

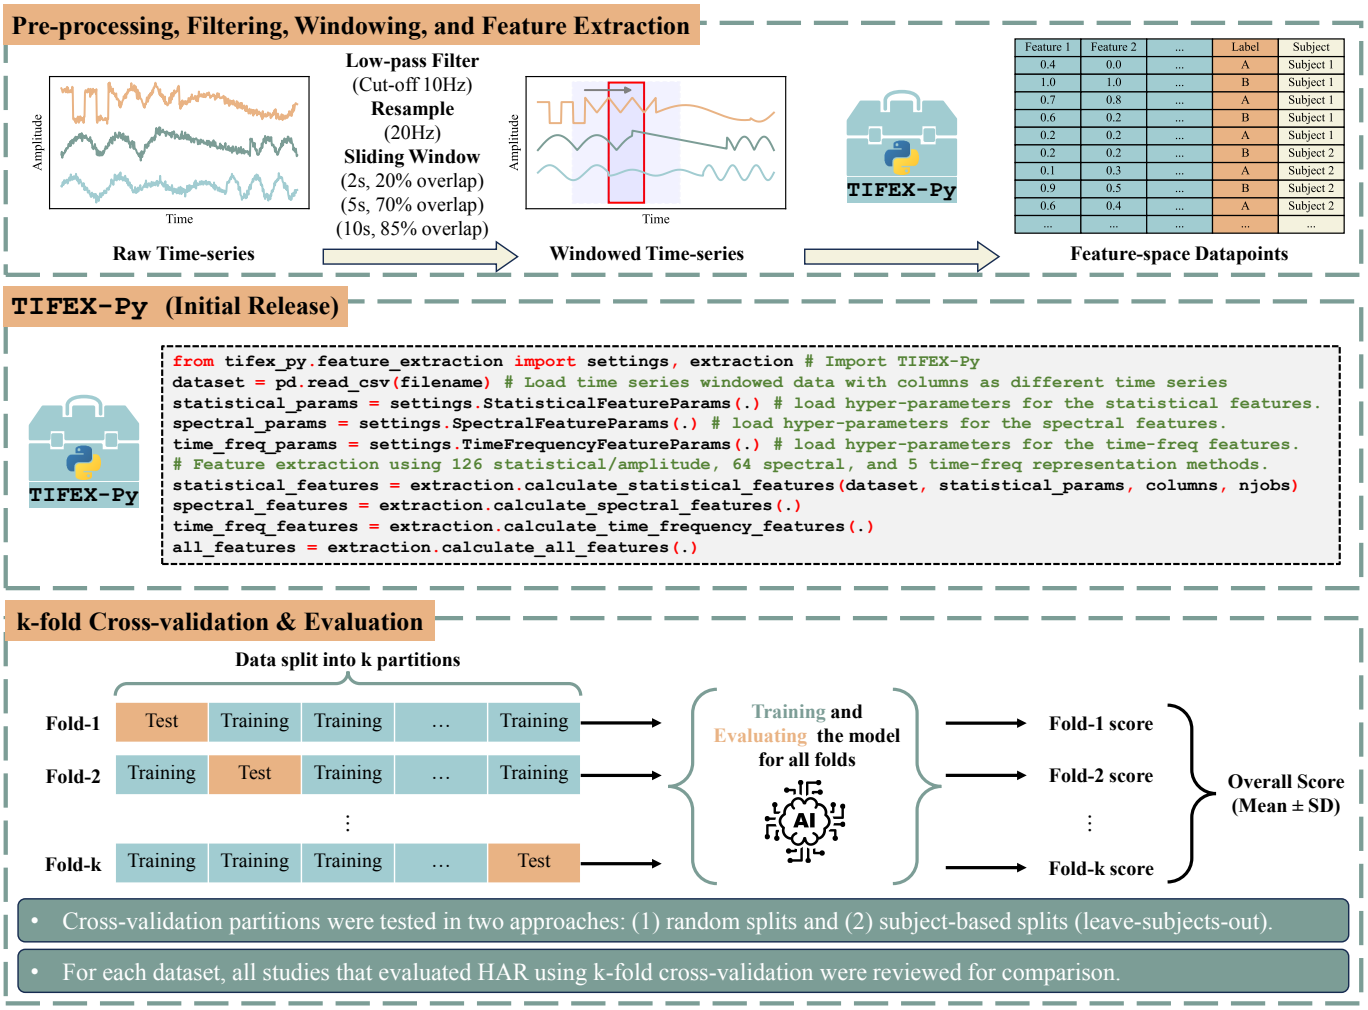

Fig. 1. Flow diagram of the pre-processing (filtering, resampling, windowing), feature extraction (including snippets from TIFEX-Py used for extracting features in statistical/amplitude, spectral, and time-frequency domains), and evaluation stages (including the cross-validation diagrams).

statistical and amplitude (125 methods), spectral (64 methods), and time-frequency (5 methods) domains. This extensive compilation makes TIFEX-Py the most comprehensive Python package for time series feature extraction. Several Python-based toolboxes for time series feature extraction exist, including *TSFEL* [12], which offers over 60 methods, and *tsfresh* [13], which provides 64 feature extraction methods. By offering a broader range of features, TIFEX-Py extends the capabilities of these toolboxes and, when combined with effective feature selection and hyperparameter tuning, has the potential to improve time series representation and classification performance.

TIFEX-Py is built upon widely used Python data analysis libraries such as NumPy and Pandas, ensuring compatibility with standard data processing workflows. The toolbox is open-source and publicly available[1]. Documentation, tutorials, feature implementations, feature references, computation time benchmarks, and additional details are available in the repository. The current paper corresponds to the initial release of the toolbox, which is archived in the ETH Data Archive[2].

With the current version of TIFEX-Py, users are responsible for: (1) pre-processing the input time series data (e.g., normalizing, filtering, and resampling), (2) feature selection, as TIFEX-Py compiles features available in the literature, but their selection should be incorporated into machine learning pipelines, and (3) hyperparameter tuning, as many feature extraction methods include adjustable parameters that can be fine-tuned to optimize performance for specific datasets.

B. Data

A total of 11 open-source HAR datasets were employed to evaluate the effectiveness of TIFEX-Py in generating representative features for time series data. These datasets included accelerometer and gyroscope data collected from various body locations, encompassing a diverse range of activities and events relevant to rehabilitation, such as ADLs,

[1] TIFEX-Py repository: https://github.com/mehdieji/tifex-py.

[2] TIFEX-Py initial release archive: https://doi.org/10.5905/ethz-1007-861.

physical exercises, and fall-related events. ADLs include sitting, standing, lying supine, lying on the side, stair climbing, walking, jogging, running, cycling, rowing, ironing, vacuuming, watching television, working on a computer, driving, and folding laundry. Recreational and sports activities include playing basketball, playing soccer, and exercises such as trunk twisting and forward bending. Fall-related events involve falling backward from standing, falling backward while seated, falls with protective strategies, falling forward, and lateral falls to the right or left. Additional scenarios include syncope (loss of consciousness), collisions with obstacles during falls, and wheelchair propulsion. Table I summarizes the datasets used in this study.

C. Pre-processing & Feature Extraction

Accelerometer and gyroscope time series data from all datasets were processed using a 5th-order Butterworth low-pass filter with a cut-off frequency of 10Hz [3]. The filtered time series were then resampled to 20Hz to reduce computational complexity. The pre-processed time series data were segmented using a sliding window approach. Based on the evaluation of SOTA methods across the datasets, optimal window sizes ranged from 1s to 10s. To ensure comparability with SOTA, this study utilized three window sizes: 2s, 5s, and 10s, with sliding windows overlapping by 20%, 70%, and 85%, respectively, to ensure a comparable number of resulting windowed datapoints, enabling fair comparisons between different window sizes. The `TIFEX-Py` default features (detailed on the repository) were extracted for each windowed segment. The concatenated features from all time series within a segment constituted the feature space input to the model.

D. Experiments & Evaluation

The feature-space datapoints were used to train and evaluate an ML model. This study employed an XGBoost (XGB) model [51] due to its proven effectiveness in feature selection and HAR performance [3]. The evaluation used a k-fold cross-validation (CV) approach with two splitting strategies based on the literature: 1) random split and 2) stratified by subjects [7]. The value of k was set to 10, or 5 when the number of subjects in the dataset was insufficient for 10 folds. In this study, no hyper-parameter tuning was performed, and the default parameters of the XGB model and `TIFEX-Py` were used. Classification metrics [52], including accuracy, balanced accuracy, precision, recall, and F1-score, were calculated for each fold and averaged across all folds.

Under both splitting strategies, experiments were conducted for three window sizes (2s, 5s, and 10s). The results were compared against AutoFE- and ManFE-based SOTA benchmarks, considering all studies that utilized k-fold cross-validation. However, only the highest reported performance for each dataset is reported in this paper. The comparison is fair as it follows similar evaluation metrics, including cross-validation and window size. By centering the evaluation on classification performance, this study provides a direct assessment of `TIFEX-Py`'s effectiveness in time-series representation. Notably, if an XGB model, even without hyperparameter tuning, achieves performance comparable to or surpassing existing SOTA benchmarks, it highlights the strength of `TIFEX-Py`'s feature space in capturing meaningful patterns for classification.

III. Results & Discussion

Fig. 2 presents the mean and standard deviation (SD) of classification metrics across all datasets and window sizes (window size of 10s was not possible for REALDISP due to its provided length of activities), evaluated using CV with randomly shuffled splits, compared to SOTA benchmarks (where available) with similar splitting strategy. Similarly, Fig. 3 shows the results for the subject-stratified split CV.

In both figures, comparisons with SOTA were conducted separately for each classification metric, as different studies report only a subset of these metrics. For each metric, the highest reported benchmark from SOTA was used for comparison. Where SOTA values were unavailable for specific metrics or datasets, results are marked as N/A. A review of SOTA performance reveals no clear advantage between AutoFE- and ManFe-based methods, supporting the effectiveness of manual feature extraction in achieving competitive results compared to automated feature learning.

Examining both random and subject-stratified split results shows that larger window sizes generally improve performance across most datasets. This improvement may result from the richer information and enhanced spectral representation provided by larger windows. However, DSADS and MHEALTH in the subject-stratified setting deviate from this trend, indicating that optimal window size selection might depend on activity types and inter-subject variability in activity durations.

For random splits in (Fig. 2), where the test subjects' data is partially used for training the model, our pipeline consistently outperforms or matches SOTA across all datasets and classification metrics, achieving mean values close to 100% for all metrics. This is particularly valuable for cases where the model needs to be adapted to new subjects, by training partially on the new subjects' movement data (adaptation data). Moreover, the low SD values indicate the robustness and consistency of the feature set combined with the XGB model, when the model is provided with adaptation data for the test subjects.

In contrast, the subject-stratified results in Fig. 3 (with no adaptation data for test subjects), generally underperform compared to the random split results, a trend also observed in the corresponding SOTA results. This is expected, as the subject-stratified setup introduces a domain shift due to subject-specific variability. Furthermore, the higher SD values for subject-stratified metrics highlight the challenges in achieving robust performance for completely unseen subjects' data.

To evaluate the contribution of different feature extraction methods, we computed feature importance scores output by XGB classifier across 11 datasets. For each dataset, the importance values were first averaged over folds and then normalized to account for scale differences. By mapping

TABLE I

OVERVIEW OF THE HAR DATASETS USED IN THIS STUDY, INCLUDING THE NUMBER OF ACTIVITIES, TIME SERIES, SUBJECTS, AND AVERAGE DURATION PER ACTIVITY. FOR EACH DATASET, THE HIGHEST-PERFORMING SOTA BENCHMARKS WERE IDENTIFIED BY REVIEWING ALL PUBLISHED STUDIES THAT UTILIZED THE DATASET. WHILE ONLY THE TOP-PERFORMING METHODS ARE REPORTED, A BROADER RANGE OF APPROACHES WAS CONSIDERED.

Dataset	No. Activities	No. Time series	No. Subjects	Avg. Duration per Activity (s)	Benchmark ManFE SOTA Model	Benchmark AutoFE SOTA Model
DSADS [14]	19	30	8	2400	SVM, RF [8]	MLP, Bi-GRU, MBi-GRU [8], [15], [16]

USC-HAD [44]	12	6	14	2343	RF [35]	ResNet, DeepConvLSTM + LLM [5], [45], [46]
WARD [47]	13	25	20	2208	-	-
WISDM [48]	6	3	36	15628	RF [7]	LSTM-CNN, ResNet, Bi-GRU [5], [43], [49], [50]

individual features to their corresponding extraction methods, we aggregated these normalized scores to obtain a representative importance for each method. The methods were ranked based on their mean normalized importance across datasets. The top 100 methods were selected for further analysis. As shown in Fig. 4, we used boxplots to display the distribution of importance scores: the upper subplot shows the top 50 methods, while the lower subplot shows those ranked 51–100. The boxplots illustrate not only the median importance for each method but also the variability across different datasets and iterations. A Kruskal–Wallis test revealed statistically significant differences in the distributions of importance scores (H = [H-statistic], p = [p-value]) across datasets. This figure also provides an example of useful feature extraction methods for HAR tasks. The ranking highlights that effective features come from diverse domains, including fractal features such as Higuchi's fractal dimension, which captures the complexity of signals, amplitude-based features like minimum and maximum values, statistical features such as mean and variance, and other features, including autocorrelation, spectral characteristics derived from Fourier analysis, and wavelet-based features. A key takeaway from these results is that no single feature extraction method is universally optimal. Instead, different datasets or modalities benefit from different feature sets, emphasizing the need for dataset-specific feature selection.

It is important to note that this study did not include hyper-parameter tuning or feature selection based on unseen subjects' data, which could further improve performance in this setting. Despite this limitation, the results confirm that a comprehensive feature extraction approach, as made possible by `TIFEX-Py`, when combined with an effective feature selection strategy, leads to classification performance that is comparable to SOTA methods. However, it is important to note that the comparison with SOTA methods in this study is limited to those previously evaluated on the 11 selected datasets, and the evaluation metrics reported in SOTA studies. A more comprehensive analysis could extend beyond these datasets to include a broader range of existing SOTA approaches, also ensuring identical CV splits of data among all approaches. This would enable a more exhaustive comparison between SOTA methods and the ManFE-based approach leveraging `TIFEX-Py`, providing deeper insights into its generalizability and effectiveness across diverse HAR tasks.

IV. CONCLUSION

This paper introduced `TIFEX-Py`, the most extensive Python toolbox for time series feature extraction, specifically designed to support HAR applications in healthcare and rehabilitation. `TIFEX-Py` enables researchers to extract a diverse set of informative features across statistical, amplitude, spectral, and time-frequency domains. This comprehensive feature space allows for the development of robust and efficient HAR systems, capable of matching or surpassing SOTA automated feature learning approaches, such as DL models. In rehabilitation, the use of handcrafted features enhances interpretability, providing clinicians with more explainable insights into movement patterns from wearable sensors. Such insights can aid in optimizing rehabilitation plans and improving patient outcomes. Future work will focus on expanding `TIFEX-Py` by integrating feature selection techniques and predefined feature extraction settings. These enhancements will further streamline the analysis pipeline and strengthen its applicability in healthcare and rehabilitation.

ACKNOWLEDGMENT

This study was partially funded by the Schweizer Paraplegiker Stiftung (SPS) and the ETH Zürich Foundation through the 2021-HS-348 ETH-SPS Digital Transformation in Personalized Healthcare for SCI individuals. The authors would also like to thank Kang Wang and Amelie Schopper for their valuable input and assistance during this research.

Adaptive Negative Damping Control for User-Dependent Multi-Terrain Walking Assistance with a Hip Exoskeleton

Giulia Ramella[1,2], Auke Ijspeert[2], and Mohamed Bouri[1,3]

***Abstract*— Hip exoskeletons are known for their versatility in assisting users across varied scenarios. However, current assistive strategies often lack the flexibility to accommodate for individual walking patterns and adapt to diverse locomotion environments. In this work, we present a novel control strategy that adapts the mechanical impedance of the human-exoskeleton system. We design the hip assistive torques as an adaptive virtual negative damping, which is able to inject energy into the system while allowing the users to remain in control and contribute voluntarily to the movements. Experiments with five healthy subjects demonstrate that our controller reduces the metabolic cost of walking compared to free walking (average reduction of 7.2%), and it preserves the lower-limbs kinematics. Additionally, our method achieves minimal power losses from the exoskeleton across the entire gait cycle (less than 2% negative mechanical power out of the total power), ensuring synchronized action with the users' movements. Moreover, we use Bayesian Optimization to adapt the assistance strength and allow for seamless adaptation and transitions across multi-terrain environments. Our strategy achieves efficient power transmission under all conditions. Our approach demonstrates an individualized, adaptable, and straightforward controller for hip exoskeletons, advancing the development of viable, adaptive, and user-dependent control laws.**

I. Introduction

Hip exoskeletons for walking assistance are gaining popularity for their versatility to assist users across diverse contexts. Initially designed for rehabilitation purposes, these wearable devices are now increasingly used to assist healthy users. In recent years, there have been significant advancements, but developing control strategies that seamlessly synchronize with users remains a major challenge [1]. This is particularly critical with healthy users, where the exoskeleton's assistive actions must align with voluntary movements and individual intentions. To achieve a synchronized assistance, control algorithms must account for individual gait patterns, terrain variability, and diverse walking styles [2].

Multiple control approaches have been proposed to achieve a compliant human-exoskeleton interaction. Adaptive oscillators [3] and fixed-shape torque profiles [4] are effective, but do not address individual walking patterns. Human-in-the-loop optimizations achieve highly personalized control [5], but they involve computationally-intensive and time-demanding procedures. Energy-shaping methods [6] are precise and effective, but demand complex modeling of the system. Previously, researchers used the GEMS exoskeleton to implement a delayed output feedback control that relies on hip joint angular positions [7]. However, this approach requires manual tuning of delays, as these signals do not naturally align with hip torques. Similarly, assisting users with estimated biological hip torques is a highly advanced technique but requires tuning of delay parameters [8]. Overall, further explorations are needed to address the following research question: how can a hip exoskeleton control strategy be designed to align the assistance with the wearer's voluntary movements while adapting to individual gait patterns across diverse terrains?

Fig. 1: The user-dependent and multi-terrain walking assistance with the hip exoskeleton eWalk. Participants walked on treadmill and in varied unstructured environments.

When designing control strategies, researchers widely agree on the importance of the positive mechanical power transmitted from the exoskeleton to the user [5], [7], [9]. To regulate the energy transfer, existing research has explored a virtual modification of the mechanical impedance of the human-exoskeleton system [10]–[12]. For instance, negative damping has been used to modulate the dynamic response of the human-exoskeleton system, while keeping the wearer in control of the movements [10], [11]. Knowing that damping naturally causes energy dissipation, providing

Giulia Ramella received funding from the European Union's Horizon 2020 research and innovation program under the Marie-Sklodowska-Curie Grant Agreement No. 945363.

[3] Mohamed Bouri is with the TNE Laboratory, Institute of Neuro-X, Ecole Polytechnique Federale de Lausanne (EPFL).

negative damping can inject energy into the system. As damping is proportional to the joint velocities, the resulting assistance is inherently dependent on the wearer's motion. In theory, negative damping alone introduces positive feedback, risking instability and torque escalation. However, in the practical case of human-exoskeleton interaction, these issues are prevented thanks to pendulum dynamics, musculoskeletal damping, and torque limits. Preliminary implementations with a knee exoskeleton [10], [11] suggest that bounded negative damping holds great promise to provide partial assistance with wearable devices.

In this work, we design a negative damping control for the hip exoskeleton eWalk. With this approach, the exoskeleton torques assist wearers according to their own volitional movements. We experimentally evaluate the impact of our control strategy on users' walking energetics by comparing the assisted and the exoskeleton-free conditions. To assess the synchronization between the users' movements and the exoskeleton torques, we compute the transmitted mechanical powers. This quantity is defined as the product of the exoskeleton torque and the user's hip angular velocity, and positive powers indicate alignment between the users' movements and the assistive torques. Moreover, we measure the lower-limbs kinematics to analyze if the exoskeleton assistance preserves the natural walking movements.

Afterwards, we evaluate our controller's ability to assist users in unstructured environments (Figure 1). During multi-terrain locomotion, exoskeletons must dynamically adapt the assistance strength to meet varying demands across terrains [13]–[15]. Existing studies have proposed terrain recognition algorithms based on the data from onboard sensors [16]–[18], but these methods are prone to misclassification. In contrast, we propose a Bayesian Optimization framework to adjust the assistance level to different scenarios (flat walking and stairs descending/ascending) relying only on the exoskeleton's kinematic signals observed over a defined time window.

In summary, we present a novel control approach that injects energy into the human-exoskeleton system. We design an adaptive virtual negative damping control, where the assistive torques are generated based on the users' hip kinematics. Compared to existing works, our algorithm encompasses both individualization and terrain adaptation, while maintaining a straightforward and versatile approach. The main contributions are: (i) the design of the hip assistive torque profile based on the wearer's volitional movements; (ii) an experimental evaluation of the efficacy of our control to reduce the metabolic cost of walking, while preserving individual walking kinematics; and (iii) a validation of the adaptability of our control across varied locomotion terrains.

The rest of this paper is organized as follows. In Section II we describe our algorithm for hip exoskeleton assistance, and the methodologies to validate our strategy. Section III presents the results and discussion for the experiments performed on a treadmill and on unstructured environments. Section IV presents the conclusions and the future directions of this study.

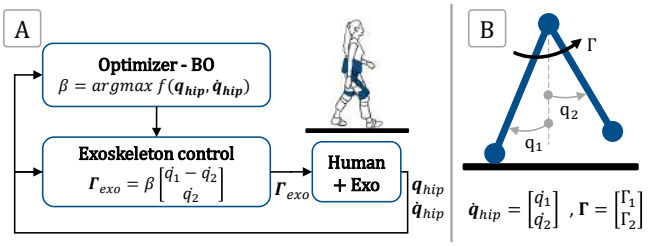

Fig. 2: (A) Schematic representation of our control framework. The torque profile is defined by a control law consisting of a Virtual Adaptive Negative Damping. The multiplicative coefficient (β) for the assistance strength is optimized with a Bayesian Optimization (BO). (B) Schematic representation of the compass-gait model and its main variables, where q_1 represents the hip angle of the stance leg, and q_2 the hip angle of the swing leg.

II. Methods

A. Assistive Control Law

We designed the torque profile provided by our hip exoskeleton eWalk as a virtual negative damping. This approach is able to inject energy into the system, while keeping the user in control of the movements [10], [11]. In order to apply the control action, a model for human locomotion is required. Although human walking has been described by diverse models of varied complexity [19], we opted for the simple compass-gait biped [20], where the legs are represented as rigid links connected at the hip joint. This approach has demonstrated a remarkable ability to capture fundamental characteristics of bipedal locomotion [21]–[24], the legs coupling [25], and the energy exchanges in human-exoskeleton interactions [6]. This method assumes no foot dynamics, and describes walking as a series of alternating swing and stance phases. At each heel-strike event, the stance and swing leg roles are switched between the feet.

The model's state variables consist of the hip joint positions and velocities for the stance and swing legs, denoted by q_1 and q_2 respectively ($\mathbf{q}_{hip} = [q_1; q_2]$). The hip input torques are defined as $\boldsymbol{\Gamma} = [\Gamma_1; \Gamma_2]$, as shown in Figure 2B. The control is implemented as the product of the coupling matrix $\mathbf{R} = [1 \;\; -1 \;; 0 \;\; 1]$ (inspired from [20]), and the user's hip joints angular velocity vector $\dot{\mathbf{q}}_{\mathbf{hip}}$ measured by the exoskeleton motor encoders at each sampling time. A damping factor β (Nms/rad) allows to modulate the strength of the assistive torques. The resulting the total expression is $\boldsymbol{\Gamma}_{\mathbf{exo}} = \beta \mathbf{R} \dot{\mathbf{q}}_{\mathbf{hip}}$ ("Exoskeleton control" in Figure 2A). The value of β is bounded to prevent the exoskeleton assistance from disrupting the movements or overpowering the users. The control torque is computed in real time at each sampling step by the exoskeleton's embedded controller.

At heel-strike, the swing leg becomes the new stance leg, causing a reset in the velocities and joint configuration. The coordinate change from before (-) to after (+) the heel-strike event is expressed as: $q^+ = [0\ 1; 1\ 0] q^\infty$. To detect the stance and swing leg, we analyzed the signs of the hip angular velocities as suggested in a previous study [26]. We avoided using joint angular positions to eliminate the ambiguity caused by the surjective mapping of joint angles to gait phases [1]. Instead, we relied on hip joint angular velocities that can differentiate the stance and swing legs based on their

opposite signs during continuous locomotion. We represented the hip flexion with positive increasing angles. The leg with hip extension (negative velocities), and counter-leg in flexion (positive velocities), was identified as q_1 (stance), and the other leg as q_2 (swing).

The exoskeleton assistive torques are designed to inject energy into the system, and the resulting total energy of the human-exoskeleton system can be expressed as $E_{tot} = E_{human} + E_{exo}$. By ensuring that E_{exo} remains bounded and lower than the human energy contribution, the exoskeleton assistance synchronizes with the user's walking cycle. Adjusting and limiting the assistive strength (β) allows the control to dynamically support natural cyclic motion without disrupting the user's gait.

In order to incorporate the hip angular velocities in the control law, we filtered the signals measured be the exoskeleton motors encoders, as suggested in previous research [7], [27]. Pilot testings were performed to define the cutoff frequency that could reduce the signal peaks while preserving the majority of its frequency components. A power-spectrum analysis guided our choice to filter joint velocities at $4Hz$. Filtering also ensures that quasi-static movements and static standing (with quasi-zero joint velocity) do not result in a jittery assistance, but keep the torque values close to zero.

B. Torque Amplitude Optimization

To modulate the assistance strength across varied locomotion scenario, we implemented a real-time optimization procedure to adapt the multiplicative coefficient β (where $\beta \in [1.0, 2.5]$, with bounds tuned experimentally). With the Optuna framework [28], [29], we developed a Bayesian Optimization algorithm based on features computed from the hip exoskeleton kinematics ("Optimizer - BO" in Figure 2A). Unlike traditional mapping approaches, this optimization framework enables iterative updates of the algorithm based on the system's status and conflicting objectives. Additionally, designing the optimization based solely on kinematic variables eliminates the need for complex terrain-recognition algorithms or continuous manual tuning of torque coefficients [17], [30].

Our real-time multi-objective optimization balances two objectives. On one hand, we need to increase the torque during larger hip range of motion (ROM, the difference between minimum and maximum measured hip angles), as in stair or slope ascending [31]. On the other hand, we want to limit the transmitted torque in case of increased movement jerkiness (where the jerk is computed as the derivative of the acceleration). The resulting objective is expressed as $f_{obj} = q_{rom} - \ddot{q}_{mean}$. At the end of a fixed 2 s observation window, the Bayesian Optimization maximizes the value of the kinematics-based objective function, providing as output the optimal value of β.

C. Experimental Protocol

Five healthy subjects volunteered to participate in the study (age: 29 ± 2.8 yrs old, height: 1.73 ± 0.10 m, weight: 65.8 ± 6.4 kg). The experimental procedures were approved by the human research ethics committee of Canton de Vaud (CER-VD) under the protocol number 2023-02305. Participants provided an informed consent before the experimental evaluation, and the study was conducted in compliance with the principles of the Declaration of Helsinki.

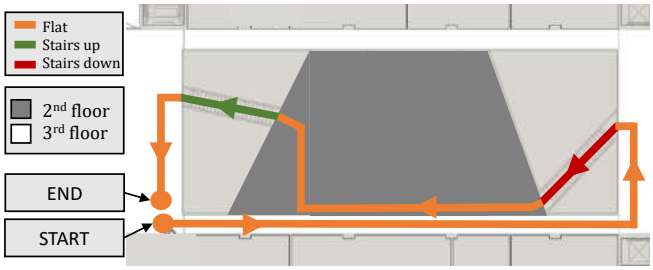

Fig. 3: Representation of the walking path for the varied terrain locomotion session (top view). The terrain consists of stairs (up and down), flat bouts, and changes of direction.

The experimental evaluation was divided into two sessions. Initially, we evaluated the performance of our controller in steady-state walking conditions on a treadmill. Participants were first familiarized with the exoskeleton assistance by walking with the device for 10 minutes on a treadmill. Then, they performed two 5-minute treadmill walking tests, one without the device and one with the exoskeleton assistance. Subjects walked at a fixed speed of $1.1\ m/s$, and the experimental conditions were proposed in a randomized order. In the assisted condition, the same value of $\beta = 2.3$ was used to facilitate intra-subject comparisons.

In a second session, we investigated the adaptability of our control in an unstructured environment. Participants walked with the assistive device in a varied terrain, consisting of flat sections, stairs ascending/descending, changes in direction, and variations in the walking speed. The duration of each segment was timed and kept consistent across participants, with the total duration set to 90 s. One of the buildings of EPFL was used for this scenario, and the walking path (from a top view) is represented in Figure 3.

D. Measurement Setup

In our study, we used the hip exoskeleton eWalk [14], an active hip orthosis developed in a collaboration between the BioRob-REHAssist group of EPFL and the company Sonceboz. This exoskeleton provides partial assistance during walking, with an actuated joint to assist hip flexion/extension and a passive degree of freedom for hip abduction to facilitate natural walking movements [32]. The version of the device used in this study weighs 4.4 kg, and it is attached to the user's body with a corset and two thigh attachments. eWalk is actuated by two DC servo motors (PowerSolutions, X8 Pro, maximum torque 32 Nm and reduction ration 1:9, China), and controlled by an embedded computer (BeagleBoneBlack, Texas Instruments, USA) running at 500 Hz.

To record the kinematic data of the lower limbs during walking, we used the portable motion capture system XSens (XSens, Movella, The Netherlands). The system has a custom interface to collect and process IMU data and to reconstruct the body movements. Data collection was performed at

$100Hz$, and the IMUs were calibrated for each participant according to the recommended procedure.

We measured the walking energetics in real-time through indirect calorimetry, by using the Q-NRG MAX metabolic monitoring device (COSMED Srl, Rome, Italy).

During the experiments, we used two separate computers. The first one was used to collect kinematic data in real-time with the XSens software. A second device was connected to the exoskeleton via Wi-Fi in order to monitor the exoskeleton data from a custom GUI. This second computer was also used to perform the optimization during the unstructured walking session.

E. Metrics

After the experiments, the collected data was processed in custom routines in MATLAB 2023b (The MathWorks, Natick, MA, USA). Before the analysis in MATLAB, XSens data was pre-processed in the custom software in order to reconstruct the walking kinematics of each user. We computed dedicated metrics for all participants, indicated as S1, S2, S3, S4, and S5. For treadmill walking trials, data was collected from the exoskeleton, XSens, and the indirect calorimetry device. For the walking session in the unstructured environment, we recorded data from the exoskeleton.

1) Exoskeleton data - treadmill: From the exoskeleton data, we extracted the applied torque profiles, the values of hip joint angular positions and velocities measured by the motor encoders, and the values from the inertial measurement unit on the exoskeleton corset. These kinematic signals were segmented into individual gait cycles with an algorithm developed in our laboratory [33]. These signals were averaged across gait cycles and between legs to derive the mean profiles for each participant. Finally, we computed the maximum torque value normalized by the weight of each user ($\frac{\Gamma_{exo,max}}{weight}$, in Nm/kg).

Power profiles were calculated by multiplying the joint angular velocities ((t), rad/s) by the torque applied by the exoskeleton ($\Gamma_{exo}(t)$, Nm), according to the formula $P(t) = \quad (t) \cdot \Gamma_{exo}(t)$, for $0 \leq t \leq T_{\text{gait cycle}}$. The resulting power profiles were averaged across gait cycles, and then normalized by each user's weight. We also evaluated the power transmission efficiency between the exoskeleton and the wearer. To this end, we computed the positive power, representing efficient energy transmission, and the negative power, an indicator of energy losses. To quantify power losses, we calculated the percentage of the negative power area relative to the total area under the power profiles.

2) Walking energetics data: To compute the metabolic energy expenditure, we integrated into the Weir equation [34] the values of oxygen and carbon dioxide measured by indirect calorimetry. For each treadmill trial, with and without the exoskeleton, we calculated the mean energy consumption during the final two minutes. Then, we subtracted the resting metabolic rate measured during the two minutes prior to the start of the experiment. This procedure allowed to isolate the activity-related energetic expenditure. Finally, we determined the percentage reduction in metabolic cost (MC) between the two experimental conditions as $\frac{(MC_{exo} \infty MC_{noexo})}{MC_{noexo}} * 100$.

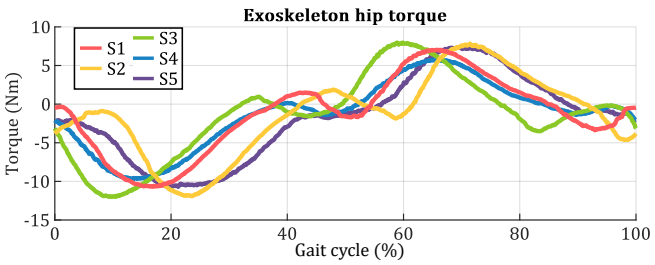

Fig. 4: Hip exoskeleton torque profiles resulting from our control strategy, for each participant to the experiment, when walking on the treadmill.

3) Kinematic data: Lower-limbs kinematic data was extracted from the XSens software after being processed to reconstruct individual movements. We extracted the vertical displacement of the center of mass (COM) and the flexion/extension angles of the hip joint. Then, we segmented the data using the heel-strike information of XSens, and computed the mean values for each subject. We also calculated the cadence ratio between exoskeleton-assisted and device-free walking conditions. Finally, we computed the ratio between the stance time and the swing time, and verified the statistical significance ($\alpha < 0.05$) between the two experimental conditions for each participant.

4) Exoskeleton data - unstructured terrain: When subjects walked in the unstructured environment, we recorded the applied torques, and the hip joint angular positions and velocities measured by the exoskeleton. From this data, we analyzed the torque profiles resulting from our optimization framework across the various walking conditions. To evaluate the efficiency of the power transmission, we calculated the negative power area (representing power losses) as a percentage of the total power area.

III. Results and Discussion

In our study, we successfully developed a hip exoskeleton control strategy that assists the wearers based on their volitional movements. The exoskeleton assistance adapts to individual gait patterns, and dynamically adjusts the support across various terrains. In this section, we first discuss the resulting user-specific hip torque assistive profiles. Then, we analyze the effectiveness of the assistive control strategy to reduce the walking energetics, while preserving individual kinematic patterns. Finally, we demonstrate the adaptability of the control framework to assist users in a variety of locomotion terrains.

1) Exoskeleton data - treadmill: We succeeded in generating exoskeleton hip torques to assist users during walking. The exoskeleton torques supported participants during both hip flexion and extension, with smooth transitions between gait cycles. Participants exhibited varied hip assistive torques profiles depending on their individual walking pattern and corresponding joints kinematics (Figure 4). The obtained torque profiles closely resemble the exoskeleton hip torques obtained with human-in-the-loop optimization techniques [5]. However, our approach did not require extensive tuning,

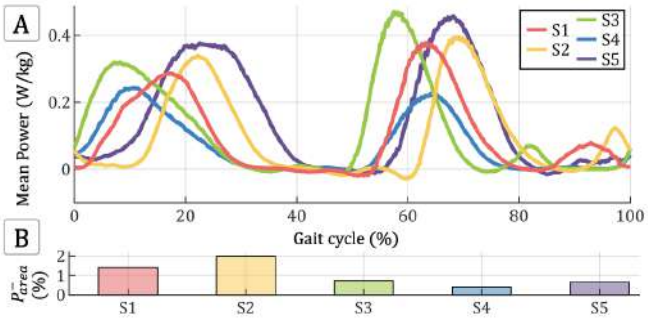

Fig. 5: (A) Power profiles calculated as the product of the hip exoskeleton torque and the hip joint angular velocities, for each participant. (B) Percentage of negative power area with respect to the total power area.

TABLE I: Metrics of our experiment.

Metric	*S1*	*S2*	*S3*	*S4*	*S5*
$\frac{(MC_{exo}-MC_{noexo})}{MC_{noexo}} * 100$ (%)	-5.6	-7.7	-3.9	-7.7	-11.0
$\frac{\Gamma_{exo,max}}{weight}$ ($\frac{Nm}{kg}$)	0.17	0.17	0.18	0.13	0.19
$\frac{Cadence_{exo}}{Cadence_{noexo}}$ ( )	1.00	1.04	1.01	1.02	0.97

as the torque curves were derived directly from the users' movements.

The peak torque timings varied between participants, but they were generally consistent with previous results in the literature [5], [15], [27], [35]. Most importantly, these timings were not manually adjusted for each participant. Instead, torque profiles were automatically synchronized with users' movements by incorporating joint angular velocities, thus the movements direction, into the control law. This is a crucial aspect because modifying the timing of assistive torques has been proven to affect the total power transferred from the exoskeleton to the user [5], [35], [36].

The power profiles shown in Figure 5A further emphasize the user-dependent nature of our control strategy. These profiles show peaks at different phases of the gait cycle, reflecting individual movements and torque profiles. Participants showed power profiles with peaks timings similar to the biological powers reported in the literature [37]. Conversely, the exoskeleton torque profiles appeared to be delayed compared to their biological counterparts [37], [38].

The power curves remained positive for most of the gait cycle, indicating that our control strategy remained aligned with users' movements. This efficient power transmission is further supported by the percentage of negative power remaining below 2% for all participants during the gait cycle (Figure 5B). Negative power indicates torques are not synchronized with the wearers' movements, therefore minimizing this value is essential to ensure seamless human-exoskeleton interaction [5], [7], [9], [35].

2) Walking energetics data: All participants exhibited reduced metabolic cost when walking with the exoskeleton against the condition without the device (Table I). In our experiments, we achieved an average reduction of $7.2 \pm 2.6\%$. This result demonstrates that the energy delivered into the human-exoskeleton system by our negative damping control can lead to a decreased energetic demand for the wearer.

The variability in the metabolic cost reductions may

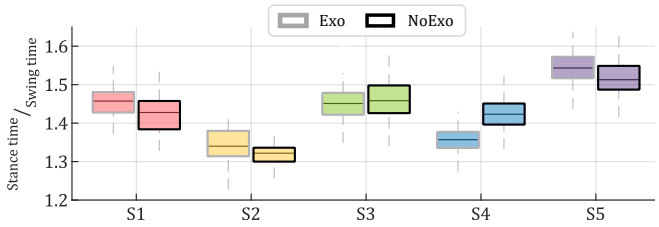

Fig. 6: The stance-to-swing ratio for each participant, and for each of the two experimental conditions.

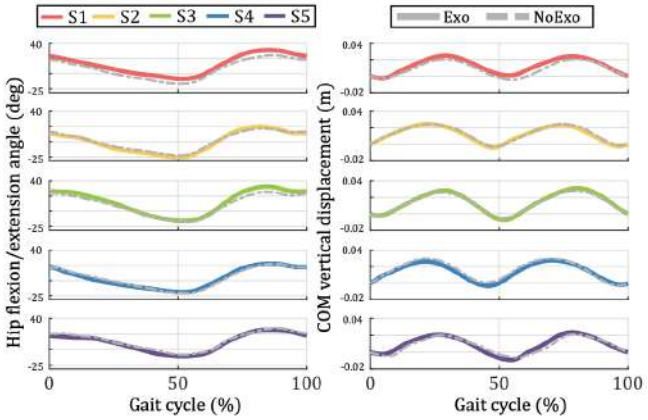

Fig. 7: Kinematic variables during the assisted and unassisted walking conditions. The center of mass (COM) vertical displacement and the hip flexion/extension angles are shown for each participant to the experiment.

be attributed to differences in participants' anthropometric characteristics. This is because, despite using the same β for all participants, the exoskeleton transmitted the mechanical power differently to each user. Consequently, the shortest participant experienced the greatest decrease in metabolic cost (S5, Table I). This user also received the greatest power relative to their body weight (Figure 5), and the highest peak torque normalized by body weight (Table I).

3) Kinematic data: During the assisted and unassisted walking conditions, participants adopted a similar walking strategy. This is demonstrated by the consistent stance-to-swing time ratio (Figure 6), and the cadence ratio close to 1.0 for all subjects (Table I). This finding confirms that our control strategy could assist users without causing forced movements. Conversely, disruptions of wearers' walking kinematics may occur in case of non-synchronized or excessively strong torque profiles [13].

The stance-to-swing time ratio was further analyzed using statistical methods, and a Friedman non-parametric test revealed significant differences between participants. This result can be attributed to the fixed treadmill speed used for all users, which led subjects to adjust their walking strategies accordingly. For instance, we observed that shorter participants adopted a longer stance time to increase stability [38]. These results are consistent with previous research showing that gait phase durations are influenced by anthropometric dimensions [39] and deviations from individual preferred walking speed [40]. On the other hand, within each subject, pairwise post-hoc comparisons indicated no significant difference between assisted and unassisted conditions.

Furthermore, for all subjects, the hip joint angle and the

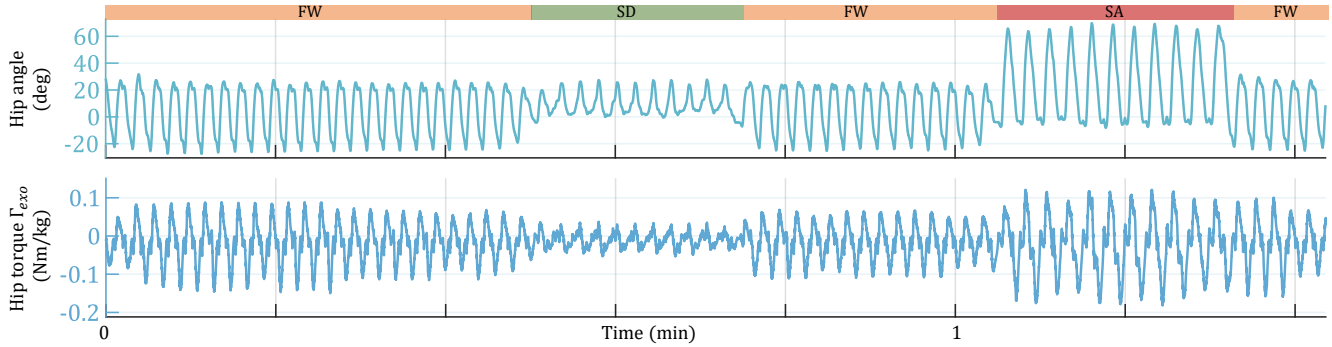

Fig. 8: Data collected during the varied environment walking trial. The user's hip flexion extension angle is shown, along with the hip assistive torque resulting from our control strategy. Tags: FW = flat walking, SD = stairs descending, SA = stairs ascending.

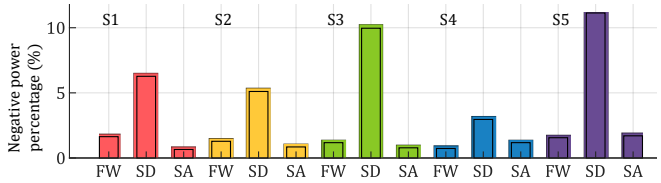

Fig. 9: Negative power area percentages for each subject in each unstructured environment. Center tags: FW = flat walking, SD = stairs descending, SA = stairs ascending.

vertical displacement of the center of mass (COM) remained unchanged in the two experimental conditions (Figure 7). Avoiding increases or decreases in the COM movement is crucial to avoid higher energetic cost during walking [21], [41], [42]. This finding also consolidates our results on the decreased metabolic cost measured when walking with the exoskeleton. With our approach, we achieved energetic cost reductions through efficient exoskeleton power transmission and without altering the users' walking kinematics.

4) Exoskeleton data - unstructured terrain: Our control strategy succeeded in assisting users in diverse walking conditions. The exoskeleton provided smooth support during gait transitions, and adapted the assistance to changes in terrain and walking directions (Figure 8). The assistance strength was dynamically adjusted in real-time through the designed optimization. Our multi-objective Bayesian optimizer remained unaware of the specific walking conditions, and, rather than performing a terrain classification, it relied only on the user's kinematics. The optimizer increased the torque strength during stairs ascending, a condition characterized by higher hip power demands [31], [43]. Conversely, intermediate assistive torques were applied during flat walking, while the assistance strength was decreased during stair descent. Our findings align with previous research on unstructured walking with hip exoskeletons [7], [14], [15], reinforcing the importance of modulating assistance strength across different conditions. Achieving this adaptability is essential for delivering seamless exoskeleton support across varied terrains and gait styles transitions [17].

The mechanical power exchanged between the users and the exoskeleton varied depending on the walking scenario (Figure 9). During flat walking and stairs ascent, the exoskeleton assistance generated low negative power, implying that the exoskeleton's assistive torque was synchronized with the wearers' movements. In contrast, stairs descent exhibited slightly higher negative power (still below 11% of the total power area), despite the lower assistance strength in this walking condition. These results are consistent with previous findings [7], and highlight the ability of our control framework to provide adaptive and synchronized assistance across varying terrains.

IV. Conclusion

In this work, we present a novel adaptive and user-dependent control strategy for the hip exoskeleton eWalk. We design the assistive torque as an adaptive virtual negative damping, capable of injecting energy into the human-exoskeleton system while keeping the users in charge of the movements. Our approach results in a torque profile that smoothly follows individual gait patters. Additionally, our control strategy reduces the energy expenditure of walking while preserving the natural joint kinematics. When tested in unstructured environments, our multi-objective Bayesian Optimization framework modulates the assistance strength by relying only on the exoskeleton kinematic variables. Notably, the exoskeleton assistance remains synchronized with users' movements across different terrains, as indicated by the low percentages of negative mechanical power transmitted from the device. In future work, we will evaluate the efficacy of the control with a wider population, test other dynamic optimization techniques, and evaluate our control on more unstructured terrains.

In conclusion, we introduce a simple but powerful strategy to provide partial walking assistance with the hip exoskeleton eWalk. Our control strategy provides individualized and adaptable assistance in various walking scenarios, without the need for extensive modeling or coefficients tuning. Overall, our approach contributes to advancing the development of viable, adaptive, and used-dependent control strategies for hip exoskeletons.

The Relationship Between Stroke-Related Cognitive Impairment and Robotic Proprioceptive Assessment

Caitlin M. Callaghan, Christopher A. Johnson, Piyashi Biswas, Jill See, Lucy Dodakian, Vicky Chan, Po T .Wang, Steven C. Cramer, Zoran Nenadic, An H. Do, and David J. Reinkensmeyer, *Senior Member, IEEE*

***Abstract*— The interplay between proprioceptive and cognitive impairment following stroke is not well understood, along with the implications it may have on the design of robotic proprioception assessments. To examine the relationship between proprioceptive and cognitive impairments, we used a robotic device to measure ankle proprioception in 37 chronic stroke patients. Participants also completed the Montreal Cognitive Assessment (MoCA) and NIH stroke scale (NIHSS). We found that overall MoCA score was correlated with both active (R_s = -0.32 p=0.034) and passive proprioception ability (R_s = -0.52, p = 0.01). When we examined the MoCA subscores, we found that the Visuospatial/Executive subscore was moderately correlated with measures of both active (R_s = -0.57, p=0) and passive (R_s = -0.42, p=0.01) ankle proprioception ability. When we removed 5 individuals who were identified as having unilateral neglect using the NIHSS, the correlations remained significant. The Attention subtest was also weakly correlated with active proprioception ability (R_s = -0.36, p=0.03). Thus, proprioception ability is interrelated with specific cognitive impairments after stroke besides neglect. This suggests that cognitive tests should be conducted alongside robotic proprioceptive tests after stroke, to identify where cognitive factors may be contributing to measured proprioceptive error.**

I. Introduction

Over half of people who have experienced a stroke exhibit proprioception impairment [1]. These impairments predict functional ability of the upper [2] and lower extremities [3], [4] as well as ability of the upper extremity to benefit from rehabilitation therapy [5], [6], [7]. Further, proprioceptive impairment itself is treatable with targeted training after stroke [8]. Despite this, few rehabilitation therapists routinely assess proprioception [9]. The sparse technological landscape for clinical proprioceptive testing likely contributes to this situation. Clinical assessments are coarse, and there is a lack of practical technologies for sensitively measuring proprioception in the clinic or at home.

Given this need, there is increasing interest in developing technologies, including robotic devices, that enable routine, quantitative testing of proprioceptive ability after stroke [10], [11]. A challenge in developing these technologies, however, is that it is currently unclear which aspects of proprioception they should measure. Proprioception is a complex skill involving an array of different types of biological sensors, multiple brain areas that integrate information from those sensors, and complex computational processes that form the dynamic body models used for proprioceptive decision making [12], [13]. As a result, although over 1000 proprioceptive testing procedures have been developed, they rarely produce results that generalize between themselves [11].

It is clear that cognitive ability must play a role in proprioceptive ability. At a minimum, proprioceptive assessments require individuals to pay attention to the test and to internally model the sensed body movements. Over half of people who have experienced a stroke exhibit cognitive impairments [14], [15]. Despite this, there is limited information about how various aspects of cognitive impairment impact proprioceptive ability after stroke. Specifically, while it has been established that post-stroke individuals with unilateral neglect often show worse proprioception [16], the role of other cognitive abilities, such as attention and spatial reasoning is less clear.

One recent study found no significant correlation between a common test of cognitive ability, the Montreal Cognitive Assessment (MoCA), and wrist position sense measured with a quantitative testing paradigm [17]. Another group recently included participant data in a paper that described a study that

tracked proprioceptive recovery of the fingers after stroke using a robotic device. This allowed us to perform our own analysis of the relationship between the MoCA and finger proprioceptive ability [18], which showed no correlation.

The goal of this study was to quantify the interplay of cognitive and proprioceptive impairment after stroke, with a view toward gaining insight on how to optimize robotic technology for assessment of proprioception. We asked 37 people in the chronic phase following stroke to perform active and passive proprioceptive tasks with the ankle using a novel robotic device, as part of a larger study focused on rehabilitating foot drop. We assessed cognitive ability with the MoCA, identifying subscores on different subsections as well.

II. Methods

A. Participants and clinical assessments

These data were collected as part of a clinical trial designed to evaluate the efficacy of a brain-computer-interface, functional electrical stimulation system for treating foot drop in chronic stroke participants [4]. Inclusion and exclusion criteria can be found in [19]. The local ethics committee approved this study, and written informed consent was obtained from each participant prior to participating, following procedures established by the University of California Irvine Institutional Review Board. For this study we only used baseline measurements.

We evaluated cognitive ability with the MoCA, a widely-used and validated screening tool for mild and moderate dementia [20], [21]. The MoCA tests eight areas of cognition: Visuospatial/Executive Ability, Naming, Memory, Attention, Language, Abstraction, and Delayed Recall. The MoCA is scored out of 30 points; scores of 26+ indicate normal cognition, 18-25 indicate mild cognitive deficits, 10-17 moderate deficits, and <16 severe cognitive deficits. [20]

B. Robotic Proprioceptive Assessments

The robotic proprioceptive assessments were completed using the Ankle Measuring Proprioceptive Device (AMPD, Fig. 1) [22], a custom-designed device for which the foot platforms have two impedance states, mechanically rigid and mechanically transparent. These impedance states are achieved by engaging and disengaging a rack and pinion system driven by a motorized lead screw. Rotary encoders were used to measure ankle rotation at 200 Hz. Participants sat with their shank perpendicular to the ground and the ankle flexion/rotation center aligned to foot pedal shaft.

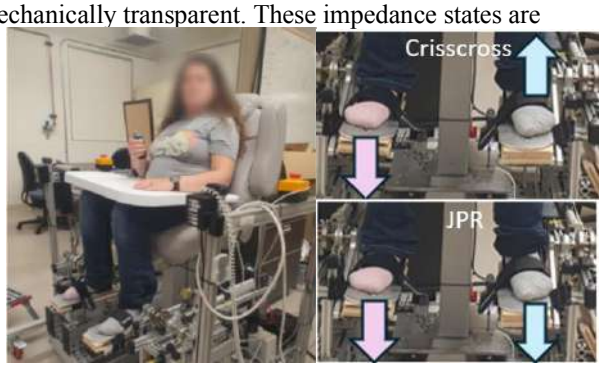

Figure 1: AMPD allows robot-driven or user-driven ankle movement for each pedal. For the Crisscross assessment (top right), the passive feet are robot-driven past each other and the participant must push a button when they cross. For the Joint Position Reproduction (JPR) assessment (bottom right), the impaired foot is robot-driven and the participant tracks it with the unimpaired foot. JPR involves dynamic and static periods. During static periods, the participant adjusts the feet to match if needed and then pushes the handheld button to signal readiness to return to dynamic tracking. Participant view of feet was obfuscated with a removable table top.

We used AMPD to measure two forms of proprioception. Passive proprioception is one's sense of limb position and movement when muscles are relaxed. Passive proprioception sense is built from sensory signals from the muscles, tendons, joint capsules, and skin. Active proprioception refers to body sense during voluntary movement, utilizing the same sensors as well as an estimate of joint movement derived from an internal forward model [12], [23].

We measured passive ankle proprioceptive ability using the Crisscross test originally developed by the UCI Biorobotics Lab for the fingers after stroke [4], [24], [25]. This involved AMPD in its mechanically rigid state moving the ankles in opposing directions to the participant's maximum dorsiflexion and plantarflexion, and participants pressing a handheld button when they believed their ankles aligned (Fig. 1). Passive range of motion was measured by a trained therapist and set as the limits. Crossing speed and position were randomized. Crisscross error was defined as the absolute angular difference between ankles at button press, averaged across trials.

We measured active ankle proprioceptive ability using a joint position reproduction (JPR) task. A range of JPR tasks have been developed for both the upper and lower extremities, testing the ability to reproduce an active or passively imposed movement. JPR has good test-retest reliability [26], [27]. The JPR task implemented here was a contralateral passive-active task with periods of dynamic position tracking mixed with periods of static position matching. Dynamic tracking involved AMPD moving the passive, impaired foot 5 deg/s through its passive ROM. Participants were instructed to actively move their unimpaired foot to match the movement of their impaired foot. Following a dynamic tracking period of random duration, the robot stopped moving and participants were instructed to adjust their unimpaired ankle to align with their impaired one, as needed, and then press the button once they believed the feet were aligned, at which point the dynamic tracking task resumed. Dynamic JPR error was quantified as the mean absolute difference between the ankle angles during dynamic periods. Static JPR error was the angle difference at button press.

TABLE I. Participant Characteristics (N = 37)

	Mean ± SD
Age (years)	60 ±12
Time Post Stroke (months)	35.6 ± 31.7
NIH Stroke Scale Severity (0 42)	6 ± 3
Sex M/F	23/14
Side Affected L/R	11/26
Ischemic/Hemorrhagic/Both	19/15/3
Montreal Cognitive Assessment (MoCA) (0 30)	24 ± 5
10M Walking Test (m/s)	0.43 ± 0.19

C. Data Analysis

MoCA subtests scores are ordinal data. Shapiro-Wilk testing of the MoCA subtests indicated that the MoCA scores were not normally distributed. Therefore, two-sided Spearman correlation was used for correlation analysis with alpha = 0.05. Group comparisons were performed using Kruskal-Wallis tests, also with alpha = 0.05.

III. Results

We measured ankle proprioception ability of 37 post-stroke individuals using a robotic device. We compared their proprioception error for active and passive tests to the overall MoCA score and to selected subscores. Of the 39 original participants, one was excluded due to an incomplete MoCA test, and one for an incomplete proprioception test, resulting in 37 participants. Table I provides an overview of participant characteristics as well as several clinical assessments given at baseline by an experienced therapist.

A. Proprioception error was correlated with overall MoCA score

Overall MoCA score was weakly and negatively correlated with Crisscross error ($p = 0.034$, Spearman's Correlation $R_s = -0.35$) and moderately correlated with JPR dynamic error ($p = 0.01$, $R_s = -0.42$, Fig. 2), using common correlation strength descriptors [28].

As unilateral neglect is common after stroke and known to affect proprioception assessments [7], we identified five individuals with neglect using the 'Extinction and Inattention" subscore of the NIHSS (formerly the Neglect score). When we omitted these five participants, these correlations were still significant for both Crisscross Error ($p = 0.047$, $R_s = -0.35$) and JPR dynamic error ($p = 0.002$, $R_s = -0.52$).

B. Proprioception error was correlated with two MoCA subscores: Visuospatial/Executive and Attention

The total MoCA score is obtained by adding subscores on the 7 subtests that are scored: Visuospatial/Executive, Naming, Attention, Language, Abstraction, Delayed Recall, and Orientation. The Memory task is used to scaffold the Delayed Recall task and does not contribute to the total score. We found that subscores on two of these tests were correlated with ankle proprioceptive error. First, the subscore on the Visuospatial/Executive (VSE) subtest was negatively correlated with error for the passive Crisscross Task (Fig. 4, $p < 0.001$, $R_s = -0.55$), as well as both the static and dynamic portions of the JPR task ($p < 0.0001$, $R_s = -0.47$, and $p=0.01$ $R_s = -0.57$, respectively). Omitting the five participants with neglect slightly weakened this correlation for all metrics, but the correlations remained significant. Crisscross error ($p = 0.006$, $R_s = -0.48$), JPR static error ($p = 0.017$, $R_s = -0.42$), and JPR dynamic error ($p = 0.001$, $R_s = -0.55$) all remained moderately negatively correlated with VSE score.

The Score on the Attention subtest was weakly correlated with JPR dynamic error ($p = 0.03$, $R_s = -0.36$, Fig. 2). Omitting participants with neglect strengthened this correlation ($p=0.003$, $R_s = -0.51$).

C. Neglect and robotic proprioceptive assessment

Although omitting individuals with neglect did not change the correlation results, we were interested in whether individuals with neglect had worse proprioception. We therefore compared proprioception error for the 5 individuals identified using the NIHSS as having neglect to those without neglect. Only dynamic JPR error was significantly different ($p = 0.037$, Table II), though for all metrics participants with detected neglect had equal or higher error than those without detected neglect. Neglect comes in multiple forms depending on lesion location and severity [29]. NIHSS emphasizes visual and tactile aspects of neglect, while the Clock Drawing task used in the MoCA Visuospatial/Executive subtest measures spatial awareness. In the Clock Drawing task, spatial neglect is indicated by digit clustering on one side of the clock [30]. None of the clock drawings of the participants who were identified by NIHSS as having neglect showed digit clustering (Fig. 3).

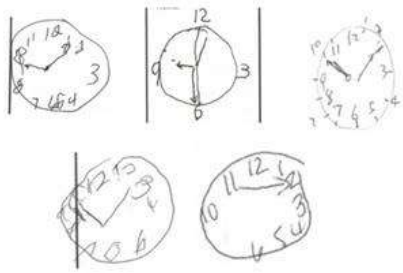

Figure 3: Clock Drawing Task results for 5 participants indicated by NIHSS as having neglect. None showed digit clustering on one side of clock.

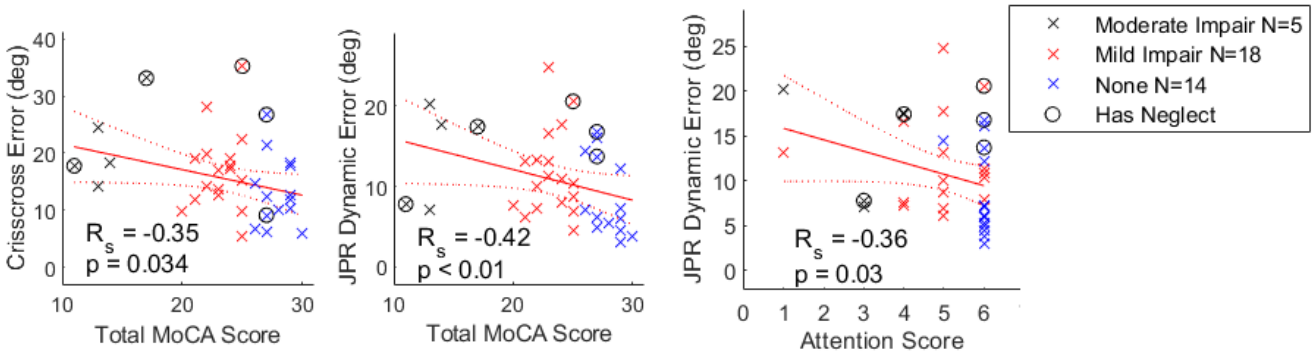

Figure 2. Proprioceptive error for the Crisscross test (left) and JPR Dynamic test (center) was significantly correlated with the total MoCA score. JPR Dynamic Test Error (right) was also correlated with the MoCA Attention score. Circled points are individuals identified as having neglect on the NIHSS.

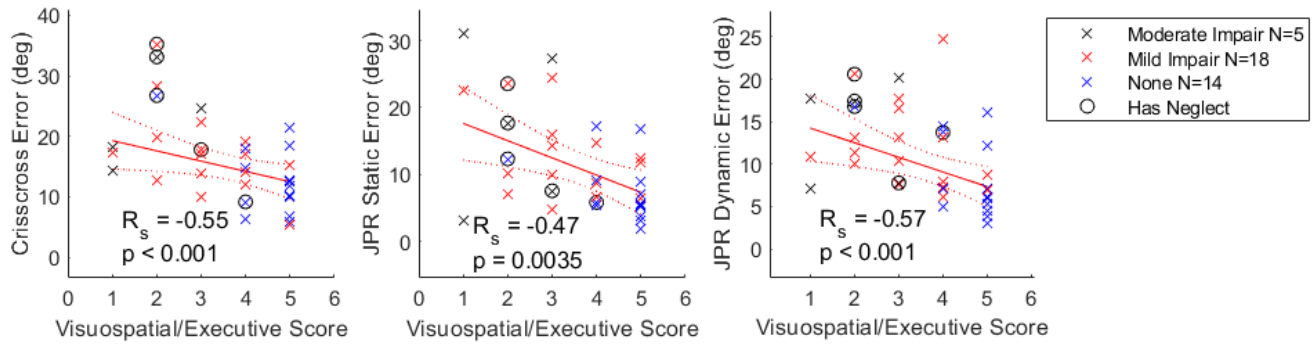

Figure 4. Proprioceptive error for the Crisscross test (left), JPR Static test (middle), and JPR Dynamic test (right) was significantly correlated with the VisuoSpatio subscore of the MoCA test. Circled points are individuals identified as having unilateral neglect on the NIHSS.

TABLE II. COMPARISON OF PROPRIOCEPTION ERROR FOR INDIVIDUALS WITH AND WITHOUT UNILATERAL NEGLECT ON THE NIHSS.

Proprioception Metric	***No Neglect (N=32)***	***Neglect (N=5)***	***p***
CC Error (deg)	14.9 ± 5.46	24.4 ± 10.9	0.068
JPR Static Error (deg)	10.9 ± 7.3	13. 4 ± 7.3	0.33
JPR Dynamic Error (deg)	10.2 ± 5.3	15.3 ± 4.8	0.037

IV. DISCUSSION

Proprioception assessment involves cognitive processes such as attention, but little is known about how cognitive impairment affects proprioceptive assessment after stroke. Here we found that the overall MoCA score was significantly correlated with active and passive ankle proprioception error after stroke. Two of the MoCA subscores, the Visuospatial/Executive and Attention subscores, accounted for this correlation. We discuss these results now plus limitations and directions for future research.

A. Overall cognitive impairment and proprioception impairment after stroke

Although it is well known that individuals with unilateral neglect after stroke exhibit worse proprioception [16], only a few studies to our knowledge have looked at how overall cognitive ability relates to proprioception impairment. A recent study found that hand proprioception ability was not correlated with total MoCA score [17], a finding at odds with the results of this study. The difference could arise due to the difference in joints tested (hand vs. ankle), or the difference in proprioceptive testing protocol. In individuals with multiple sclerosis [31] and mild cognitive impairment [32], proprioception ability was found to be correlated with MoCA score. Future research should seek to understand which aspects of proprioception at which joints and for what types of stroke most closely relate to overall cognitive impairment.

B. Specific aspects of cognitive impairment that correlated with proprioception impairment

The correlation with overall MoCA score most likely arose from the correlations present with subscores related to the Attention and Visuospatial/Executive (VSE) subsections. The finding that attention is related to proprioceptive error is not surprising: proprioception tests, including the ones used here, require the participant to pay continuous attention to their limbs. Further, attention deficits are common among stroke patients, and are associated with proprioception-related injuries such as heightened risk of fall injury [13]. However, the attention subscore positively correlated only with JPR dynamic error, not Crisscross or JPR static error. Dynamic JPR may be a more attention-demanding test than either passive proprioception (Crisscross), or matching static limb position (Static JPR), because active position tracking requires constant updates to both the passively-generated estimate of impaired side ankle position and motor planning to match that position with the other ankle.

The finding that VSE subscore was correlated with ankle proprioception was surprising and the reason is unclear. VSE ability is measured in the MoCA by completing three drawing tasks with the unimpaired hand: an alphanumeric "connect-the-dots" task, cube drawing, and clockface drawing. It is unclear why performance on these tasks is related to ankle proprioceptive performance. However, the fact that the tasks were completed with the unimpaired hand, whereas we measured proprioception of the impaired ankle, suggests that a higher-level cognitive process required for both types of tasks, joints, and sides is involved.

One possibility is that unilateral neglect plays a role. Unilateral neglect, the lack of awareness of stimuli on one side of the body, measurably affects 30% of chronic stroke patients [7]. Neglect has several modalities: visual, tactile, auditory, spatial, motor, or personal inattention [8], [9], [10]. Proprioception losses are associated with spatial neglect, typically associated with damage to the parietal lobe, especially for lesions in the nondominant hemisphere [11][16]. However, the correlations observed here were robust to omitting participants indicated by the NIHSS to have neglect. Neglect-style symptoms among chronic stroke patients are self-reported at a higher rate than neglect tests actually detect [33], which suggests neglect that does not meet the level of clinical detection may be common among stroke survivors. Thus, more subtle forms of neglect could still have played a role in the results of the current study. Future studies should assay neglect with more sensitive instruments to determine if it accounts for the findings here.

If neglect too mild to be detected by existing techniques is a contributing factor to both cognitive and proprioceptive assessment results, this would motivate future research into

using combinations of proprioceptive and cognitive assessments in the development of new, highly sensitive techniques for detection of neglect. Given the heightened injury risk associated with neglect, identifying mild cases may be important for assessing patient injury risk factors.

C. Limitations, Future Directions, and Clinical Implications

Participants handedness was not recorded at intake. Patients with stroke in the dominant hemisphere have significantly lower scores in the MoCA [34], and this may have added noise to the VSE subscores that we did not account for. Though the affected side and type of stroke were recorded, location of lesion was not. Spatial neglect is most common in participants with parietal lobe damage in the non-dominant hemisphere [24]; knowledge of lesion location could have indicated participants likely to experience neglect-type symptoms even if the NIHSS did not detect it.

Side-affected was not controlled for equal distribution. For MoCA distribution, the parent study for this paper had a minimum cutoff of 22, but the protocol allowed for the possibility of lowering this cutoff at the discretion of the clinical team for individuals with aphasia, which was done for eight participants. As a result, there were low MoCA score participants in this study, but relatively few of them (8 such participants, mean MoCA score 16 +- 4). Low MoCA score is frequently used as an exclusion criterion in proprioceptive studies; this may have limited the ability of studies to detect a relationship between cognitive impairment and proprioception. The selected statistical tests – Spearman Correlation and Kruskal-Wallis test – were selected for robustness against outliers as well as their tolerance for non-normally distributed ordinal data, but inclusion of more participants with severe and moderate cognitive impairment is an important direction for future research.

We asserted that the finding of correlation between a drawing task performed with the unimpaired side with impaired-side proprioception for a different limb suggests a higher-level cognitive process is at play in both assessments. This assertion would be strengthened by performing similar analysis on proprioceptive studies on other joints. The sparsity of proprioception studies that are inclusive of participants with low MoCA scores may require design of studies specifically targeting this relationship through a battery of proprioceptive assessments suitable for participants with a wide range of MoCA scores.

Future research will analyze the different drawing tasks that comprise the VSE subtest to identify which is most predictive of proprioceptive error. Though the clock drawing task is well known in neglect assessment, the other tasks may offer further insights into why the VSE subtest is correlated with proprioception ability.

We also plan in future research to include dual-tasking to modulate the attention load during proprioception assessment. Augmenting the attention load through the addition of a simultaneous task stressing a sensory pathway not involved in the proprioception task, such as visual or audio signal interpretation, could indicate how much influence attention load has on active and passive proprioception assessment results, and whether active proprioception truly is more sensitive to heightened global attention load. Further, identifying the influence of task-specific attention demands on proprioceptive assessment results would provide insight into appropriate assessment design for patients with attention deficits.

That proprioception of the ankle and VSE score correlations were weakened by the omission of subjects identified to have neglect by NIHSS suggests non-detected neglect may still be contributing to both tasks. More sensitive tests for neglect may have detected its presence in more of our subjects. Future research that compares performance on other tests for spatial neglect, such as Semi-structured Scale for Functional Evaluation of Hemi-inattention [35], to proprioceptive assessment results, would indicate the importance of detecting and controlling for neglect in both proprioceptive and cognitive assessments.

Finally, an important clinical implication is accounting for cognitive factors in proprioceptive assessment. At a minimum, the current results suggest that robotic proprioceptive tests should be performed alongside cognitive tests, as cognitive impairment may explain some aspects of proprioceptive error. Proprioception assessments rely on attention and memory while common cognitive assessments rely on sensory motor control of the hand (to draw pictures, for example). Therefore, it is conceivable that impairments in one area may be confounded as impairments in the other. Designing a minimally viable set of quantitative, clinical tests that comprehensively characterizes the essential elements of proprioceptive skill is an important goal for rehabilitation practice.

V. Conclusion

Overall MoCA score, as well as the Visuospatial/Executive and Attention subscores, were correlated with proprioception ability of the ankles after stroke. This implies the existence of a shared neural impairment (or impairments) that affects performance on both proprioceptive and cognitive assessments. New technologies for clinical proprioception testing after stroke should determine how to account for the interplay of cognitive impairment with proprioception impairment, given the high frequency of cognitive impairment after stroke.

***Abstract*—Affective touch is crucial for human development, social bonding, and emotional support, while physical interaction plays a key role in rehabilitation, aiding motor recovery and well-being. Although AI has advanced verbal and non-verbal communication, replicating human-like physical interaction remains a challenge. This paper explores whether robots can convey emotional touch. Using a soft brush as a haptic transfer mediator, we isolated temporal and spatial touch characteristics to assess their impact on human perception.**

We implemented Cartesian dynamic movement primitives to replicate the human touch and adapt it to individuals by sampling geometric points on the forearm. Questionnaire analysis revealed that robotic touch at $3\,\mathrm{cm/s}$ was more effective in replicating the pleasurable sensations of human touch compared to $0.3\,\mathrm{cm/s}$. Our findings indicate that the human-like quality of robotic touch depends more on temporal factors than spatial trajectories. However, robotic touch was still distinguishable from human touch, with 75.71% of participants correctly identifying it as robotic.

These results contribute to robotic rehabilitation by improving the understanding of affective touch, with potential applications in motor recovery, sensory stimulation, and emotional well-being.

***Index Terms*—Affective Touch, Robotic Touch, Human-Robot Interaction, Haptic Transfer Interface, Humanization of Robot Touch**

I. Introduction

Humans are social beings and rely on cooperation with each other to survive. Such cooperation builds on verbal and non-verbal interaction processes with affective touch being one of them. Affective touch is friendly interpersonal contact and it fosters the initiation and maintenance of human bonds [1] [2]. This type of touch typically involves the activation of a specialized set of cutaneous nerve fibers, known as C-tactile fibers, leading to a pleasant or calming sensation and an accompanying decrease in physiological arousal [1] [3], especially in the face of stress [4].

The involvement of C-tactile nerve fibers in the transmission of affective touch has been identified through microneurography studies, which revealed that slow stroking stimulation activates this specific set of touch-processing fibers, whose response characteristics differ fundamentally from other cutaneous fibers involved in somatosensation [5]. Specifically, slow stroking with velocities of 1, 3 or $10\,\mathrm{cm/s}$ CT activates those fibers more, and is perceived as more pleasant, as compared to stroking with 0.1, 0.3 or $30\,\mathrm{cm/s}$ [6]. The experiments underlying this finding are typically performed by stroking with a soft goat hair brush over a participant's forearm and the inverted U-shaped curve of pleasantness perception has been replicated multiple times in group results, although it cannot be found in each single individual [7]. Interestingly, slow stroking with C-tactile nerve fiber targeted velocities does not only lead to feeling pleasant, but also more "human" than stroking at other velocities [8] [9].

This finding leads us and other researchers to believe that touch speed may be one of the important features reshaping interpersonal touch. A similar situation exists in the spatial characteristics of touch, where trajectories tend to be deterministic for robots, whereas human behavior is relatively more uncertain, e.g., it is difficult for humans to draw a straight line. Therefore, if the robot will only deliver fixed trajectories as in previous studies (e.g. linear haptic stimulators - Dancer design), comparing it to human-to-human interaction becomes challenging. We aim to introduce more flexible and relatively random trajectories of robotic touch to better assess the emotional impact of robot-applied touch on humans and compare it to human behavior.

Overall, the goal of this work is to use spatial and temporal (trajectory and velocity) to investigate whether robots can create natural, pleasurable experiences for humans. The study aimed to test whether we could: a) replicate typical inverted U-shaped velocity-related pleasantness with touch provided by a fully robotic arm; and b) whether participants could distinguish between touch provided by humans and robots.

II. Related Works

A. Affective Robotic Touch

Most haptics-related algorithms for robot motion planning or control currently focus on the industrial sector to perform better assembly tasks or to make robots more flexible so that they can share workspaces with humans [10]. On the other hand, research on affective social touch has rarely focused on human-like tactile reproduction or motion planning of robots.

1) Vibration or Other Actuators without Robot Arm and Hand: Specific actuators can stimulate the receptors for emotional touch, even if they do not yet provide the exact sensation of a fully realistic human touch. For example, vibrotactile [11], air pressure [12], or specially designed mechanical stimuli [13] can stimulate different mechanoreceptors.

2) NAO: The NAO robot has been utilized in numerous studies to achieve robotic touch. For example, it was employed to comfort people by trying to touch the shoulder or big arm of the experimenter for $10 - 40$ seconds while some scary scenes were shown [14] [15]. However, neither test mentions specific robot-related data.

3) PR2: Previous iterations of HuggieBot [16] focused on static hugs, identifying hug firmness, duration, and joint angle during the hug as key factors. Inspired by the human prolonged hugs, attention was shifted to several different contact features on HuggieBot 3.0, including rubbing, patting, and squeezing [17]. However, no advanced stroking mechanisms were implemented. The PR2 robot executed rubbing movements by changing the shoulder joint angle. Law et al. [18] conducted several studies on robotic touch, primarily involving a robot assisting a human when the screen suddenly goes black. Most experiments indicated that people felt more comfortable in situations where the robot was in contact with them (by placing its hand on the experimenter's shoulder), yet no specific robot-related data is mentioned in the text. It is assumed that the usual software and hardware configuration of PR2 was used.

4) Human-like Contacts: Guidelines on how robots touch humans were proposed at an early stage [19]. Zheng et al [20] used the female robot Erica to explore the effects of touch on participant arousal and whether the robot was able to convey specific emotions by varying the type of touch (touch or tap), the length of the path of the touch, and the location of the touch (hand or fingers). Teyssier et al. [21] define four important parameters of robotic touch: spatial (position of contact), temporal (length of contact), dynamic (pressure or vibration), and other parameters (e.g. temperature, texture, and softness). In the study, they also evaluated each type of parameter and chose eight specific dynamic touches to explore the effects of robotic touch on human emotions. However, they did not compare the robot touch with the human touch and used only classical robot control algorithms in their experiments. The study closest to the goal of this work is [22], which researched the effect of touch exerted by humans, the Nao robot, a mannequin arm, and a plastic tube on human comfort. Stroking touches at a velocity of ca. 3 cm/s were rated as the most pleasant, which is similar to the results of the human touch study [6]. Robot touch was not rated as significantly more pleasant than touches applied with the mannequin hand or tube and was lower than human-applied touch. However, participants evaluated the comfort and pleasantness of the touch through a video in which the participant was not actually being touched.

To the best of our knowledge, a gap still exists in the comparison between human and robotic touch, which is the focus of this work. As Teyssier states, the parameter space for human touch is too large (including, but not limited to the four-parameter types he summarized), and to better enable robots to replicate human-like touch, we use a brush as a mediator to limit the touch parameter space to spatial, temporal parameters.

B. Motion Planning and Control for Human-like Robotic Touch

The field of robotic movement and its adaptation from human behaviors has garnered considerable attention, aiming to endow robots with the capability to perform tasks with human-like dexterity and adaptability. Among the techniques explored, Dynamical Movement Primitives (DMPs) have emerged as a potent method for modeling and replicating human movements, facilitating the teaching and execution of complex motor tasks in robots.

Key contributions include the foundational framework that introduced DMPs for capturing and replicating motor behaviors, demonstrating their potential for robotic applications [23]. Pastor et al. furthered this by showing how robots could learn and generalize motor skills from demonstrations, highlighting the versatility of DMPs [24].

DMPs were applied to robot table tennis, showcasing their adaptability in dynamic sports environments [25], while Ude et al. expanded DMPs to include orientation tasks [26]. Force feedback modulation was also introduced into DMPs, allowing for real-time adjustment based on environmental interactions [27].

At the control level, Ishikura et al. [28] used impedance control and a hand modeled on a human to perform a gentle stroke on the back, which has positive emotional effects in tactile care. However, the pressure and speed of the end effector also remain constant. Contact with constant force can hardly be defined as human-like contact and therefore has an impact on the evaluation of the social touch imparted.

In general, DMPs are well suited to the needs of affective robotic touch scenarios as an important method for encoding human behavior and enabling the robot to reproduce it. Therefore, we use DMPs in the Cartesian coordinate system as the basis of this work and eliminate as much as possible the influence of the robot's dynamic touch features (force or acceleration, etc.) on human perception by using a soft brush.

III. Affective Robotic Touch

Based on our research objectives, we propose the following hypotheses:

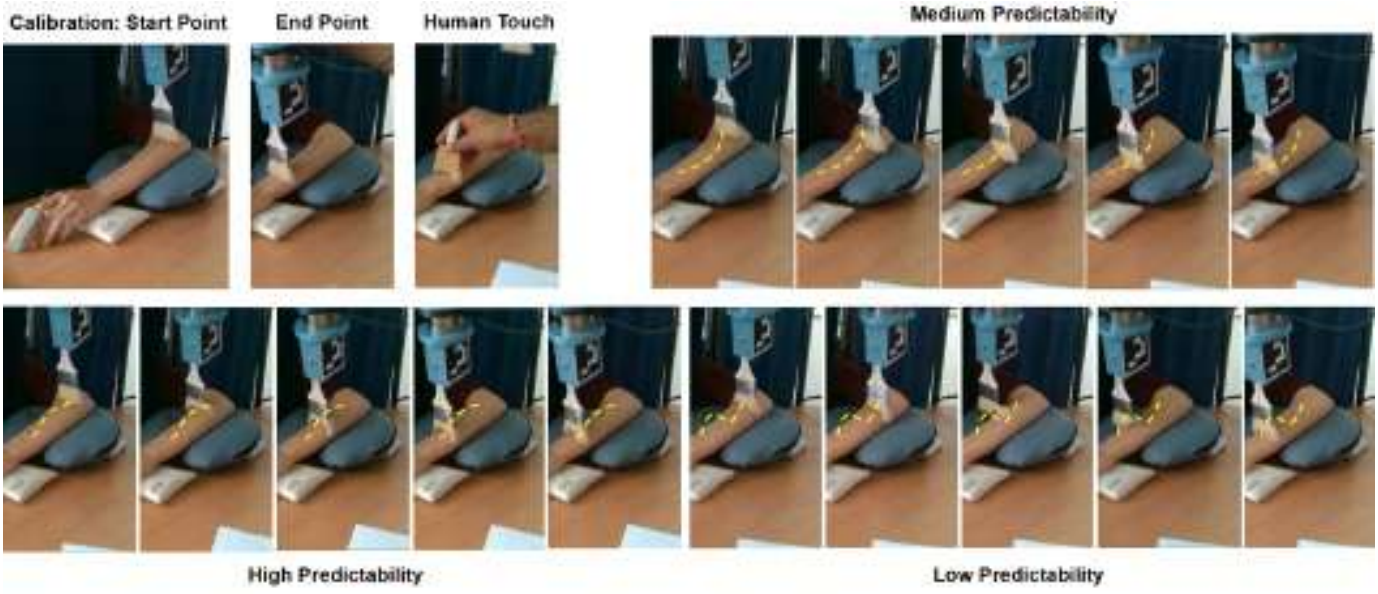

Fig. 1. **Spatial Characteristic (Trajectory) of the stroking:** At the beginning of the experiment, the robot will first calibrate the forearm of the experimenter, which involves collecting pose data on the start and end points. Trajectories resembling straight lines are defined as having high predictability. In contrast, curvilinear trajectories with three waypoints are considered to have medium predictability, and S-shaped trajectories with four waypoints are deemed to have low predictability.

- **H1:** Stroking at a velocity of $3\,\mathrm{cm/s}$ will be perceived as more pleasant than stroking at $0.3\,\mathrm{cm/s}$, regardless of whether the stroking is performed by a human or a robot.
- **H2:** The predictability of stroking trajectories will influence the perceived pleasantness, with higher predictability leading to more pleasant experiences.
- **H3:** Participants will be able to distinguish between human and robotic touch, and this ability will be influenced by the trajectory predictability.

As we want to explore the spatial and temporal characteristics of touch, short-duration spatially invariant touch patterns such as tapping will not be explored in this work. The focus of the experiments will be on long-distance strokes with different trajectories, while uncertainty (which can also be called randomness or predictability) similar to human behavior will also be introduced in the trajectory chapter. For clarity, within the context, the spatial characteristics of touch will be synonymous with the trajectories of the robot's Tool Center Point (TCP).

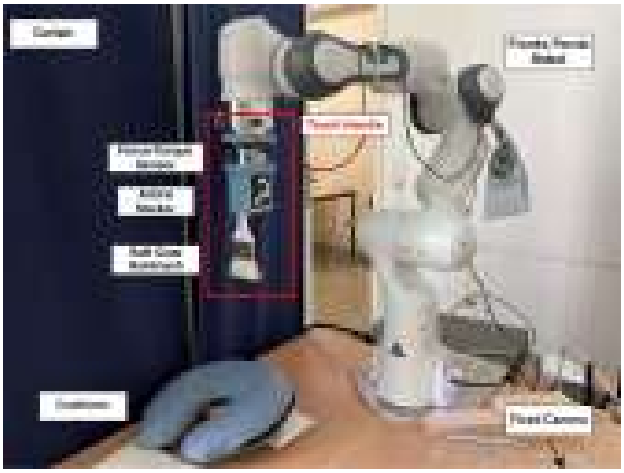
A. Stroking with a Robotic Arm

In this section, we will detail how different stroking can be realized with a robotic arm. As mentioned in the introduction, our objective is to investigate whether the spatial and temporal characteristics of stroking influence the perception and effect of affective touch, while it is also a very worthwhile question for robotics to explore whether it is possible to produce a touch effect comparable to that of a human utilizing a robotic arm. In the experimental scenarios, affective touch was achieved through a soft brush, which simplifies the haptic problem for robots in reproducing human-to-human touch. Therefore, this section will concentrate on explaining the choice of robots and sensors as well as the choice of motion planning and control algorithms in reproducing affective touch.

1) Hardware Setup: Our primary objective was an arm-stroking motion produced by the robot that closely approximates the characteristics of human motion. Therefore some hardware prerequisites are necessary, including providing joint torque feedback, a torque control interface for compliant manipulation, and the capacity to record human strokes as references. Regarding the robotic arm, we chose to use a 7-DoF Franka Panda robot (as shown in Fig. 2). It only has a $3\,\mathrm{kg}$ payload, but it meets the needs of our touch experiment. It has a maximum reach of $855\,\mathrm{mm}$. The maximum linear speed in Cartesian coordinate system can reach $2\,\mathrm{m/s}$, and the repeatability is $\pm 0.1\,\mathrm{mm}$.

The main reason we chose this robot was its high precision, joint torque feedback, and integrated control algorithm. Franka is equipped with high-resolution joint encoders, allowing them to execute precise motions. Furthermore, Franka is also equipped with torque sensors at all 7 axes to provide the necessary feedback for the touch. Libfranka and franka_ros provide state-of-the-art control algorithms, and the torque control interface allows the Franka to move compliantly.

From our experience, the force on the end-effector of a robotic arm can be calculated from joint torque feedback, it is prone to errors due to external disturbances and abrupt changes in motion. The compliance of Franka's joints may introduce additional instability. For safety, we incorporated an additional force-torque sensor at the end-effector. The sensor not only records the precise downforce during the experiment for subsequent analysis but also supports contact detection and



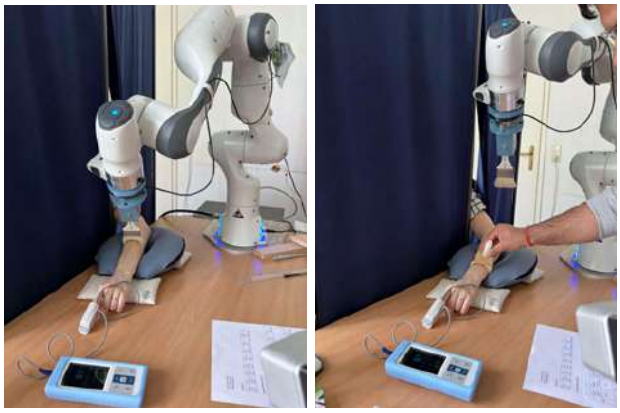


Fig. 2. **Affective robotic touch experiment setup**: The touch handle consists of a force-torque sensor, ArUco Marker, 3D printed components, and a soft goat hairbrush. It can be used to apply human touch alone or mounted on a robot to apply robotic touch. The fixed FRAMOS D400e camera records RGB-D video for capturing touch trajectories and for archiving experimental data.

(a) (b)

Fig. 3. **Robots and humans perform strokes:** physiological information such as heartbeat is recorded while the experimenter is applying the strokes, and an evaluation is required at the end of each stroke. The entire procedure is recorded by a fixed camera. When a human applies a stroke, the robot provides a reference trajectory directly above it, while ensuring that the noise of the robot's movement is present during each stroking motion.

force control, ensuring the robot does not exert excessive force.

To capture the trajectory and force of human stroking movements, we designed a handle with force-torque-sensor and ArUco marker. A soft wool brush for stroking was mounted underneath the handle. We plan to record the Cartesian trajectory of stroking through the FRAMOS D400e camera and the ArUco marker, as well as the 6D force information of stroking through the force-torque-sensor. This is used as a reference value for the robot to reproduce the touch. So far the experimental table composed of a robotic arm, force sensor, the camera fixed on the table, ArUco code, and soft brush is completed (as shown in Fig. 2).

During the preparation of the experiment, we observed that the camera and ArUco marker solution introduced additional errors, leading to unreasonable waypoints in the trajectories. To mitigate this issue, we mounted the brush handle on the robot, allowing the person providing the reference stroking trajectory to use the robot's interactive mode. This setup enabled stroking on the experimenter's arm while recording waypoints in the Cartesian coordinate system.

2) Selecting the Methods: Considering the uniqueness of each individual—variances in forearm diameter, surface curvature, hardness, and even sitting position and reactions to stroking intensity—our technical goal was to deliver as consistent a touch as possible to each subject. Since all human-initiated touches in the experiments were also delivered by a single individual, we aimed for the 8 different variants share common characteristics, such as downward pressure on the forearm surface, which can also be interpreted as a relatively consistent position of the brushes perpendicular to the forearm. This allows for a better validation of whether robotic touch is distinguishable from human touch.

We chose the Cartesian DMPs [26] [29] with given feature points as our motion planning method. DMP can encode and reproduce movement patterns from demonstration, which means once reference trajectories are available, the generated trajectories could be the same type of shape but with specific characteristics (Size, starting point and goal. . .). The Cartesian DMPs can capture complex Cartesian trajectories and are therefore suitable for mimicking human stroking movements, which involve coordinated movements in multiple dimensions.

At the beginning of the experiment, we sample the start and end points of the stroking motion of the subject's forearm so that we can implicitly obtain information such as forearm position, inclination, diameter, etc. Cartesian DMPs can combine the reference stroke trajectory we recorded and the start and end positions to produce a forearm stroking trajectory that is appropriate for the subject.

3) Trajectory: We use Moveit Cartesian Interpolator [30] as the interface between the DMPs and the controller. It is the default Cartesian Interpolator functionality in MoveIt, which provides a greedy interpolation between the waypoints defined by the user. Furthermore, when this function tries to get the IK solution of the waypoints, it will pass these points plus a random noise within tolerance, rather than pass the exact waypoints position to the IK solver. This is done to deal with situations where a particular IK solution may be sensitive to initial conditions. However, this situation also gives us unpredictable computational results, for which we can influence the randomness of the whole generated trajectory by defining different numbers of reference trajectory waypoints.

Also, since the algorithm used is greedy interpolation, which means the trajectory between waypoints is not optimized for factors like joint limits, kinematic singularities, or collision avoidance. This can result in suboptimal trajectories. The number of waypoints affects the results of the IK solver and thus changes the predictability of the whole trajectory. In short, if the whole trajectory is given only the start and end points, then the randomness of the trajectory is defined only by the

random values attached to the start and end points at the time of solving and the randomness of the two IK solver processes. At the same time, the predictability is greatly improved due to the relatively smooth point-to-point trajectory. As the number of waypoints increases, the randomness of the entire trajectory increases, and more standing points can make the robot's trajectory elusive.

In our experiments, we defined trajectories close to straight lines as high predictability, curvilinear trajectories with three waypoints as medium predictability, and s-shaped trajectories with four waypoints as low predictability (Fig. 1).

IV. Experiment Details

A. Participants

34 female participants aged $19 - 25$ (20.70 ± 1.69) were tested. All of them were students and received course credits or a small financial compensation for participation. None of the participants reported any mental health issues as screened by PHQ4 [31] questionnaire (3.61 ± 1.84). According to the questionnaire on touch experiences and attitudes (TEAQ [32]), participants had a normal attitude to interpersonal touch (62.32 ± 8.05). The first six participants tested were not included in the final analysis due to initial technical issues with the robotic arm, leading the brush to lose contact with the participant's arm.

B. Study Instructions to Participants

Participants were informed that the study involves interacting with a robot designed to replicate affective touch. They were briefed on the nature of the touch (soft brush strokes on the forearm) and that their reactions and perceptions would be recorded via questionnaires after each interaction. Instructions emphasized that their participation was voluntary, and they could withdraw at any time without penalty. Our procedures were designed to prioritize participant comfort and privacy, including measures to de-identify data and protect participant anonymity.

C. IRB Approval

This study was approved by the local ethical committee (FSV 22/102), ensuring adherence to ethical guidelines for research involving human participants.

D. Informed Consent

All participants provided informed consent before participating in the study. The consent process involved explaining the study's purpose, procedures, potential risks, and benefits, ensuring participants were fully informed. Participants were also assured of their right to withdraw from the study at any time.

E. Procedure

After informed consent, participants were asked to answer demographic and health-related questions, the short version of the questionnaire on touch experiences and attitudes (TEAQ), and the brief Patient Health Questionnaire (PHQ-4). For the experiment participants were placed on a comfortable chair in front of a computer screen. They placed their left forearm on a soft cushion behind a curtain to avoid seeing the stroking agent. The participants were stroked in 8 different conditions on their left forearm. The stroking material was always a soft goat hairbrush ($3\,\mathrm{cm}$ width). Three of the conditions were performed by a human and five by the robot arm. The order of presentations was randomized, and each presentation was repeated twice. Two of the robot conditions included linear stroking with a velocity of 3 or $0.3\,\mathrm{cm/s}$, and the other three included non-linear stroking with small, medium, and large deviation (low, medium, high predictability) from linear movement and a velocity of $3\,\mathrm{cm/s}$. The manipulation of trajectory was included to enhance ecological validity, as natural touch typically does not follow strict linear movements [33]. As mentioned above (Fig. 1), we show the randomness, predictability, and degree of deviation of the trajectories by defining different numbers and poses of waypoints. The human experimenter stroked with linear with a velocity of 3 or $0.3\,\mathrm{cm/s}$, and non-linear with a velocity of $3\,\mathrm{cm/s}$. The linear (straight line) trajectories were visualized on the participants' forearm using a kajal pen, the non-linear (medium deviation) trajectory will be displayed by the robot above. This ensured stroking reliability, which was further facilitated by the experimenter following the movement of the robot, which ran at the same time but did not touch the participant. Hence, there was always a sound of the robot's arm, so the participants could not differentiate human vs robot conditions based on sound effects.

F. Assessment of Stroking Perception

After each of the 16 stroking events, the participant was asked to rate the pleasantness, intensity, and human-likeness on a VAS with the endpoints from "not at all pleasant/intense/human-like" (0) to "very pleasant/intense/human-like" (10). In addition, the receiver was asked to decide for each stroke whether it was performed by a human or by a robot.

G. Statistical Analysis

First, we calculated the mean pleasantness, humanness, and intensity score over repetitions for each condition (Tab. I). Then, we conducted separate statistical analyses using R (version 4.2.3). To test whether stroking with $3\,\mathrm{cm/s}$ was rated more pleasant than stroking with $0.3\,\mathrm{cm/s}$ (H1), we computed an ANOVAs for repeated measurements with the within-subject factors velocity (2) and agent (2). We repeated the analysis for the dependent variable of "human-like". To test whether the predictability of stroking is related to the perceived pleasantness (H2), we computed an ANOVA for repeated measurements with the within-subject factor trajectory (3), using the three non-linear robot conditions. Post-hoc-Tests were performed with paired t-tests and are presented Bonferoni-corrected. The analysis was repeated for the dependent variable of "human-like". Finally, we explored whether participants could distinguish robot from human touch and

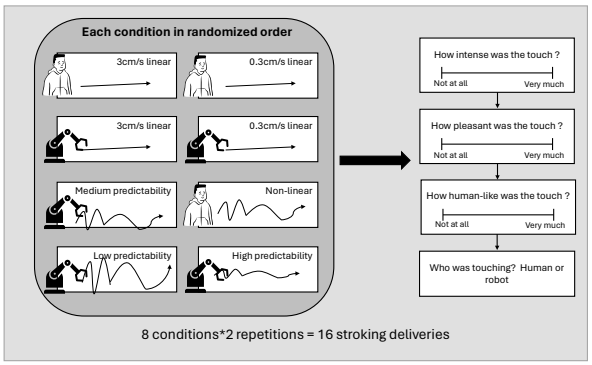

Fig. 4. **Experiments design**: The participants were stroked in 8 different conditions on their left forearm by a soft goat hairbrush. Three of the conditions were performed by a human and five by a robot. Two of the human touch conditions included linear stroking with a velocity of 3 or $0.3\,\mathrm{cm/s}$, the third condition included non-linear stroking. Two of the robot conditions included linear stroking with a velocity of 3 or $0.3\,\mathrm{cm/s}$, the other three included non-linear stroking with low, medium, and high predictability.

whether this related to predictability (H3) and determined for all conditions, whether choices deviated significantly from the 50% chance using χ^2 tests.

V. Results

We confirmed previous results showing higher pleasantness ratings for $3\,\mathrm{cm/s}$ as compared to the slower 0.3 cm/s stroking conditions ($F(1,27) = 51.15, p < .001, \eta^2 = 0.31$, Figure 5). There was no significant effect of agent ($F(1,27) = 0.51, p = 0.481 \eta^2 = 0.002$) and no significant velocity by agency interaction ($F(1,27) = 2.73, p = 0.11 \eta^2 = 0.017$), indicating that robot and human-delivered touch were not perceived as different in pleasantness (H1).

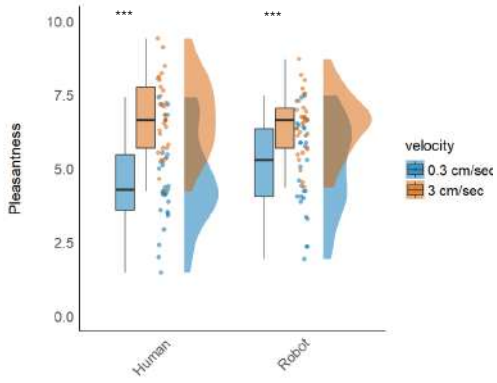

Fig. 5. **Pleasantness ratings in human and robot touch.** There was a significant effect of the main effect of the velocity ($p < 0.001$)

For human-likeness, we observed no significant effect of velocity ($F(1,27) = 0.69, p = 0.413, \eta^2 = 0.008$, Figure 6) and not significant velocity by agency interaction ($F(1,27) = 0.35, p = 0.55, \eta^2 = 0.002$). A significant effect of agency ($F(1,27) = 5.71, p = 0.024, \eta^2 = 0.051$, Figure 6) however indicates that the human-delivered touch was perceived as more human-like than the robot-delivered touch.

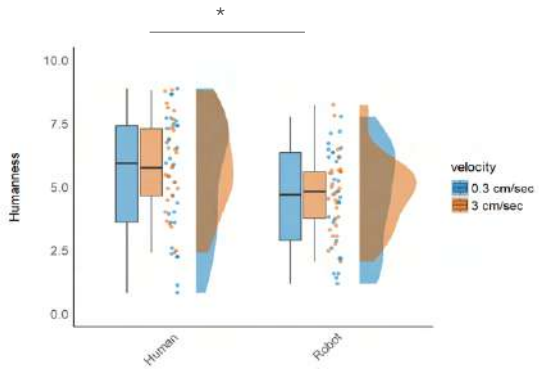

Fig. 6. **Humanness ratings in human and robot touch.** There was a significant effect of the main effect of the agent ($p < 0.05$) and the touch performed by the human was perceived as more human-like as compared to the robot touch.

For the different stroking trajectories, we observed a significant effect of trajectory on pleasantness ($F(2,54) = 9.52, p < .001, \eta^2 = 0.15$), but not on humanness ($F(2,54) = 1.87, p = .163, \eta^2 = 0.034$). Post-hoc-Test revealed reduced pleasantness perception during the low predictable conditions as compared to the high ($t(27) = -3.85, p < 0.001$) and medium ($t(27) = -3.13, p = 0.004$) ones (H2).

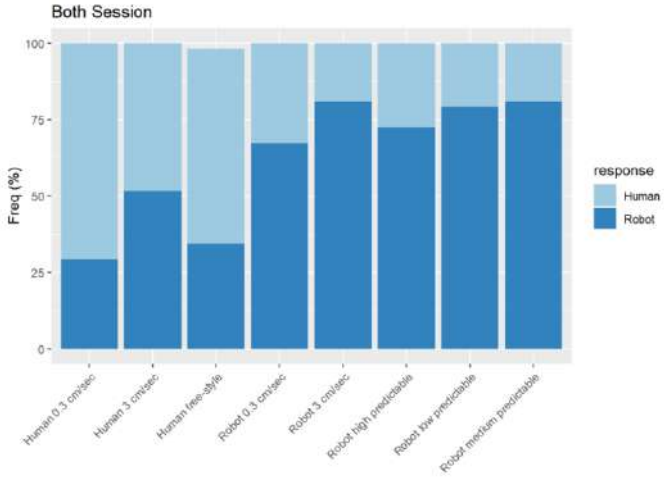

Fig. 7. **The percentage of the touch recognition delivered by agents**

Over all conditions, 75.71% of the participants correctly recognized the robotic touch as delivered by the robot ($\chi^2 = 26.45; p < 0.001$), and 60.12% of the participants correctly recognized the human touch as delivered by human ($\chi^2 = 4.37; p = 0.036$, Figure 7) (H3).

The recognition of robot touch (H3) did not relate to the trajectory ($\chi^2 = 1.70; p = 0.427$). For the human touch, correct recognition related to the touch characteristics and exceeded chance level for the linear $0.3\,\mathrm{cm/s}$ ($\chi^2 = 15.44, p < 0.001$) and non-linear 3cm/s ($\chi^2 = 9.38, p = 0.002$) conditions.

TABLE I
MEAN VALUES OF THE PLEASANTNESS, INTENSITY, AND HUMANNESS SCORES GENERATED AT THE DIFFERENT VELOCITIES AND CONDITIONS.

		Pleasantness		Intensity		Humanness	
Agent	**Condition**	**Mean**	**SD**	**Mean**	**SD**	**Mean**	**SD**
Human	0.3 cm/sec, linear	4.65	2.04	5.31	1.98	5.36	2.73
	3 cm/sec, linear	6.82	1.52	5.16	1.88	5.87	2.24
	3 cm/sec, medium deviation	6.67	1.51	5.13	1.64	6.18	1.97
Robot	0.3 cm/sec, linear	5.13	2.22	3.56	2.21	4.62	2.5
	3 cm/sec, linear	6.59	1.33	4.86	1.63	4.82	2.13
	3 cm/sec, small deviation (high predictability)	6.53	1.41	5.00	1.46	4.93	2.05
	3 cm/sec, large deviation (low predictability)	5.29	1.62	5.52	1.96	4.2	2.09
	3 cm/sec, medium deviation (medium predictability)	6.29	1.61	5.32	1.48	4.62	2.05

VI. DISCUSSION AND CONCLUSION

In this paper, we employ the Cartesian DMPs to emphatically replicate the spatial and temporal characteristics of human stroking. Thanks to the use of a soft brush as an intermediate transmitter of touch, we can eliminate as many other touch characteristics as possible, such as material, texture, temperature, etc., and even the dynamic characteristic (strength, pressure, acceleration) of the touch can be neutralized by the brush. As a result, we can more clearly analyze the influence of stroke velocity and stroke trajectory on the interpersonal haptic experience, and also analyze whether the robot can perfectly reproduce human strokes from these two perspectives alone.

Our results show that we were able to replicate the typical pleasurable sensations associated with human touch when the robot touched at a speed of 3 cm/s compared to the slow speed of 0.3 cm/s.

The results of robotic touch recognition show that the degree of humanization of robotic strokes is independent of trajectory. The speed of touch (a temporal parameter) played a role in participants' ability to predict the initiator of the touch, but a human-initiated touch at 3 cm/s had nearly a 50% chance of being predicted as robotic, whereas the probability of a robot-initiated touch being judged correctly exceeded 70% for all touches. It can be concluded that spatial and temporal parameters alone are not sufficient for the replicative reconstruction of human touch and that the strength and intensity of touch need to be the next focus of research in future work. For the robotic scope, the hybrid position and force controller and Cartesian compliant DMPs may serve as a tool for reproducing the dynamic parameters of touch.

Meanwhile, the main reason why human behavior is more easily confounded is that we did not extract features from the individual human who applied the touch, which resulted in the touch applied by the robot being based more on the forearm geometry of the person being touched than on the touch habits of the person applying the touch itself. The fact that humans are more adaptable than robots when applying strokes also leads to experimental bias as humans involuntarily mimic the stroking behavior of the robot above them. Enhancing video capture capabilities to precisely record the human operator's touch velocity and trajectory could facilitate future studies in achieving a more accurate mimicry of human touch.

In conclusion, affective touch holds great promise for advancing robotic rehabilitation by supporting motor recovery, enhancing sensory stimulation, and improving the emotional well-being of patients. Robotic affective touch could play a transformative role in clinical applications, such as stroke rehabilitation, where controlled stroking movements may facilitate sensory relearning and neuroplasticity. Furthermore, robotic touch therapy presents exciting opportunities for neuropathic pain management and as a non-invasive approach to reducing anxiety in hospitalized patients. With continued research and development, these innovations could significantly enhance patient care and well-being.

Analysis of Induced Muscle Activations by an Affordable, Reconfigurable Robot for Comprehensive Post-Stroke Rehabilitation

Nova Y. Meng*[1], Erica L. Waters*[2], Gary Lin[3], Samuel Gaardsmoe[4], Alwyn Johnson[5], Laura A. Hallock[6], Rochelle J. Mendonca[7], Pamela Z. Cacchione[8], and Michelle J. Johnson[9]

***Abstract*— Post-stroke upper-limb impairments affect millions of people worldwide. Low-degree-of-freedom (DoF) end-effector (EE) rehabilitation robots have the potential to provide more affordable and accessible rehabilitation, but there is concern that sacrificing complexity could reduce the efficacy of robotic rehabilitation. In this paper, we present preliminary evidence that a 1-DoF EE rehabilitation robot with multiple configurations can provide comprehensive upper limb exercise. Specifically, we introduce the reconfigurable Rehab CARES system, an expansion of the Haptic TheraDrive robot, and analyze muscle activation data (as measured by surface electromyography, or sEMG) from 11 post-stroke participants performing range of motion (ROM) movements in 3 different robot positions, each of which simulates a different activity of daily living. Our findings indicate that collectively, these positions elicit comprehensive activation of the arm muscles in post-stroke individuals, and that induced motor patterns differ across both positions and levels of user impairment, some of which are likely reflective of compensatory movement strategies. We conclude that with smart reconfiguring, a 1-DoF EE robot is capable of inducing different muscle activation patterns, but does not prevent the user from employing these undesirable compensatory strategies, suggesting that such robots are a promising platform for low-cost rehabilitation exercise and characterizing pathological synergistic movements.**

I. Introduction

Globally, over 12.2 million people experience a stroke each year [1]. Upper-limb impairments are common following a stroke, with prevalence estimates ranging from 40–80% [2], and these impairments are associated with a lower quality of life [3]. Effective and accessible rehabilitation methods are crucial for these individuals to regain functional independence. Rehabilitation robots are one solution for post-stroke upper-limb exercise and are capable of delivering affordable, high-quality therapy that is tailored to individual needs. Rehabilitation robots can be categorized into two types based on their mechanical structure: end-effector (EE) robots, which interact with the hand or distal limb to move the entire arm, and exoskeleton (Exo) robots, which are wearable devices that support and guide arm movement.

Single degree-of-freedom (DoF) EE robots are cost effective compared with complex EE and Exo robots, making them a desirable option for affordable care [4]. Stroke survivors who train with low-DoF EE robots may actually increase activity and participation compared with stroke survivors who train with Exo robots [5]. However, the lack of control at specific joints can allow users to rely on compensatory movements. Meta-analysis of randomized controlled trials with rehabilitation robots show that they can significantly reduce motor impairment but often do not result in significant improvements in motor capacity or performance of activities of daily living (ADL) compared with standard of care therapy [6]. This disparity between improvements in motor impairment measures and lack of improvement in ADL performance could be the result of compensatory strategies [6]. Post-stroke individuals often rely on compensatory strategies such as trunk movements [7] or abnormal muscle synergies, especially between the shoulder and elbow [8]. Although compensatory strategies can help people regain functional performance after a stroke, the long-term use of such strategies can be maladaptive and detrimental to motor recovery [9]. Therefore, it is necessary to understand which muscles stroke survivors recruit during robot-based exercise to better understand whether such exercises train "normal," healthy movement strategies or reinforce maladaptive compensatory strategies.

Due to the limited motion patterns they enable, 1-DoF robots may be less effective in activating all the important muscle groups required for upper limb therapy compared with multi-DoF robots. A survey of rehabilitation robots, for example, highlighted multiple-single-active-DoF robots,

including eleven targeting elbow flexion/extension, one targeting the forearm pronation/supination, and four targeting wrist flexion/extension, but the survey found no 1-DoF robots that assisted whole arm movements [10]. 1-DoF robots that can be configured in multiple positions may provide a solution that maintains affordability while also exercising a variety of muscle groups. The MIT Manus was one of the first reconfigurable rehabilitation robots and can provide both arm and wrist rehabilitation [11]. Other 1-DoF reconfigurable rehabilitation robots include the Bi-Manu-Track [12], which provides bimanual forearm pronation/supination and wrist flexion/extension, and the CR2-Haptic [13], which targets ten different movements of the shoulder, elbow, forearm, wrist and hand. Training with these robots allowed stroke survivors to improve on clinical metrics [12], [13], but the effectiveness of a 1-DoF reconfigurable rehabilitation robot at inducing different muscle activations has not been investigated.

In this study, we assess the ability of a 3-configuration, 1-DoF EE rehabilitation robot, the TheraDrive to activate muscle groups of the arm by analyzing surface electromyography (sEMG) muscle activation patterns during standardized movements. We analyze sEMG data from the impaired limbs of 11 post-stroke participants who completed a 1-day exercise protocol with the TheraDrive as part of the Rehabilitation Using Community-Based Affordable Robotic Exercise Systems (Rehab CARES) clinical trial [14]. Specifically, we investigate muscle activation patterns in three distinct configurations of the robot: a simulated reach-to-grasp movement (Pos. 1), a standard planar movement involving shoulder abduction/adduction (Pos. 2), and a wrist pronation/supination movement (Pos. 3), for both mildly and moderately/severely impaired individuals, as measured by the Fugl-Meyer assessment of the upper extremity.

Note that this is a preliminary publication on the Rehab CARES system, and analyses of many aspects of the system and data collection protocol are beyond the scope of this paper, as noted in future sections. In particular, the protocol we describe includes participants performing a number of assessment tasks and therapy games, which are discussed in another publication [15]. In this paper, we restrict our analyses to the sEMG activation and kinematic data collected during standardized range of motion (ROM) movements performed on the robot in different configurations.

II. Rehab CARES System Design

The Rehab CARES project is a community-based approach to rehabilitation that uses multiple affordable, reconfigurable 1-DoF TheraDrive robots to provide solo and group therapy to individuals after stroke. The Rehab CARES robot gym approach has been tested in both Mexico and the USA [16]. More information about the updated Rehab CARES system is available in our collaborators' publication [15].

In previous work, the TheraDrive was primarily investigated in a single configuration—a simulated reach to grasp movement (Position 1). The present study investigated the TheraDrive in three distinct positions, shown in Figure 1.

A. Position 1 – Reach-to-Grasp

Figure 1a shows the TheraDrive in Position 1 (Pos. 1). In this configuration, the robot is positioned to the side of the user with the workspace parallel to the sagittal plane. The EE for this configuration is a cylindrical handle that attaches perpendicular to the crank arm. In this position, we expect the user to exhibit flexion/extension of the shoulder and elbow. This configuration of the robot simulates a reach-to-grasp task, replicating movements typically used in opening cabinets and closets.

B. Position 2 – Shoulder Abduction/Adduction

Figure 1b shows the TheraDrive in Position 2 (Pos. 2). This position was designed to involve more abduction/adduction of the shoulder than Pos. 1. To achieve this movement, the robot is positioned vertically with the workspace along the user's transverse plane. The same EE from Pos. 1 is used. Pos. 2 replicates the movements used for wiping down a table or a window, and mimics the planar motion studied in much of the rehabilitation literature.

C. Position 3 – Wrist Pronation/Supination

Figure 1c shows the TheraDrive in Position 3 (Pos. 3). This position was designed to target wrist and forearm pronation/supination. For this position, the robot is in the horizontal position, and the user is turned to face the robot so that the robot workspace falls along the user's frontal/coronal plane. The EE is replaced with a handle parallel to the crank-arm. This new handle allows the user to perform internal/external arm rotations and replicates wrist movements used to turn faucets and door handles.

III. Methods

We outline our methodology to assess differences in muscle activations across positions in a pilot cohort of post-stroke users, including data collection, processing, and analysis.

A. Participants

Patients were recruited from Good Shepherd Penn Partners and stroke support groups at the University of Pennsylvania hospitals. Our inclusion criteria for the participants were that the patients must be: 18 years or older, clinically diagnosed with hemiparesis resulting from a stroke, at least 3 months post-stroke, able to undergo therapy, and having some level of voluntary activity on the impaired side, evidenced by some active elbow ROM and some finger flexion.[1] Participants were excluded if they had cerebellar stroke, seizures before stroke, had depression scores on the NeuroQoL Depression measure of > 32, or pain measure of > 4. This protocol was approved by the Institutional Review Board of the University of Pennsylvania (protocol 849090). For the initial evaluation of the rehabilitation platform, 11 stroke survivors (60 ± 10 years, 4F/7M) were recruited, presenting varying degrees of motor and cognitive impairment, as detailed in Table I.

[1]Participants unable to grip the handle were not excluded; a passive grip assist was used for those unable to maintain grip.

(a) Position 1 (Reach-to-Grasp)

(b) Position 2 (Shoulder Abduction/Adduction)

(c) Position 3 (Wrist Pronation/Supination)

Fig. 1: The Rehab CARES TheraDrive robot in each of its 3 ADL-inspired configurations. The TheraDrive's 1-DoF EE reconfigurable design allows the device to remain affordable while supporting a variety of motor rehabilitation tasks.

TABLE I: Participant Clinical Assessment Scores

ID	MoCA	CT1	CT2	UE-FM	BBT	9-HP
001	24	0.90	-0.51	65	61	19.09
003	29	0.90	1.25	65	52	19.03
004	23	-0.13	0.53	65	71	16.72
005	15	-6.51	-6.45	57	43	64
007	17	-7.09	-9.98	33	8	DNC
009	22	-0.11	-1.11	65	40	25.53
010	22	–	–	56	40	43.97
011	24	0.19	0.31	30	23	131.37
012	25	-7.62	-3.36	51	27	52.23
013	17	-1.62	-2.35	54	37	40.47
014	12	-2.70	-7.93	13	0	DNC

BBT and 9-HP are reported only for the affected limb. BBT is reported as the number of blocks and 9-HP is reported as time in seconds. CT1 and CT2 are reported as z-scores.

TABLE II: Sensor Placement and Activating Motions

ID	Location	Expected Activating Motions
1A	biceps brachii	shoulder flex, elbow flex, wrist sup
1B	posterior deltoid	shoulder (ext, ex-rot)
1C	anterior deltoid	shoulder (flex, in-rot)
1D	middle deltoid	shoulder abd
2A	triceps brachii (long head)	shoulder (ext, add), elbow ext
2B	wrist flexor bundle	wrist flex
2C	wrist extensor bundle	wrist ext
2D	brachioradialis	elbow flex, wrist (pro, sup)

Activating motion abbreviations: flexion (flex), extension (ext), adduction (add), abduction (abd), external rotation (ex-rot), internal rotation (in-rot), pronation (pro), supination (sup)

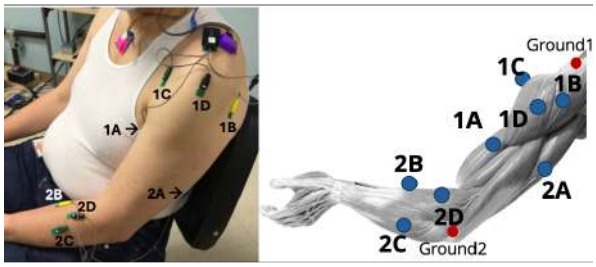

Fig. 2: Placement of sEMG sensors on the impaired arm.

B. Experimental Protocol

The data analyzed in this paper were collected during a larger validation study consisting of 3–4 experimental days for each participant: 1 clinical assessment day; 1–2 days performing robot-based assessments tasks, ROM movements, and therapy games; and 1 day of qualitative interviews on their experiences with the robot. If a second robot exercise day was necessary, data were re-collected at each ROM position to ensure consistent sEMG placement. Only the clinical assessments and a selection of the robot exercise tasks are analyzed in this work and are discussed below.

1) Clinical Assessment Day: On the day of the clinical assessment, participants worked with a trained occupational therapist to complete cognitive and motor assessments. The cognitive assessments included the Montreal Cognitive Assessment (MoCA), Color Trails 1 (CT1), and Color Trails 2 (CT2). Motor assessments included the Fugl-Meyer Upper Extremity Assessment (UE-FM), the Box and Block Test (BBT), and the 9-hole Pegboard Assessment (9-HP). Table I reports the results of the clinical evaluation for all participants.

2) Robot Exercise Day(s): The robot exercise day(s) consisted of two main phases: first, sensorization; and second, data collection during sensor calibration, ROM movements, assessment tasks, and therapy games.

a) Sensorization Phase: Participants were outfitted with sEMG sensors, 2 inertial measurement unit (IMU) sensors, a galvanic skin response (GSR) sensor, and a heart rate (HR) sensor [15]. Surface EMG data were collected from the subject's impaired arm via two four-channel sensor motes (Trigno Quattro, Delsys, Inc., Natick, MA, USA), each of which also contained an associated 6-DoF IMU. Targeted muscles were selected to comprehensively probe joint motions of interest induced by TheraDrive interaction and grounding sensors (and internal IMUs) were placed atop nearby bones (the acromion at the shoulder and olecranon at the elbow) as recommended by the manufacturer. A list of all sensor placements and associated motion(s) is shown in Table II; an image of all sensor placements is shown in Figure 2. Sensors were adhered to the subject using Trigno adhesives (Delsys, Inc., Natick, MA, USA) and transparent "transpore" surgical tape. Data were collected at 222 Hz via Trigno Discover software (Delsys, Inc., Natick, MA, USA).

b) Data Collection Phase: Once sensorized, participants performed the tasks outlined in Figure 3, including sensor calibration, ROM movements, assessment tasks, and therapy games while all sensor data described above were collected. All study days began with collection of a trial in

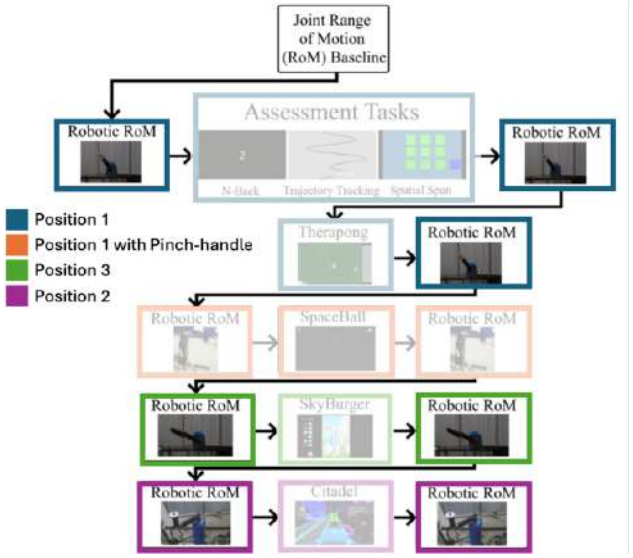

Fig. 3: Experimental workflow during robot exercise. Participants performed assessment tasks and therapy games, interleaved with ROM movements, at each position shown in Figure 1. Only the ROM movements are used in this work to analyze muscle activations in each position..

which the participant sat unmoving, with their eyes closed, and in silence, to establish a baseline for GSR and HR sensors.[2] The participant was then moved over to the haptic robot in Pos. 1 and completed a ROM task, in which the patient was instructed to move the handle of the robot as far as possible in both directions with their affected limb, in a rhythmic pattern while guided by a video, as shown in Figure 4. Participants first performed this task while unrestrained, and then again while restrained to their chair with a harness to prevent compensatory trunk motions. They then performed several assessment tasks (previously described for individuals with both HIV and stroke [17]). The robotic ROM task was then completed again after the assessment tasks in reverse order (restrained, then unrestrained), a therapy game was played in this position (Therapong), and a final unrestrained ROM trial collected.

All remaining activities were completed while unrestrained. This pattern—move to a new position, perform an initial ROM task, followed by a therapy game, followed by a final ROM task—persisted for all remaining experimental activities.[3] Each position had an associated therapy game developed by collaborators at enAble Games LLC; analysis of these games is the subject of a recent publication [15].

In this work, we analyze only the sEMG and associated IMU data collected during ROM trials at each position. The ROM trials are highly controlled movements that serve as an ideal starting point for initial understanding of what muscle activation patterns are induced in each of the three positions.

[2]Some participants also completed joint ROM tasks, but these tasks were ultimately eliminated from the protocol because they were too time-intensive.

[3]The Pos. 1 with pinch-handle trials were not analyzed due to the handle malfunctioning in many of the trials.

C. Data Processing

To compare muscle activations across participants (who performed ROM motions at inconsistent rates) and robot positions, sEMG data were clipped at the start of the first movement and at the end of the last movement. The beginning and end of the ROM movement was determined based on the accelerometer data from the y-axis of the elbow IMU, which showed the cleanest motion onset and end, as illustrated in Figure 4. Once segmented, the raw sEMG data were then put through a high pass filter at 10 Hz to remove any low frequency noise. Baseline offset was removed by subtracting the median of the overall signal. The resulting signal was then rectified and passed through an envelope with a window size of 80 samples (320 ms) to smooth the data. A rolling window outlier removal method was applied with a window size of 100 samples (3 s) and a threshold of 3 standard deviations away from the mean of the window. Lastly, for each subject, each of the eight channels were normalized to the highest signal value recorded for that channel across all ROM trials for that particular subject.[4]

D. Data Analysis

The primary metric used to quantify muscle activation was the area under the curve (AUC) for each muscle, calculated over the entire ROM during the movement cycle. The AUC of the clipped data was normalized by dividing it by the total number of samples throughout the movement, ensuring that the final activation metric was expressed as a percentage of the maximum possible activation [18], [19].

To examine the overall activations, we analyzed the AUC of each muscle across the factors of robot position and impairment group. Impairment group was defined by score on the UE-FM. Specifically, participants were classified as having "mild impairment" if they had a UE-FM > 50 and "moderate/severe impairment" if they had a UE-FM ≤ 50.

Due to small sample size and non-normality, we used the Mann Whitney U nonparametric test for all data comparisons. We first investigated if there were differences between initial and final AUC for each muscle and position with a paired Mann Whitney U. This test revealed no significant effects, so we chose to combine the initial and final AUC for all subsequent analyses. Next, we analyzed each position with an unpaired Mann Whitney U between impairment groups for each muscle. We also used an unpaired Mann Whitney U to compare the AUC of different muscles across positions (data collapsed across impairment groups). Bonferroni adjustment was used to account for multiple comparison.

IV. Results

We outline preliminary differences in muscle activation patterns across robot positions and impairment levels.

[4]We note that Subject 3 only completed the movements in Pos. 1. Additionally, some trials were removed due to excess noise, such as varying offsets that could not be removed. Some trials were also lost due to sensor malfunction at the time of data collection. Based on their statistical similarity (noted below), we combined initial and final ROM trials in our analysis. Subjects 5 and 9 did not have any data for Pos. 1. All other participants had either (or both) initial and final ROM for all positions.

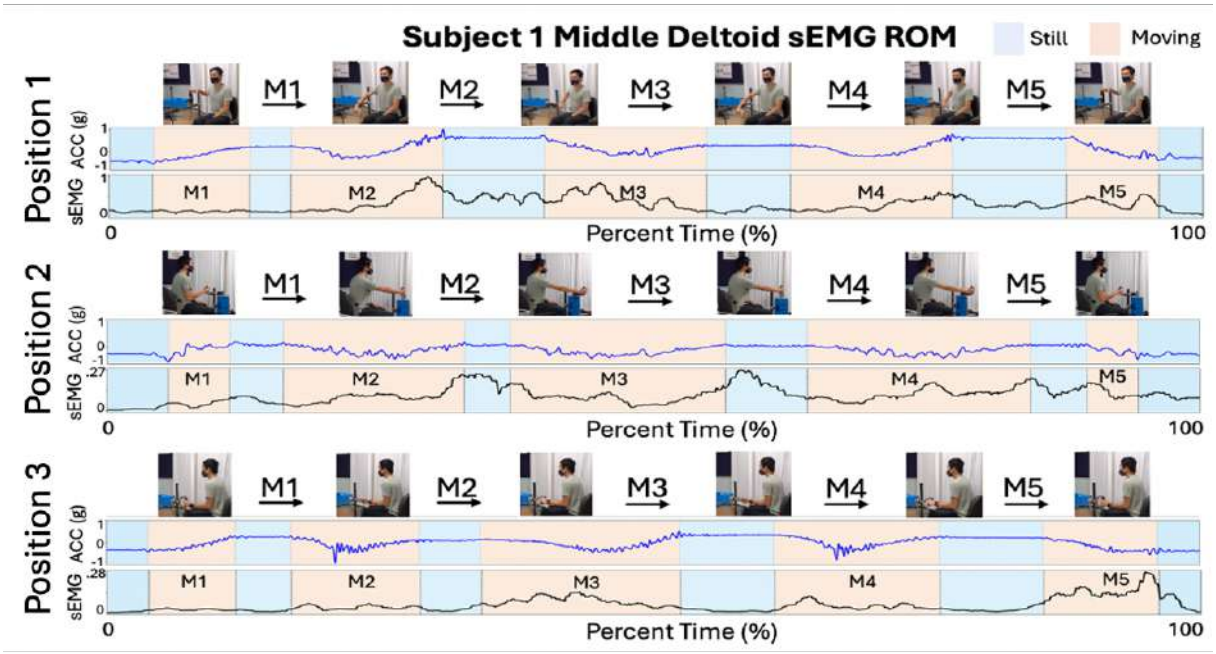

Fig. 4: Example normalized sEMG plots of the middle deltoid activation during ROM movements at each robot position from Subject 001. To compare data across participants performing this motion at various speeds, movement divisions are determined by kinematic data from the y-axis accelerometer.

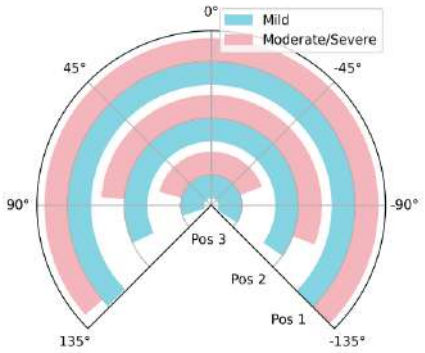

Fig. 5: Average ROM for three positions of the TheraDrive robot. Note that the moderate/severe impairment group has reduced ROM compared to the mild impairment group.

A. Variation Across Impairment

Figure 5 shows the average ROM for the different impairment groups in the three positions. The moderate/severe impairment group has a smaller ROM than the mild impairment group, which is particularly pronounced in Pos. 2 and Pos. 3. Figure 6 shows the observed variation in activation across levels of impairment at each robot position.

1) Position 1 – Reach-to-Grasp: As shown in Figure 6a, the brachioradialis AUC showed a significant difference between impairment groups when analyzed with a Mann Whitney U. Specifically, the mild impairment group (median AUC $= 22.1 \pm 6.92$) had significantly higher brachioradialis AUC than the moderate/severe impairment group (median AUC $= 12.7 \pm 6.05$), $z = 45,\ p = 0.036$.

2) Position 2 – Shoulder Abduction/Adduction: As shown Figure 6b, the biceps and middle deltoid showed significant differences in AUC between impairment groups when analyzed with a Mann Whitney U. For the biceps, the mild impairment group (median AUC $= 21.4 \pm 6.11$) had significantly higher biceps AUC than the moderate/severe impairment group (median AUC $= 10.8 \pm 6.49$), $z = 38,\ p = 0.042$. For the middle deltoid, the moderate/severe impairment group (median AUC $= 23.0 \pm 8.25$) had significantly higher middle deltoid AUC than the mild impairment group (median AUC $= 11.1 \pm 7.61$), $z = 6,\ p = 0.029$.

3) Position 3 – Wrist Pronation/Supination: As shown in Figure 6c, the anterior deltoid showed a significant difference in AUC between impairment groups when analyzed with a Mann Whitney U. Specifically, the mild impairment group (median AUC $= 28.8 \pm 9.74$) had significantly higher anterior deltoid AUC than the moderate/severe impairment group (median AUC $= 13.8 \pm 8.99$), $z = 56,\ p = 0.0202$.

B. Variation Across Position

Figure 7 shows the Mann Whitney U comparison between positions for each muscle's AUC. As shown, several muscles exhibit varied activations across positions: in particular, the middle deltoid and wrist extensor show significant differences in AUC across positions. Pos. 1 (median AUC $= 25.9 \pm 12.6$) had significantly higher middle deltoid AUC than Pos. 3 (median AUC $= 10.3 \pm 4.79$), $z = 217,\ p = 0.001$. Likewise, Pos. 2 (median AUC $= 18.1 \pm 9.52$) had significantly higher middle deltoid AUC than Pos. 3 (median AUC $= 10.3 \pm 4.79$), $z = 180,\ p = 0.029$. For the wrist extensor, Pos. 2 (median AUC $= 25.6 \pm 8.47$) had significantly higher activation AUC than Pos. 1 (median AUC $= 8.23 \pm 8.37$), $z = 35,\ p = 0.005$. No other muscles showed significant differences across positions.

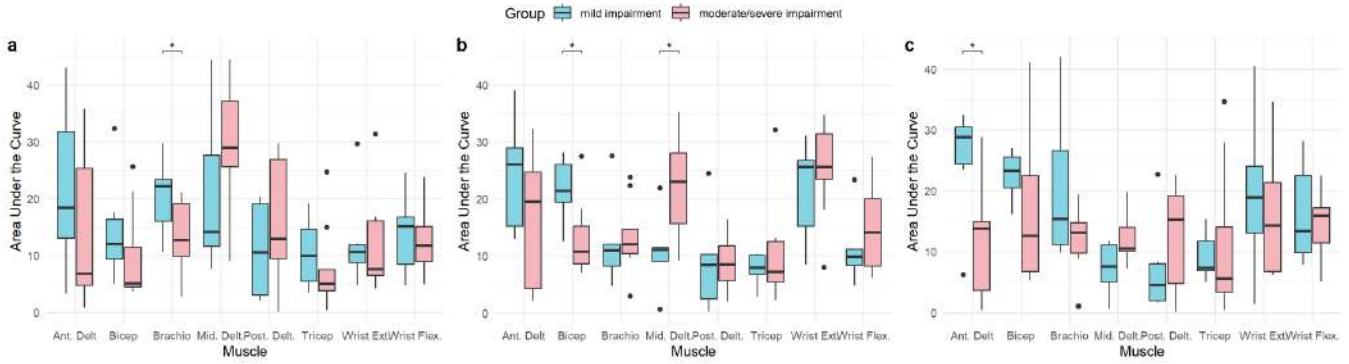

Fig. 6: AUC-quantified muscle activations for all three positions. **a:** Pos. 1; more severely impaired individuals show increased activation of the middle deltoid and decreased activation of the brachioradialis. **b:** Pos. 2; more severely impaired individuals show even more increased activation of the middle deltoid than observed in Pos. 1. **c:** Pos. 3; more severely impaired individuals show increased activation of the posterior deltoid and decreased activation of the anterior deltoid.

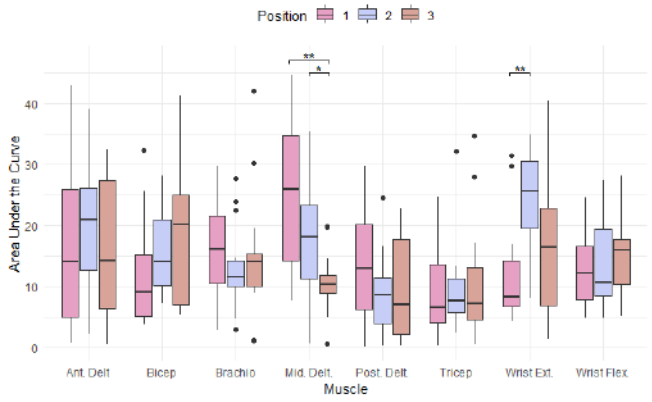

Fig. 7: Activation of each arm muscle, as quantified by AUC of the sEMG signal, at each position of the robot. Observed muscle activations vary substantially across positions (most saliently, the middle deltoid and wrist extensors).

V. Discussion

Prior to data collection, an occupational therapist outlined the expected movements for each position; we discuss the results above in the context of those expected behaviors to assess the TheraDrive's efficacy in activating expected motor patterns and identify potential compensatory strategies in users. Many participants had limited ROM due to their impairments. Figure 5 illustrates the variation in robot ROM angles across subjects and positions. The moderate/severe impairment group had relatively lower ROM in both Pos. 2 and Pos. 3 but were still able to attain the desired movements, indicating that the robot configurations are usable for rehabilitation. Notably, the moderate/severe impairment group's lower ROM suggests that reduced muscle activation may be influenced by the distance moved.

The expected movement for Pos. 1 is the flexion/extension of the shoulder and elbow, which involves the biceps, posterior deltoid, anterior deltoid, triceps, and the brachioradialis. As shown in Figure 6a, the mild impairment group showed significantly higher activation of the brachioradialis, suggesting that the moderate/severe impairment group may struggle with activating this muscle, compensating instead with shoulder abduction, as is indicated by greater middle deltoid activation. Although not significant, the moderate/severe impairment group showed greater middle deltoid activation than the mild impairment group. Middle deltoid activation is associated with shoulder abduction, which has been shown to correlate with motor impairment of the shoulder and elbow [20]. This result suggests that individuals with greater motor impairments may compensate with the middle deltoid in order to complete the reach-to-grasp movement of Pos. 1.

In Pos. 2, the expected movement is shoulder abduction/adduction, primarily involving the middle deltoid and triceps. As shown in Figure 6b, both impairment groups exhibited activations of the biceps, anterior deltoid, and wrist extensors. The moderate/severe impairment group demonstrated greater activation of the middle deltoid, indicating use of shoulder abduction, which aligns with the expected movement. However, given the over activity of the middle deltoid in Pos. 1, compensatory movement cannot be ruled out as a contributing factor. The mild impairment group exhibited higher activation in the biceps and the anterior deltoid, indicating that the shoulder flexes and the elbow bends simultaneously—an abnormal synergy commonly observed in post-stroke patients with hemiparesis [21]. The mild impairment group's co-activation is unexpected when compared with the more severely impaired group. Video data of the Pos. 2 ROM task, however, show that the more severely impaired subjects tend to use trunk compensation to complete the movement while maintaining a straighter arm. This reliance on trunk compensation could reduce bicep activation in the mild impairment group.

The expected movement for Pos. 3 involves forearm pronation and supination, which primarily activates the brachioradialis and biceps. The results shown in Figure 6c show that both groups display moderate activation of the wrist flexors and extensors, likely indicating wrist stiffening to better control the movement. The moderate/severe impairment group showed nonsignificant greater activation of the middle deltoid and the posterior deltoid, possibly due to compensatory shoulder twisting, while the mild impairment group relied more on the anterior deltoid and biceps.

In Figure 7, a comparison of muscle activation across positions shows significantly lower activation of the middle deltoid during Pos. 3, which aligns with the expected muscle activation pattern for wrist pronation/supination. We also found higher activation of wrist extensors in Pos. 2, suggesting that this position may involve wrist stiffness to stabilize the handle. In general, muscle activation varied across positions, with Pos. 1 activating the middle deltoid, posterior deltoid, and brachioradialis, Pos. 2 primarily activating the anterior deltoid and wrist muscles, and Pos. 3 showing the highest activation of the biceps and wrist flexors. An additional finding was the consistently low activation of the triceps across all positions, despite their expected activation during Pos. 1 and Pos. 2. Challenges with electrode placement on the triceps may have led to data inaccuracies.

VI. Conclusion

The Rehab CARES system effectively activates diverse muscle patterns across a range of motions that mimic daily activities through its three configurations. However, sEMG activation patterns suggest the presence of compensatory behaviors in all three positions, especially in the moderate/severe impairment group. Without a control group, it is difficult to definitively determine whether muscle activation in each position corresponds to the intended movement or reflects compensatory strategies. Future work could use the TheraDrive to compare pathological and healthy movements.

This study represents a first attempt at understanding how different positions of a reconfigurable 1-DoF robot activate muscles in a post-stroke population. This initial work has several limitations, including small sample size, low sampling frequency of the sEMG, and low task complexity. Future work may involve a more in-depth analysis of agonist–antagonist muscle pairings to characterize compensatory behaviors and more advanced analytical techniques, such as statistical parametric mapping, which enables time-resolved comparison of muscle activation across the movement cycle, or an analysis of muscle synergies. Additionally, a longitudinal study of behavior during the core assessment tasks and therapy games will be necessary to evaluate the long-term effectiveness of the rehabilitation system. This study—part of the Phase I Rehab CARES clinical trial—provides preliminary data on muscle activation patterns in each position, informs strategies to prevent compensatory behavior, and helps to assess the system's overall impact on muscle activation.

***Abstract* -** Arm use and arm function are inextricably linked; nonuse leads to a decline in fuctionality, while proper and consistent usage maintains functionality and can lead to further improvement. Many individuals with impairment are discharged from therapy with functional levels that are too low to promote self-use of arm and hand function at home. However, with gravitational support to the arm, some of these same individuals could experience immediate improvements in reachable workspace. To increase arm function and usage, we developed a custom wearable shoulder exoskeleton with variable levels of gravitational support and evaluated its effect on three participants with chronic impairment from stroke, measuring planar reach area during a single session (assisted vs unassisted). We also measured baseline arm use at home with wrist-mounted activity trackers to evaluate the amount of use vs. nonuse of the impaired limb during daily activities. With exoskeleton assistance, participants achieved average gains in planar reach area of 11%, 1.3%, and 14.2% in the transverse, sagittal, and frontal planes, respectively, relative to unimpaired function. Baseline unassisted arm usage was also measured by numerically integrated accelerometry activity counts which may offer a quantitative way to compare the difference in arm usage with and without provision of an assistive exoskeleton.

Keywords—activity tracking, arm, assistance, body-mounted, exoskeleton, gravity-balancing, shoulder, wearable

I. Introduction

Cerebral damage from stroke leaves about half of survivors with long-term impairment in the arm and hand, leading to significant disability in activities of daily living (ADLs) [1]. One-sided impairment (hemiparesis) is one of the most common post-stroke symptoms, marked by weakness and abnormal muscle synergies (groups of muscles that contract together). During active self-support of the impaired arm against gravity, the flexion synergy causes simultaneous contraction of biceps, forearm supinators, wrist flexors, and finger flexors. When severe, the combined contraction pattern restrains the hand close to the torso, limiting the ability to reach for objects.

Intensive rehabilitation, even in the chronic phase (>6 months post-stroke), leads to better functional outcomes [2]. However, gains in performance are often used to justify continuation of care, and many clinical assessment scores plateau (due to insensitivity of metrics) before functional recovery can be fully reached. Particularly evident in the US, the need for rehabilitation services is outpacing the supply of physical and occupational therapists, putting strain on the rehabilitative care system [3, 4]. Despite growing workforce shortages, it is known that function at discharge significantly impacts future recovery trends. Patients discharged with higher function have been shown to be more likely to enter a positive cycle of continued use and recovery. In comparison, those with lower function are more likely to enter a negative cycle of disuse and decline [5].

Given these facts, it is probable that early discharge of partially rehabilitated patients increases the population of individuals with long-term impairment who are unable to incorporate their affected arm into ADLs without external assistance. These individuals develop (and are taught in therapy) compensation strategies that rely on the unimpaired limb [6]. Unfortunately, this approach contributes to the decline and further neglect of motor function in the impaired limb [5]. This trend creates an opportunity for wearable assistive exoskeletons to bridge the gap between function and performance. Provision of gravity support to the hemiparetic arm can, in many cases, improve active (i.e., self-driven) range of motion (AROM), facilitating greater functional use of the arm [7, 8]. Gravity support effectively lowers the barrier to spontaneous use of the impaired limb and, if available in the home setting, has the potential to increase arm use and thereby maintain or improve function.

Chair- and table-mounted mobile arm supports (MASs) have been used by wheelchair-bound individuals for decades to increase range of motion and function, but commercial MASs are not available as wearable body-mounted systems. Only a few prototypes have been directly mounted to impaired users, such as the WREX [9] and the WREX Mini [10]. The reported limitations of body-mounting are device size and weight [11, 12], aesthetics (e.g., profile and appearance) [13-15], and/or a

Funded by an award from the National Institute of General Medical Sciences (NIGMS), National Institutes of Health (NIH) under grant number U54 GM104944.

low level of perceived benefit considering the limitations [13, 16]. Within the last decade, a number of lightweight wearable exoskeletons have finally reached the market, but so far, these devices have been targeted toward able-bodied users in industrial settings only [17-19], aiming to reduce bilateral shoulder strain during repetitive overhead tasks. While their acceptance in the workplace continues to grow, similar wearable products have not yet emerged for individuals with impairment.

Successful implementation of body-mounted systems intended for long-term use at home necessitates design improvements to ensure that devices are lightweight, durable, easy to use, comfortable and safe, particularly since they are intended to be used in environments with little or no professional supervision. Creating user independence and establishing ease of use for donning/doffing and adjustment is a high priority since patients at home may not have access to assistance. Toward this objective, a wearable shoulder exoskeleton has been under development at the University of Idaho [20, 21]. The device aims to provide gravity support to a single arm, adjustable from no support to full support, reducing shoulder effort and the undesirable synergies that typically impede reaching after neurological impairment.

In this paper, we report on preliminary experiments with a body-mounted exoskeleton to improve the active range of motion in the arm of individuals with chronic hemiparesis from stroke. We also explore a method of analyzing arm use metrics in individuals with impairment using off-the-shelf wrist-mounted activity trackers as a means to evaluate the effectiveness of assistance provision at home.

II. Methods

A wearable shoulder exoskeleton (Fig. 1) is designed and built from custom and off-the-shelf components. Structural links are created from carbon fiber rods and 3D-printed thermoplastics; energy storing springs are constructed from natural latex rubber tubes [22]; and low-stretch Vectran™ cables.

Four subjects with arm impairment were recruited to participate in an arm mobility and usage study, with three of the four subjects participating in both parts. Subjects had experienced a single stroke that occurred between 14 and 51 months prior and demonstrated limited ability to elevate the arm against gravity.

A. Testing Procedure

The testing protocol was approved by the University of Idaho's Institutional Review Board (IRB Protocol #23-041). Testing included a set of intake measures followed by two substudies: 1) AROM sub-study, measuring active range of motion with and without external assistance from a body-mounted exoskeleton; and 2) Spontaneous Arm Use sub-study, measuring normal arm use in the home setting. The AROM sub-study was conducted in a laboratory setting during an initial 90-minute session, starting with informed consent, anthropometric measures, and baseline functional assessment tests. In preparation for the AROM sub-study, subjects provided input through trial and error on the level of assistance that they felt best facilitated their arm range of motion. For the Spontaneous Arm Use sub-study, each subject was sent home with two Axivity AX6 data loggers (3-axis accelerometer and 3-axis gyro). These devices were worn on each wrist for 3–5 days to measure daily usage of the impaired and non-impaired arm. The data loggers are contained in waterproof silicone straps, enabling continuous wear by subjects in all daily activities (e.g., showering, washing dishes, etc.).

B. Intake Measures and Baseline Assessments

Intake measures included subject age, gender, height, weight, approximate time since stroke, 60-sec Box and Blocks test (BBT) scores, grip strength, and finger-thumb pinch strength (TABLE I). Two subjects were primarily wheelchair-bound and did not perform strength tests due to the severity of tone in their affected hands; one of these two was also self-withdrawn from the AROM sub-study due to

the level of tone and spasticity present in the affected arm on the day of testing.

C. AROM Substudy: Active Range of Motion Evaluation

Subjects were seated and secured with a 4-point harness to an experimental chair [23] and then fit with a custom glove-based marker set (Fig. 2). The marker set forms a rigid body around the hand with a centroid located approximately along the grip line of the palm at the level of the metacarpophalangeal (MCP) joint. This point represents the reach distance for the subject (i.e., their unimpaired reach work area). Subjects were instructed to perform a planar reach motion to circumscribe the largest area possible in each of three planes (transverse, sagittal, and frontal). The movements were demonstrated on video and in-person, and subjects were allowed to practice them as needed. The movements were performed first with the unimpaired side, allowing confirmation that the subject understood the task instructions, and were then repeated with the impaired side. Movements in each plane were repeated 3 to 5 times, depending on the level of difficulty for the subject. Each movement was recorded and analyzed. Impaired-side range of motion trials were repeated with and without assistance from the body-mounted exoskeleton, where the level of assistance had been previously determined with input from each subject.

A 5-camera motion capture setup (OptiTrack with 5 Flex13 cameras) recorded hand movements at 120 Hz using OptiTrack's Motive software. Movement data was processed in MATLAB to compute the planar reach area. The outline of the reach works areas were smoothed using *smoothdata()* (moving average filter with window size N = 50) and the areas were calculated using polyarea(). For comparison between subjects, the smoothed reach areas are plotted (Fig 3), illustrating the differences in size, shape, and relative location of subject reaching ability with and without exoskeleton assistance. Range of motion of the

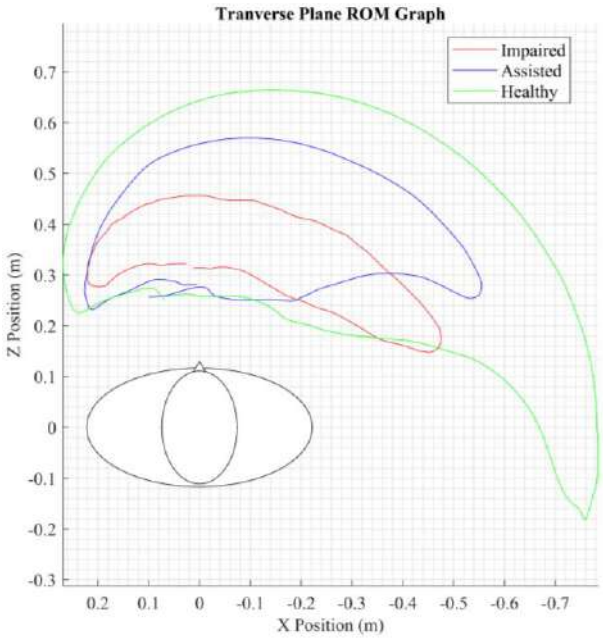

Fig. 3. Active range of motion area for impaired-unassisted (red), impaired-assisted (blue), and healthy (green) arm reach for subject M5704 as measured by hand displacement in the transverse plane. Healthy side (left arm) AROM has been mirrored across the sagittal plane for comparison.

unimpaired arm was mirrored across the sagittal plane to provide a reference for impaired-side range of motion.

D. Arm Use Substudy: Evaluation of Spontaneous Arm Use

An AX6 multi-sensor data logger is attached to each wrist (left and right) via a silicone wristband to be worn at home during the subject's normal activities. The set of onboard sensors are pre-configured via Open Movement's OpenGUI subject identifiers, sensor attachment locations, and recording start and stop times. Data collection rates were set to 100Hz with sensitivities set to ±8g for linear acceleration and 500 degrees per second (dps) for angular velocity. The recording duration depended on the subject, but all subjects provided at least 3 days (72 hours) of continuously recorded data. Subjects were instructed to always keep the sensors on if possible and to set the AX6 devices on a stationary surface if removed.

After completion of the 3–5-day accelerometry collection, data was downloaded via the OpenGUI software, and data files were converted from raw measures into activity counts using *cwa-to-counts*, a Windows command script available in Open Movement's open-source repository [24]. The converted data is imported into MATLAB to apply a moving average with a window size of 10 minutes via the *envelope()* function. Finally, MATLAB's *trapz()* function is used to compute the discrete integration of the accelerometry data to estimate the average overall activity level in order to compare the datasets of impaired and non-impaired arm usage.

III. Results

At the time of writing, four subjects were enrolled in the overall study, and three were eligible to participate in the AROM sub-study. One subject was removed due to the reasons described in Section II B.

A. Arm Range of Motion Evaluation (AROM Sub-study)

Providing gravity assistance to the shoulder of individuals with significant impairment in the arm and hand produced varying changes in active range of motion. Subject M6603 saw the highest relative gains in reach range of motion (relative to baseline performance), while subject M5704 saw the highest absolute gains (relative to healthy performance). Both subjects M6603 and M5704 had similar absolute gains with percentage increases relative to their unimpaired arms of 14-20% in the transverse and frontal planes while the most severely impaired of the three (subject M4601) had more modest improvements of 1.5-3.5% of healthy ROM in these planes (Fig. 4 and TABLE II). Although one subject achieved gains in all three planes, two of the three saw slight decreases in sagittal plane ROM. For all subjects, shoulder assistance increased AROM in the frontal plane the most, followed by transverse AROM, and then the sagittal AROM. Subject M5704 achieved a 20% improvement in the frontal plane and an 18% improvement in the transverse plane, both with respect to full range of motion of the subject's healthy (left) arm. The frontal plane AROM task is shown in Fig. 5 with a

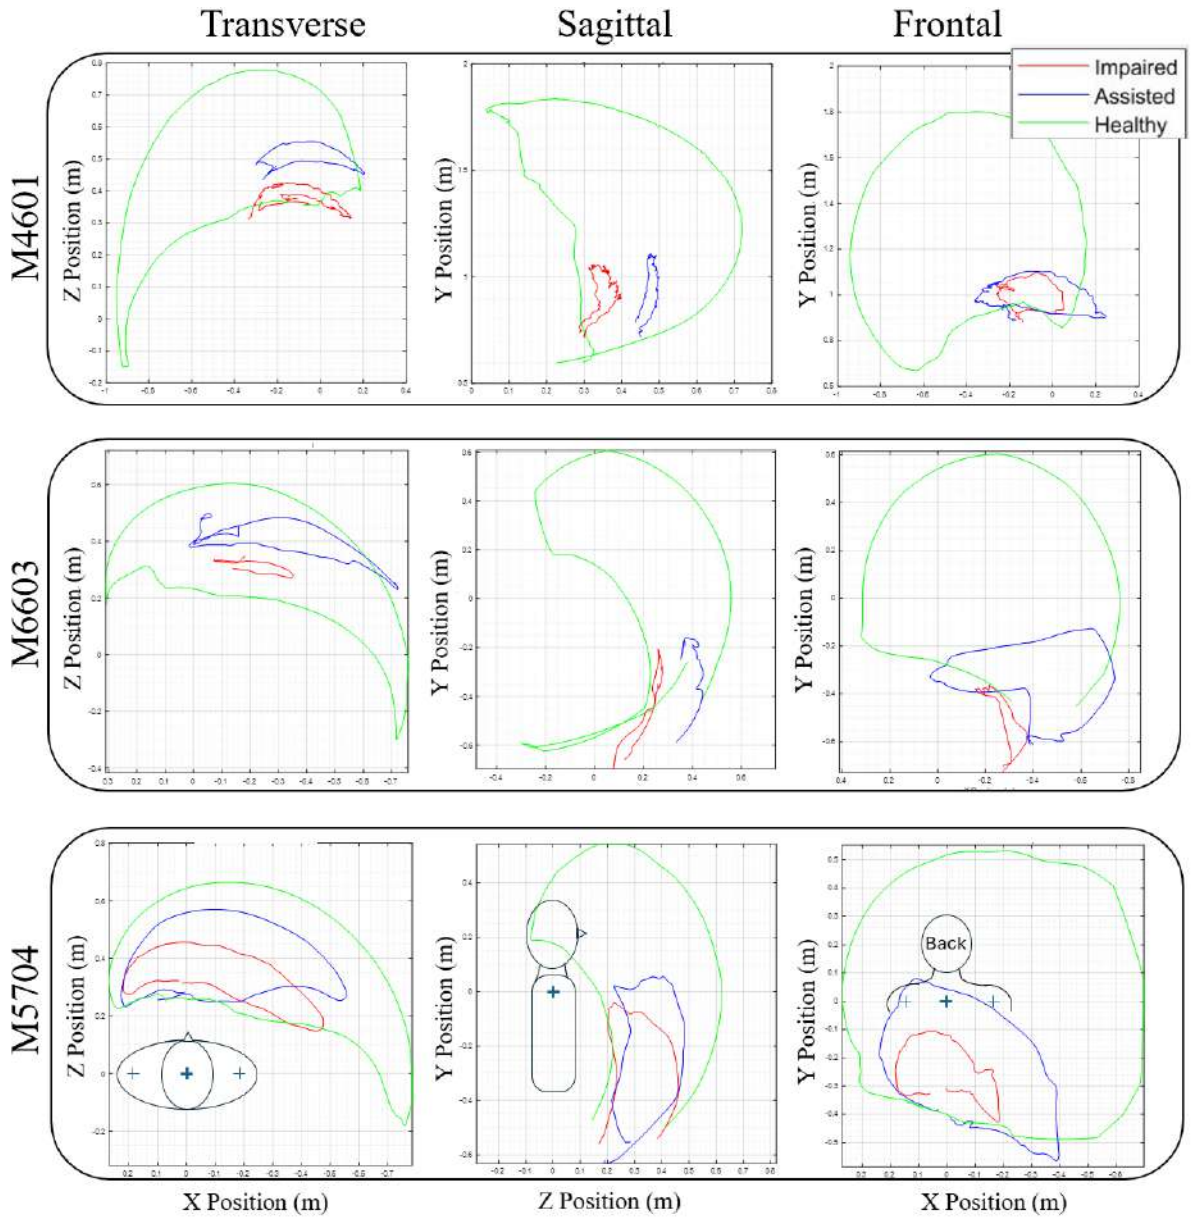

Fig. 4. Active range of motion for impaired arm-unassisted (red), impaired arm-assisted (blue), and healthy arm (green), in the transverse (LEFT column), sagittal (MIDDLE column), and frontal (RIGHT column) planes for subjects M4601 (TOP row), M6603 (MIDDLE row), and M5704 (BOTTOM row). Subplots for M5704 included approximation of human torso locations based on measurements from shoulder markers included in the mocap. Shoulder locations for M4601 and M6603 datasets were not recorded, and therefore healthy data (green plots) may not be accurately mirrored relative to the impaired data; however, the relative sizes of work areas within each subplot are accurate and comparable for scale.

TABLE II. Active arm reach range of motion measures in three planes without assistance (Unassisted) and with assistance (Assisted) expressed in cm^2 and as a percent of range of motion of the subject's healthy (H) side. Relative change in range of motion area also provided with respect to (w.r.t.) the unassisted (U) area and the healthy (H) side area.

Subj. Num.	Motion Plane	Range of Motion Area				Relative Change	
		Unassisted		*Assisted*		*w.r.t. U*	*w.r.t. H*
		(cm^2)	*w.r.t H (%)*	*(cm^2)*	*w.r.t H (%)*	*(%)*	*(%)*
M4601	Transv.	17.3	4.1	23.6	5.6	36	1.5
	Sagittal	12.0	2.6	9.5	2.2	-20	-0.5
	Frontal	39.0	4.4	70.7	7.9	81	3.5

	Sagittal	1037	24	1012	24	-2	-0.5
	Frontal	603	6.7	2297	25	281	20
					Average	287	8.9

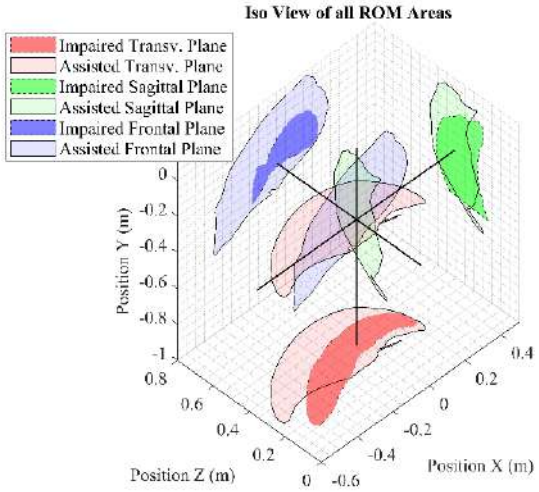

Fig. 6. AROM data from subject M5704 in transverse (red), frontal (blue), and sagittal (green) planes without (dashed line, darker fill) and with (solid line, lighter fill) assistance from a wearable shoulder exoskeleton. Assisted range of motion results are also overlaid in the center to illustrate the 3D volume reachable for the subject with exoskeleton assistance.

sequence of images that illustrate, left-to-right, the progression of movement and top-to-bottom the relative difference between unassisted and assisted workspaces. In Fig. 5, transverse planar AROM areas are compared for impaired (assisted and unassisted) and healthy sides. Without assistance, the impaired side is able to achieve 24% of the full unimpaired AROM, but with partial gravity assistance from the exoskeleton, transverse AROM increases by 18 percentage points (with respect to the healthy arm) to 42% of healthy range of motion. Fig. 6 illustrates the difference between assisted (solid) and unassisted (dashed) AROM for the same subject in each of the three planes.

B. Spontaneous Arm Use Evaluation (Arm Use Sub-study)

The amount of recorded activity in impaired extremities was significantly less than the unimpaired extremity for all subjects. Fig. 7 shows recorded activity from subject M5704 over a 24-hour period starting and ending at midnight. The numerically integrated counts for the impaired (right) side totaled 4.35×10^4, while the non-impaired (left) side totaled 61.2×10^4 counts. TABLE III shows integrated count values, representing the total amount of use of each arm, as well as a ratio between the level of impaired vs. unimpaired arm use for all subjects.

Fig. 5. Task progression of a subject performing arm reach range of motion task in the frontal plane without (TOP row) and with assistance (BOTTOM row). Timeline progresses left to right with the starting pose shown in the left-most image.

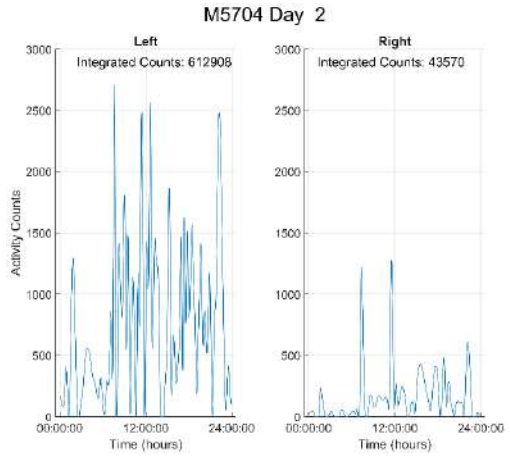

Fig. 7. Activity comparison between left (unimpaired) and right (impaired) of subject M5704 for a 24-hour period.

TABLE III. Activity counts comparison between impaired (I) and unimpaired (U) arms.

Subject Number	Day	I Counts (x 10^4)	U Counts (x 10^4)	I/U Activity Ratio (%)	I/U Average Activity Ratio (%)
M4601	1	8.08	116	6.97	6.53
	2	5.08	80.1	6.34	
	3	4.72	68.9	6.85	
	4	4.94	84.5	5.85	
F7302	1	2.82	52.5	5.37	6.8
	2	10.7	150	7.13	
	3	10.8	152	7.11	
	4	-	-	-	
M6603	1	25.0	136.94	18.26	20.07
	2	39.68	198.73	19.97	
	3	46.26	213.59	21.66	
	4	19.78	101.98	19.40	
M5704	1	1.53	17.2	8.90	6.73
	2	4.35	61.2	7.11	
	3	2.39	45.8	5.22	
	4	1.25	17.3	7.23	

Fig. 8 shows a side-by-side comparison of integrated counts between impaired and unimpaired arms for all subjects over a 24-hour period. The average activity ratio varied greatly per subject, with the lowest at 6.53% and the highest at 20.07%. It can be seen that the common range of activity ratios for subjects measured at the time of writing is 6-7%.

IV. Discussions and Conclusions

A wearable exoskeleton was developed to lessen the shoulder effort required to support the arm against gravity with the goal of increasing active range of motion post-stroke. AROM of the impaired arm with and without the exoskeleton assistance was evaluated in a laboratory setting through motion capture. Three subjects participated in the laboratory evaluation, and four also took part in an at-home assessment of arm use measured by wrist-mounted wearable trackers.

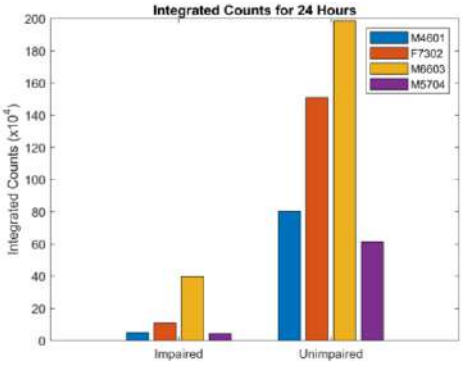

Fig. 8. Comparison of impaired and unimpaired integrated counts over 24 hours (midnight to midnight) for all subjects.

While wearing the exoskeleton, all subjects saw significant improvement in the frontal and transverse planes. Changes in the sagittal plane were more varied, with two subjects showing decreased AROM in that plane when using the exoskeleton. There are two reasons for this effect: 1) The exoskeleton spring support design does not take into account elbow angle and will under-support the arm when the elbow is extended and over-support when the elbow is flexed. 2) the direction of the range of motion task can either work with or against this under/over-support limitation. The subjects in this experiment were asked to perform the motion in the direction that would work against the support limitation, minimizing the resulting range of motion. This resulted in reduced range of motion over the unassisted condition for two of the subjects, the change was negligible for one, and the third subject still achieved an increased range of motion. Future subjects will perform the sagittal plane AROM tasks in both directions to compare AROM capabilities when taking advantage of the device's ability to over-support when lifting and under-support when lowering the arm. It can also be seen that there is a portion of the unassisted AROM that lies outside of the assisted AROM for some; this can be attributed to a range of motion limitation in the exoskeleton version used in this study which prevented full shoulder adduction. A redesign is underway to address this adduction limit.

Other constraints imposed by the current design are a limited ROM and inability to actively move the limb. The design currently limits the range of assistance to between 17 and 90 degrees of elevation from the side. As a passive device, it can only amplify the subject's already existing motion capabilities, so AROM increases are dependent on the subject's strength prior to testing. This can be seen by comparing the average activity ratio and the relative increases in AROM in each subject. Those with a higher average activity ratio had higher relative changes in assisted AROM values.

It was observed during testing that the wearable exoskeleton can make useage of the impaired arm less strenuous. This was not a metric that we originally intended to measure, but after this observation the study protocol was modified to allow measurement of electromyography

(EMG) during the AROM assessment to evaluate muscular effort along with AROM. Regardless of whether improvements are in AROM or effort, there is potential for these improvements to increase subject motivation and ability to use their impaired arm in daily life. The goal is to adequately match user impairment with the proper assistance level from the exoskeleton to maximize impaired arm use at home.

The preliminary work in measuring arm use at home clearly shows a difference in arm use and establishes a baseline against which to compare future measurements of arm use at home with exoskeleton assistance. Future steps of this study will send participants home with the assistive exoskeleton and monitor changes in the impaired-to-unimpaired arm use activity ratio. Following the preliminary results of Section IV, we expect exoskeleton assistance to produce increased activity levels in the impaired extremity, and higher scores in standardized functional assessment tests.

In conclusion, the designed exoskeleton provides immediate improvement of subject AROM in the frontal and transverse planes of motion, and we believe it will also provide increased sagittal plane AROM if the characteristics of the gravity support are properly leveraged. We believe these preliminary results provide strong, positive evidence of the potential benefits of wearable exoskeletons for stroke rehabilitation.

ACKNOWLEDGMENT

The authors would like to thank Jeremiah Schroeder and Zhihui Wang for their prior contributions to the design and development of the shoulder exoskeleton prototype, and Abishek Rathod for his contributions to spring characterization.

Fabrication and Evaluation of Woven and Crocheted Strain Sensors for Soft Rehabilitation Robots

Meghan Newkirk, J. Guillermo Colli Alfaro, and Ana Luisa Trejos, *Senior Member, IEEE*

***Abstract*— Recent advancements in technology have made possible the use of soft wearable mechatronic devices for musculoskeletal rehabilitation. Soft sensors are crucial components of these devices, as they are used for user data collection and device control. However, current fabrication methods are expensive, complex, and not available to those in low resource communities. To address this issue, this paper presents advances in low-cost textile sensors created using either crocheting or weaving. The performance of four different types of sensors was evaluated in terms of working range, linearity, hysteresis, sensitivity, and repeatability. The results showed that a fully crocheted sensor made with elastic and silver-plated conductive thread performed the best. This sensor demonstrated high repeatability, an excellent working range (49.76%), and relatively good hysteresis (20.12 $\pm$ 19) and linearity (R^2 of 0.7741 $\pm$ 0.03). Overall, these results indicate that soft textile strain sensors created using simpler techniques, such as crocheting, have the potential to be used in applications requiring tracking of human motion, meaning that they could be used as integral components of soft wearable robots. This low-cost approach could make soft wearable rehabilitation technologies more accessible and affordable, paving the way for broader implementation and improved patient outcomes.**

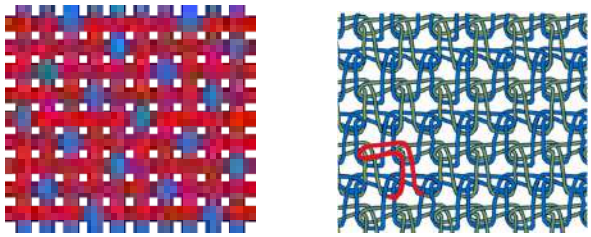
***Index Terms*— textile sensors, crocheted materials, strain sensors, soft robotics, wearable sensors, rehabilitation robotics.**

I. Introduction

The use of soft wearable mechatronic devices in musculoskeletal rehabilitation is a research topic that has been gaining traction in recent years. Within these devices, sensors are one of the most important elements, as they can be used to collect data from activities of daily living [1], to estimate forces exerted by wearable robots during walking [2], and to control the behaviour of the robotic device [3] by detecting changes in the position of the wearer [4].

To comply with the soft aspect of the wearable mechatronic device, recent studies have explored the use of textile sensors due to their comfortable fit and easy integration into everyday clothing. These sensors are often fabricated using carbon-based techniques [5]–[7], screen-printed with conductive inks [8], or using chemical-based methods [9]. Although these manufacturing techniques show promise, they require specialized equipment and complex processes, limiting access and widespread availability. Simplifying the manufacturing process and reducing material costs may be sufficient for regions with limited funds to be able to produce functional textile wearable sensors.

To make these solutions widely available, low-cost manufacturing processes that provide high-quality measurements are essential. Methods such as sewing, and embroidering [10]–[12] use simpler techniques, but still require specialized machinery that might limit accessibility in under-resourced communities. On the other hand, two low-cost manufacturing alternatives are weaving and manual crocheting, with crocheting offering the lowest cost solution. Woven sensors are created by interlacing a set of threads perpendicularly to a different set of threads. In woven structures, the set of threads arranged vertically are known as warp threads, and the horizontal threads are known as weft threads (Fig. 1a). Crocheting, on the other hand, consists of interlocking loops of threads to create rows of a tightly bundled structure (Fig. 1b). By using weaving and crocheting in combination with conductive threads and elastic materials, textile sensors can be designed to meet specific needs. For example, it can be possible to substitute or combine multiple rows of the crochet structure with a conductive thread to detect changes in resistance when the crochet structure is stretched. Similarly, for woven sensors the warp and weft threads can be substituted by an elastic element and a conductive thread, respectively, to create a strain sensor.



Unfortunately, the use of weaving and crocheting for the development of textile strain sensors has only been explored in few studies. For example, in [13] an elastic crochet structure was created using non-conductive threads. This piece of material was then coated with a conductive polymer to create a strain sensor. Similarly, in [14] a strain textile sensor was created using a weaved structure, which was made of fibres that had been previously coated with a conductive polyurethane. Although effective, these methods relied on a chemical process to provide electrical characteristics to the sensors. In another study [15], a simple textile strain sensor was created using a double crochet pattern. This sensor was used to measure elbow joint motions. However, the double crochet pattern created a structure with wide gaps, which affected the performance of the sensor over time.

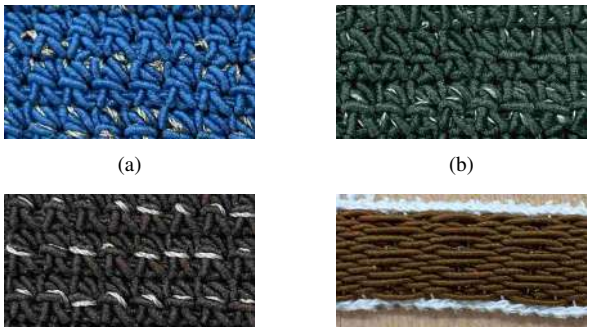

Fig. 1. a) Path of threads in a woven material, using the satin weave pattern. The red lines represent the weft threads, and the blue lines represent the warp threads. b) Path of the threads in the single crochet sensor. The blue lines represent the base, elastic thread and the green lines represent the elastic and conductive threads crocheted together. One single crochet stitch is outlined in red.

While some efforts have been made towards the development of textile strain sensors using the crochet and weaving techniques, fabrication and affordability issues still need to be addressed before they can be fully integrated into soft wearable mechatronic devices. Therefore, this study focuses on the development and assessment of textile strain sensors using the crochet and weaving techniques. The main objective of this study is to compare both techniques, and to provide a low-cost alternative for the development of stretchable textile strain sensors that can be potentially used during robot assisted therapies.

II. Materials and Methods

In order to achieve this objective, four different types of sensors were constructed and tested using a Madeira HC-40 silver-plated thread, a Bekinox VN14/1x90/100Z stainless steel conductive thread, and VistorHies elastic thread (model #CIDSTECA_3276258350). All of the crochet sensors were manually fabricated, whereas the woven sensors were created using an eight-shaft table loom (Ashford Handicrafts Ltd.). To assess variability, four sensors of each of the following types of sensors were created:

1) *Silver-plated full crochet (SPFC)*: These sensors were fully crocheted, 25 stitches long and 11 rows high. Silver-plated conductive thread was crocheted with the elastic thread every third row. This left a two-row buffer of elastic thread between rows where conductive thread had been used (Fig. 2a).
2) *Stainless steel full crochet (SSFC)*: These sensors had the same pattern and dimensions as SPFC, but used stainless steel as the conductive thread (Fig. 2b).
3) *Silver-plated backstitch (SPBS)*: A 25 stitch by 11 row sensor was made using only elastic thread. Silver-plated conductive thread was then sewn into the sensor using the backstitch. The backstitches were made by looping the conductive thread around the v-shaped pattern of the crocheted material, as shown in Fig. 2c. The stitching was completed for every other row on the crochet material for a total of five rows.
4) *Silver-plated satin weave (SPSW)*: A woven sensor made with the satin weave pattern was created in order to directly compare the crocheted sensors to woven sensors. The sensors were made with one row of plain weave, and four sets of the satin weave pattern, making 20 rows of satin weave, and then 1 row of plain weave at the end (Fig. 2d). The rows of plain weave allow for the pairs of warp thread to be tied off surrounding the last weft thread, keeping everything in place. There were 9 rows of conductive thread in the sensor. They were placed after every 2 rows of satin weave and embedded in the sensor using a plain weave. There is no layer of conductive thread after the last 2 rows of satin weave as it would slide out of place. A layer of fabric glue was applied to the edges of the sensor, to keep the warp threads from loosening when cut.

(a) (b) (c) (d)

Fig. 2. Four types of sensors created: a) Silver-plated conductive thread crocheted with elastic thread sensor; b) Stainless steel conductive thread crocheted with elastic thread sensor; c) Elastic thread crocheted base with silver-plated conductive thread embedded through a backstitch; and d) Satin weave sensor with silver-plated conductive thread embedded.

(a) (b)

Fig. 3. a) Crochet end pieces attached to one end of the sensor. b) Non-stretch nylon strips were sewn to the crochet end pieces. A piece of conductive fabric and snap were attached to the nylon, providing a contact point for the ends of the silver-plated or stainless steel thread.

Along the edge of each sensor, 12 rows of 10 single crochet stitches were added, as shown in Fig. 3a. Two layers of cotton sewing thread (Cansew Inc. model CG 24/4 6) were used on these ends, in order to give the end pieces more strength when pulled. Also, a non-stretch nylon strip was sewn onto the crocheted end pieces, with a patch of conductive fabric on top Fig. 3b. This conductive patch served as an interface between the conductive thread and a metal snap, which was used to connect the sensor to a data collection device.

The resistance of the sensor was recorded with a Rigol DM3058E Digital Multimeter (DMM) (RIGOL Technologies Inc., Portland, OR, USA) by attaching alligator clips at the ends of the sensors. Note that the added resistance value from the conductive fabric and snap shown in Fig. 3b was initially measured and removed from the resistance values

TABLE I

INITIAL SENSOR RESISTANCE VALUES. THE LAST COLUMN REPRESENTS THE DIFFERENCE IN RESISTANCE BETWEEN THE SENSOR WITH AND WITHOUT THE METAL SNAPS ATTACHED.

Sensor	Sensor Base Resistance (Ω)	Sensor Resistance With Snaps (Ω)	ΔR (Ω)
SPFC1	21.02	22.22	1.2
SPFC2	17.48	19.23	1.75
SPFC3	14.65	16.3	1.74
SSFC1	131.81	134.61	2.8
SSFC2	122.27	129.22	6.95
SSFC3	115.21	119.52	4.32
SPBS1	51.45	52.73	1.59
SPBS2	48.58	51.62	3.05
SPBS3	53.27	55.73	2.46
SPSW1	22.89	26.78	3.89
SPSW2	31.76	33.78	2.02
SPSW3	12.52	19.41	6.88

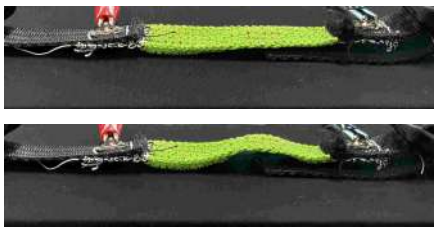

Fig. 4. a) Crochet sensor after being stretched 6 cm and relaxed. This was the maximum length that this type of sensor could be stretched without permanent deformation. b) The same crochet sensor after being stretched 7 cm. After the sensor was stretched to this length, it could no longer be restored back to its initial form.

obtained throughout testing. The initial resistance for each sensor is shown in Table I.

III. PERFORMANCE EVALUATION

In order to evaluate their performance, each sensor was stretched for 100 cycles while measuring the resulting change in resistance. All fo the sensors were tested in a dry, cool environment, at approximately 22.5 ± 0.5 °C. One property of the elastic thread is that its cross sectional area decreases when stretched. This allows the loops in the crocheted stitches to be pulled closer together, as the thread is thinner. The result is an increase in the length of the sensor, as the extra thread that used to be in the loops is now spacing out the stitches. When the tension is removed from the sensor, the extra length causes ductile deformation to occur. For example, Fig. 4a shows a sensor that was stretched but did not start to buckle, while Fig. 4b shows a sensor that was stretched past this maximum amount resulting in buckling.

One of the four sensors made for each pattern was used to determine the maximum distance that the sensor could be stretched before permanently deforming the material. This was done by stretching and relaxing the sensor in one centimeter increments. The maximum deformation that the sensor could withstand was determined to be about one centimeter below the permanent deformation distance. The remaining three sensors of the same pattern were stretched to this length for 100 cycles. Table II shows the average strain values applied to each sensor.

TABLE II

AVERAGE STRAIN VALUE APPLIED TO EACH TYPE OF SENSOR.

Type of Sensor	Average Initial Length (mm)	Distance Stretched (mm)	Average Strain (%)
SPFC	74.66	60	80.36
SSFC	73.91	30	40.59
SPBS	65.87	35	53.13
SPSW	95.52	20	20.94

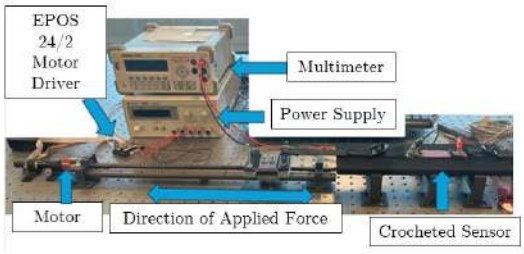

Fig. 5. Testing set-up used to stretch the sensors for 100 cycles.

The nylon strips were attached to the testing set-up using buckles, Fig. 5. The motor was set to rotate at 2000 revolutions per minute (rpm) and the DMM recorded the resistance of the sensor at a frequency of 2.5 Hz. The table under the sensor supported the weight of the buckles and DMM clamps, keeping all parts of the sensor level.

After the cycling was complete, the following properties were measured:

1) Working Range: This is the range over which the resistance changes due to the strain progression acting on the sensors. The range begins at the strain percentage where the loading and unloading cycles have a consistent decreasing or increasing monotonic behaviour, and extends to where the monotonic behaviour changes.
2) Sensitivity: The sensitivity of the sensors refers to the resolution and range that the sensors can measure [10]. To determine the sensitivity, the gauge factor (GF) was used, which relates the change in resistance (ΔR) with respect to the applied strain. A higher gauge factor indicates that a smaller amount of strain is needed to observe a change in the resistance. This is given by the gauge factor, as follows:

$$GF = \frac{\Delta R/R_0}{\varepsilon}, \tag{1}$$

where R_0 is the initial sensor resistance, and ε is the applied strain, which refers to the change in length (ΔL) of the sensor with respect to its initial length (L_0). The strain is given as follows:

$$\varepsilon = \frac{\Delta L}{L_0}. \tag{2}$$

3) Hysteresis: This is a measure of the difference in energy as a load is applied and released from a material. Ideal sensors would have no hysteresis. This would mean that the sensors show no loss of energy between

loading and unloading in the form of friction [10]. For these sensors, strain is used to measure hysteresis. The following formula is used:

$$H = \frac{\Delta\varepsilon_h}{\varepsilon_{max} - \varepsilon_{min}} \times 100, \quad (3)$$

where H denotes the hysteresis value in percentage units, $\Delta\varepsilon_h$ is the maximum difference in strain between the loading and unloading cycles, and ε_{max} and ε_{min} are the maximum and minimum applied strain, respectively. Since there were slight variations in the maximum and minimum positions recorded for each cycle, the average of the 100 cycles was used to calculate the hysteresis of each sensor.

4) Repeatability: The repeatability of a sensor represents the ability to maintain electrical and elastic properties over an extended number of cycles. Changes in the sensor performance over time are known as drift. The repeatability can be evaluated by comparing the resistance values of each cycle and how these values change as the cycling progresses.
5) Linearity: The linearity is given by the R^2 value. As the R^2 value approaches 1, the data set becomes more linear, demonstrating a higher level of consistency and energy retention in the sensors.

IV. Results

After collecting data from each sensor, the performance metrics outlined in the previous section were obtained for each sensor pattern. The results of these performance metrics are presented in the following paragraphs.

For each sensor sample, the working range was assessed on the 2nd, 11th, 30th, 75th, and 100th stretching cycles. This was done to observe the change of the working range of each pattern over each stretching cycle. It is important to mention that the first 10 stretching cycles were excluded from the analysis due to the Mullins effect, which relates to the stress softening of rubber materials [16].

The working range of each sensor sample of each pattern is illustrated in Fig. 6. For the SPFC and SSFC sensors, a decrease in the working range was observed before stabilizing around the 30th cycle. For example, for the SPFC1, an initial 68% working range was observed before decreasing to a 54% working range by the 30th cycle. On the other hand, the working range of the SPBS sensors stabilized around the 10th cycle. However, of all the patterns analyzed, the SPSW showed an inconsistent working range across all of its sensor samples. For SPSW1, a working range between 14–21% strain was observed from the 2nd to the 100th stretching cycle. This was not the case for SPSW2 and SPSW3, with the latter showing a working range that stabilized around the 75th cycle.

The second metric assessed was the gauge factor. This metric was calculated by first averaging the response of each of the sensor samples on cycles 11 to 100. Then the gauge factor was computed over this averaged data and over the working range found in the previous section. The gauge

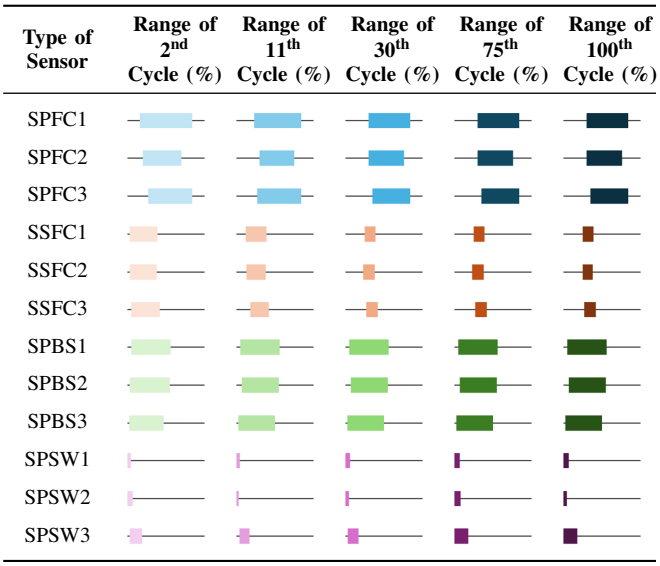

Fig. 6. Working range of the 2nd, 11th, 30th, 75th, and 100th cycle of each sensor. Each horizontal line represents a 0 to 100% range. The total working range of each sensor pattern is represented by the coloured boxes on the horizontal lines. The upper limit of each box is the maximum strain applied to that sensor.

TABLE III

Performance evaluation metrics for the tested sensors.

Sensor Number	Gauge Factor	Hysteresis (%)	Linearity (R^2)
SPFC1	1.12	28.21	0.8002
SPFC2	1.09	2.340	0.7405
SPFC3	0.954	39.80	0.7815
Average	**1.05 ± 0.09**	**20.12 ± 19**	**0.7741 ± 0.03**
SSFC1	1.00	38.25	0.6910
SSFC2	0.958	47.96	0.6558
SSFC3	0.425	38.23	0.6538
Average	**0.795 ± 0.3**	**41.48 ± 5.6**	**0.6669 ± 0.02**

factor of each sensor sample and each pattern is shown in Table III. From this table, it can be observed that a gauge factor between 0.795 and 1.05 was obtained for the SPFC and SSFC sensors, with the SPFC sensors showing a more consistent value. The worst overall gauge factor was obtained for the SPBS sensors. However, these sensors showed less variation when compared with the SPSW sensors, which showed varying gauge factors between 2 and 10.6.

The hysteresis measurements were computed using the same averaged data used to compute the gauge factor. The hysteresis of each sensor pattern can be observed in Fig. 7. Note that this figure shows the sensor response of each pattern averaged across cycles 11 to 100, and across all of the three sensor samples. On the other hand, the individual hysteresis value of each sensor sample is shown

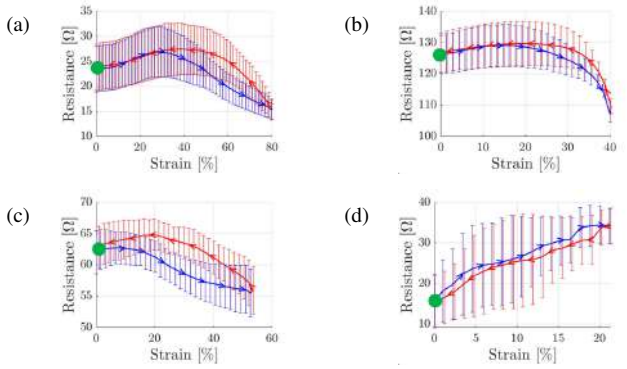

Fig. 7. Average sensor response of each sensor pattern. a) SPFC b) SSFC c) SPBS d) SPSW. Data from cycles 11–100 were averaged among the three sensors samples made from each pattern. The error bars show the standard deviation of the three patterns for the stretching (blue) and relaxing (red) portions of the cycles. The green dot shows where the cycles started and ended, and the direction of the arrows represents the path of motion.

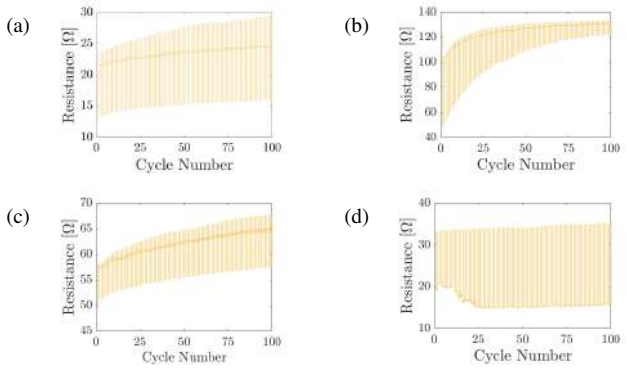

Fig. 8. Resistance readings as a function of cycle number for the average values across the three sensors made from each pattern. a) SPFC b) SSFC c) SPBS d) SPSW. The cycle number increases in increments of 1. The darker line in the middle or at the bottom of the graphs are where the data switch between cycle numbers. This change in resistance shows the readings at the beginning of each cycle.

in Table III. For each pattern, hysteresis varied within each sensor sample, with the SPSW sensors showing the lowest overall hysteresis and the SSFC having the highest hysteresis. However, the SSFC sensor hysteresis varied less between the sensor samples (38.23–47.96%), compared to the SPFC, which showed high hysteresis variability with values between 2.34% and 39.8%. A similar performance was observed for the SPBS sensors, whose hysteresis values ranged between 16.09% and 44.25%.

The next metric assessed was the repeatability of each sensor pattern. This metric was obtained by averaging the sensor resistance readings of each cycle across all of the three sensor samples of each pattern. The resulting data are shown in Fig. 8. All of the sensor patterns showed a drifting behaviour that trended upwards. *i.e.*, the sensor base resistance drifted towards higher values after each stretching cycle. Another important aspect that was observed among the sensor patterns is how their resistance range changed over time. The SPSW sensor pattern showed a major increase on its resistance range during the first stretching cycles that stabilized around the 25th stretching cycle. Also, this sensor pattern showed a minor drifting behaviour (Fig. 8d). In contrast, the SPBS sensor pattern showed an increased drifting behaviour between stretching cycles. However, no reduction on its resistance range was observed (Fig. 8c). A similar drifting behaviour was observed for the SPFC pattern, which showed no variability on its change in resistance between cycles but a positive drifting trend (Fig. 8a). Interestingly, the SSFC pattern showed little to no drift after the 40th stretching cycle. Unfortunately, it also showed the greatest reduction on its resistance range (Fig. 8b).

The last metric computed for each sensor pattern was the sensor linearity. The linearity values are displayed in Table III, and were calculated as the R^2 value obtained over the working range of each sensor sample. The linear response of each sensor pattern did not show high variability among their sensor samples. For example, an overall R^2 of 0.8972 $\pm$ 0.04 was found for the SPSW sensor pattern. The second best linear response was achieved by the SPFC pattern, whose sensor samples showed an average R^2 of 0.7741 $\pm$ 0.03. This was followed by the SSFC and the SPBS sensor patterns with R^2 of 0.6669 $\pm$ 0.02 and 0.6171 $\pm$ 0.04, respectively.

V. Discussion

The results of this study show that the crochet and woven sensors demonstrate good performance characteristics, which can be advantageous when integrated into soft wearable rehabilitation robots. Among the four sensor patterns, the SPFC and SPBS sensors demonstrated an average working range between all of its three sensor samples of 49.67% and 48.83%, respectively, after 100 stretching cycles. These working ranges are more than the suggested 30% for measuring joint data that can be used to control a wearable mechatronic device [17], which makes these patterns a great candidate for these applications. Although it would be expected to observe a similar behaviour across all of the three crochet sensor patterns, the SSFC was not able to achieve a usable working range. This can be observed in Fig. 8b, where the change in resistance of the sensor decreases drastically over time. This reduction on resistance has a direct impact on the working range performance of the sensor. This behaviour can be attributed to the stainless steel conductive thread used for the fabrication of this pattern. As opposed to the silver-plated thread, the stainless steel thread is composed of staple fibres that fray when being tensioned. Furthermore, whenever the stainless steel thread is stretched, the staple fibres tend to create new contact points that reduces the overall resistance of the conductive material [10].

Regarding the SPSW sensor pattern, the poor performance on the working range can be attributed to how the silver-plated thread behaves under tension. Differently to the SPFC pattern whose change in resistance occurs due to an increase in the number of contact points when the loops of the crochet pattern tighten, the change in resistance of the SPSW happen due to axial forces acting on the surface of the conductive thread. As its name implies, the silver-plated thread consists of a non-conductive thread (typically nylon), that has been coated with a conductive layer. Whenever this thread is

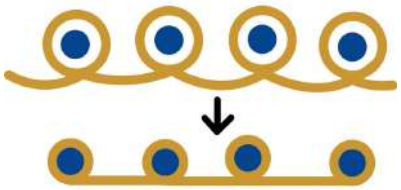

Fig. 9. Change in the crochet backstitch's conductive thread when stretched. The gold lines represent the conductive thread and the blue dots represent the posts of the crochet material the conductive thread wraps around. As the sensor is stretched (bottom), the number of points where the thread touches itself increases.

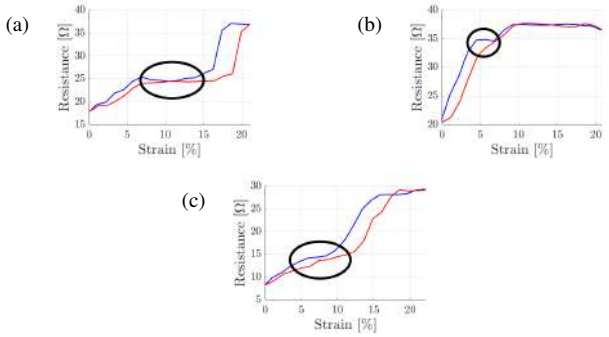

Fig. 10. a) SPSW1 b) SPSW2 c) SPSW3. All graphs compare the resistance readings to the displacement applied to the sensors. The region of limited change in resistance readings is circled in black. The stretching portion of the sensor is shown in blue and the relaxing is shown in red.

put under axial tension, cracks form on the surface of this conductive layer, which increases the overall resistance of the conductive thread [18]. However, because the thread is not elastic, there is a limit on how much it can be stretched. This is the reason why the working range of the SPSW pattern is less than 30%.

Regarding the gauge factor, the sensor that showed the lowest performance was the SPBS. This is because when fabricating this sensor pattern, the backstitches looped around the posts of the crocheted stitch base. When the sensor is stretched, the loops of the conductive thread tighten around the crocheted post as seen in Fig. 9. This increases the number of contact points in the conductive thread, reducing the overall resistance of the sensor. This limits the sensitivity of the sensor, as a larger amount of strain is required for change in resistance to be detected.

Compared to the SPBS, the SPFC and the SSFC had a larger number of initial contact points in the conductive thread. Therefore, only a smaller amount of strain was required to create a change in the sensor resistance. The exception was for the SSFC3, where the gauge factor was approximately half as small as the SSFC1 and SSFC2 sensor samples. This was because the initial length of SSFC3 sensor sample was shorter than the others. To account for this difference in length and to keep consistency during testing, the SSFC3 sensor had to be stretched to a distance that matched the length of SSFC1 and SSFC2 sensor samples. Since a larger value of strain was applied before testing, the amount of effective strain achieved by this sensor sample was reduced, which in turn affected the overall sensitivity.

As for the SPSW pattern, the large variation in the gauge factor among its sensor samples can also be explained by the initial lengths of the sensor samples, and by the inconsistent crack formation on the surface of the conductive thread. The change in resistance is then a function of the number of cracks, and the width and length of each crack [19]. Due to these inconsistencies, the sensor response varied among each of the sensor samples of the SPSW pattern (Fig. 10).

With respect to the linearity and hysteresis, the SPSW pattern showed the lowest hysteresis among all of the 4 sensor patterns and a consistent R^2 across all sensor samples. This was expected, as the underlying behaviour of these sensors was based on the crack propagation of the conductive thread, and not on the number of contact points at any given time. For the SPFC, SSFC, and SPBS sensors the hysteresis observed was due to the elastic thread used during the fabrication of these sensors. Since the elastic thread is made of rubber, it losses energy due to the viscoelasticity of the material [20]. The hysteretic behaviour on these crochet sensors can also be attributed to the number of contact points between the conductive thread. After stretching the sensors, the restoring force of the elastic band causes loosening of the conductive thread that was looped around the crochet stitches. This creates a sudden increase in the resistance of the sensor before it stabilizes to the base resistance. This behaviour can be observed better on Figs. 7a to 7c, in which during the unloading phase of the crochet sensors, higher resistance values can be observed compared to the resistance values during the loading phase. In contrast, the woven sensor showed lower resistance values during the unloading phase compared to the resistance values observed during stretching of the sensor, Fig. 7d.

Finally, all of the sensor patterns displayed a drifting behaviour. Similar to the other metrics, the SPSW sensors showed the lowest drift among the sensor patterns. This was thanks to the cracks on the surface of the conductive thread that created the drift in the resistance readings. When these cracks are formed, the initial resistance of the sensors cannot be reached again. As the sensor undergoes through more stretching cycles, more cracks are formed until a maximum number of cracks are created.

As for the crochet sensors, both the SPFC and the SPBS sensor patterns shown a similar upwards drift. During the experiments, it was observed that the conductive thread on the crochet sensor deviated from its original position. This was caused by the elastic band used during the fabrication of these sensors. When the sensors were stretched, the cross-sectional area of the elastic material decreased. This caused the sensors to slide across the crochet structure and thus, loosening the loops of the conductive thread. Regarding the SSFC, the other phenomenon that affected the repeatability of these sensors was the composition of the stainless steel thread. As the stainless steel conductive thread rubbed against itself, small fibres that form the stainless steel thread are pulled or broken out of place, causing a drift in the sensor resistance.

Overall, the best performing sensor pattern was the SPFC sensor due to its high repeatability and consistent gauge factor among its sensor samples. Regarding the hysteresis and linearity of this sensor pattern, they could be improved by implementing simple algorithms, such as neural networks, during the data processing step [21]. Similarly, the gauge factor can be improved even more by implementing a self-compensating Wheatstone bridge [18] in a diagonal bridge configuration.

VI. Conclusions and Future Work

This work provided an evaluation of different types of textile strain sensors manufactured using weaving and crocheting for applications involving soft robot assistive devices. Three crochet sensor patterns and one woven sensor pattern were created and evaluated. These sensors were assessed in terms of linearity, working range, sensitivity, hysteresis, and repeatability. The results of this study found that the sensor that performed best was the SPFC sensor—a fully crocheted sensor made of elastic thread and a conductive thread embedded every third row. However, before being able to be integrated into a soft wearable mechatronic device, the sensor design needs to be improved in terms of hysteresis and linearity. The SPSW sensor (a woven sensor made with the satin weave pattern) showed the second best performance among the four tested patterns. Although the working range of this sensor pattern is limited due to the inherent woven structure, this sensor may be used in applications where the sensing of a wide range of motions is not required. Some of these applications include early stages of rehabilitation, where joint mobility is limited.

In future work, the linearity and hysteresis performance of these sensors will be improved by implementing some deep learning models as part of the data processing algorithms. After improving these performance metrics, the sensors will be tested on human subjects and under different testing conditions, such as under different temperature and humidity settings. Although the sensors presented in this study show potential for applications involving monitoring of human motion, the performance of these sensors should be assessed against similar sensors in the literature. Beyond the low-cost aspect, this assessment would provide an insight regarding the similarities between crochet sensors and chemical-based sensors. These comparisons should be accompanied by a statistical analysis to highlight the differences between sensors. Similarly, future work should focus on the development and testing of different crochet patterns (*e.g.*, double crochet and chain crochet) to see whether the performance metrics assessed can be improved. Also, it is important to test the sensors under different conditions such as torsion and bending motions. Finally, in this study, sensors were stretched for 100 cycles, which is similar to the testing conditions presented in other studies. However, it would be important to increase the number of stretching cycles to more than 1000. This would allow observing if the performance of the sensors changes over time, and also to assess the fatigue of the sensors.

Overall, the sensors presented in this study provide an accessible alternative to traditional soft sensors. By implementing simpler manufacturing methods, it will be possible to make soft wearable rehabilitation robots accessible in communities with limited resources.

***Abstract*—Rehabilitation robots and assistive devices that detect the motor intent of their users can provide more intuitive and effective control. Pupil dilation occurs when people perform motor activities, but its utility for detecting motor intent has not been explored previously. In this work, a human participant research study is conducted to determine if pupillometric data can be used to differentiate between a person's intent to pick up or observe an object. Thirty participants were recruited to perform 120 trials of picking up and observing objects while their pupil dilation was recorded by an eye tracking headset. Features were extracted from the time series data and used to train a neural network classifier. The classifier was tested using leave-one-out cross-validation. The classifier achieved an average accuracy of 59.4% and F1 score of 0.578 across the thirty test datasets. The performance varied significantly depending on the participant used for testing, suggesting that the pupillometric approach to intent detection may be better suited to some participants than others. Future work should determine whether intent detection can be improved with more advanced machine learning methods, such as convolutional neural networks (CNN), and whether intent detection can be performed in real time.**

I. Introduction

Stroke survivors often lose the ability to move one of their arms because of brain damage. They can recover by participating in rehabilitation therapy. The most effective therapy engages the patient's effort and relates to activities of daily life, but this kind of therapy is difficult for patients with severe arm impairment. Rehabilitation robots can assist such patients in therapy activities; however, they must ensure that the patient is always engaged and making an effort [1].

Although the user of a rehabilitation robot or assistive device could manually indicate their engagement, such as by pressing a button or giving a verbal command, this results in a slow and awkward interface. Ideally, these devices would react automatically to the user's intent as if reading their mind, thus creating a seamless experience that simulates the natural behaviour of their limb. This approach is called intent detection: the robot only activates its assistance when it can detect an intent to act from the user. In literature, robots have been designed to measure brain activity, muscle activity, and forces applied by the patient to detect intent [2]. Brain activity is the most relevant signal for intent, since intent originates in the brain. However, it is difficult to isolate the signals of interest and sensor placement is difficult for an untrained user. Muscle activity is the next most relevant signal, but it is only appropriate if the user is able to produce measurable, voluntary muscle activations. Force measurements are the furthest removed from intent but are the easiest to isolate. They require that the user can produce sufficient force in a controlled manner to reliably indicate what they are attempting to do. Disabled people want more intuitive interfaces [3], but due to the limitations of automatic intent detection, most assistive devices in practice use joysticks or manual control.

Eye tracking has been explored as an interface for controlling assistive devices. A person's gaze contains information about their intended interactions in an environment: they tend to look at objects before manipulating them [4], [5]. Existing assistive device interfaces focus on eye motion, tracking fixations, smooth pursuit motions, or saccades [6]. These methods suffer from the "Midas Touch Problem" [7], where eye movements to gather information (observations) are interpreted incorrectly as eye movements to interact (actions). Previous approaches to solve this intent detection problem include adding additional confirmation dialogs [8], requiring more complex eye gestures [9], or adding a separate input device, such as a switch, to confirm actions [10].

The use of pupillometry (pupil dilation measurement) and gaze information is an unexplored approach to intent detection. The pupil dilates slightly when a person performs, or even imagines performing, an action like reaching for an object [11], [12]. To the authors' knowledge, no previous research has attempted to use pupil diameter as a method of determining motor intent for controlling an assistive device. Detecting arm and hand motor intent from gaze tracking and pupillometry could therefore present several advantages: it precedes object manipulation, meaning it could anticipate intent before muscle activity or force sensing methods; it could be used to distinguish between fixations for observing an object versus physically interacting with an object; it could work even if the person has no voluntary movement of their arm; and it is easier to set up an eye tracking system than surface electroencephalogram (EEG) or electromyogram (EMG) sensors. A disadvantage of pupillometry is the pupil's sensi-

tivity to other stimuli, such as lighting conditions, emotional state, medications, and even cognitive load. Nonetheless, it could still be useful in controlled environments or when combined with other sensor data.

The purpose of this work is to determine the potential effectiveness of pupillometry for arm and hand motor intent detection. This work contributes to the understanding of motor intent and its relation to pupil dilation. A pupil response dataset is collected from human participants and analyzed, and important features and differences in pupil response between participants are discussed. A classifier is trained based on features extracted from the pupil data and its performance and generalizability are analyzed. The classifier demonstrates a proof of concept for novel pupillometric intent detection systems. Limitations of this approach are discussed as well as potential areas for improvement.

II. Study Design

Human participants were recruited to gather eye tracking and pupillometry data. The study was approved by the Dalhousie University Social Sciences and Humanities Research Ethics Board (Study #2024-7211).

A. Target Population and Recruitment

The target population was healthy people aged 18 years or older with normal or corrected to normal vision and hearing. Healthy adults were chosen as a target population to determine if a reliable, measurable pupillometric differences exist before involving a more vulnerable population like stroke survivors. Normal or corrected-to-normal vision is required because vision impairments could result in different gaze behaviours among the participants. Participants were considered to have normal vision if they could comfortably read the number off of a die at arms-length without squinting or straining. The eye-tracking hardware used in this study, the PupilLabs Pupil Core headset, does not fit over glasses but other corrections such as contact lenses were permitted.

Participants were excluded if they had muscular or neurological impairments, or an inability to follow auditory instructions. Muscular impairments of the eye, head, or neck could lead to compensatory movement that affects the way that a participant gazes at their environment. Neurological impairments could have a similar effect and could also change the responsiveness of the pupil.

Participants were recruited through word of mouth, physical posters, and advertisements shared via departmental email lists at Dalhousie University. A $15 honorarium was offered as an incentive to all participants.

B. Participant Demographics

Thirty-two people were recruited, of which two did not participate. One chose not to participate after the briefing, and one had an eye impairment that required them to be excluded. All participants gave informed consent before participating in the study. The demographics of the 30 participants are presented in Table I.

Approximately 73% of the participants were men and 23% were women. Half of the participants were in the 18 - 24 age group, and the next largest group was the 25-44 age group. All participants except one were right-handed.

TABLE I
Participant Demographics

Age Group	18 - 24 15 (50%)	25 - 44 12 (40%)	45 - 64 3 (10%)
Dominant Hand	Right 29 (97%)	Left 1 (3%)	
Gender ID	Man 22 (73%)	Woman 7 (23%)	Nonbinary 1 (3%)

Fig. 1. The participants' view of the experiment setup. Four dice are placed in a square on a small platform on top of a table. A computer monitor provides a neutral background with the gaze starting position (cross). Two speakers provide auditory instructions to the participant. A set of AprilTags are placed at the corners of the platform to allow post-experiment calibration and head movement tracking. The calibration marker is in the bottom right.

C. Experiment Procedure

Participants were asked to perform a series of tasks with and without motor action while their gaze and pupil dilation were recorded by an eye-tracking headset. All participants were briefed on the purpose and process of the experiment beforehand and their consent was recorded.

Experiments were conducted in a windowless room with ceiling-mounted lights. The experiment setup is shown in Fig. 1. Participants were seated at a table covered by a black tablecloth with four dice placed on a raised platform. The dice were placed in a square approximately $14\,\mathrm{cm}$ on a side. The dice were numbered one to four, left to right, top to bottom. Multiple dice were used to encourage different eye movements within the participant's field of view. AprilTags were placed at the corners of the platform to allow head movement tracking and post-recording calibration if necessary, but they were not used in this work.

Participants donned a PupilLabs Pupil Core headset [13]. The headset was calibrated with the calibration marker, shown in the bottom right of Fig. 1, placed in the center of the square of dice. Calibration was considered successful if the resulting model accuracy, the difference between the

predicted gaze position of their eye and the actual position, was less than or equal to 2.5° and the calibrated field of view encompassed all four dice and the cross on the background.

Participants were asked to perform one of two tasks selected at random: pick up one of the dice or read the number value on one of the dice without touching it. These two tasks represented the desired classes to differentiate: looking at an object with motor intent and action (an **Action** task) versus looking at an object without motor intent or action (an **Observation** task). Each trial began with the participant looking at the cross on the background. The experimenter triggered the start of each trial when the participant's gaze stayed on the cross for a few seconds. One second of data was recorded as a baseline [14], then an audio instruction would begin to play from the speakers. The audio instruction was either "Pick up" (**Action**) or "Read off" (**Observation**), followed by a number corresponding to the die with which to interact. The number of the die was randomized for each trial. In an **Action** task, the participant would reach with their dominant hand to pick up the commanded die, lift it from the platform and place it on the table, then return it to its original position. The recording would end once the participant placed the die on the table. In an **Observation** task, the participant would look at the commanded die without moving their hand and report the number to the experimenter. The recording would end once the participant reported the die number. After reporting the number, the participant would wait approximately two seconds, pick up the die, roll it on the table to get a new number, and then return it to its place on the platform. The dice were rolled to ensure that the participant would not be able to memorize the number on each die over the course of the experiment. Participants were asked to avoid reading or memorizing the dice numbers between trials. If the participant made a mistake, such as interacting with the wrong die or getting distracted, the trial would be repeated.

Tasks were assigned at random until the participant had done each task 60 times, for a total of 120 trials. The headset was re-calibrated every 30 trials to ensure that it had not slipped and was still reporting accurate eye measurements. The total experiment duration was approximately one hour.

III. Data Processing and Analysis

A. Data Processing

The data recorded by the Pupil Core headset consists of estimates of pupil diameter and pupil direction based on 2D image tracking of the eye mapped to a 3D eye model. Each estimate has a confidence measure from zero to one based on the goodness of fit between the detected ellipse in the camera frame and the eye model. The estimates are performed in real time, resulting in an inconsistent sample rate as some frames take slightly more time to process than others. A consistent sampling rate simplifies other processing steps, such as filtering, so the data was resampled to a fixed sample rate of 100 Hz. This rate was selected because 99% of samples were found to have $10\,\mathrm{ms}$ or less between them. The resampling was performed using a weighted average of all samples within each $10\,\mathrm{ms}$ period, with the confidence of each sample as the sample weight. In rare cases were no samples fell within a resampling period, a zero-order hold was used based on the value of the previous timestep.

After resampling, low-confidence samples were removed from the dataset. The Pupil Core documentation recommends discarding samples with less than 0.6 confidence. Removed samples were replaced by linear interpolation [14]. Two out of the 3600 total trials had a large amount of samples with less than 0.6 confidence and were discarded.

Another necessary data transformation involved the pupil diameter estimate. The Pupil Core measures each eye with a single camera, therefore there is no way to get an absolute measure of the pupil's diameter. To provide its estimate in millimetres, the Pupil Core's 3D algorithm fits a sphere of known diameter to the eye measurements during calibration. This can result in pupil diameter estimates that vary between eyes and between calibrations. Therefore, it is useful to normalize the pupil diameter in each trial to a baseline to allow comparisons between eyes and between trials. As described in Section II-C, the first $1\,\mathrm{s}$ of data in each trial was a baseline measurement, where the participants observed a neutral background before receiving their instructions. Therefore, the average pupil diameter for $0 \leq t \leq 1$, $d_{baseline}$, could be used to normalize the rest of the data in the trial according to,

$$d_{norm}(t) = \frac{d(t)}{d_{baseline}} - 1, \tag{1}$$

where $d(t)$ is the pupil diameter at time t. The value d_{norm} therefore represents the proportional change in pupil diameter relative to the baseline over the course of the trial.

Finally, the discrete pixels of the camera images and the nature of the pupil tracking algorithm leads to some "wobble" in the tracked pupil. The maximum frequency of interest for pupillometric data is approximately 9 Hz [14], therefore an $18\,\mathrm{Hz}$ low-pass, 3rd-order Butterworth filter was applied to the data to smooth this sensor noise.

B. Pupil Diameter Analysis

Representative, normalized eye diameter trendlines for each task type from four participants are shown in Fig. 2. The time range in which the participants received the instruction, from 1.0 to $2.5\,\mathrm{s}$, is labelled in each plot. The most common behaviour is illustrated by Fig. 2a: at the start of the instruction, the pupil diameter begins to increase for both task types, with a greater increase over time for the **Action** task. This behaviour was observed in 12 out of 30 participants. Fig. 2b shows the second most common behaviour, observed in 11 participants: the average pupil diameter increases for both tasks without a clear difference between them. The third most common behaviour, shown in Fig. 2c, where the pupil diameter increases more for the **Observation** tasks than the **Action** tasks, was only observed in three participants. Fig. 2d illustrates a behaviour observed in two participants: on average the pupil diameter increases for the **Action** trials but stays nearly constant for the **Observation** trials. Finally, one participant not illustrated in Fig. 2 showed negligible average

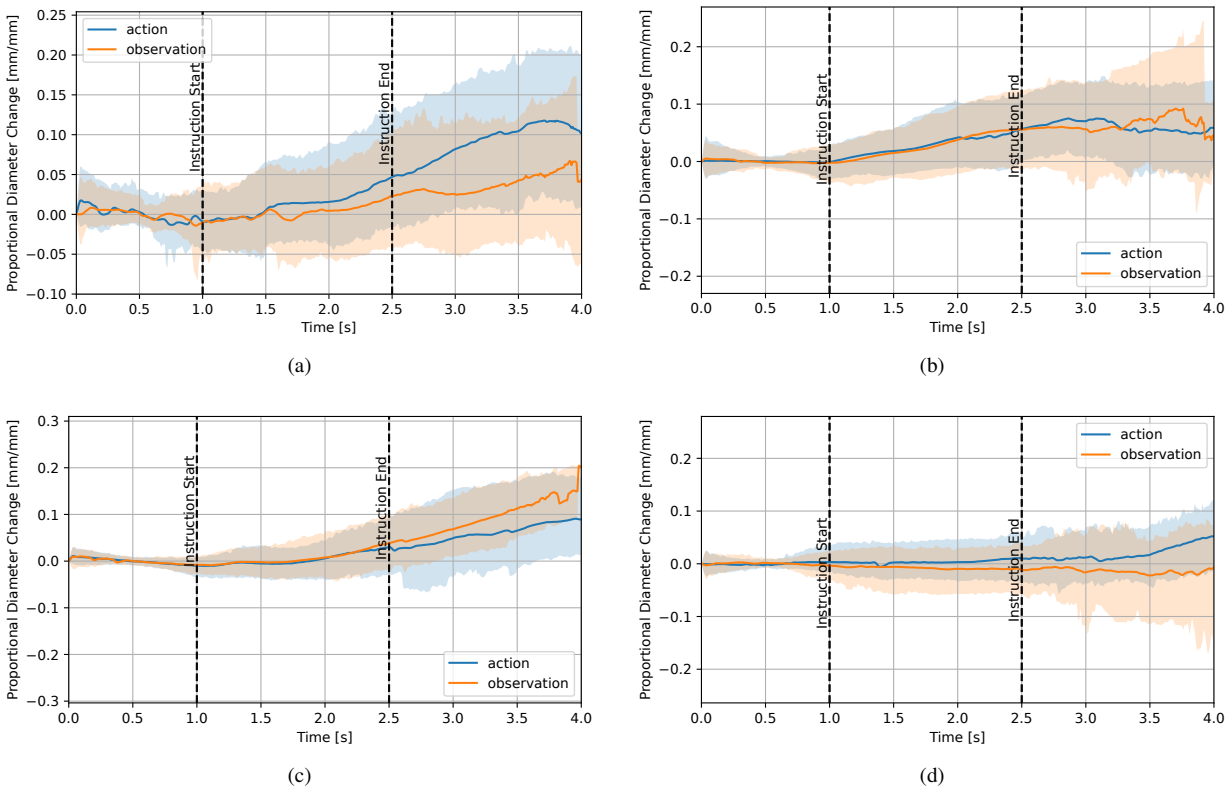

Fig. 2. Selected plots of average proportional pupil diameter change (d_{norm}) over all trials for several participants. The shaded regions show the 5th and 95th percentile ranges of the pupil diameter. (a) P23, showing a higher diameter for **Action** trials, (b) P06, showing a minimal difference between trial types, (c) P21, showing an increase in diameter for **Observation** trials compared to **Action** trials, and (d) P30, showing a difference without an increase in diameter for **Observation** trials

pupil diameter change for either task type, and one participant showed a decrease in pupil diameter of approximately the same amount on average for both task types.

IV. Classifier Design and Results

A. Classifier Design and Training

To train a simple classifier, features must be extracted from the normalized pupil diameter trajectory of each trial. Four features were selected for both eyes, for eight features in total. The selected features were: the mean normalized pupil diameter, the maximum normalized pupil diameter, the mean of the absolute value of the rate of change of normalized pupil diameter ($\left|\frac{d_{norm}}{dt}\right|$), and the maximum rate of change of normalized pupil diameter. These features were calculated from the post-baseline data in each trial, in other words for $t > 1$ s. Histograms of the selected features for Eye 0 (the right eye) are presented in Fig. 3. Each feature shows a noticeable difference between the **Action** and **Observation** task types, with **Action** tasks being biased to higher magnitudes.

A multi-layer perceptron classifier with two hidden layers of 50 neurons each using ReLU activation functions implemented in Scikit-learn [15] was trained on the selected features. The model was tested using leave-one-out cross-validation: 30 separate models were trained on the dataset where a different participant was left out of the training data for each model. The data of the left-out participant were then used to test the respective model.

B. Classifier Results

The classifiers were able to achieve results better than random chance for most of the testing data. The average confusion matrices for the training and testing data in Fig. 4 show an average accuracy of 67.3% on the training data and 59.4% on the testing data, with an approximately equal number of false positives and false negatives.

Fig. 5 provides a further breakdown of accuracy and F1 score across all 30 test sets. The accuracy histogram, Fig. 5a, shows three distinct clusters of results: the classifier achieved approximately 70-80% accuracy on 13 of the test sets, slightly better than random chance on 10 of the test sets, and at or worse than chance on 7 of the test sets. The F1 score histogram, Fig. 5b, shows a cluster of five test sets on which the classifier performed particularly poorly.

V. Discussion

The distribution of classifier performance in Fig. 5 demonstrates that the performance depends very strongly on which participant's data was set aside for testing. These results align with the observations in Section III-B that the participants' pupil responses could be classified into four main groups with clear differences. The features chosen for classification were particularly well suited for classifying the pupil responses

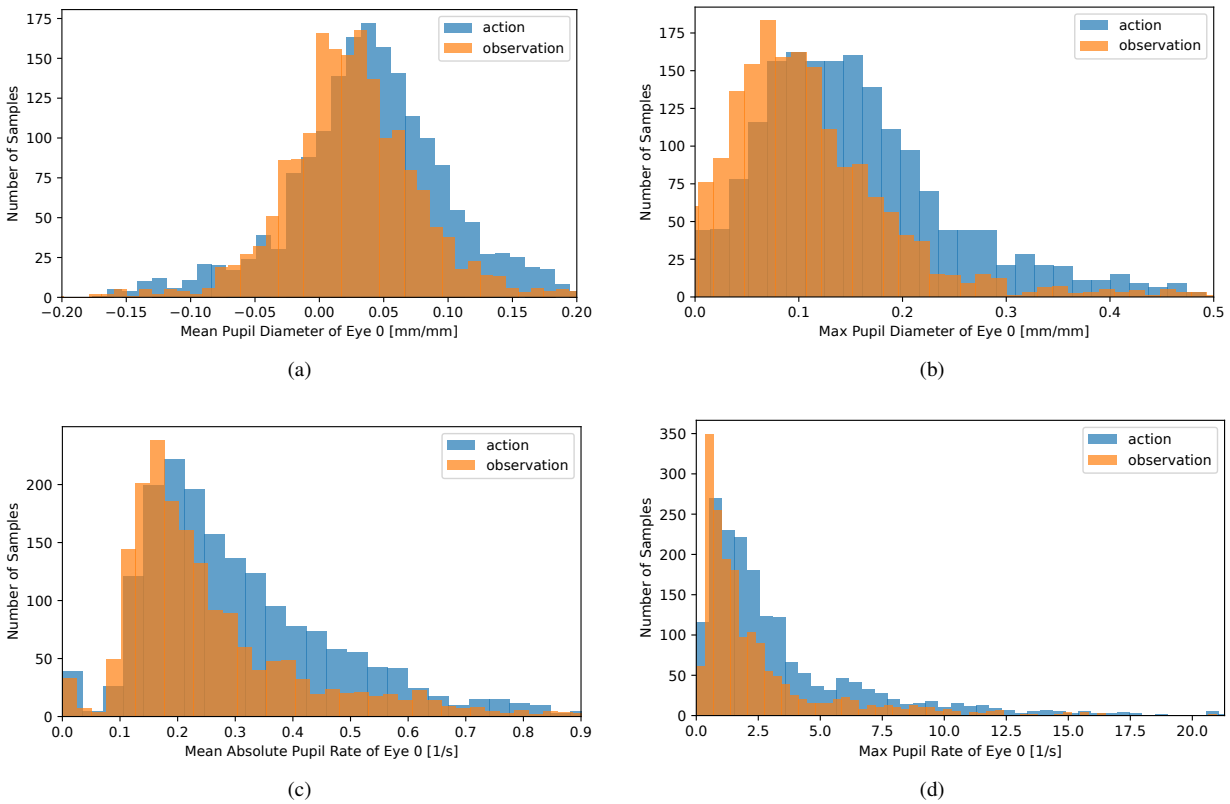

Fig. 3. Histograms showing the distribution of the four selected features used to train the model across all participants (3598 samples in total) for Eye 0 (the right eye). The plots for the other eye are similar. The distributions each show a small difference in bias between **Action** and **Observation** task types. (a) The mean pupil diameter for each trial. (b) The maximum pupil diameter for each trial. (c) The average absolute value of the rate of change of pupil diameter for each trial. (d) The maximum rate of change of pupil diameter for each trial.

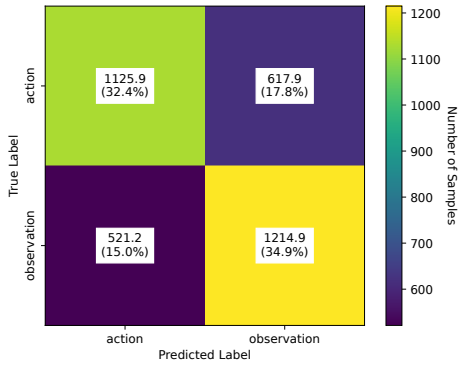
in the first group: those who showed a larger pupil dilation for **Action** tasks versus **Observation** tasks. Since that group was the largest of the identified groups, it would dominate the training data and the classifier would be expected to perform better on participants with similar pupil responses. This would explain the distribution of classifier performance.

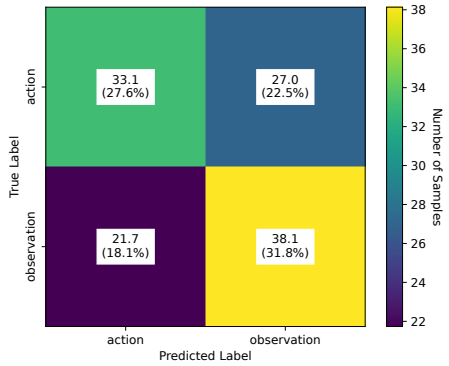
Other factors that could have impacted the results include fatigue over the course of the experiment and whether the participants were using any medications that affect pupillary response. The lack of gender diversity in the participants also prevents conclusive analysis of gender effects on the pupillometric data, if those effects exist.

The distribution of the classifier results suggests a few possible considerations for applying pupillometry to intent detection. Intent detection much better than random chance, in some cases up to 80% accuracy, can be achieved for some people. For those people that pupillometry works well, it could serve as a useful tool for intent detection. Stroke survivors and therapists have advocated for seeking a variety of approaches to rehabilitation technology rather than looking for a 'one-size-fits-all' solution [16], so pupillometry being a poor approach to some potential users does not disqualify its utility.



In this work the feature extraction was performed heuristically, using statistics that seemed to differentiate different classes. However, there may be other features within the time series data that are not as visible that could result in more effective classification. There are also additional time series signals, such as pupil orientation, that could be incorporated into the classifier. The training parameters and other properties of the neural network could also be tuned to provide better performance. Other network types could also be applied: convolutional neural networks and transformers are specialized for extracting features out of sequential data like time series [17] and could provide better performance.

To make the classification of the users intent useful, it must be performed in real time and quickly after the intent forms. Therefore, future investigation is necessary to determine if a classifier can work well on strictly causal data and how quickly it can identify intent after that intent forms in the mind.



Finally, this work demonstrated the potential of this approach using healthy, mostly young participants. It remains to be seen how effective this approach will be for stroke survivors, which tend to be older and may have conditions that affect the reactivity of their eyes and pupils.

VI. Conclusions

Intent detection using pupillometric data shows mixed results. For some participants in the study it performed very well, while for others it performed poorly. This approach may not be suitable for all potential users of rehabilitation robots

or assistive devices, but it could serve as another tool in a broader intent detection toolbox. Better performance could be achieved with more advanced classification methods.

***Abstract*—Individuals with lower-limb amputation often experience significantly decreased daily activity due to difficulty in completing sitting and standing tasks. Additionally, due to the lack of power provided by their passive prosthetic limb, their movements are typically asymmetric, leading to increased rates of osteoarthritis and lower back pain. A study by Welker et al. introduced a novel data-driven controller implemented on a powered knee-ankle prosthesis to aid individuals with transfemoral amputation in sitting and standing by providing a biologically inspired torque to both the knee and ankle, which saw reductions in ground reaction force loading asymmetries. The purpose of this study is to further investigate asymmetry in kinematics and kinetics when wearing the powered prosthesis with the same novel controller. For our study, two participants performed various sit/stand tasks at three stool heights and two speeds. Using optical motion capture and ground reaction forces to determine inverse kinematics and inverse dynamics revealed significant differences between the intact and prosthesis side hip and knee torques, but still showed reduced asymmetry in kinematics and kinetics compared to previous literature with passive and powered prostheses. These results suggest the controller's potential to alleviate secondary conditions like osteoarthritis by improving these asymmetries.**

I. Introduction

An estimated one million Americans are currently affected by amputation of the lower limb [1], with over 150 thousand undergoing amputation every year [2]. Lower-limb prosthesis users (LLPUs) typically compensate by loading their intact limb more than the affected limb during walking [3, 4], sitting, and standing, resulting in kinetic and kinematic asymmetries [5, 6, 7]. As a result, many LLPUs experience secondary conditions from these compensatory mechanisms, including osteoarthritis, back pain, and reduced mobility, resulting in decreased quality of life [8]. Where only 2-11% of the general population experience knee or hip osteoarthritis, 16–60% experience knee osteoarthritis [9], and 14% experience hip osteoarthritis in the LLPU population [10]. Osteoarthritis in all populations leads to increased joint pain, stiffness, and reduced mobility [11], which has a greater impact on populations with limited mobility.

During the day, the average adult transitions between sitting and standing 60 times a day [12]. An impaired ability to stand up from a seated position predisposes the LLPU population to a sedentary lifestyle, where more than 61% are "not sufficiently active," and 30% are classified as sedentary [13].

Currently, most LLPUs wear passive prostheses that cannot provide net power. The lack of power in passive devices has caused LLPUs to move slower, less efficiently, and less symmetrically than healthy individuals [14]. In Teater et al. [15], transtibial passive prosthesis users generated peak knee torques $\sim$300% greater on the intact limb than the prosthesis limb with only 36-48% greater peak ground-reaction force asymmetry. Although studies in this population have been limited, it is likely that these asymmetries would be even more exaggerated for individuals with above-knee amputation, given their missing knee joint. Even though LLPUs wearing passive prostheses have significantly worse clinical metrics during sit/stand transitions [5], powered prosthesis controller design in this area of research remains understudied [16], and it is unclear which types of asymmetries lead to secondary conditions. Our goal is to explore these asymmetries further using a novel-powered prosthesis controller.

Although limited, previous work has shown benefits of wearing a powered prosthesis compared to a passive prosthesis when performing sit/stand transitions. Highsmith et al. [6] investigated the commercially available first-generation Power Knee (Össur. Reykjavik, Iceland), which has a quadriceps-mimicking function to provide some assistance in both sit-to-stand and stand-to-sit motions. Compared to the LLPUs' prescribed passive device, they found that even though users of the Power Knee did not fully activate the torque capabilities of

TABLE I
PARTICIPANT DEMOGRAPHICS

2	M	40	79.2	180	L	38	23	Rheo Knee/Freedom Maverick Xtreme AT	Cancer	Low

the controller, affected limb hip moment production was found not to be significantly different than the unaffected control group [6]. However, [6] also found a degree of asymmetry ($\overline{DoA}$) of 124% for peak knee torques during sit-to-stand and 87% during stand-to-sit comparing the intact and affected limb. It is also important to note that during the study, some subjects used armrests while performing sit/stand tasks, reducing the reliability of their results.

Powered prostheses frequently use impedance control

$$\tau = \kappa(\theta_{eq} - \theta) - \beta\dot{\theta} \tag{1}$$

which determines joint torque as a function of the joint's angular position and velocity, and parameterized by a stiffness κ, damping β, and equilibrium coefficient θ_{eq} [18, 19]. This controller design typically involves manually tuning the coefficients for segments of the sit/stand transition per individual and has been found to reduce asymmetry in peak vertical acceleration compared to a passive prosthesis [19]. Although these results are promising, manual tuning can extend prosthesis fittings by multiple hours [19].

Other sit/stand controllers are designed without impedance control, yet still involve manual tuning [20]. Hunt et al. [20] designed a sit-to-stand quasistiffness controller with a look-up table to match the prosthesis knee torque output based on the relationship of knee-flexion position to knee torque output seen in able-bodied biomechanics. During their study, subjects increased the peak knee torque output on the prosthesis side during sit-to-stand movements compared to their passive prosthesis [20]. They also found improvements in asymmetric loading, stand-up duration, and vastus medialis activation when subjects used the powered prosthesis compared to their passive device [20]. However, towards the end of the movement, there were increases in kinematic asymmetries and weight-bearing asymmetry with increasing torque magnitude assistance from the powered prosthesis.

In recent literature, phase-based controller design has made progress in limiting asymmetries during gait and sit/stand loading [21, 22]. Best et al. [21] designed a novel controller for adaptive speed and incline walking. This minimal tuning controller design focuses on a data-driven approach, using able-bodied data and an optimization problem (Eqn. 2) to estimate continuous knee and ankle impedance parameters across a given motion. The optimization problem identifies the set of impedance parameter coefficients $\kappa^*_{\chi_p}$ for each task χ_p that best reproduces the dataset's mass-normalized joint torques τ with given kinematics $(\theta, \dot{\theta})$ over all n data points at χ_p:

$$\begin{aligned} \kappa^*_{\chi_p} &= \arg\min \frac{1}{n}||\tau - \hat{\tau}||_2^2, \\ \text{where } \hat{\tau} &= \kappa_{\chi_p}\Big]\theta_{\text{eq},\chi_p} - \theta\Big) - \beta_{\chi_p}\dot{\theta}. \end{aligned} \tag{2}$$

When using this controller for sitting and standing tasks, participants experienced significant reductions in average ground reaction force loading asymmetry and decreased time to complete sit-to-stand and stand-to-sit at multiple stool heights and trial speeds compared to the participants' prescribed passive device [22]. However, their study only investigated loading and lacked further investigation of the powered prosthesis's kinematic and kinetic effects.

Currently, multiple outcomes and metrics are used to measure impact when comparing powered and passive prostheses. Various papers only report significant changes in loading [22, 20], kinematics [20], or kinetics [6], but it is unclear which asymmetries are the largest cause of negative secondary conditions and how they may be related. The goal of this manuscript is to perform a preliminary investigation of the impact of the same novel sit/stand prosthesis controller from [22] on asymmetries when comparing the unaffected and affected side for kinematics and kinetics and to compare these same metrics with prior work in passive and powered prostheses.

II. METHODS

A. Participants

The Institutional Review Board of the University of Michigan (HUM00166976) approved this protocol. To validate the experimental controller designed by Welker et al. [22] for improving kinematic and kinetic asymmetries, three participants completed a series of tasks while wearing a powered knee-ankle prosthesis [23], with the implemented novel sit/stand controller. During the trials, participants wore a ceiling-mounted safety harness, and a certified prosthetist was available and assisted in the fitting of the powered prosthesis. Three participants completed the study; however, due to extreme motion-capture recording artifacts, Participant 3's data was unusable and excluded from analyses. The demographics of the two remaining participants are described in Table I. Both participants had previous experience wearing a powered prosthesis. Participant 1 had previous experience in both a walking study and a sit/stand study with an earlier version of the controller, and Participant 2 had participated in only a walking study prior to this data collection.

B. Controller Design

The controller previously designed by Welker et al. [22] was implemented on the powered prosthesis worn by participants

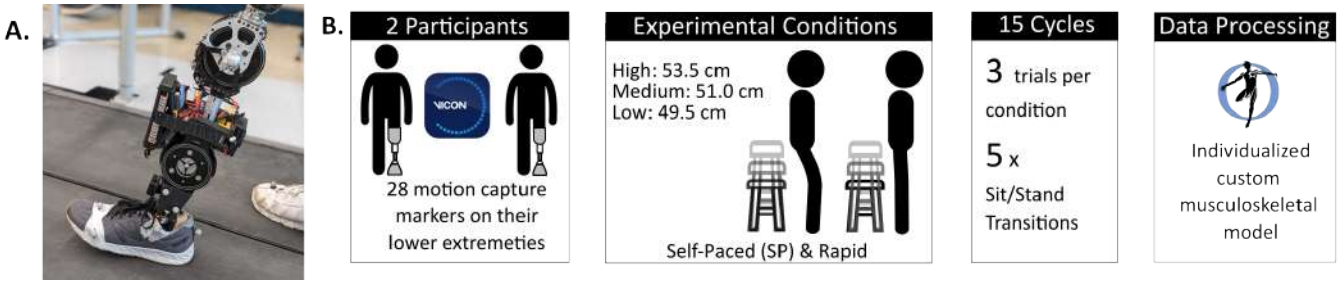

Fig. 1. **A.** Detailed marker placement on the prosthetic limb. The markers shown are the lateral knee, two shank markers, the lateral ankle, two toe markers, and the heel. **B.** Protocol overview showing two participants wearing their powered prosthesis for three stool heights (49.5, 51.0, and 53.5 cm) and two speeds, performing 15 sit/stand movements per condition. The VICON Nexus motion capture data was analyzed using OpenSim [17] and an individualized custom musculoskeletal model for each participant.

during the study. This controller takes a novel approach using a phase variable to determine the progression of the user's sitting or standing motion. Global thigh angle was used as this phase variable due to its monotonic decreases during sit-to-stand and increases during stand-to-sit. This allows the phase variable to accurately predict the direction of the movement and only requires one controller for sit-to-stand and stand-to-sit. Using experimental data [24] combined with the optimization problem model from Equations 1 and 2 and able-bodied kinematics and kinetics during sit-to-stand and stand-to-sit at a self-selected pace, impedance parameter functions were optimized for both the knee and ankle [22]. This controller was then implemented on a powered knee-ankle prosthesis previously validated for open-loop impedance control [23].

C. Experimental Protocol

Participants completed the experimental protocol while wearing the powered prosthesis with the implemented novel controller after being fit by a certified prosthetist. During the trials, ground-reaction forces were recorded from two in-ground force plates (AMTI, MA, USA) at 250 Hz and lower-body kinematics were recorded at 100 Hz using a 32-camera motion capture system (Vicon, UK). 28 reflective markers were worn along the lower extremities of each participant, which were affixed to the hip (6), thighs (7), knees (2), shanks (5), ankles (2), and feet (6). On the intact side, markers were attached to the lateral malleolus, the calcaneus tuberosity, and the first and second metatarsal head. On the prosthesis side, as seen in Fig. 1A, markers were placed at the powered ankle joint, at the same height as the calcaneus marker, and estimated toe markers on the shoe based on the intact side. For the tibial markers, markers were placed just above the powered prosthesis ankle joint due to geometric limitations.

Participants were given 15 minutes of training with a loading symmetry visual aid (see details in [22]), including 5 minutes of exploratory training, 5 minutes where they were instructed to increase their asymmetry by loading the biological limb as they would while using their passive prosthesis, and 5 minutes where they were instructed to try to minimize their asymmetry. Once training was completed, the visual aid was removed, and participants began the study. Participants performed sitting and standing tasks at two different speed conditions (self-paced and rapid) and three stool height conditions (low, medium, and high, at 48.5 cm, 51.0 cm, and 53.5 cm), totaling six different conditions. All self-paced trials involved cues to sit or stand at a comfortable pace, and rapid trials had the participants perform the five-times sit/stand movements as fast as they comfortably could. For each trial, participants completed five sit-to-stand movements at the specified stool height and assigned speed for three trials, totaling 15 sit-to-stand movements per condition. Participants were asked to keep their hands across their chest and prevent themselves from using their arms to aid in the movement.

D. Modeling

Marker trajectories and ground reaction force data were filtered using Butterworth low-pass filters at 2 Hz and 6 Hz, respectively, as in [22]. Using custom-scaled musculoskeletal models modified from [25], the VICON motion capture data from each trial was processed in OpenSim [17] to calculate joint angles and joint torques. The mass, moment of inertia, and center of mass of each biological body segment in the musculoskeletal model were scaled for each individual based on segment lengths. Following an adapted protocol of Willson et al. [26], the mass of the residual limb (the femur) was scaled to 55% of the mass of the intact limb, and the center of mass was shifted to be closer to the hip joint by 30%. The prosthetic device model was scaled alongside the musculoskeletal model to match the length of the device and then manually changed to the experimentally determined mass of the shank and foot of the powered prosthesis. The center of mass and moment of inertia for each prosthesis segment (foot and shank) were estimated from a CAD model of the prosthesis [23].

E. Segmentation

Sit-to-stand and stand-to-sit segments were isolated using peak detection for the prosthesis knee angle velocity, where peak positive and negative velocities indicated a movement transition (Fig. 2). Steady-state knee angular velocities found before and after the detected peaks were then used to determine initiation and completion events. Specifically, in sit-to-stand segments, an initiation event was marked when knee-angle velocity first fell outside of a threshold where it was less than zero but greater than -1.0 deg/sec, and sit-to-stand completion was determined as the last instance when knee

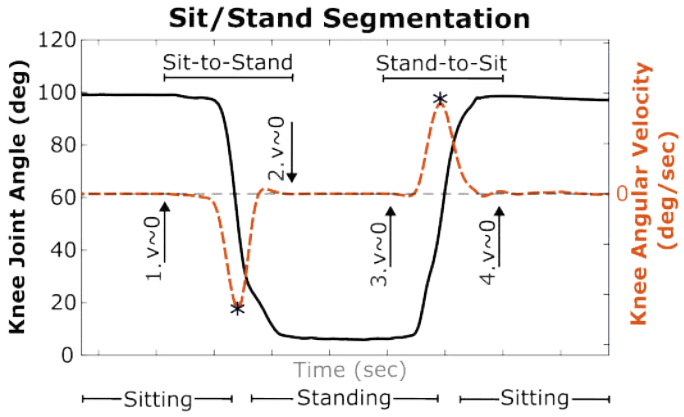

Fig. 2. Example segmentation for both sit/stand movements. Segments were initially isolated using peak detection for knee angle velocity (indicated by the asterisk), which marks that a movement event is occurring. The labels 1-4 show the initiation and completion events of sit-to-stand and stand-to-sit, when the knee velocity either left or entered a steady state of approximately zero.

velocity was greater than -1.0 deg/sec before reaching a steady state angular velocity of zero. During stand-to-sit designated segments, initiation was determined when knee velocity first fell outside of a threshold where it was greater than zero, but less than 1.0 deg/sec, and completion was marked as the last occurrence of the knee velocity being greater than 1.0 deg/sec. Joint angles and joint torques were segmented for every trial using the time points from the segmentation above.

F. Symmetry Calculations

There has been little work done quantifying kinematic asymmetries during sit-to-stand, but [20] recently reported kinematic asymmetries while wearing a powered prosthesis controller. In order to directly compare to their values, we adapted their approach as follows. The sit/stand segmentation described in Section IIE includes a stationary period at rest, whether sitting or standing, allowing us to examine torques generated before the movement initiates. However, this sit/stand segmentation prevents the joint angle transitions from being monotonic as typically investigated [20]. Adding a secondary segmentation for kinematics allows us to find the joints' start and end positions for monotonic movements. Then, to quantify the kinematic differences between the intact and prosthetic sides, each side was independently normalized to a start and end position (0-100), as in [20]. Calculating the normalized difference between each joint allows for a direct comparison between the biological and affected limb for the entirety of the motion and provides greater insight into kinematic asymmetries. Kinematic asymmetry peak-to-peak estimates were calculated from the difference between the maximum and minimum normalized difference of each trial and then averaged across trials.

For every participant, joint torques were normalized by body mass. Peak extension moments were found for each sit/stand transition and individual limb. The degree of asymmetry ($\overline{DoA}$) was calculated between the intact and prosthesis sides for knee and hip torques. $\overline{DoA}$ was calculated as

$$\overline{DoA} = (Intact - Pros.)/(Intact + Pros.) * 100 \quad (3)$$

where positive $\overline{DoA}$ corresponds to a larger value on the intact side, and a negative value indicates a larger magnitude on the prosthesis side. For all reported kinematic and kinetic profiles, outliers three standard deviations outside the mean were removed (an average of 0.5% of data points were considered outliers across trials for joint angles and torques).

G. Statistical Analysis

A linear mixed effects model was fit to determine differences in maximum torque at each joint for each sit/stand movement at each speed (self-paced or rapid). The fixed effects for each model were stool height and leg side (intact or prosthesis side), and the random effect was the participant, which included a subject-specific intercept. Statistical significance was determined using Bonferroni corrections. Due to two comparisons being made (stool height and leg side), the significance was set to $p<0.025$.

III. Results

Fig. 3 and Fig. 4 show the mean joint angles and torques during both sit-to-stand and stand-to-sit for the knee and hip. From these curves, we were able to calculate kinematic asymmetries in Fig. 5 and torques in Fig. 6.

A. Kinematics

Fig. 5 shows that for sit-to-stand, the prosthesis side had a greater rate of change for most of the sit-to-stand transition in both the knee and hip until the end of the trial, where the intact limb began to progress quicker. For the highest stool height, the sit-to-stand movement remained more symmetric than both the medium and low stool heights. During stand-to-sit trials, the limbs moved fairly symmetrically until about 40% through the movement, when the prosthesis side started to progress more quickly.

Kinematic peak-to-peak values were calculated to determine the range of asymmetry across the trial, as in [20]. Sit-to-stand self-paced trials had an average kinematic peak-to-peak difference of 7.66±2.5% in the hip and 7.01±1.75% in the knee. There was a slight increase in the rapid trials, with the hip averaging 8.4±1.24% and the knee 8.84±0.95%. These ranges increased for stand-to-sit, with self-paced averaging at 11.94±2.07% for the hip and 7.49±2.85% for the knee and rapid trials averaging 11.4±1.27% for the hip and 8.69±2.21% for the knee.

B. Kinetics

Peak hip extension torques were calculated for each condition for both sit-to-stand and stand-to-sit movements. For sit-to-stand trials, participants experienced a greater average maximum hip torque on the intact side than on the prosthesis side (0.90±0.02 Nm/kg vs 0.63±0.13 Nm/kg) for self-paced trials, with an average $\overline{DoA}$ of 17.05±4.12%. For rapid trials, participants experienced an increased average maximum hip

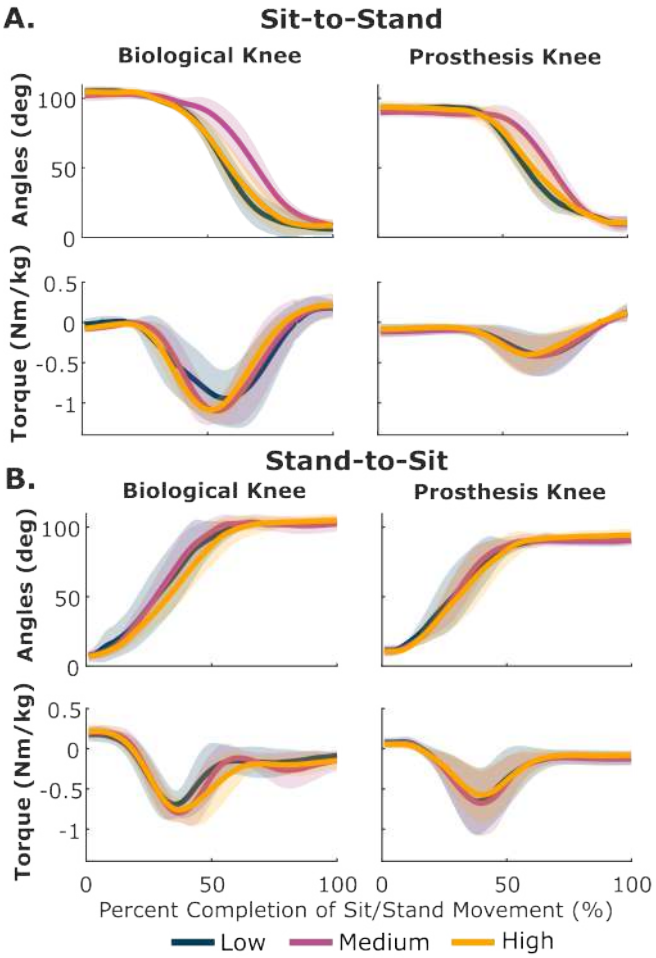

Fig. 3. Kinematic and kinetic knee profiles for self-paced trials on each the intact and prosthesis side, during sit-to-stand **(A.)** and stand-to-sit **(B.)** movements. The shaded region on each curve represents one standard deviation from the mean. Knee flexion is represented in the positive direction and knee extension is in the negative direction.

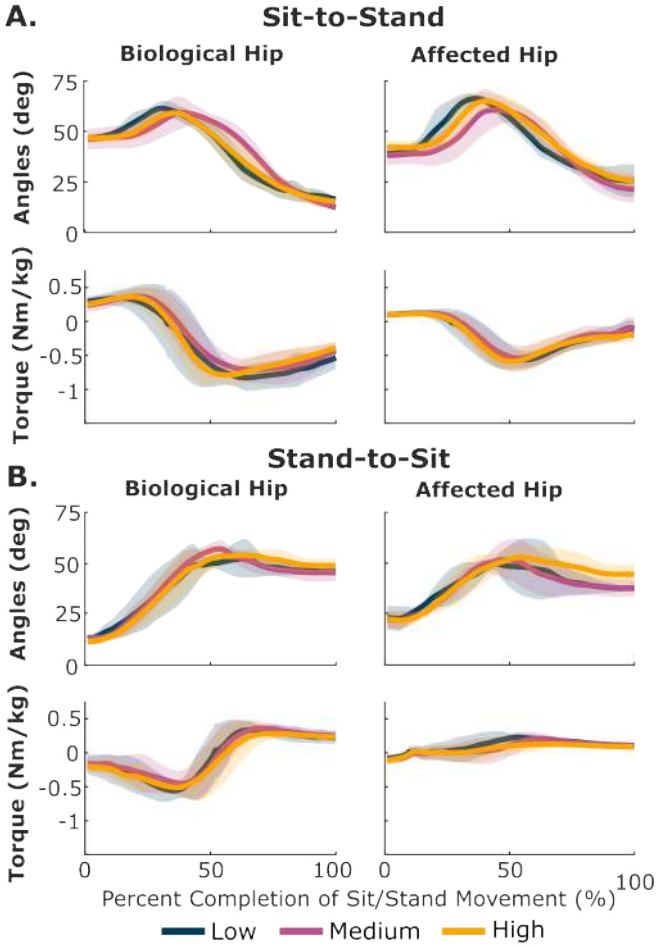

Fig. 4. Kinematic and kinetic hip profiles for self-paced trials on the intact and prosthesis (affected) side, during sit-to-stand **(A.)** and stand-to-sit **(B.)** movements. The shaded region on each curve represents one standard deviation from the mean. Hip flexion is represented in the positive direction and hip extension is in the negative direction.

torque and similar prosthesis side torque 0.97±0.21 Nm/kg vs. 0.63±0.16 Nm/kg to the self-paced trials, with an average $\overline{DoA}$ of 21.55±10.47%. During stand-to-sit trials, the self-paced maximum hip torque of the intact limb (0.59±0.06 Nm/kg) was lower than the sit-to-stand trials, as well as for the rapid trials (0.59±0.26 Nm/kg), but the $\overline{DoA}$ was worse (61.8±4.4% for self-paced, and 44.2±13.8% for rapid trials) due to the decreased peak torques values on the prosthetic limb, of 0.13±0.01 Nm/kg and 0.23±0.07 Nm/kg (self-paced and rapid), respectively. Peak hip torque asymmetry was statistically significant regardless of condition. Stool height was statistically significant for peak hip torques during rapid sit-to-stand trials and self-paced stand-to-sit trials. During rapid sit-to-stand trials, the $\overline{DoA}$ increased as stool height increased (see Fig. 6A), and in self-paced stand-to-sit trials, the peak hip torque on the intact limb decreased for higher stool heights (see Fig. 6B).

The peak knee torque during self-paced trials was 1.19±0.06 Nm/kg on the intact side and 0.46±0.03 Nm/kg on the prosthesis side. The $\overline{DoA}$ was 44.59±1.52% for the self-paced trials. Rapid sit-to-stand trials had similar values, where the intact limb had a peak knee torque of 1.13±0.46 Nm/kg, and the prosthesis side had an average of 0.09±0.01 Nm/kg with a $\overline{DoA}$ of 42.0±2.74% for the rapid trials. For stand-to-sit, the average peak knee torque during self-paced trials was 0.90±0.03 Nm/kg on the intact side and 0.75±0.06 Nm/kg on the prosthesis side. For self-paced trials, there was an average $\overline{DoA}$ of 9.32±4.7%. During rapid trials, the intact peak knee torque stayed close to the self-paced trials (0.92±0.57 Nm/kg), where the prosthesis side decreased (0.57±0.09 Nm/kg), resulting in a slightly larger $\overline{DoA}$ of 23.6±7.72% compared to the self-paced trials. Peak knee torque asymmetry was statistically significant regardless of condition.

IV. Discussion

This pilot study investigated the lower-limb kinematics and kinetics of two participants with an above-knee amputation using a powered prosthesis with a previously developed con-

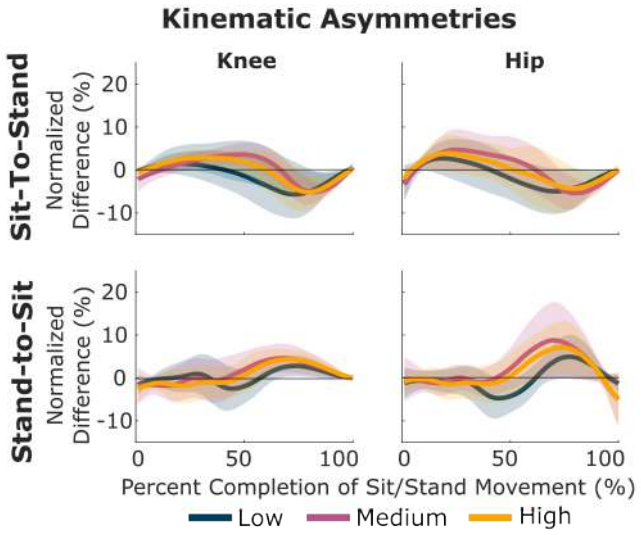

Fig. 5. Knee and hip kinematic asymmetry during sit-to-stand and stand-to-sit for self-paced trials. The normalized difference was calculated as the difference between the normalized intact and normalized prosthesis joint angles. Positive values indicate that the prosthesis side is progressing more quickly than. The shaded region represents one standard deviation from the mean.

troller [22]. We investigated asymmetries in kinematics and kinetics and compared the results to previous literature with passive and powered prostheses.

Although the kinematic profiles for the knee and the hip were similar across the prosthetic and biological sides, there was a notable difference seen in steady-state knee flexion angle during seated positions (Fig. 3A-B). While in a seated position, the biological knee is flexed greater than 100 degrees in all conditions, whereas the prosthesis side is flexed to approximately 90 degrees. The prosthetic side maximum knee flexion angle mimics the able-bodied dataset used for controller development that reaches similar maximum knee flexion angles [22], so it is possible that the difference in the biological leg is due to differences between conditions in our experiment and the dataset used for controller development. Additionally, during the trials, the fore/aft position of the feet in the frontal plane was not constrained, and because of this, the placement of the biological foot and prosthetic foot may have differed, which could have increased the knee flexion angle on the biological side.

Our kinematic asymmetry results are similar to those of Hunt et al., who investigated a powered prosthesis that provided a similar magnitude of knee torque. When using a controller with applied knee torques of up to 0.8 Nm/kg, Hunt et al. [20], found maximum kinematic peak-to-peak asymmetry values of $\sim$12%. Interestingly, the peak-to-peak kinematic asymmetry in their baseline passive prosthesis trial was $\sim$9% in the knee and $\sim$8% in the hip, the lowest of all conditions. Our self-paced and rapid trials showed similar results to both their powered and passive prosthesis kinematic asymmetries at 7.66$\pm$2.50% for the hip and 7.06$\pm$1.75% for the knee, respectively. During sit-to-stand, we saw that the prosthetic joint led the intact limb for a majority of the transition (see Fig. 5). This reflects the qualitative analyses from Welker et al. [22], who noted that their experimental phase estimate led the able-bodied data set. Additionally, during stand-to-sit, they found the opposite, where their experimental phase estimate lags behind the able-bodied data set, which is also reflected in our stand-to-sit results (see Fig. 5), showing the intact limb initially leading the stand-to-sit movement.

Although we determined significant differences between the peak torques in the knee and hip when comparing the intact and prosthesis sides, the controller still shows some improvement compared to previous passive and powered prosthesis literature. Prior work investigating the effects of a powered knee-ankle prosthesis during stand-to-sit movements found that participants produced a 0.39$\pm$0.05 Nm/kg peak knee torque on their prosthesis side with a $\overline{DoA}$ of $\sim$41.%, [27]. Our stand-to-sit peak knee torques increased compared to [27], and saw a decrease in $\overline{DoA}$ to 9.32$\pm$4.7% for self-paced trials, and 23.6$\pm$7.72% during rapid trials (Fig. 6). The improvement in peak knee torques during stand-to-sit is reflective of preliminary loading results from [22], who found an improvement of 79% for average ground reaction force loading asymmetry. Interestingly, while participants could more effectively use the controller in stand-to-sit to produce knee extension torques, they could not produce a hip extension torque on their affected side comparable to the intact side (see Fig. 4).

During the study, we also received qualitative data that may help explain the differences in asymmetry reduction during sit-to-stand and stand-to-sit. Participants reported initially struggling with stand-to-sit movements, but with training found it easier to activate the powered prosthesis by adjusting their center of mass posteriorly as the prosthesis resisted knee flexion. In contrast, to progress through the sit-to-stand motion with the controller, the biological limb likely needs to be more activated to position the user's center of mass appropriately to initiate the movement, which may have contributed to larger asymmetries.

Comparing to previous passive prosthesis research, [15] found that peak knee flexion moments for chair heights of 28 and 38 cm were $\sim$300% greater on the intact side than the prosthesis side for people with transtibial amputations wearing passive prostheses during sit-to-stand. In comparison, using the same method to calculate percent difference, the intact side produced knee torques only $\sim$60% greater compared to the prosthesis side when wearing our powered prosthesis in our study. In addition, when comparing to the first generation Power Knee as investigated in [6], our powered prosthesis saw decreased $\overline{DoA}$ metrics for both the knee and hip torques in sit-to-stand and stand-to-sit. Specifically, [6] found a $\overline{DoA}$ of 124% for the knee and 34% for hip torques during sit-to-stand, where we found a decreased $\overline{DoA}$ for the knee of $\sim$42-45%, and similar reductions in the hip (17.05$\pm$4.13% and 21.6$\pm$10.47%). Similar trends were found in stand-to-sit, with [6] reporting $\overline{DoA}$ of 87% for the knee and 45% for the hip, compared to our findings of 9.32$\pm$4.71% and 23.5$\pm$7.7% (self-paced and rapid) in the knee, and 61.8$\pm$4.41%, and

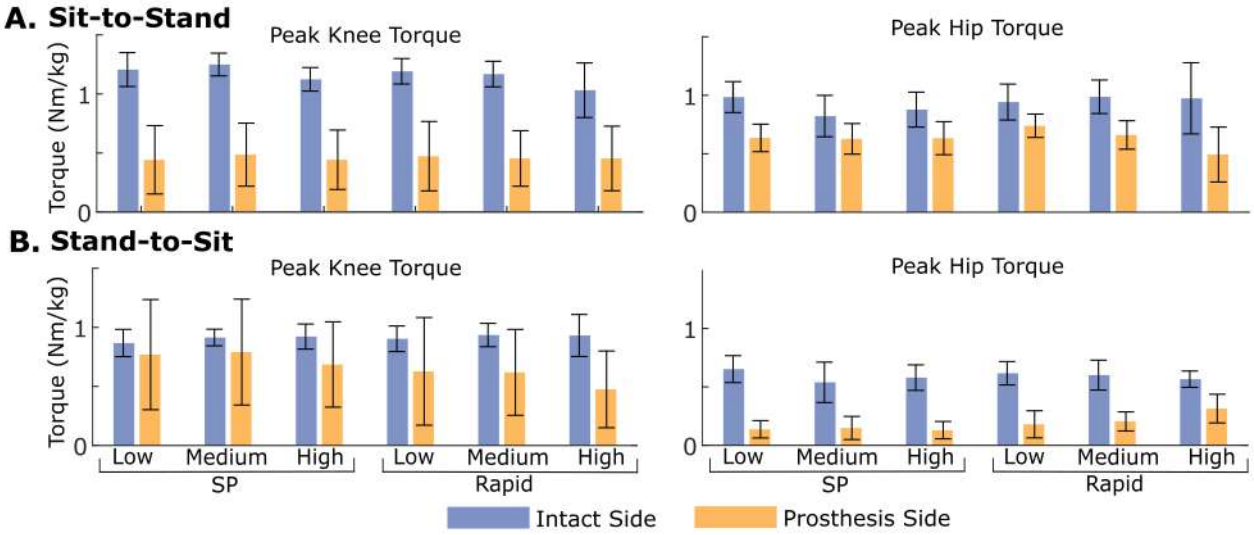

Fig. 6. Peak knee and hip extension torques were significantly different when comparing the intact and prosthesis side ($p<0.025$). Rapid paced sit-to-stand (**A.**) trials saw a significant effect due to stool height in peak hip torque extension, as seen by the decreasing peak hip torque on the prosthesis side ($p<0.025$). During self-paced stand-to-sit (**B.**) trials peak hip extension torque also experienced a significant effect due to stool height, as seen by the overall decreasing intact side hip extension torque as stool height increased ($p<0.025$). No significant effects were found on peak knee extension torques due to stool height.

$44.3\pm13.8\%$ for the hip.

Movement asymmetries, including ground reaction force loading, are known to have negative long-term effects on LLPUs. However, it is unclear what asymmetries (loading, kinematic, or kinetic) have the largest negative impact. The ground reaction force loading asymmetries found previously in [22] using the same controller indicate less uneven joint loading during sit/stand movements and, as a result, may reduce the chances of osteoarthritis. Additionally, the normalized kinematic asymmetries indicate more symmetrical movements compared to other passive and powered prostheses, which are closer to movements produced by unimpaired individuals. Although ground reaction force loading influences resulting lower-limb joint torques, the position and acceleration of the bodies in the lower-limb also have an effect that is important to quantify.

The results of this pilot study are promising but come with limitations. Due to the small sample size, the trends cannot be generalized, but they still indicate potential impact for participants when using this novel controller on a powered knee-ankle prosthesis. Additionally, comparisons across studies can be limited due to differences in participant's prescribed passive prostheses and their familiarity with powered prostheses. Each participant only had 15 minutes of training with the novel prosthesis controller. Furthermore, one participant had previous experience with a prior sit/stand controller that could affect their results and ability to use the powered prosthesis. Further work is needed to investigate the kinematic and kinetic differences between the participants' prescribed passive devices and the powered prostheses worn in this study.

V. Conclusion

This pilot study presented promising findings in kinematic and kinetic asymmetries while wearing a powered sit/stand prosthesis controller. These results reflect similar results to other powered prosthesis controllers, with decreased kinematic asymmetries and reduced $\overline{DoA}$ for both peak knee and hip torques compared to passive prostheses during sit-to-stand, and stand-to-sit, at two different speeds. Our results suggest that this controller can potentially reduce negative secondary conditions associated with long-term prosthesis use and thus improve the quality of life for LLPUs.

PRISM: Parameter Recovery Identification from Synthetic Modeling

Adriana Cancrini[1,2*], Bruno Borghi[1,2], Naveed Reza Aghamohammadi[1,2], Arturo Ramirez[1,2], Courtney Celian[2] and James L. Patton[1,2*]

***Abstract*— Identifying parameters of human motor learning dynamics remains an open-ended question despite significant research in the field. While robotics and system identification offer tools for modeling dynamical systems with precision, few studies have investigated persistent excitation of human dynamics to produce accurate models. Here, we tested a forward-inverse method to estimate joint stiffness and damping as well as feedback gains in reaching when disturbed. Planar arm movements were first simulated with a synthetic model, then regression was used to identify gains, and the most crucial trial conditions (task and disturbance) were identified as those that brought the most accurate information about the gain parameters. Our results indicate that a set of 40 movements performed under specific perturbation conditions yielded the best parameter estimation ($R^2 = 0.97$). Such technique employs simulated or digital twin methods to best estimate the arm's control properties, offering a framework to optimize the experimental design and paving the way for more individualized approaches.**

I. INTRODUCTION

Gaining insight into motor learning is a challenging aim that requires more than generic approaches. One of the main limitations in this field is the lack of personalized learning models that account for individual differences and tailored needs. Current protocols often rely on repetitive exercises and generic frameworks that might not always be adequate to address individual differences in sensory-motor contributions [1]. To improve outcomes, a more customized approach is needed that integrates sensory feedback input, such as muscle and vision, into the dynamics of movement. This would reduce the number of repetitive movements required, optimize treatment time and, in the end, lead to enhanced and tailored learning programs.

Sensory feedback plays an essential role in motor recovery [2], [3] by providing crucial information about errors caused by external disturbances or intrinsic variability within the motor system [4]. Rapid corrective responses to errors during reaching are primarily produced by two main mechanisms: muscle stretch-dependent motor responses [5], [6], and visuomotor responses, the latter of which adapt based on shifts in the visual position of the hand [7]–[9]. Vision is used to guide the detection of movement targets, but signals from muscles also play an essential role in monitoring the position and motion of the limbs and facilitating smooth and coordinated actions. These feedback pathways provide rapid and accurate reactions to unexpected disturbances, making their identification crucial for modeling effective motor control dynamics. Several studies have contributed significantly by modeling sensory integration [10]–[12], demonstrating that different types of feedback contribute uniquely to the planning of reaching movements [13]. Although each feedback mechanism plays a role in compensating for external perturbations, their precise weighting values, contributions, and differences remain unclear. Intrinsic differences in sensory filtering characteristics and coordinate reference frames may distinguish their roles in motor control [14]. Given the pivotal role of sensory feedback, the first step in developing a personalized learning model is to accurately identify the sensory input gains and establish the experimental requirements necessary for identifying these contributions. Here, we present Parameter Recovery Identification from Synthetic Modeling (PRISM), a methodological framework designed to find the optimal experimental conditions necessary for accurately identifying gain parameters in sensorimotor models. We employ synthetic data in simulation to create known prior data, allowing us to explore and understand the mathematical inversion methods seen in system identification. Next, we perform an inversion process to identify important model parameters such as sensory feedback gains (Fig. 1). To refine our identification methods, we test various sensory perturbations and tasks, enabling a more accurate determination of model parameters.

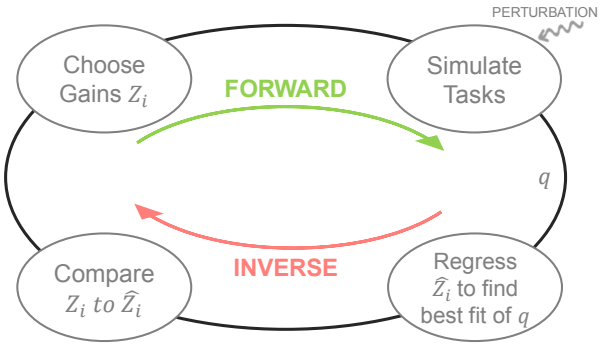

Fig. 1. Overview of the forward-inverse process. The forward process begins with selecting sensory feedback gains (Z_i), simulating tasks with perturbations, and generating system outputs (q). The inverse process involves using regression to estimate feedback gains ($\hat{Z}_i$) that best fit the observed outputs. Finally, the estimated gains are compared with the initial gains (Z_i) to evaluate model accuracy and refine the process.

By identifying these optimal conditions, we can simplify the experimental process, reducing both the physical effort required from participants and the overall costs associated with data collection. This approach aims to enhance the customization of rehabilitation protocols, enabling a more precise and efficient recovery process tailored to individual sensory profiles. Central to this effort is the development of a prior mathematical model that can identify and provide optimal experimental conditions and designs.

II. METHODS

A. Biomechanical model

We simulated the 2D planar reaching movement of a human arm using a second-order linear biomechanical system (Fig. 2), described as:

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + G(q) = \tau_{ff} + \tau_{fb} + \tau_{ext} \quad (1)$$

where q is a point in the configuration space, $\dot{q}$ and $\ddot{q}$ its first- and second-time derivatives [15]. The vector $G(q)$ represents the contribution of gravity to the joint torque. This term becomes null when the gravity field acts orthogonally to the trajectory, as in the case of a horizontal, planar movement. On the other hand, the mass-inertia and Coriolis matrices $M(q)$, $C(q,\dot{q})$ respectively, are in the form:

$$M(q) = \begin{bmatrix} I_1 + I_2 + b + a + c + d + e & L_2 + a + e \\ L_2 + a + e & I_2 + e \end{bmatrix}$$

$$C(q,\dot{q}) = \begin{bmatrix} -L_1 M_2 R_2 (2\dot{q}_1\dot{q}_2 + \dot{q}_2^2)\sin(q_2) \\ L_1 M_2 R_2 \dot{q}_1^2 \sin(q_2) \end{bmatrix} \quad (2)$$

where:

$$a = L_1 L_2 M_2 \cos(q_2), \quad b = \frac{L_1^2 M_1}{4} + L_1^2 M_2,$$

$$c = \frac{L_2^2 M_2}{4}, \quad d = L_2 M_2 R_2 \cos(q_2), \quad e = M_2 R_2^2,$$

where the state vector is $\mathbf{s} = [q_1, q_2, \dot{q}_1, \dot{q}_2]^\top$, L represents the length of the links, M is the mass of each link, I denotes the moment of inertia, and R is the distance from the joint axis to the center of mass of each link.

The right side of (1) models the external and control torques acting on the system. If during the movement trajectory, the subject is required to apply force while maintaining the desired trajectory, the muscles will produce additional torque τ_{ext}. This torque will be equal in magnitude to those generated by the external forces acting on the limb. A feedforward control mechanism τ_{ff} is also considered. This component, computed through inverse dynamics, tries to predict the required torques for a desired motion trajectory, minimizing the reliance on feedback correction and ensuring smoother and more accurate movements. We added a feedback torque τ_{fb} to simulate the presumed control mechanisms from the central nervous system, enabling adaptive response during movement. This feedback control is modeled using a linear approximation of joint stiffness and damping characteristics, along with visual feedback gains.

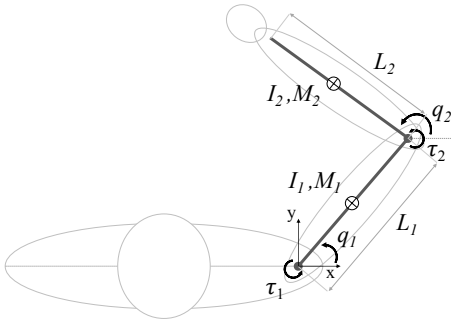

Fig. 2. Experimental apparatus for simulating arm trajectories in the horizontal plane.

This control component is analyzed in detail and expanded to account for the specific sensory channels considered in this study: muscle and vision. Equation (3) describes the sensory feedback torque τ_{fb} as the summation of all sensory contributions, providing a comprehensive model of how sensory inputs affect motor control. In particular, the feedback torque is the result of summing the individual sensory inputs, defined by the term Z_i, which represents the sensory impedance components (e.g., muscle *m* and vision *v*). This term involves the properties of stiffness, damping, and visual feedback gains collectively.

$$\tau_{fb} = \sum_{i=1}^{N_{senses}} Z_i \chi(\delta) = Z_m \chi + \eta'_m + Z_v T \chi(\delta_v) + \eta'_v \quad (3)$$

The state matrix $\chi(\delta)$ captures the joint position and velocity errors, defined as the difference between the current and ideal positions over time ((4) for the expanded version). The ideal trajectory is based on the minimum jerk model, which minimizes the rate of acceleration change (jerk) to produce smooth, natural movements commonly observed in human motor behavior [16]. In this context, δ represents the sensory response delay. It can be observed that muscle feedback has zero delay [17], reflecting the near-instantaneous response of muscles to force generation and positional changes. In contrast, vision introduces a delay, which is modeled as 70 ms [18], corresponding to the time required for visual information to be processed by the brain and integrated into motor control pathways. Incorporation of this delay is crucial in accurately modeling how vision contributes to motor learning and control. Further examination of (3) reveals that the operator T is a transformation matrix that converts signals from the cartesian coordinate system, where visual input is defined, into the joint coordinate domain where feedback is applied. Finally, η' represents the noise added to the system, modeled as Gaussian white noise, with zero mean and constant variance (10^{-3}) across all frequencies, representing random disturbances in sensory signals. To ensure model robustness while accurately capturing sensory input variability, the noise is controlled by an appropriate signal-to-noise ratio. In our implementation, white noise was specifically added to velocity components, as this induces a Brownian process in position, aligning with the assumption that human movement exhibits stochastic drift over time [19].

We can break down (3) as follows.

$$\tau_{fb} = K_m(q_d - q) + B_m(\dot{q}_d - \dot{q} + \eta_m) + \\ + J(q)^\top K_v(x_d - x) + J(q)^\top B_v(\dot{x}_d - \dot{x} + \eta_v) \quad (4)$$

Equation (4) [20], [21] shows how the terms Z_m and Z_v, which represent the sensory impedance components, are divided into components dependent on both position (K) and velocity (B). All position and velocity-dependent gains are defined as 2×2 symmetric matrices that are modeled as constant with respect to joint configuration [22]. This approach simplifies the dynamic model while still providing an accurate representation of feedback responses. Equation (5) details the sensory gain matrices.

$$K_m = \begin{bmatrix} K_{ss} & K_{se} \\ K_{es} & K_{ee} \end{bmatrix} \frac{\text{Nm}}{\text{rad}}, \quad K_v = \begin{bmatrix} K_{xx} & K_{xy} \\ K_{yx} & K_{yy} \end{bmatrix} \frac{\text{N}}{\text{m}}, \\ B_m = \begin{bmatrix} B_{ss} & B_{se} \\ B_{es} & B_{ee} \end{bmatrix} \frac{\text{Nms}}{\text{rad}}, \quad B_v = \begin{bmatrix} B_{xx} & B_{xy} \\ B_{yx} & B_{yy} \end{bmatrix} \frac{\text{Ns}}{\text{m}}. \quad (5)$$

In this model, muscle operates within the joint domain, specifically involving shoulder (S) and elbow (E) joints. On the other hand, vision is represented in the cartesian coordinate domain, which refers to the external spatial coordinates (XY) used to describe the movement of the limb in the environment. In this context, vision gains influence the model by modulating the response to errors between the perceived and actual hand motion. In Table I, the reference values used in the simulation model are detailed. Values from previous studies [22], [23] were used, with visual gains selected also to maintain system stability. The ultimate goal is for these values to be customizable, allowing the model to reflect the individual characteristics of different subjects.

TABLE I

MECHANICAL PARAMETERS OF THE SIMULATED HUMAN ARM

Upper Arm	
Mass	1.930 kg
Center of mass	0.165 m
Length	0.330 m
Inertia	0.0141 kg·m^2
Forearm	
Mass	1.520 kg
Center of mass	0.190 m
Length	0.340 m
Inertia	0.0188 kg·m^2
K_m	$\begin{bmatrix} /15 & /6 \\ /6 & /16 \end{bmatrix}$ N·m / rad
B_m	$\begin{bmatrix} /2.3 & /0.9 \\ /0.9 & /2.4 \end{bmatrix}$ N·m·sec / rad
K_v	$\begin{bmatrix} /120 & /30 \\ /30 & /50 \end{bmatrix}$ N / m
B_v	$\begin{bmatrix} /6 & /2 \\ /2 & /5 \end{bmatrix}$ N·sec / m

B. Measurement setup and perturbation signal

The simulated movements are 20 cm in length, which provides sufficient time and space to apply external perturbations and observe their effects on motor control. Movement directions follow a random walk pattern to ensure variability, and the workspace is defined as the entire range of space reachable by the hand under standard conditions. The model simulates at a frequency of 100 Hz. External perturbations play a critical role in the analysis and control of dynamic systems, especially in the context of system identification. When a system is subjected to external forces or disturbances, its response can reveal key properties about its underlying dynamics, allowing for better understanding and fine-tuning of the system's parameters. The idea of persistent excitation becomes particularly important in this context: using input signals with a rich enough frequency spectrum to stimulate all modes of a dynamic system is crucial for ensuring that the system's response contains enough information to identify any unknowns in the model accurately [24]. For this reason, different input signals have been systematically designed to obtain reliable and informative responses from the system: single-double step signal, amplitude-modulated Pseudo-Random Binary Sequence (PRBS), and chirp signal [25], [26]. These signals were implemented as external force perturbations and/or visual distortions (Fig. 3). A detailed explanation can be found below.

- *Single-double step.* This approach was used to create visual distortions by inducing sudden cursor jumps and simulating visually induced motor perturbations. These signals dictate the movement pattern of the cursor (which represents the hand position) and are characterized by abrupt shifts following either a single-step (one abrupt change) or double-step (two changes) pattern. The cursor's displacement occurred in random directions and covered distances ranging from 2 to 8 cm. These jumps would require participants to adjust their motor commands to maintain the desired trajectory (Fig. 3, panel A).

- *Amplitude-modulated PRBS.* A binary signal that switches randomly between predefined values was used to design external perturbations. This signal modulated a force applied to the system, with amplitudes randomly chosen between 5 and 15 N. The direction of the force was also varied randomly, creating controlled but unpredictable disturbances (Fig. 3, panel B).

- *Chirp signal.* A sinusoidal waveform with a frequency that gradually increases over time was used to design both external forces and visual distortions. For the external forces, the amplitude varied randomly between 5 and 15 N, while the frequency was chosen within a range of 0.5 to 3 Hz, aiming to excite low-frequency dynamics. For the visual distortions, the same frequency range was used, with continuous cursor shifts ranging from 2 to 8 cm (Fig. 3, panel C).

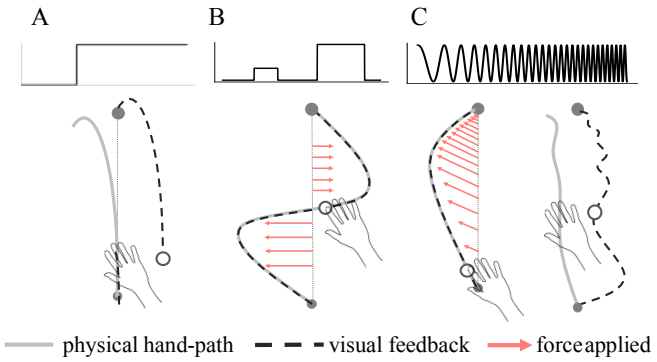

Fig. 3. The figure illustrates the application of three types of signals - a single-double step signal (A), a Pseudo-Random Binary Sequence (PRBS) signal (B), and a chirp signal (C) - which were used to simulate perturbations to the system in the form of external forces and/or visual distortions. In the first row, the waveforms of these signals are displayed. The second row shows an example output trajectory when the corresponding perturbation is applied. The solid gray line represents the hand path, the dashed line indicates the visual feedback, and the arrows depict the external forces.

C. Identification strategy

In our model, the first step included the generation of a dataset of 100,000 unique movements, each described by one of the perturbations listed above, with specified starting points and targets. The breakdown of movements by perturbation type is approximately equal, with each category accounting for about $\frac{1}{4}$ of the total number one-fourth of the total. Additionally, the structure of each perturbation was randomly selected, meaning that even when the same type of perturbation was applied, parameters such as amplitude, frequency, and duration varied across different movements. We used an incremental *play the winner* approach to estimate sensory feedback gains effectively. We began by selecting a random subset of 5 movements and fitted the model by solving a system of equations that included both muscle and vision inputs. To analyze the output data, we applied linear regression with Ridge regularization, trying to prevent overfitting and ensure smooth and reliable parameter estimates. This process was repeated 100 times, each time with a different random subset of 5 movements. The subset that achieved the highest accuracy (*winner*), as measured by the coefficient of determination comparing the estimated gains to the prior initial guess established at the beginning of the simulation, was selected. To this winning set, 5 additional movements from the remaining pool were added, and the expanded set of 10 movements was analyzed using the same process. At each stage, a new subset of movements was added to the winning set from the previous iteration. This iterative process of selection and expansion was repeated progressively increasing the size of the subset to 10 movements and reaching a total number of considered movements equal to 120. It was observed that adding movements beyond this number did not alter the results, and the analysis was therefore halted upon reaching a clear plateau (Fig. 4). By focusing on subsets that showed the best accuracy at each stage, this strategy allowed the model to refine the identification of the sensory feedback parameters more effectively. It also ensured that the most informative movements were prioritized, avoiding redundant or less meaningful data. This approach allowed us to explore how the quantity and quality of movements impact the accuracy of parameter estimation and identify when adding more movements no longer improved the fit. To ensure the robustness of the identified sensory feedback gains and to avoid the risk of overfitting, an additional validation step was implemented. After analyzing the quality of the fit for gain identification during each iteration, the best-performing set of gains was selected. This set was then used to predict the trajectories of 30 unseen perturbed and unperturbed movements that were not included in the training data. Although the perturbations were of the same general type, they were defined differently—exhibiting, for instance, higher amplitudes or longer durations—compared to those used during training. The predicted trajectories were compared to those generated using the initial dataset of gains, and the coefficient of determination was calculated based on this comparison. Unlike the previous step, where R^2 measured the model's fit to the training data, this evaluation focuses on how well the identified gains generalize to new, untrained movements. By shifting the validation metric to trajectory prediction, this step provides a more precise assessment of the model's ability to capture the underlying dynamics of motor control.

III. RESULTS

Fig. 4 provides a general overview of the synthetic model analysis, illustrating the relationship between the number of movements considered and the model's ability to identify sensory feedback gains (goodness of fit). In panel Fig. 4.A, the light-gray solution represents the overall performance using the *play the winner* strategy described earlier. Initially, as the number of movements increased, the coefficient of determination improved, indicating that additional data enhanced the model's ability to explain variance in sensory feedback gains. However, this improvement decreased over time, and the curve eventually reached a plateau. This plateau suggests that adding more movements beyond a certain point provides only marginal improvements in predictive accuracy. Focusing on the primary outcome of our analysis, the dark-gray solution highlights the best-performing set of movements for each quantity considered. The analysis identified the optimal set of 40 movements as producing the highest accuracy.

At this stage, it is important to address the potential for overfitting, particularly given that the analysis relied on training data and the sensory feedback gains themselves. Overfitting occurs when the model captures noise or specific details in the training data rather than generalizable patterns, reducing its effectiveness when applied to new scenarios. To evaluate and mitigate overfitting, the coefficient of determination was calculated by comparing model-predicted trajectories with actual test trajectories. For validation, as described before, a set of 30 test movements -not included in the training process- was used. Using the best-performing

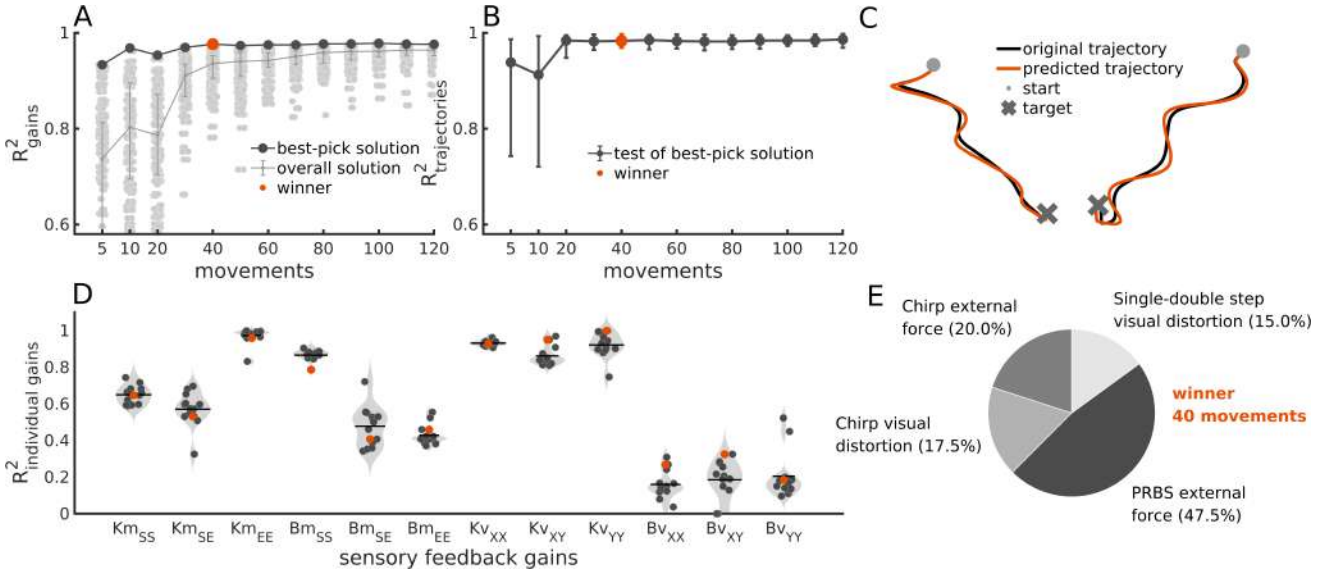

Fig. 4. Overview of the synthetic model analysis. Panel A shows the optimal set of 40 movements achieving the highest accuracy. Panel B confirms the model's generalizability with high R^2 values on unseen test movements. Panels C and D detail trajectory comparisons and the accuracy of individual sensory feedback gains, highlighting velocity-dependent vision gains as the most challenging. Panel E illustrates the distribution of the optimal set across perturbation types, with PRBS forces being the most effective.

gains identified during the iterative process (Fig. 4.A), the model predicted the test trajectories. These predictions were then compared against trajectories generated using the initial guessed gains. This validation process was applied exclusively to unseen movements in order to evaluate the model's generalizability. The results displayed in Fig. 4.B, show that the coefficient of determination remained consistently high and stable across the selected range of movements. This stability confirms that the model accurately captured the dynamics without overfitting, ensuring reliable predictions in new scenarios.

Fig. 4.C presents examples of trajectory comparisons, showing both the predicted paths (generated using the estimated gains) and the original model-generated paths (referred to as original). At this stage, our primary goal is to assess the accuracy of the identification process for each sensory feedback gain, enabling a detailed evaluation of how well each component was estimated. Fig. 4.D provides a breakdown of performance for each best pick, presenting the accuracy results for individual gains. This visualization highlights and shows how the identification process varied across different components. Interestingly, the velocity-dependent vision gains were the most challenging to identify. Additionally, the gains highlighted in red represent those included in the best-performing set, which achieved the highest overall accuracy in the previous analysis. This best set establishes the optimal conditions for reliable parameter estimation. Fig. 4.E provides a detailed illustration of how the selected set of movements, which enables the best parameters identification, is distributed across the various perturbation types. This distribution provides valuable insights into which types of perturbations were more effective and which were less represented in achieving accurate parameter estimation. As can be seen, an external force following a Pseudo-Random Binary Sequence profile resulted as the most effective in enhancing the accuracy of parameter identification. In summary, the optimal set that best identifies the sensory feedback gains consists of 40 movements, distributed as follow: 47.5% PRBS external force, 20% Chirp external force, 15% Single-double step visual distortion, 17.5% Chirp visual distortion. Within this design, the various impedances—such as muscle stiffness, damping, vision-dependent position and velocity—are identified with the following percentages of accuracy: Km_{SS} (65%), Km_{SE} (53%), Km_{EE} (96%), Bm_{SS} (79%), Bm_{SE} (41%), Bm_{EE} (46%), Kv_{XX} (93%), Kv_{XY} (95%), Kv_{YY} (99%), Bv_{XX} (27%), Bv_{XY} (33%), Bv_{YY} (19%).

IV. DISCUSSION

This work supports the importance of developing a solid mathematical model to guide data collection, optimize experimental sessions, and enhance their effectiveness. PRISM aims to address a critical gap in neurorehabilitation: the lack of robust generative models capable of predicting outcomes and prescribing personalized interventions. By replacing qualitative observations with mathematically driven, quantitative models, this approach allows for a systematic exploration of optimal conditions to improve identification strategies. Although advancements in technology, such as robotics, have revolutionized rehabilitation, a major challenge remains: the development of effective software to fully leverage these tools. Current methods often lack inverted models—mathematical frameworks designed to be directly tested and optimized for guiding applications [27]. These models have the potential to contribute significantly to both general training and

neurorehabilitation [28], [29]. By utilizing individual subject data, they can predict the outcomes of interventions, identify the most effective treatment strategies, and determine the conditions necessary for improving motor function or accelerating recovery. In this way, PRISM represents a step toward more personalized, data-driven, and effective approaches in neurorehabilitation. This strategy differs from traditional identification methods in that the focus is on recovering the underlying parameters driving the synthetic model rather than just assessing the quality of fit. The main goal is to identify the minimum but most informative set of movements that allows for accurate sensory feedback gain identification. Identifying the specific types of perturbations and conditions necessary to accurately determine these gains represents the main aspect of this work. This approach balances between maximizing data precision and information with minimal effort and exercise. Once this first step of parameter identification is accomplished, it will form the basis for the development of an individualized intervention that will involve customized exercises aimed at achieving the best possible outcomes without extra repetitions that can cause disengagement in patients and physical exhaustion. This work is related to surrogate models and digital twin approaches that are increasingly being used in complex systems for simulating, predicting, and optimizing outcomes. Within neurorehabilitation, these frameworks assure powerful tools for modeling responses of individual subjects and optimization of therapies.

Focusing on the results obtained, there is still room for improvement in identifying sensory feedback gains, especially those related to velocity. It can be assumed that velocity-dependent gains are linked with position-dependent components, which may lead to collinearity in the parameter estimation process. Changes in one gain could be masked or partially compensated by adjustments in the other, making it challenging to isolate and clearly identify the specific impact of velocity-dependent gains on system behavior. Additionally, the current *play the winner* strategy may favor similar tasks due to its random selection process, which can bias gain identification toward frequently explored perturbations. Future versions could include a diversity measure in task selection to promote a broader exploration of the perturbation space. Furthermore, introducing new, targeted external perturbations may better stimulate the system. However, these perturbations must also be translatable to real-world scenarios and practically implementable. While their selection does not affect simulations, it is crucial to determine whether they could be disruptive and inadvertently alter natural movement patterns in reaching tasks. The final goal is to develop a protocol design that can be directly used as an experiment. This requires striking a balance between creating perturbations that maximize system stimulation and ensuring their feasibility in real-world contexts, bridging the gap between theoretical precision and practical usability. Future work will also prioritize validating the proposed model in real-world settings to transition from synthetic simulations to practical applications. The synthetic model's output —designed and based on specific individual's parameter— will serve as the input and experimental design for identifying sensory gains. While the aforementioned experiments are derived from synthetic data with assumed gain values, real-world environments introduce additional variability that may challenge the model assumptions. One such challenge is the role of inertia. In the current model, inertia is solely attributed to the human arm, with external forces applied by an ideal force source. However, in practical implementations, the inertia and damping of the robotic system can be comparable to those of the human, complicating the estimation of human dynamics. A critical step will, therefore, be to assess whether the model remains robust under these conditions and whether the initially hypothesized gain space accurately reflects reality. The real-world application will use an upper-limb robotic device, b.u.r.t. [30], in combination with the augmented reality interface LookinGlass [31], which enhances user immersion. This setup will allow the robotic system to gather precise position data and apply controlled forces to participants, while a virtual environment, developed using the Unity game engine, will provide interactive visual feedback.

Our model, while providing a solid framework for understanding sensory gain identification, can be further enriched with elements that better reflect real-world motor dynamics. In particular, it does not explicitly incorporate reflex components, as its primary focus is on voluntary control mechanisms. However, reflexes play a crucial role in motor control by enabling rapid corrections to perturbations and enhancing movement stability. Extending the model to include reflex contributions would allow for a more comprehensive representation of motor responses. Additionally, refining the framework to incorporate multiple sensory modalities could further enhance its applicability in neurorehabilitation. By integrating diverse sensory inputs, we aim to explore how specific excitation methods can optimize system parameter identification. These advancements will refine the model, making it more adaptable to individual needs and more effective for tailoring interventions in complex, multi-modal systems. Ultimately, this work represents a step toward developing robust, data-driven methodologies that enhance neurorehabilitation strategies by closing the gap between theoretical models and their practical application. By integrating these approaches, it aims to improve the effectiveness of rehabilitation techniques in real-world settings.

***Abstract*—Movement coordination disorders can originate from congenital abnormalities, traumatic injuries, or severe infections. These conditions can manifest in various ways, such as hypertonia, hypotonia, and involuntary movements, significantly impairing an individual's ability to perform daily tasks. This research focuses on the development of a soft exoskeleton designed to enhance the quality of life for individuals with cerebral palsy, particularly those affected by athetosis – a condition marked by involuntary, fluctuating muscle tone and associated balance challenges. The exoskeleton aims to provide conductive education (also known as the Pető method) for maintaining motor functions and facilitating precise movements, thereby contributing to the social and professional integration of individuals living with mobility disorders.**

This manuscript emphasizes the simulation phase of the exoskeleton development, which supports the physical design process through numerous iterative cycles. During the research, we utilized three different movement data sources, we developed a whole and a partial simulated model (reduced degree-of-freedoms) of our real exoskeleton, and investigated two different control methods in simulation. At the end of the day we achieved a qualitatively similar behavior in simulation what we produced with the physical exoskeleton at its current development stage.

***Index Terms*—control design, soft exoskeleton, OpenSim**

I. Introduction

Neural disorders remain a significant focus of modern medicine, particularly in treatment and rehabilitation. While robotic solutions have shown success in addressing well-defined diseases with deterministic mechanisms, such as Parkinson's disease [1], they often fall short in managing non-deterministic conditions requiring complex regulation. This is particularly important in conductive education, where conductors (therapeutic specialists) work to facilitate motor learning and development. For neural disorders with motor impairments, precise symptom characterization is crucial, particularly through motion capture and analysis. Techniques combining cameras and inertial measurement units (IMUs) provide detailed tracking of complex movements, addressing limitations of single-sensor systems [2], [3]. Additionally, sensor fusion techniques improve accuracy and reliability by compensating for issues such as gyroscopic drift or limited field of view, enabling the precise mapping of motion trajectories [4]. Biomechanical simulators like OpenSim further enhance analysis by simulating muscle activations and joint forces, offering a deeper understanding of motion mechanics without extensive physical trials [5].

Soft robotic systems, such as cable-driven exoskeletons, are becoming increasingly popular due to their ability to combine functionality with user comfort, ensuring effective therapy over extended periods [6], [7]. However, challenges such as soft tissue artifacts and sensor displacement during movement underscore the need for robust correction methodologies to maintain accuracy in real-world applications [8]. These advancements reflect the ongoing trend toward integrated, adaptive systems that prioritize precise motion tracking and user-specific customization [9], [10], [11].

Athetosis, a specific type of cerebral palsy, exemplifies the complexities of non-deterministic motor disorders. It arises from disrupted cortical control, typically due to damage to the basal ganglia, resulting in involuntary, unpredictable move-

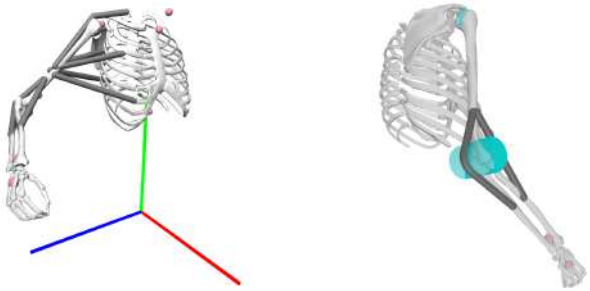
ments [12]. These movements often intensify during voluntary actions, significantly impairing tasks requiring fine motor control. While the muscles themselves function normally, the inability to regulate movement at the neural level creates significant challenges for therapeutic interventions.

This research focuses on leveraging OpenSim, a biomechanical simulation environment, to support the iterative development of a physical soft exoskeleton designed to address the needs of individuals with athetosis. OpenSim's ability to model multibody dynamics and simulate muscle activations enables the creation of highly customized solutions. Multibody systems treat the body as interconnected segments – bones, muscles, and joints – that interact dynamically to produce motion, making them ideal for analyzing complex biomechanical tasks. OpenSim employs this methodology to model the human musculoskeletal system, enabling precise analysis of joint forces, muscle activations, and motion dynamics. Beyond this, OpenSim supports the integration of experimental data, such as motion capture and electromyographic signals, and provides tools for simulating movement under various conditions. To meet individual needs, OpenSim models can be customized to reflect specific anatomical and functional requirements. Achieving such a high degree of personalization often involves using the software's API, which enables developers to extend functionality and create tailored workflows, ensuring the exoskeleton meets the unique challenges posed by athetosis.



II. Methodology

A. Exoskeleton models

The goal of this research is to develop a soft exoskeleton that supports motion coordination and quality of life for individuals with athetosis. The exoskeleton utilizes lightweight paracord lines (Paracord 350 and 550), which are tensioned or relaxed to produce the required forces for movement, routed through sleeves that guide their paths for stability, and adjusted by motors to generate supportive forces for arm movements. Currently, the device interacts with the arm at seven distinct points, though in the current physical version only four motors actively control two primary movements: elbow flexion-extension and shoulder flexion-extension. The current sensory feedback system of the exoskeleton measures the tension in the inflexible cords, which provides an estimate of the system's operational state.

To refine the exoskeleton's functionality, the system was modeled and simulated in OpenSim. The `ClutchedPathSpring` actuator was identified as the most suitable option, as it mimics the real system by applying forces only when needed, allowing free movement otherwise. The actuators were attached at anatomically appropriate points on the simulated model, in line with the physical design of the exoskeleton (Fig. 1a). To guide the cords along specific paths and prevent intersection with bones during elbow flexion, wrap objects were used to ensure realistic tension distribution. In particular, a cylindrical wrap object was positioned perpendicular to the elbow joint, aligned with both the flexor and extensor paths, mimicking the setup of the physical prototype.

To match the physical settings, the complex 7-actuator model was simplified to a 2-actuator version, using only the elbow actuators (extensor and flexor, acting as agonist and antagonist actuators), as only these actuators currently have the required tension-producing ability and measurement accuracy in the physical system (Fig. 1b). The other actuators are under development and will be integrated into simulations upon reaching the necessary performance standards.

(a) Exoskeleton model in the simulation environment equipped with 7 actuators.

(b) Simplified 2-actuator system along with the additional cylindrical wrap object.

Fig. 1: Exoskeleton models in simulation

B. Data sources

In this research phase, three different data sources were investigated one after the other till the qualitative reproduction of the hardware's behavior.

To characterize the unique movement patterns associated with athetosis, a series of measurements were conducted at the András Pető Faculty of Semmelweis University (commonly known as the Pető Institute), using the Xsens MVN AWINDA (Xsens Technologies B.V., Enschede, Netherlands) motion capture system (research ethics approval ETT TUKEB IV/8514-3/2021/EKU, IV/8515-3/2021/EKU, participators' informed consent was also collected). The recorded data were subsequently processed and visualized in OpenSim, revealing that the underlying movements frequently exceeded the joint range limits defined in the simulation, primarily due to the involuntary and abnormal motions typical of individuals with athetosis. Furthermore, the lack of consistent, followable motion planes and the absence of reliable reference trajectories presented additional challenges for utilizing the data in a 2-actuator system. It should also be noted that in most of the cases, the required Xsens system calibration protocol cannot be carried out, as the subjects could not remain still for 10 seconds and could not walk around during the calibration stage. Thus, the quality of the recorded data was mostly bad. These complexities rendered the real Xsens data unsuitable for tasks such as testing control algorithms for reference exercises in our early stage, as they necessitated overly complex regulatory models.

To simplify the analysis and gain better control over input variables, synthetic data was generated for use in simulations.

These datasets were designed to meet specific requirements: the motions were confined to a single plane, avoided extreme joint angles, and included both smooth and perturbed trajectories to simulate tremors. The synthetic data incorporated variability in both amplitude and phase to emulate realistic motion patterns without exceeding the constraints of the simulation. Joint angle trajectories, primarily focused on elbow flexion-extension, were generated using MATLAB (R2022b, The Mathworks Inc., Natick, Massachusetts). The resulting `.mot` files acted as inverse kinematics outputs, storing the motion as joint angle data over time.

The baseline motion consisted of a smooth flexion-extension movement between 32° and 82°, chosen to reflect a part of natural range of motion for the elbow, to respect the current dynamical range of the real hardware while avoiding extreme joint angles that could lead to simulation errors.

Tremors were introduced by combining sinusoidal and cosine components with varying amplitudes and phases, designed to mimic irregular, non-deterministic movements characteristic of athetosis. The parameters were tuned to qualitatively replicate the athetosis tremor patterns observed in the real Xsens data, though projected in 2D and focused solely on the elbow joint. The amplitude of the perturbations ranged between 0.15° and 1.98°, while the phase values varied randomly within 0.28 to 0.42 radians (16.043° and 24.064°, respectively). Using these rules, five distinct movements were generated for the simulations. One served as a baseline, representing smooth elbow flexion and extension without perturbations. The remaining four included tremors: one with a single larger tremor applied at the midpoint of the motion and three with moderate tremors distributed at the beginning, middle, and end of the movement. In the rest we will refer to these as *synthetic data*. Using the *synthetic data*, `Computed Muscle Control` (`CMC`) was run in OpenSim to determine the muscle excitations required for the model to accurately track the input kinematics.

The third data source in this study is real-measurement based, synthetically aligned (for the simulations, afterwards referred as *real&synthetic*). One of the authors was the subject of these recordings. Before the measurement, he was verbally informed about the circumstances, and he participated voluntarily. The actuator length data was recorded and used with slight scaling in the simulated replication. The three movements in this set consisted of a baseline measurement (smooth movement), an involuntary movement recording with multiple instances of sudden jerks (with a constant-toned actuator tension without intervention), and a third movement recording also with involuntary movements, but with activated physical exoskeleton in order to prevent the sudden and intensive direction changes. During these measurements, the arm moved from a straight position (Fig. 2a) to a flexed state (Fig. 2b), with the jerks noted near the fully flexed point. The goal was to return the arm to its original position after each movement. Beyond the actuator length-change recordings, we also recorded surface electromyographic (sEMG) data with built-in acceleration informations at the sites of the biceps, triceps and hand (Cometa MiniWave Waterproof, Cometa Systems Srl., Bareggio (MI), Italy). The input data for the simulations were generated based on the flexor length changes with slight scaling applied on it.

C. Controls in simulation

In this research phase, we have examined two different control strategies. The first one is in connection with the *synthetic data* source, a pure PD-controller on the basis of the joint angles. The second one is in relation with the *real&synthetic* source, realizing multiple control rules with PD-extension to well align with the physical systems built-in control. (The exact control mechanism of the physical system is based on the patent of the driving mechanism (Patent no. US9933055B2).)

As the first control strategy, the elbow actuator controller implemented in this study is a custom controller class derived from the OpenSim `Controller` class. As a result, the new elbow controller inherits basic control functionalities, such as updating the connected actuator set, without requiring additional development. Its primary purpose is to adjust the elbow joint's flexion angle to match a reference value, accounting for the current angle and its deviation from the desired position. Based on the control signal calculated by a proportional-derivative (PD) controller, the appropriate actuator is activated. Depending on the output, actuators either tighten or loosen (as the two actuators produce opposing motions, activation is determined by the sign of the control signal). Additionally, the controller ensures that the control signal remains within specified bounds (the `ClutchedPathSpring` actuator accepts control signals between 0 and 1).

The first version of the control simulation not only integrated the custom controller into the system but also implemented movement based on muscle activations using the `ControlSetController` class. These calculations were performed by the `Manager` class in OpenSim. This manages the simulation workflow, including the integration of dynamic models, and dynamically adjusts time step size during the simulation based on the motion's complexity and specified settings, ensuring both accuracy and stability. Outputs include kinematic and dynamic variables, providing detailed insights into the model's behavior under dynamic conditions.

After achieving a functional 2-actuator system in simulation, we aimed to validate the simulation by comparing it with the current physical device, this is the second control strategy. For this purpose, the elbow controller was modified to operate based on actuator length, as this was the only built-in numerical value that could be directly measured for evaluation.

III. Evaluation

A. Results

The simulations were performed on a Microsoft Surface Pro 3 laptop (Intel Core i5-4300U, 8GB RAM, 256 GB SSD, Windows 10 Pro). The *synthetic data* used in the simulations, including tremors, and the corresponding reference data were each 5 seconds long. The runtime of the `CMC` for each measurement ranged from 2 to 4 hours, using only elbow flexion,

(a) Initial straight position of the arm. The image also shows the flexor cord (a thin black cord on the forearm) and the EMG sensors positioned on the biceps.

(b) Almost fully flexed state of the arm. The Figure also shows the hand EMG, placed on the hand.

Fig. 2: Snapshots from the physical measurement

with other joints fixed to reduce computational time. The runtime of the C++ simulation (first control strategy) depended mainly on the integration settings (e.g., maximum step size and accuracy) and the frequency of output data logging, with a simplified configuration resulting in a simulation time of 2–3 minutes. The measurements *real&synthetic* (generated from the physical system) lasted approximately 15–30 seconds. The `CMC` ran the optimization for approximately 10–14 hours, while the C++ simulation (second control strategy) ran for 6–8 minutes.

As we analyzed the *synthetic data* in the context of the first control strategy, the baseline movement of it (the smooth movement without any perturbations) served as reference value for the control signal. The different alterations (in phase and in amplitude) helped the detailed examination of the dynamic characteristics of the controller. The tuning of the PD parameters were performed knowing that the control signal should remain in the range $[0, 1]$ while effectively smoothing dynamic movements without overshooting. This also required the correct parametrization of the simulator's integrator, as different integrators showed varying abilities to maintain stable muscle activation values and to track dynamic movements. It was also found that the more detailed the simulation, the smaller the steps required to compute the error signals, enabling faster and more accurate convergence.

The selected PD parameters for the analyses were: $P = 1.0$, $D = 0.4$. The integrator (`Manager` class) used the `RungeKuttaMerson` method with an accuracy of $10^{\propto 5}$, a minimum step size of $10^{\propto 7}$, and a maximum step size of 10^{0}. The PD parameter settings were determined empirically by testing 10 different parameter pairs. Although the coefficients did not significantly impact the final result, smoother solutions were preferred for better control of the physical device. This was demonstrated in Fig. 3, which shows a section of the smoothing performed using three different PD coefficient pairs.

The impact of different smoothings were analyzed from the viewpoint of the elbow flexion angle, determined by

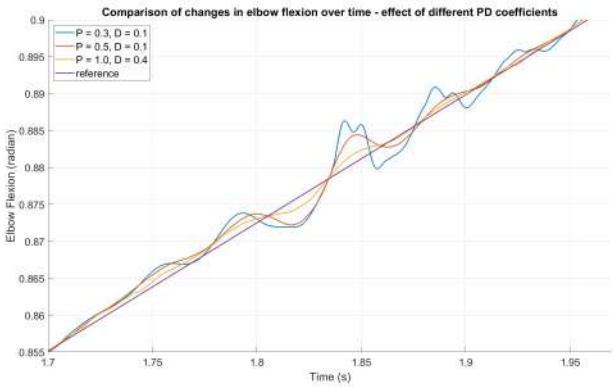


Fig. 3: Comparison of elbow flexion angles smoothed using three different PD coefficients. Among the movement paths shown in the figure, the simulation with parameters marked in yellow (P = 1.0, D = 0.4) proved to be the most effective in terms of mean square error (MSE), compared to the reference signal (purple). The mean square errors for each trajectory are: $3.528632 \times 10^{\propto 6}$ (blue), $7.126799 \times 10^{\propto 6}$ (red), $3.947505 \times 10^{\propto 7}$ (yellow), respectively.

the `Manager` class' calculations, utilizing the precalculations of the `CMC` modul. Fig. 4 illustrate the outcomes of these analyses.

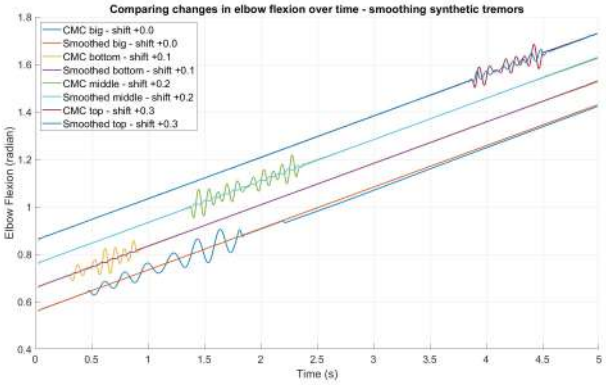

Fig. 4: Comparisons of the generated movement (performed during `CMC`) and the smoothed movement in simulations. The results are shifted along the y-axis to better visualize the differences.

In the case of the *real&synthetic* source, the actuator length data was recorded. As described earlier, here the second control strategy was utilized with the modified elbow controller.

Testing revealed that the uncertainty in the flexion-extension movement at the elbow joint is 6–8 degrees, as the current sensory feedback system of the exoskeleton measures the tension in the inflexible cords. Meanwhile, the useful length-change in cord length measurements for the flexor cord is approximately 8–10 cm, and around 5 cm for the extensor cord. Similar range of length-changes are observed at the shoulder joint, though precise measurements are still being

finalized. Additionally, the spatial accuracy of the wrist was assessed using an Azure Kinect depth camera, which provided a positional accuracy of 5–10 cm, with 3–5 cm of this variability attributed to the limits of the Kinect system itself.

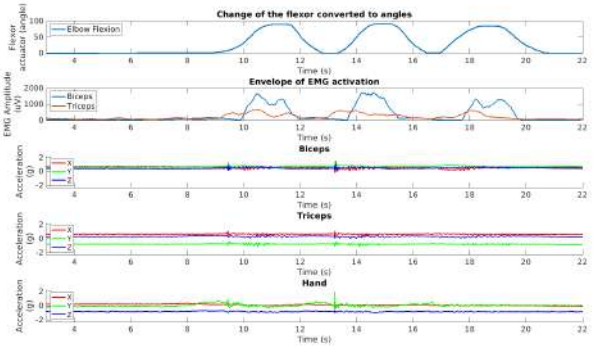

Fig. 5: The results of the baseline movement, during which no actuation was performed by the flexor. The figure illustrates the elbow angles (derived from the flexor), the EMG activation of the biceps and triceps, as well as the acceleration data from the three EMG sensors placed on the arm.

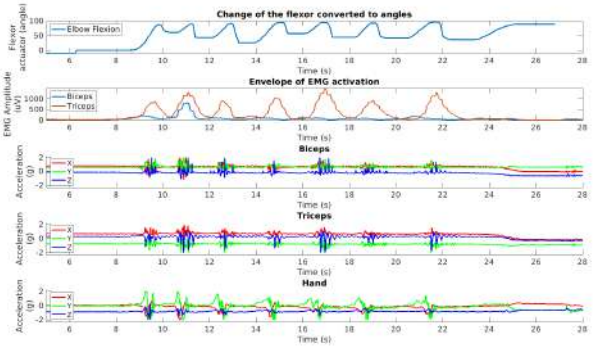

Fig. 6: Results of the involuntary movements measured with the physical soft-exoskeleton model. The figure shows the elbow angles, the EMG activation of the biceps and triceps, and also the acceleration of the three sensors.

The evaluation and visualization of the physical measurements indicate that the flexor can effectively alter the trajectory of the arm. Biceps EMG signals (Fig. 6) were lower compared to the baseline measurement (Fig. 5), which suggests that the arm was not moving. Despite this, movement is still observed, as indicated by accelerometer data and changes in elbow angle, which occurred due to the flexor's exertion of force.

Furthermore, Fig. 7 and Fig. 8 demonstrate that the simulation on *real&synthetic* data source with the second control strategy (using the custom controller designed to replicate the physical system) can effectively adjust the arm's position under the given parameters and working conditions. The system operates similarly to the physical counterpart, as activation occurs only in response to unhealthy/twitching movements.

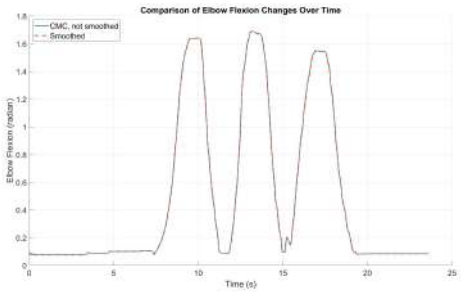

Fig. 7: The simulation of healthy movement showed no unusual behavior. The actuator required no adjustments.

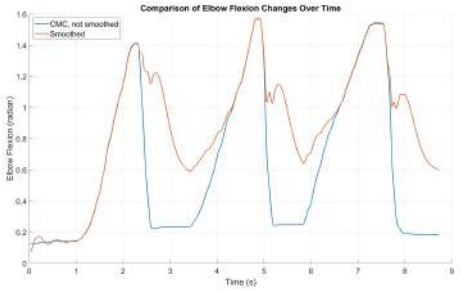

Fig. 8: When twitching was detected during the simulation, the actuator was activated and smoothed the movement.

B. Discussion

Based on the results, it can be concluded that the exoskeleton model is effective at smoothing movements. Various types of tremors were examined during the simulations in *synthetic data* source, and significant smoothing was achieved in all cases of the first control strategy. For larger phase tremors, the system proved particularly effective ($MSE = 3.528632 \cdot 10^{\propto 7}$), while for smaller phase tremors, the system achieved smoothing with an error approximately an order of magnitude higher ($MSE_{bottom} = 1.328081 \cdot 10^{\propto 6}$, $MSE_{middle} = 2.579348 \cdot 10^{\propto 6}$, $MSE_{top} = 1.484697 \cdot 10^{\propto 5}$). This discrepancy is mainly attributed to the simplicity of the controller and to the PD params initially set for larger tremors.

The effectiveness of smoothing was also analyzed based on smaller tremors, focusing on the ratio of the agonist-antagonist actuator moment arm and elbow flexion angle. Both visual observations and computed mean square errors indicated that the elbow extensor actuator exerted greater force in an extended elbow state compared to a flexed state when using the same control signal. This suggests that changes in the moment arm significantly impact actuator performance, which is an important consideration for fine-tuning controller parameters. (A more elaborated tendon system description in the *synthetic data* case with the help of its Jacobian (moment arm matrix, angular-dependent tendon length derivatives with respect to the angles) could lead to an enhanced control with gradient search to have the necessary actual tendon tightening, as presented eg. in [13], but it was out-of-scope for this phase.)

However, simulations controlled purely by muscle activations did not always follow the desired movement accurately. The observed drift was likely due to inaccuracies in the computed muscle activations. The `CMC` optimizer selects the best solution from the viable alternatives. Poorly chosen parameters can lead to cumulative deviations from the desired trajectory, resulting in significant discrepancies, which can be seen in the `CMC` output file. Reviewing and adjusting these errors can provide valuable insights into the accuracy of the computed muscle activations. An example is the `lookahead window`, which represents the foresight on the target movement path. Although optimizing this would likely improve simulation accuracy, it would also increase the required simulation time.

Talking about the physical system (which has different direct and indirect state variables), one issue identified is that the system cannot detect all movements accurately, especially when the arm moves in subspaces the cord-based sensing cannot capture. To address this, the moment arm of the extensor cord at the elbow joint was modified (increased) to support effective force application, and the integration of an IMU-based sensor system has been proposed. The other actuators at the physical level are still under development, their integration into the simulations will follow once their performance reaches the necessary standards, which would help us in future research to focus on incorporating synthetic 3D data. At the software level there are no obstacles to implement this, as all seven actuators have been constructed in the exoskeleton model, and the `ControlSetController` can control all muscle data. After validating the 3D system, real movements recorded at the Pető Institute is likely to become integrable into the simulation environment.

The developed simulation system shows promise for advancing the physical device as it can help to determine the optimal placement and orientation of actuators on the exoskeleton. It also allows consideration of factors like the mass of model components during the simulation. From a control perspective, refining real-time feedback with IMU sensors and adapting parameters based on patient characteristics or movement type could significantly enhance system performance.

IV. Conclusion

The aim of this research was to develop an exoskeleton model that operates similarly to the physical version, allowing the control system to be tested and improved for the physical exoskeleton. Actuators were integrated to closely replicate the functionality of cable-driven motion support, similar to how cables shorten and release through a sleeve mechanism. The validation of the exoskeleton model was carried out through simulations and later compared with physical measurements.

`Computed Muscle Control` (`CMC`) calculations were used in the simulation to determine muscle activations. These formed the basis for dynamic simulations, where movements were controlled using the predefined muscle activations, implemented through the `Manager` class.

Several simulations were performed using synthetic data and physical measurements, which allowed testing different aspects of the simulation system, including tremor smoothing and movement tracking, and the working principle of the physical system. The results of these simulations demonstrated that the developed system was capable of effectively smoothing tremors, supporting the conclusion that the exoskeleton model and simulation system can efficiently support movement coordination and attenuate tremors. The next steps involve parallel developments with the physical exoskeleton, as well as integrating 3D data, which will be accompanied by creating and theoretically designing a more complex controller to ensure that the exoskeleton model can provide optimal support for users in real environments.

Analysis of Different Sensor Modalities for Movement Classification in Physical Therapy

Sebastian Dill[1]*, Luise Herrmann[1]*, Arjang Ahmadi[2], Martin Grimmer [2,3], Dennis Haufe[2], Yanhua Zhao[1], Maziar Sharbafi[2] and Christoph Hoog Antink[1]

***Abstract*— This study investigates feature analysis and feature fusion from different sensor modalities for the task of identifying movement errors in physiotherapeutic exercises, using squats as a case study. Incorrectly performed exercises can lead to injuries, underscoring the need for accurate monitoring tools. In an experiment, ten participants performed squats in three variations: correct execution, forward lean, and lateral tilt. To identify movement patterns, we evaluated muscle activation through electromyography (EMG), kinematic data through Motion Capture (MoCap) and joint angles from video footage through MediaPipe Pose. Distinct movement patterns were identified for the erroneous variations: forward lean altered hip and knee angles, while lateral tilt caused asymmetries in posture. In the EMG signal, deviations in the activity of distinct muscles correlated clearly with specific erroneous movements. Activation in the Gluteus Maximus was higher for the forward lean, while activity in the Quadriceps was lower. For the lateral tilt, a clear difference between left and right muscle activation was visible. Signal processing techniques extracted key features, such as muscle activation peaks and joint angle deviations, that we used to discern between the different squat types with a decision tree model. MoCap-based features offered the highest precision when used on their own, but fusing different sensor modalities achieved the best results. Although the video-based classifications were less accurate, its cost-effectiveness and ease-of-use suggest potential for home rehabilitation. Future research should enhance marker-less technologies and enable real-time feedback for broader applications.**

I. INTRODUCTION

Physiotherapy plays a vital role in the rehabilitation process, helping patients recover their health and improve their quality of life [1], [2]. Rehabilitation programs are typically designed and guided by medical professionals to meet individual needs. Traditionally, physiotherapists supervise patients during their rehabilitation exercises to ensure proper execution and prevent errors that could worsen the condition or cause additional injuries [3], [4]. While this personalized approach is highly effective, it is also resource-intensive, requiring therapists to dedicate substantial time to individual patients, which limits efficiency.

Therefore, in recent years, a wide variety of sensors have been used in the attempt to make sensor-based physiotherapy possible [5][6][7]. They can generally be divided into contact-based (obtrusive) sensors and contactless (unobtrusive) sensors. Contact-based sensors have to be attached directly to the patient, which typically necessitates the involvement of an expert for proper placement, making their use both complex and costly. Since the signal quality depends highly on the contact to the subject's body, they are also less suitable for applications involving extensive movement. Examples for contact-based sensors that are often used in physiotherapy include Electromyography (EMG), which directly assesses the electrical activity of the muscles and marker-based Motion Capture (MoCap), which provides highly accurate 3D pose information that can be used to calculate the subject's kinematics.

Contactless sensors are more versatile and can be used by the patients themselves, even at home. Typical contactless at-home sensors include marker-less MoCap through cameras (both red-green-blue (RGB) and depth cameras like the Microsoft Kinect) and radar [8]. These sensor are cheaper than marker-based MoCap or EMG, while also giving the user more freedom to perform the movement [9]. The 3D human pose estimation (HPE) library MediaPipe Pose [10], which is based on the BlazePose model [11], is particularly popular due to its higher computational efficiency and ease of use compared to other methods, and the fact that it is open-source. The downside is that systems based on contactless sensors tend to reach their limits when recording complex movement patterns, especially in terms of accuracy [12] and need calibration and extensive data processing.

Combinations of contact-based and contactless sensors have been used to assess the causes of movement disorders as early as 2000, when Harlaar et al. introduced the SYBAR system for combined recording of video, EMG and force plate data [13]. At that time, however, the analysis was still performed manually by clinicians who used the recorded data to support their decision. Since then, the integration of multiple data sources has proven to offer significant advantages, particularly in gait and running analysis [2]. More recent studies have explored the relationships between different sensing modalities, such as estimating joint angles from EMG data [14].

In this work, we will utilize three types of sensors, namely marker-less MoCap via camera, marker-based MoCap and surface EMG (sEMG) sensors, to collect data of a squat as an typical physiotherapeutic exercise. Squats were chosen

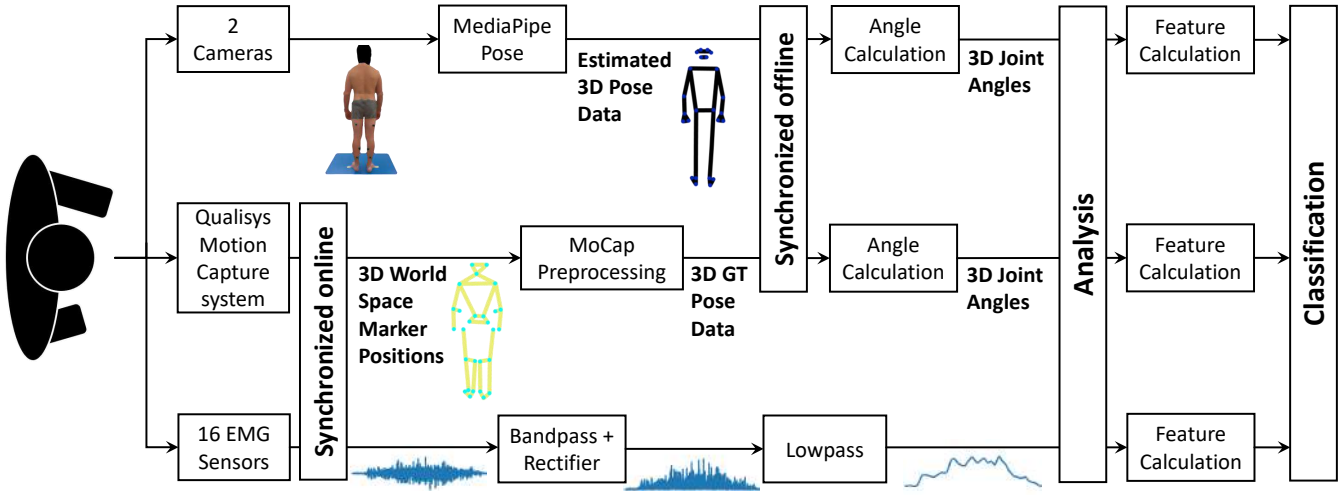

Fig. 1: Flowchart depicting the overall data collection and processing. Three different sensing modalities form three different data paths: Video, MoCap and surface EMG. Each of these paths have their own processing and synchronization. Then the data gets analyzed visually and in a correlation analysis. Finally we calculate features like maximum angle changes and mean muscle activities used in a classification.

for their advantages as a standardized exercise with a slow and controlled movement pattern, making them particularly suitable for detailed movement analysis. We will calculate features like maximum angle changes and mean muscle activities and investigate, which features show significant changes when the exercise execution is wrong. We also analyse the correlation between data from different sensors to explore potential to replace contact-based with contactless sensors. A decision tree model will be employed to differentiate between correctly and incorrectly performed squats, providing insights into the effectiveness of sensor-based error detection. Overall, we wanted to explore three main questions: 1. How effective are contactless sensors compared to contact-based sensors at identifying movement errors in the context of physiotherapy? 2. How much does a combination of sensor modalities improve the identification of movement errors? 3. Can cross-sensor correlations be identified that indicate proportionality between different sensor modalities? Specifically, we hope to find indications that it could be possible to estimate sEMG signals from camera recordings.

II. METHODS

The goal of this work is to compare different sensing modalities, namely sEMG, marker-based MoCap and marker-less MoCap with MediaPipe Pose, to evaluate their suitability for movement classification in physical therapy. To achieve this, we created a custom dataset comprising ten healthy male subjects (mean age = 22.8±3 years; height = 1.79±0.07 m; mass = 74.8±12.8 kg) performing squats in both correct and incorrect variations. The subjects were equipped with 16 different sEMG sensors and were recorded by two video cameras and a motion capture system. We feed the image streams of both cameras into two distinct instances of the MediaPipe Pose framework [11] to receive two sets of 3D human pose joint estimations. From these estimations as well as the ground truth (GT) MoCap data, we calculated relevant joint angles. Following a visual inspection of the data, features were extracted from all sensor signals for use in a classification task. The methodology for each step is detailed in the subsequent sections, while an overview of the entire approach is illustrated in Fig. 1.

A. Experiment and Dataset

A comprehensive description of the dataset and recording setup can be found in [15]; therefore, only a brief overview will be provided here.

Ten participants took part in three different experiments, each involving thirty repetitions of a squat. In experiment one (E1), the squat was performed correctly, as defined by the following criteria:

- Shoulder-width stance with parallel or slightly V-shaped feet.
- Heels remain on the floor throughout the exercise.
- The spine remains straight throughout the exercise.
- Both legs are loaded symmetrically, i.e. the centre of the body should not deviate from the centre of the feet.

In the other experiments, the exercise was performed incorrectly, recreating typical errors identified by an expert: In the second experiment (E2), the participants bend forward excessively during the squat, which also causes rounding of the back in some cases. In the third experiment (E3), the participants shift their weight heavily to the right side, resulting in asymmetry.

The subjects were recorded by two phone cameras (1080×1920 pixels and at 30 frames per second (fps)). The phones were placed upon tripods at a height of approximately 130 cm and are positioned perpendicularly to each other and to the ground, such that cam_1 has a lateral view of the

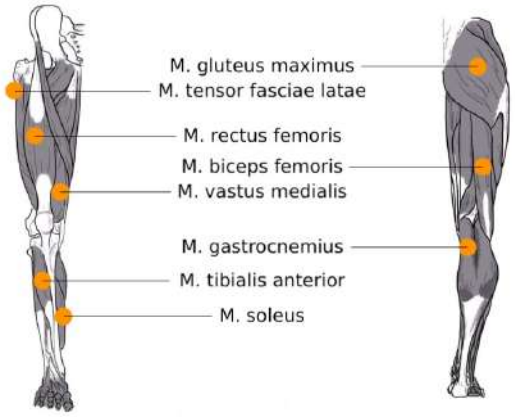

Fig. 2: sEMG sensor placement on major lower limb muscles. Abbreviations and muscle functions are provided in Table I.

TABLE I: Overview of Muscle Functions for all recorded muscles

Muscle	**Abbr.**	**Main function**
M. biceps femoris	BCF	hip extension, knee flexion
M. gastrocnemius	GAS	ankle plantarflexion
M. gluteus maximus	GLM	hip extension, external rotation and abduction, trunk extension
M. rectus femoris	RCF	hip flexion, knee extension
M. soleus	SOL	ankle plantarflexion
M. tensor fasciae latae	TFL	hip flexion, internal rotation and abduction
M. tibialis anterior	TA	ankle dorsiflexion, foot inversion
M. vastus medialis	VAS	knee extension

subject, while cam_2 has a frontal view of the subject. The videos are used to extract marker-less MoCap data through the MediaPipe Pose library, as described later in section II-B. To provide GT kinematic data, the participants were also recorded using a marker-based MoCap system (Qualisys, 31 markers, 11 cameras). The system is able to triangulate the 3D position of each marker with sub-millimeter precision. To quantify muscle activation timing and amplitude, surface electromyography (Delsys Trigno Avanti Sensor [16]) was used. The sensors were positioned on key muscles involved in squat movements, including the biceps femoris (thigh extension, pelvic extension), gastrocnemius (plantar flexion, slight calf flexion), and gluteus maximus (thigh extension, pelvic extension). An overview over the recorded muscles and the corresponding positions of the sEMG markers can be seen in Fig. 2, with a short explanation of their functions being given in Table I.

While the sEMG and MoCap data were recorded synchronously, the two sets of MoCap data extracted from the videos had to be synchronized to this data. To synchronize the three different joint position streams, an overall movement metric M was calculated by summing up the difference over the hip and shoulder joint coordinates between each frame. Although the pose data from all three recordings are represented in different coordinate systems, all three systems share a common axis that is vertical to the ground. This axis also corresponds to the direction with the largest range of movement, as all exercises are stationary. Therefore only this axis was considered when calculating M. The so-calculated movement metrics are normalized and correlated to determine the offset.

All participants voluntarily provided written informed consent before participation in this study. The study was conducted in accordance with the Declaration of Helsinki, and approved by the Ethics Committee of Technical University Darmstadt (protocol code EK 43/2023, date of approval: 11.07.2023).

B. MediaPipe Pose

We present a brief overview of the BlazePose model, which is utilized by MediaPipe and therefore serves as the baseline for the video-based motion capture. MediaPipe's output consists of x-y-z image coordinates of 33 different joint position. The x and y axis span the image plane, while the z axis is pointed perpendicularly away. The z-coordinate estimation is different than the estimation of the x- and y-coordinate as it is not located within the image plane. It is therefore less reliable as 3D pose estimation from monocular inputs presents an ill-posed problem, as multiple 3D predictions can correspond to the same 2D projection. MediaPipe addresses this issue by fitting their 2D projection to an internal model of a human [11]. The best fit is selected for depth estimation. We compare the 3D coordinates provided from MediaPipe both on the frontal and the lateral camera to the contact-based MoCap.

C. Motion capture and video processing

After running MediaPipe Pose on the two video streams, we receive three different sets of 3D Pose data: The GT MoCap data, the estimated data from the frontal camera and the estimated data from the lateral camera. All contain the positions of all relevant joints in a 3D world space. For each of these sets of joint positions, four different angles, relevant to the squat exercise were calculated, both for the left and right side of the body: The ankle angle connects middle toe, knee and heel. The knee angle connects hip, knee and heel. The hip angle connects shoulder, hip and knee. Finally, we define a symmetry angle that connects either the left or right shoulder to both knees. A visualization of the angles is shown in Fig. 3. The initial three angles were calculated using the three-dimensional coordinates, whereas the symmetry angle was projected onto the frontal plane (2D) in order to minimize the influence of noise.

From the angles, a series of features were extracted. To ensure comparability, we did not consider absolute angles, but instead focused on absolute angle change. Subsequently, the maximum angle change was extracted for each repetition. Additionally, for the two symmetry angles, the maximum difference between the left and right was extracted.

Fig. 3: Ankle, knee, hip and symmetry angles (from left to right).

D. sEMG Data Processing

The processing of the sEMG data involves the following stages: pre-processing, normalisation, feature extraction and methods for temporal adjustment and averaging.

In the preprocessing step, the data underwent filtering with a bandpass filter of the fourth order within the physiological spectrum with a low-cut frequency of 20 Hz and a high-cut frequency of 450 Hz. The data was then rectified and filtered once more with a second-order low-pass filter with a cutoff frequency of 6 Hz. It is important to consider that the amplitude of the sEMG is dependent on muscle properties, electrode placement, and the electrode-skin conductivity. Therefore, the signals were rescaled through a min-max-normalization.

As the data was recorded in sets of 10 repetitions, it was also necessary to split the data into the individual repetitions. For this, the sEMG signals were used. All muscles were examined in regards to noisiness, where a signal was considered to have low noise when the signal-to-noise (SNR) ratio was below 0dB. At least three muscles with low noise were selected per trial and then summed up to form one reference muscle. In this reference muscle, the initial and final timestamps of each repetition could be identified by a minimum in muscle activation. Since all other data streams were synchronized with the sEMG signal, the timestamps identified for the individual repetitions in the sEMG data could also be employed to divide the MoCap data. Additionally, the data was also normalized in length to 1,000 time steps per repetition through linear interpolation.

In the final step, several features were extracted. These included the peak amplitude (the maximum value of the filtered signal), the integral (total muscle activity) from the filtered and filtered plus normalised signals, and the mean and standard deviation for each muscle in each experiment.

E. Classification model

To analyze the meaningfulness of the different sensor modalities in general and the features specifically, we used two distinct sets of decision tree models to classify the different movement types. The first set of models was designed to identify the differences between the correct (as performed in E1) and incorrect (as performed in E2 and E3) execution of the squat. The second set of models was constructed with the objective of differentiating between experiments E1, E2, and E3, thus being more suitable to identify which specific errors were committed by the participants. Overall, from the three sensor modalities five groups of features were extracted. Group one and two consists of 16 features per repetition, namely the peaks and integrals of the sEMG signals of all 16 sensors, respectively. Groups three to five consist of 8 features each, namely the peaks of the knee, hip, ankle and symmetry angles of the contact-based MoCap, the contactless MoCap based on cam_1 and the contactless MoCap based on cam_2, respectively. An individual tree was trained, tuned and evaluated for each of these groups, as well as for combinations of feature groups.

The models were validated using a leave-one-out approach, whereby the model was trained on all subjects except one and then tested on the remaining subject.

III. RESULTS AND DISCUSSION

The initial stage of the analysis involved an exploratory visual examination of the sEMG data and the joint angles to see which sensor data might be a good predictor for bad exercise quality. Subsequent correlation analyses highlighted possible correlations between the characteristics of the various experiments and sensors, which indicates relation between the contact-based and contactless sensors. Finally, a decision tree model was trained to investigate which features and sensor combinations are particularly suitable for classifying movement errors.

A. Data Analysis

sEMG-Data: To gain an initial understanding of the data, a preliminary examination was conducted to identify any notable patterns in muscle activity. Fig. 4 shows typical results for subject S7 of the VAS and GLM, both for the right and left leg.

In E1 a symmetrical activation of all muscles was found, as exemplified in Fig. 4 for the VAS and GLM. In comparison to that, in E2 a general reduction in muscle activity, especially in the RCF and TA, accompanied by compensatory increases in activation of the hip muscles (GLM) was found. E3 reveals asymmetry in muscle activation, with the right-side muscles consistently showing higher activation levels than their left-side counterparts, most notably in the TFL and GLM.

MoCap-Data: While participants exhibited varying movement patterns, some showed more consistent movements, while others demonstrated greater variability across the different angles and trials. Fig. 5 shows typical results of a single participant with more consistent movement for the left knee angle, left hip angle and the symmetry angle difference. Even though general statements are not that easily made, some trends emerged with regard to the various angles and trials for all subjects.

The change in the ankle angle demonstrated consistent patterns with peak dorsiflexion occurring at 50 percent of the movement cycle. However, smaller peaks were observed in E2, and greater variance was evident in E3, which is likely attributable to balance issues. As anticipated, during the squat, the knee angle flexes, resulting in a positive angle change, and then extends, returning to its starting position. The most notable changes occur during the mid-cycle. In comparison to the results of E1, which demonstrated a correct movement pattern, E2 exhibited a reduced range of

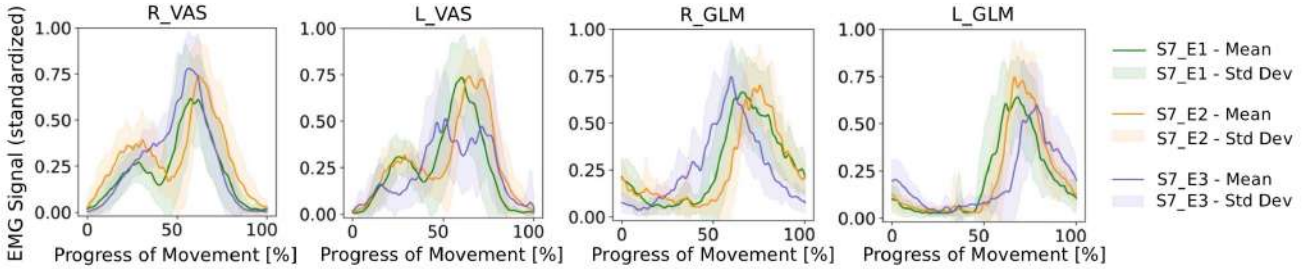

Fig. 4: Standardized sEMG signal of select muscles for subject S7, from left to right: right vastus medialis, left vastus medialis, right gluteus maximus, left gluteus maximus. Presented are the mean values and standard deviations over all 30 repetitions of each experiment.

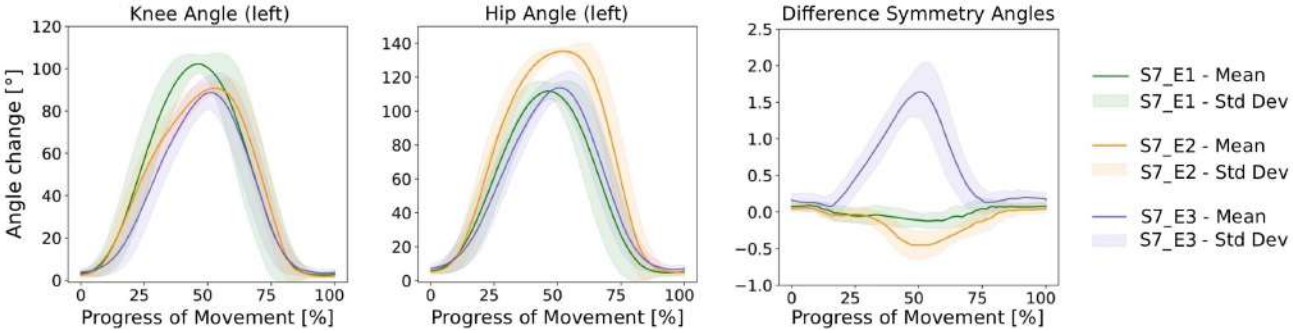

Fig. 5: Absolute angle change in degrees for subject S7, as calculated from the GT MoCap data. From left to right: left knee angle, left hip angle, difference between the left and right symmetry angles. Presented are the mean values and standard deviations over all 30 repetitions of each experiment.

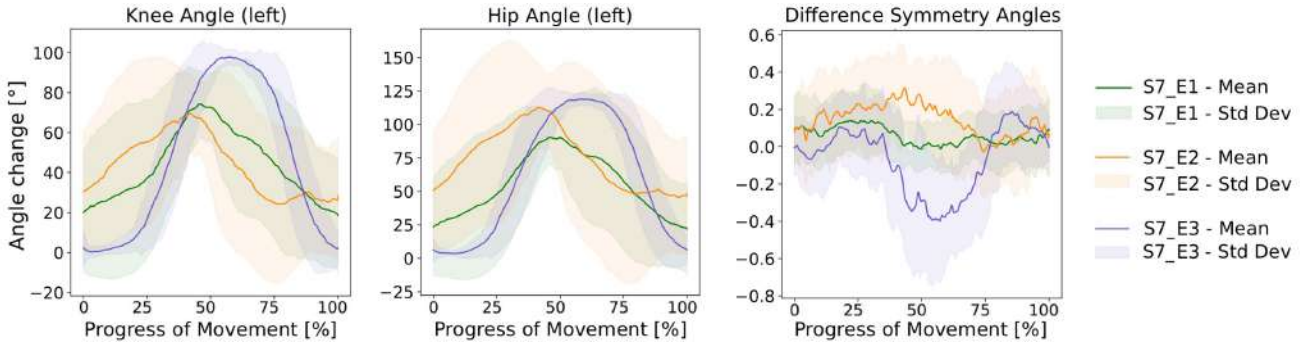
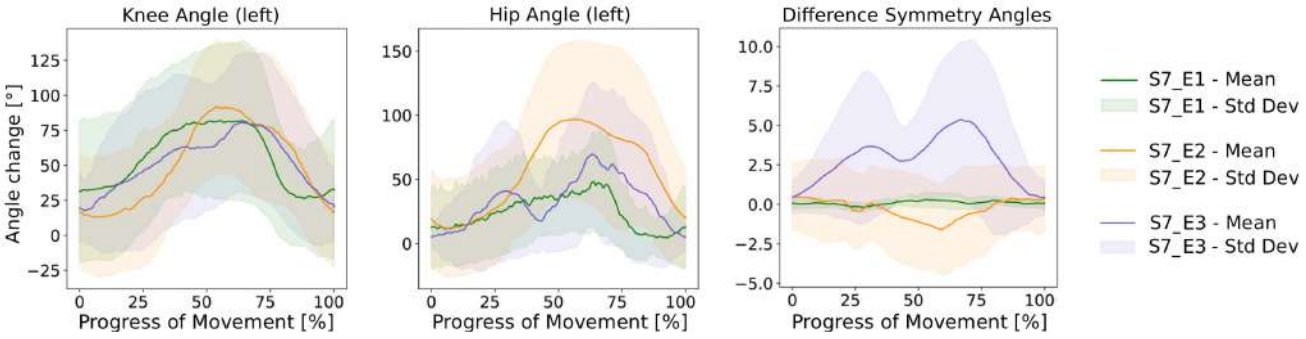
motion in the knee angle. In contrast, in E3, the range of motion on the right side was found to be greater than that on the left. The hip angle is connected to the knee angle; thus, in E2, the angle undergoes greater changes and reaches a higher peak due to the forward lean. Moreover, the asymmetry observed in E3 can be seen to manifest similarly in the hip angle. Regarding the symmetry angle, the difference remains nearly zero in Experiments 1 and 2. However, in E3, a noticeable difference emerges, with the right side showing significant asymmetry due to the side lean.

Marker-less MoCap: The marker-less MoCap data that can be seen in Fig. 6, exhibits comparable outcomes to those observed in the MoCap data, although certain constraints do exist. The data from the MediaPipe system demonstrates greater variability and is more susceptible to noise. Additionally, it exhibits lower peaks in general and irregular signal shapes. With regard to the perspectives, the two perspectives also display differences. While cam_1 (lateral view) is more effective at detecting movement in the sagittal plane, such as forward motions (E2), cam_2 (frontal view) is considerably more precise in detecting abduction/adduction and symmetry (E3). However, cam_2 is less reliable when limbs overlap, which happens at 50% of the movement cycle, when the squat reaches its lowest point.



B. Correlation Analysis

The objective of the correlation analysis was to examine the relationships between the various measurement parameters. In the initial phase of the analysis, a comparison was conducted between the muscle activation of different subjects in order to ascertain the degree of similarity in their performance across the experiment. The subject displaying the most consistent results (S7) was selected as the reference. In E1, a high correlation was observed for all muscles (median 0.85), with the exception of the GAS (0.11) and BCF (0.44). In Experiments 2 and 3, considerably weaker correlations were observed (median for E2 is 0.65 and for E3 is 0.72), indicating that when errors were made in the movement, the subjects exhibited individual compensation patterns.



A particularly intriguing aspect was the correlation comparison between specific muscles and joint angles. In this instance, four combinations were examined: VAS and RCF with the knee angles, and GLM with hip and symmetry angles. All correlation coefficients can be seen in Table II. No significant correlations (all correlations $\leq$0.4) were observed between GLM and hip/symmetry angles. Conversely, higher correlations were evident between both knee angles and VAS (mean correlation over all experiments of 0.67) and RCF (mean correlation over all experiments of 0.82) across all experiments. This suggests the potential to estimate muscle activity from camera-based kinematic observations.

C. Movement Classification

The results for the classification based on feature group 2 (integrals of sEMG signals) were very poor and are therefore excluded from the further analysis. For the remaining monomodal feature groups, the results of the binary classification

(b) cam_2 (frontal view)

Fig. 6: Comparison of absolute angle changes for subject S7, calculated from video-based MoCap extracted from cam_1 (lateral view) and cam_2 (frontal view). From left to right: left knee angle, left hip angle, difference between the left and right symmetry angles. Presented are the mean values and standard deviations over all 30 repetitions of each experiment.

TABLE II: Correlation coefficients between selected angles and sEMG signals, calculated for each Experiment.

Correlation	**E1**	**E2**	**E3**	**Mean**
Knee Angle (L), VAS (L)	0.60	0.73	0.42	0.58
Knee Angle (L), RCF (L)	0.81	0.79	0.77	0.79
Knee Angle (L), GAS (L)	-0.042	-0.12	-0.31	-0.158
Knee Angle (R), VAS (R)	0.64	0.77	0.85	0.755
Knee Angle (R), RCF (R)	0.82	0.81	0.90	0.84
Knee Angle (R), GAS (R)	-0.21	-0.27	0.22	-0.0867
Hip Angle (L), GLM (L)	-0.12	-0.13	-0.25	-0.1667
Hip Angle (R), GLM (R)	-0.22	-0.19	-0.28	-0.23
Symmetry Angle (L), GLM (L)	-0.17	-0.19	-0.25	-0.20
Symmetry Angle (R), GLM (R)	-0.28	-0.25	0.33	0.0267

(correct/incorrect) are given in Table IIIa. The table also shows the results for the combination of the features from cam_1 and cam_2. When evaluating the trees trained on these mono-modal feature groups, the trees trained on MoCap and sEMG peaks demonstrated the most optimal results, with the MoCap peaks also exhibiting the highest precision of all features. It can, therefore, be concluded that both are reliable to discern correct and incorrect movements. The results obtained from the MediaPipe angle peaks were found to be less reliable. It is noteworthy that cam_2 demonstrated superior performance compared to cam_1, indicating that the frontal view may be more advantageous in this context. The confusion matrices for the three-class-classification differentiating between error types, are given in Table IV. Overall,

TABLE III: Binary classification performance of the decision trees trained on feature groups 1 (sEMG peaks), 3 (MoCap angle peaks), 4 (cam_1 angle peaks) and 5 (cam_2 angle peaks) as well as combinations of the feature groups. *Mean* relates to the mean over all subjects, while MIN and MAX denote the lowest and highest value achieved for a single subject.

(a) Binary classification performance for mono-modal feature groups.

Feature	**sEMG**	**MoCap**	**cam_1**	**cam_2**	**cam_1 + cam_2**
F1-Score mean	0.80	0.90	0.59	0.77	0.81
F1-Score MIN	0.62	0.67	0.40	0.62	0.60
F1-Score MAX	0.91	1.00	0.75	0.89	0.98
Sensitivity mean	0.82	0.90	0.60	0.78	0.82
Specificity mean	0.79	0.90	0.56	0.75	0.81

(b) Binary classification performance for multi-modal feature group combinations.

Feature	**sEMG + MoCap**	**sEMG + cam_1**	**sEMG + cam_2**	**sEMG + cam_1 + cam_2**
F1-Score mean	0.89	0.79	0.86	0.81
F1-Score MIN	0.67	0.54	0.73	0.54
F1-Score MAX	1.00	0.95	0.99	0.98
Sensitivity mean	0.90	0.81	0.86	0.83
Specificity mean	0.89	0.78	0.86	0.80

this classification showed similar trends to the binary classification but performed consistently worse. However, we can

TABLE IV: Confusion matrices for different classification methods for the classification of the three experiments, aggregated over all subjects. Slight deviations in the absolute numbers occur because of minor errors by individual subjects like repeating one exercise eleven times instead of ten or stepping outside of the visible area of a camera.

(a) sEMG-Based Classification

		Predicted		
		E1	**E2**	**E3**
True	**E1**	217	59	25
	E2	51	203	45
	E3	26	65	208

(b) MoCap-Based Classification

		Predicted		
		E1	**E2**	**E3**
True	**E1**	223	71	7
	E2	46	234	19
	E3	10	0	289

(c) cam_1-Based Classification

		Predicted		
		E1	**E2**	**E3**
True	**E1**	122	46	133
	E2	49	177	73
	E3	119	46	124

(d) cam_2-Based Classification

		Predicted		
		E1	**E2**	**E3**
True	**E1**	203	70	28
	E2	64	201	28
	E3	23	30	226

gain some insights into what causes wrong classifications. For example, we can see that the classification based on the lateral view of cam_1 struggles with differentiating between E1 and E3. This is expected as the main difference between the two movements happens in the plane perpendicular to the camera.

In the subsequent phase, classification models were trained based on multiple feature groups, with a focus on multi-modal classification. Table IIIb shows the mean evaluation metrics over all leave-one-out iterations for these decision trees. This step resulted in an overall improvement in the performance of the model. In particular, the combination of the sEMG and MoCap peaks demonstrated a maximum F1-score of 1 and a mean F1-score across all subjects of 0.89. Additionally, the model was presented with both camera perspectives simultaneously, which also exhibited an improvement compared to the results with only one camera perspective. Due to the nature of monocular 3D pose estimation, this improvement is expected. However, combining the features of both cameras and the sEMG did not improve the results further. This might be explained by the high number of features, which might be too many for our rather small model to handle. Overall, our results suggest that the integration of muscle data with visual information can enhance the accuracy of the model.

IV. CONCLUSION

In response to the questions raised in the introduction, the following results were obtained: sEMG data displayed a high contribution to correctly identifying movement errors. For the squat, the vastus medialis and gluteus maximus were of particular importance. The results of the decision tree analysis shows that a multi-modal feature fusion improves error recognition further, when angle features are calculated from contact-based MoCap data. While results based on features calculated from camera data are overall worse, we could see the same improvement when combining these features with sEMG data. Overall, the angle features calculated on the contactless MoCap do not contribute as much, they still proved to contain additional information relevant for the task. We could also show correlation between different sensor modalities, indicating potential to derive muscle activity from joint angles. In further studies we want to investigate the possibility to fully replace contact-based sensors with contactless ones.

Estimating Thorax and Shoulder Motion Using Magnetic-Free Quaternion-Based Functional Sensor-to-Segment Calibration

Sergio A. Salinas, *Student Member, IEEE,* Mahshad Berjis, *Student Member, IEEE,*
Katarina Grolinger, *Senior Member, IEEE,* and Ana Luisa Trejos, *Senior Member, IEEE*

***Abstract*— Wearable rehabilitation robots rely on accurate sensing of body motion. While 9-axis inertial sensors are commonly used to measure motion, signal interpretation can be challenging for upper-limb rehabilitation due to complex and unpredictable joint movements. Other studies have addressed these inaccuracies by attaching three sensor units and using magnetometer data. However, these sensors are often used near actuators that produce ferromagnetic disturbances. Therefore, the objective of this work is to develop a methodology for estimating thorax and shoulder motion using only the orientation data from two sensors, estimated by the internal fusion of accelerometer and gyroscope data. The proposed methodology involves a functional sensor-to-segment calibration that includes performing Principal Component Analysis on the data obtained during specific functional movements to identify the primary axes of rotation. The calibration aligns the sensor coordinate system with the anatomical reference frame of the body segment. Furthermore, the methodology estimates the rotation between the global coordinate systems of the sensor units. Through an experimental evaluation and a comparison with a reference sensor system, the tracking error was 4.07°–5.14° for shoulder orientation and 1.28°–3.88° for thorax orientation. The results provide a solution for tracking thorax and shoulder motion, without using the magnetometer, supporting the development of upper-limb rehabilitation robots.**

I. Introduction

For wearable rehabilitation robots to function reliably, accurate sensing of body motion is essential. This is particularly important in upper-limb rehabilitation, where joint movements are complex and unpredictable [1], [2]. Biomechanical models paired with joint angle measurements, provide a means for detecting upper limb motion. These accurate joint measurements can then be used as inputs to rehabilitation robots, in order to support patients according to their needs.

Various techniques are available to measure joint angles. The traditional method involves using a goniometer to assess the range of motion. However, this approach is prone to human error and is not suitable for measuring movement when the body is in constant motion. Camera-based methods offer an alternative for measuring joint angles during dynamic movements. However, this method can be costly, restricts the patient to a specific location, and its accuracy is affected by marker occlusions [3]. Wearable sensors, on the other hand, enable the study of human biomechanics outside of the laboratory. Currently, inertial measurement units (IMUs) are the most commonly used and promising devices for measuring joint angles in wearable technology [3]. Unlike camera-based methods, which require users to remain in a monitored location, wearable sensors can be attached to the body without the need for external devices. This allows users to seamlessly engage in their regular activities [2].

IMUs are nine-degree-of-freedom sensors that typically include a tri-axial accelerometer, gyroscope, and magnetometer. When these components are used individually to reconstruct human movement, errors can arise: accelerometers are susceptible to noise, gyroscopes can drift over time, and magnetometers may be influenced by magnetic disturbances from closely placed metals and electronic devices such as laptops, cell phones, or actuators that form part of the wearable rehabilitation device [4]. To address these issues, sensor fusion algorithms—such as the Kalman-based filters [5] and Madgwick filter [6]—are commonly employed to integrate data from the different components.

Recent advancements in IMU sensors feature embedded processors that calculate quaternions as output. This built-in functionality allows developers to focus on enhancing other aspects of the system, as the latest fusion algorithms have become more reliable. Quaternions represent rotations in four-dimensional space, eliminating the gimbal lock problem associated with three-dimensional Euler angles [7]. Additionally, combining multiple rotations is more computationally efficient when using quaternions [2], which is beneficial for real-time applications.

A. Sensor-to-Segment Calibration

IMUs are available in a compact form that can be attached to a body segment of interest. However, mounting inertial sensors on the body presents additional challenges because, if the sensors are not properly aligned with the body's bony structures, the reconstruction of human biomechanics from inertial sensor readings can be inaccurate [3].

Sensor-to-segment calibration refers to the process of aligning the coordinate system of an IMU with the anatomical reference frame of the body segment to which it is attached [3]. Accurate sensor-to-segment calibration is essential for reliable biomechanical analysis, especially in rehabilitation, sports performance, and clinical assessment applications. If misalignments are not taken into account, the resulting data can lead to significant inaccuracies in movement reconstruction [7], [8].

In the literature, various assumptions for upper-limb sensor-to-segment alignments have been made. In some papers, the reconstruction assumes that the sensor is perfectly aligned with the body segment [3].

Although this assumption simplifies the reconstruction, fully aligning the sensor with the axis of the segment is almost impossible. Previous studies have shown that the alignment of the IMU sensor with the humerus on the upper arm is particularly difficult, causing the estimated shoulder angles to be inaccurate [8]. Another approach is using predefined static postures to calibrate the sensor to the segment [9]. However, this requires the participant to be exactly in the predefined poses. In reality, it is difficult to ensure that the participant can accurately hold multiple static postures.

B. Functional Calibration

Functional calibration is another method used for sensor-to-segment calibration, in which the participant's specific joint axes are estimated using the angular velocity during rotation around a known anatomical axis (e.g., elbow flexion, shoulder flexion). During functional calibration, the axis of rotation can be determined either by averaging the gyroscope values obtained from multiple repetitions [10], or by using Principal Component Analysis (PCA) [11]–[13]. PCA is a statistical method that identifies the direction of maximum variance in the data.

To find the anatomical axes, identifying two axes is sufficient, as the third axis can be determined by using the cross product of the first two axes, or by using the gravity vector. Mainly, functional calibration methods in the literature for finding the two axes generally fall into one of two categories: 1) using rotation around only one anatomical axis, combined with the gravity vector read from the accelerometer, to determine the longitudinal axis of the body segment [8], [14]; or 2) using two functional movements, which is possible if the joint has more than one degree of freedom.

Despite the feasibility of functional calibration, there is still a need to improve the sensor-to-segment calibration process for the shoulder, as most methods developed in the literature are either not applicable or have not been tested on complex joints. Instead, these methods are often designed for joints with two degrees of freedom, such as the elbow [15], or one degree of freedom, such as the knee [16].

C. Shoulder Motion Measurement

Shoulder rotation (humerothoracic angles), with three degrees of freedom, can be estimated based on the relative orientation of the thorax and upper arm. Therefore, to determine shoulder rotation, it is necessary to perform sensor-to-segment alignment for both the thorax and the upper arm (humerus) [7], [11], [17]. Several studies in the literature have performed functional calibration for both the thorax and the upper arm. In these studies, an additional sensor was placed on the forearm to measure elbow flexion, which was used to calibrate one of the humeral axes. This resulted in a total of three sensors used for shoulder angle estimation. Unless a model for the entire upper limb is required, this approach is inefficient. When only the shoulder and thorax are studied, two IMU sensors are sufficient to find the relative angles between the two segments.

Galinski et al. [10] proposed a framework in which only data from two IMU sensors located on the thorax and the upper arm were used for sensor-to-segment calibration. To identify two axes of the humerus, participants performed flexion–extension and abduction–adduction of the shoulder. However, for the thorax, the sensor was aligned using only a static pose. Since this method has only been tested on a benchmark setup, it is unclear how the misalignment of the thorax segment with the gravity vector was compensated. Additionally, most of the developed methodologies assumed that ferromagnetic disturbances from the devices were minimal. However, in applications of IMU sensors for robotic devices, this assumption may not hold, as the sensors are often located near metallic supports used in these devices. It is necessary to further assess whether the IMU sensor-to-segment alignment in the presence of ferromagnetic disturbances still allows for correct shoulder orientation estimation, especially for long-duration measurements [17], [18].

To address the aforementioned issues, the objective of this work is to develop a methodology for estimating thorax and shoulder orientations using magnetometer-free, functional sensor-to-segment calibration with two IMU sensors located on the thorax and the upper arm.

II. Methodology for Estimating Thorax and Shoulder Orientations

A diagram of the proposed sensor-to-segment calibration approach is presented in Fig. 1. The purpose is to calculate the misalignment between one sensor and its respective segment (${}^{Seg(i)}q_{S(i)}$) and the rotation between the global coordinate reference systems of two inertial sensors (${}^{WS(i-1)}q_{WS(i)}$), where the i–sensor is attached to the i–segment and the $(i-1)$–sensor is attached to the $(i-1)$–segment. $WS(i)$ represents the global coordinate reference systems of the i–sensor and $WS(i-1)$ represents the global coordinate reference systems of the $(i-1)$–sensor. The notation ${}^{k}q_{j}$ corresponds to a normalized quaternion that represents the orientation of frame j with respect to frame k.

This methodology can be applied to any pair of segments connected by a two/three-degrees-of-freedom joint, such that one sensor is placed on each segment and two one-axis functional movements are recorded. The anatomical axes of rotation are determined by applying PCA to the functional

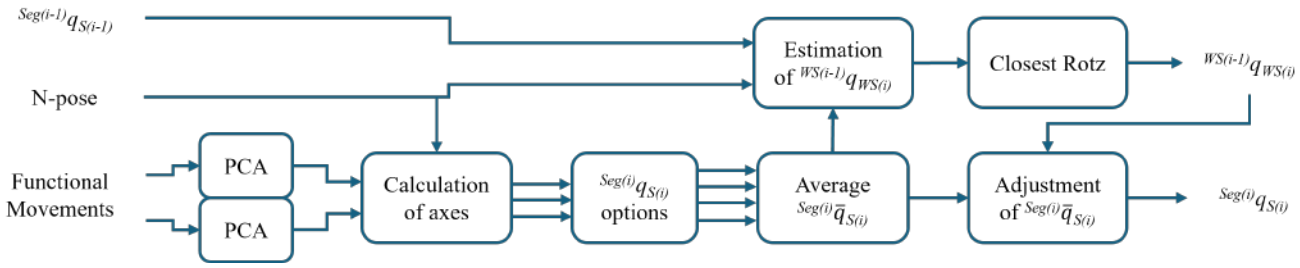

Figure 1. Sensor-to-segment calibration methodology proposed to calculate the misalignment between one sensor and its respective segment (${}^{Seg(i)}q_{S(i)}$), as well as the rotation between the global coordinate reference systems of two inertial sensors (${}^{WS(i-1)}q_{WS(i)}$), where the i–sensor is attached to the i–segment, while $(i\ /\ 1)$–sensor is attached to the $(i\ /\ 1)$–segment. Orientation data from the i–sensor, recorded during two one-axis functional movements of the i–segment and an N-pose, are used to calculate two axes of segment rotation through Principal Component Analysis (PCA). The N-pose data also help to determine the gravity vector observed by the i–sensor. Then, four options of ${}^{Seg(i)}q_{S(i)}$ are obtained using the two rotation axes and the gravity vector through orthonormalization via cross products. An average (${}^{Seg(i)}\bar{q}_{S(i)}$) of these four options, the misalignment between the $(i\ /\ 1)$–sensor and the $(i\ /\ 1)$–segment (${}^{Seg(i-1)}q_{S(i-1)}$), and orientation data from both sensors recorded during an N-pose, are used to obtain an initial estimation of ${}^{WS(i-1)}q_{WS(i)}$. The closest rotation around the z-axis of the sensors is used to refine this estimation. Finally, the result of ${}^{WS(i-1)}q_{WS(i)}$ is used to adjust ${}^{Seg(i)}\bar{q}_{S(i)}$, leading to a better estimation of ${}^{Seg(i)}q_{S(i)}$.

movement data. Similar to the approach described in the literature [16], [19], the angular velocity of the segment of interest is used to calculate the 3D vector around which the rotation occurs, corresponding to the first principal component ($PC1$) [16]. The angular velocity is estimated using quaternion data from the segment during one-axis functional movements. A third axis is computed using data from a static pose, such as the standing neutral pose (N-pose), with the arms neutrally placed alongside the body. Then, all of the possible combinations of misalignment orientation ${}^{Seg(i)}q_{S(i)}$ from the i–sensor to the underlying i–segment are identified. These combinations are averaged and then adjusted to finalize the sensor-to-segment calibration. The methodology was used in this study for estimating thorax and shoulder orientations.

A. Sensor-to-Thorax Calibration

The thorax is the first segment ($Seg1$) of interest with one inertial sensor attached to it. As shown in Fig. 2.a., the coordinate system (T), linked to the thorax, changes its orientation as a function of the thorax motion. Its z axis is the inferior–superior axis perpendicular to the transverse plane, the y axis is the anterior–posterior axis perpendicular to the frontal plane, and the x axis is the medio–lateral axis perpendicular to the sagittal plane. The orientation of T is measured with respect to a global reference coordinate system of the body (WT). This reference frame corresponds to the sagittal, frontal, and transverse planes when the participant is in an initial N-pose. The vertical axis pointing up is defined as the positive z axis, the sagittal axis from the back to the front of the body is defined as the positive y axis, and the frontal axis from left to right is defined as the positive x axis.

The IMU attached to the thorax is represented in Fig. 2.b by a box with a reference coordinate system ($S1$). The orientation of $S1$ is measured by this IMU with respect to its own global reference coordinate system ($WS1$). Data coming from this sensor is represented as ${}^{WS1}q_{S1}$. The z

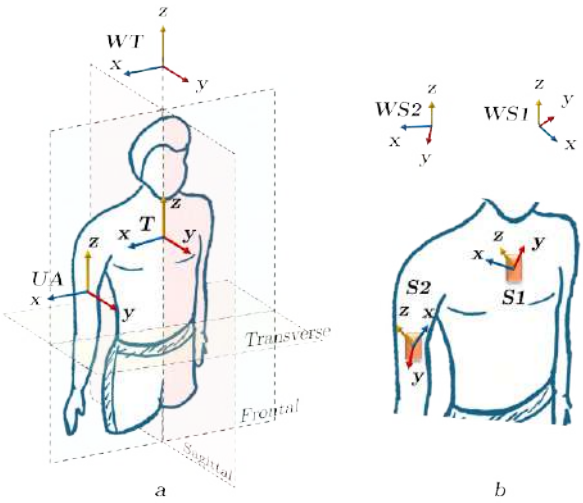

Figure 2. a. Body planes and axes of the global reference coordinate system of the body (WT) and the coordinate system (T) that moves with the thorax. b. Global reference coordinate systems of sensors ($WS1$, $WS2$) and the orientation of the thorax and upper arm sensors ($S1$ and $S2$).

axis of $WS1$ points against gravity; when the magnetometer is used, the y axis points towards the Earth's north, or when the magnetometer is not used, it points in another heading direction defined by the fusion algorithm built into the sensor [20]; finally, the x axis is computed by the same algorithm to obtain an orthonormal $WS1$.

1) Rotation axes: During functional thorax forward flexions (FF), mainly rotations around the x axis of T are expected. Similarly, large rotations around the y axis of T are expected during functional thorax lateral flexions and extensions (LFE). $S1$-orientation data collected during these functional movements are used to estimate the rotation axes of the thorax (v_{FF} and v_{LFE}, correspondingly). These axes correspond to the first principal component of PCAs, which is obtained using $S1$-orientation data. Because of the complexity of the human body structures and variations in the functional movements during the experiments, v_{FF} and

v_{LFE} are close to being aligned to the T axes, but they are not orthogonal.

2) Sensor-to-thorax misalignment options: These anatomical axes, and a third axis calculated using the z axis of $WS1$ (this axis is related to the gravity vector [20]), are used to produce four options for the sensor-to-thorax misalignment ${}^{T}q_{S1}$. As proposed by Vries et.al. [11], the thorax forward flexion axis v_{FF} and the gravity vector measured by $S1$ (g_{S1}) are used to produce the first option. g_{S1} is computed using the mean orientation of the $S1$ data while holding the N-pose (${}^{WS1}\bar{q}_{S1,Np}$), and the rotation of a vector through quaternion products [21], as shown in Equation 1.

$$[0, g_{S1}] = {}^{S1}\bar{q}_{WS1,Np} \otimes [0, z^{\mathcal{T}}_{WS1}] \otimes {}^{WS1}\bar{q}_{S1,Np}, \quad (1)$$

where ${}^{\mathcal{T}}$ represents transpose operation, $\otimes$ denotes the quaternion product, and $z_{WS1} = [0, 0, 1]^{\mathcal{T}}$ represents the z axis of $WS1$.

The first option of ${}^{T}q_{S1}$ is obtained by representing the rotation matrix ${}^{T}R_{S1,1}$ as a quaternion. The following equations are applied to build this matrix:

$$y_T = g_{S1} \times v_{FF}, \quad (2)$$

$$z_T = v_{FF} \times y_T, \quad (3)$$

$${}^{T}R_{S1,1} = \left[v_{FF}, \frac{y_T}{\|y_T\|}, \frac{z_T}{\|z_T\|} \right]^{\mathcal{T}}, \quad (4)$$

where y_T is an estimation of the y axis of T that is orthogonal to v_{FF}, z_T is an estimation of the z axis of T that is orthogonal to v_{FF} and y_T, $\times$ is a vector cross product, and $\|.\|$ represents the vector norm.

To compute the second option ${}^{T}R_{S1,2}$, a similar process is repeated but using v_{LFE} instead of v_{FF} and assuming it points in the direction of the y axis of the T coordinate frame, as shown by the following equations:

$$x_T = v_{LFE} \times g_{S1}, \quad (5)$$

$$z_T = x_T \times v_{LFE}, \quad (6)$$

$${}^{T}R_{S1,2} = \left[\frac{x_T}{\|x_T\|}, v_{LFE}, \frac{z_T}{\|z_T\|} \right]^{\mathcal{T}}, \quad (7)$$

where x_T is an estimation of the x axis of T that is orthogonal to v_{LFE}, and z_T is an estimation of the z axis of T that is orthogonal to v_{LFE} and x_T. Note that the result of this z_T is different from the z_T presented in Equation 3.

The third and fourth options, ${}^{T}R_{S1,3}$, ${}^{T}R_{S1,4}$, are calculated using only the rotation axes v_{FF} and v_{LFE}. Instead of using the gravity vector to estimate the z axis, a cross product between the anatomical axes is applied. For example, ${}^{T}R_{S1,3}$ is obtained with the following vectors being substituted on the right side of Equation 4:

$$z_T = v_{FF} \times v_{LFE}, \quad (8)$$

$$y_T = z_T \times v_{FF}. \quad (9)$$

These four options are used to compute the rotation average ${}^{T}\bar{q}_{S1}$, which is an estimation of the sensor-to-thorax misalignment ${}^{T}q_{S1}$.

3) Solutions for ${}^{T}q_{S1}$ and ${}^{WT}q_{WS1}$, and thorax orientation: Knowing that the orientation of T can be estimated using Equation 10, an estimation of ${}^{WT}q_{WS1}$ is calculated using ${}^{T}\bar{q}_{S1}$, the sensor data during the N-pose ${}^{WS1}\bar{q}_{S1,Np}$, and assuming that the thorax is approximately vertical during that N-pose so that ${}^{WT}q_T \approx [1, 0, 0, 0]$, which represents no rotation. The resulting equation for this estimation is shown in Equation 11.

$${}^{WT}q_T = {}^{WT}q_{WS1} \otimes {}^{WS1}q_{S1} \otimes {}^{S1}q_T \quad (10)$$

$${}^{WT}\hat{q}_{WS1} = [1, 0, 0, 0] \otimes {}^{T}\bar{q}_{S1} \otimes {}^{S1}\bar{q}_{WS1,Np} \quad (11)$$

Here, ${}^{WT}q_{WS1}$ is the constant rotation between the global reference coordinate systems of the thorax and its inertial sensor, ${}^{WS1}q_{S1}$ is a vector of quaternions that corresponds to the sensor orientation data, and ${}^{S1}q_T$ is the conjugate of ${}^{T}q_{S1}$, which is constant if the sensor is firmly attached during the measurements.

Due to the z axes of both WT and $WS1$ point up, ${}^{WT}q_{WS1}$ is a constant that corresponds to a rotation around those z axes. However, the first estimation of this rotation ${}^{WT}\hat{q}_{WS1}$ does not necessarily meet this constraint. Similar to Slade et.al. [22], the closest rotation about the z axis to this estimation is selected as the solution for ${}^{WT}q_{WS1}$. Using this result and manipulating Equation 11, ${}^{T}\bar{q}_{S1}$ is adjusted to obtain the solution for ${}^{T}q_{S1}$. With these two solutions, Equation 10, and data from the sensor ${}^{WS1}q_{S1}$, the thorax orientation is computed.

B. Sensor-to-Upper Arm Calibration

The upper arm is the second segment ($Seg2$). As shown in Fig. 2.a., the coordinate system (UA) linked to the upper arm changes its orientation as a function of the upper arm motion. Its z axis corresponds to the shoulder internal–external rotation axis, the y axis coincides with the shoulder abduction–adduction axis, and the x axis with the shoulder flexion–extension axis.

The IMU attached to the upper arm is represented in Fig. 2.b by a box with a reference coordinate system ($S2$). The orientation of $S2$ is measured by this IMU with respect to its own global reference coordinate system ($WS2$) and it is represented as ${}^{WS2}q_{S2}$. Same as $WS1$, the z axis of $WS2$ points against gravity; when the magnetometer is used the y axis points towards the Earth's north, or when the magnetometer is not used it points in another heading direction defined by the fusion algorithm integrated with the sensor [20]; and the x axis is computed by the same algorithm to obtain an orthonormal $WS2$. It is important to note that $WS1$ and $WS2$ have different orientations even when estimated using magnetometer data [7], [23]. However, the constant rotation between the global reference coordinate systems of the two inertial sensors ${}^{WS1}q_{WS2}$ is a rotation about their z axes.

1) Rotation axes: During functional shoulder flexions and extensions (FE), mainly rotations around the x axis of UA are expected. Similarly, large rotations around the y axis of UA are expected during functional shoulder abductions (Abd). $S2$-orientation data collected during these functional movements are used to estimate the rotation axes of the upper arm (v_{FE} and v_{Abd}, correspondingly). These axes correspond to the first principal component of PCAs, which is obtained using $S2$-orientation data. Because of the complexity of the shoulder and the variations in the functional movements during the experiments, v_{FE} and v_{Abd} are close to be aligned to the UA axes, but they are not orthogonal.

2) Sensor-to-upper arm misalignment options: The same procedure followed for the thorax is used to compute the four options for the sensor-to-upper arm misalignment ${}^{UA}q_{S2}$. The gravity vector g_{S2} is calculated using the mean orientation of the $S2$ data while holding the N-pose (${}^{WS2}\bar{q}_{S2,Np}$), and replacing the number 1 by 2 in Equation 1.

The first option of ${}^{UA}q_{S2}$ is obtained by representing the rotation matrix ${}^{UA}R_{S2,1}$ as a quaternion. The following equations are applied to build this matrix:

$$y_{UA} = g_{S2} \times v_{FE}, \tag{12}$$

$$z_{UA} = v_{FE} \times y_{UA}, \tag{13}$$

$${}^{UA}R_{S2,1} = \left[v_{FE}, \frac{y_{UA}}{\|y_{UA}\|}, \frac{z_{UA}}{\|z_{UA}\|} \right]^{\mathcal{T}}, \tag{14}$$

where y_{UA} is an estimation of the y axis of UA that is orthogonal to v_{FE}, and z_{UA} is an estimation of the z axis of UA that is orthogonal to v_{FE} and y_{UA}.

Note that Equations 12 to 14 are the same as Equations 2 to 4, replacing names and numbers of super- and sub-scripts. Therefore, the same approach is followed to find the second option ${}^{UA}R_{S2,2}$, using Equations 5 to 7, v_{Abd} instead of v_{LFE}, and g_{S2} instead of g_{S1}.

The third and fourth options, ${}^{UA}R_{S2,3}$, ${}^{UA}R_{S2,4}$ are calculated using the axes v_{FE}, v_{Abd}, and the estimation of the z axis of UA through the cross product $v_{FE} \times v_{Abd}$. The procedure is the same as explained in Section II-A.2 to find ${}^{T}R_{S1,3}$ and ${}^{T}R_{S1,4}$.

The four options of ${}^{UA}R_{S2}$ are used to compute the rotation average ${}^{UA}\bar{q}_{S2}$, which is an estimation of the sensor-to-upper arm misalignment ${}^{UA}q_{S2}$.

3) Solutions for ${}^{UA}q_{S2}$ and ${}^{WS1}q_{WS2}$, and shoulder orientation: The shoulder orientation is estimated as the relative orientation between the thorax and the upper arm [7], [24]. The following equation is used to calculate that orientation:

$$\begin{aligned} {}^{T}q_{UA} = {}^{T}q_{S1} \otimes {}^{S1}q_{WS1} \otimes {}^{WS1}q_{WS2} \\ \otimes {}^{WS2}q_{S2} \otimes {}^{S2}q_{UA}, \end{aligned} \tag{15}$$

where ${}^{S1}q_{WS1}$ is the conjugate of the $S1$ orientation ${}^{WS1}q_{S1}$, ${}^{WS2}q_{S2}$ is the $S2$ orientation, and ${}^{S2}q_{UA}$ is the conjugate of ${}^{UA}q_{S2}$.

One estimation of ${}^{WS1}q_{WS2}$ is calculated using Equation 16, the sensor-to-thorax misalignment obtained in Section II-A.3 (${}^{T}q_{S1}$), the rotation average ${}^{UA}\bar{q}_{S2}$, data of $S1$ orientation and $S2$ orientation during the N-pose (${}^{WS1}\bar{q}_{S1,Np}$ and ${}^{WS2}\bar{q}_{S2,Np}$, respectively), and assuming that the thorax is approximately aligned to the upper arm during that N-pose so that ${}^{T}q_{UA} \approx [1,0,0,0]$.

$$\begin{aligned} {}^{WS1}\hat{q}_{WS2} = {}^{WS1}\bar{q}_{S1,Np} \otimes {}^{S1}q_{T} \otimes [1,0,0,0] \\ \otimes {}^{UA}\bar{q}_{S2} \otimes {}^{S2}\bar{q}_{WS2,Np} \end{aligned} \tag{16}$$

This rotation ${}^{WS1}\hat{q}_{WS2}$ does not necessarily meet the constraint of being a rotation around z axis. Therefore the closest rotation about the z axis to this estimation is selected as the solution for ${}^{WS1}q_{WS2}$ [22]. Using this result and manipulating Equation 16, ${}^{UA}\bar{q}_{S2}$ is adjusted to obtain a final solution for ${}^{UA}q_{S2}$.

Finally, the shoulder orientation can be computed using the solutions from the sensor-to-thorax and the sensor-to-upper arms calibrations, the orientation of the sensors, and Equation 15.

C. Thorax and Shoulder Motion Representation

Although a quaternion approach is optimal for computing calculations, a more interpretable representation of thorax movements can be obtained by following the recommendations from the International Society of Biomechanics (ISB) for reporting human joint motion [24]. Accordingly, the Euler sequence XY'Z" was selected for thorax motion representation (please note that the x, y, and z axes used in this study correspond to z, x, and y axes, respectively, in the ISB convention).

In terms of shoulder angle representations, the ISB recommends the Euler sequence YX'Y" [24]. However, this sequence causes gimbal lock issues when the arm is around 0° or 90° abduction [25]. Therefore, an approach that switches between Euler sequences XY'Z" and YX'Z" was developed for representing shoulder angles. The first sequence was applied when the shoulder orientation presented a larger amplitude on the x axis. Rotations around this axis represent shoulder flexions and extensions (see Fig. 2.a). In contrast, the sequence YX'Z" was used when the shoulder orientation presented a larger amplitude on the y axis, since rotations around this axis represent shoulder abductions. In both sequences, the last rotation, i.e., the rotation around the z axis, represents shoulder internal and external rotations.

III. Experimental Setup

To test the performance of the proposed methodology, two sets of IMUs were placed on the participant's body. The first set used a BNO055-based system, which is inexpensive but able to calculate orientation in quaternions. To compare the accuracy, Xsens (Movella, USA) IMUs were also located on the same segments, as they have shown to have comparable results to the optical measurement systems [7].

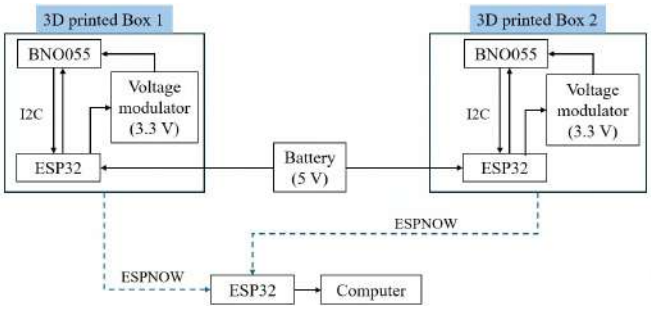

Figure 3. Block diagram of the system designed to capture IMU data. Solid lines represent the wired connections, and dashed lines represent the wireless connections.

A. BNO055-based system

The designed system included two small 3D-printed boxes; one to be placed on the thorax and the other on the upper arm. Both of the boxes had the same source of power from a 5-Volt battery that was placed on the back of the participant. Each box included a BNO055 sensor wired to an ESP32 microcontroller to receive and transfer sensor data using I2C communication. Data were captured at a sampling frequency of 60 Hz. To provide participants with greater mobility, a receiver ESP32 was connected to the lab computer, and the sensor readings were wirelessly transmitted to the lab computer using the peer-to-peer communication protocol of the ESP32 microcontrollers, ESP-NOW [26]. This method was selected for its suitability in transmitting small data packets, such as sensor readings, while maintaining low power consumption.

Fig. 3 illustrates the components used in this system and how they were connected. The BNO055 is a nine-degree-of-freedom absolute orientation IMU breakout board with built-in fusion algorithms. It offers various operating modes that allow the inclusion or exclusion of measurements from the gyroscope or magnetometer. In this study, to ensure that the quaternion outputs were based solely on accelerometer and gyroscope readings (*i.e.*, magnetometer data were not used in the quaternion calculation), the BNO055 was configured to operate in "IMU mode" [21]. Before placing the sensors on the body, both sensors were attached to a flat board to perform the calibration procedure as recommended by the manufacturer [20].

B. Xsens Motion Capture System

The Xsens system used for this experiment included wireless sensor units (called MTw, and composed of a 3D accelerometer, a 3D gyroscope, and a 3D magnetometer) and a data acquisition system (Awinda station), where the data of the sensors were synchronized at a sampling frequency of 60 Hz and sent to the host computer. This system was calibrated according to the procedure explained in the manual [27]. The Xsens sensors were stabilized by keeping them static on a desk once they were put into measurement mode.

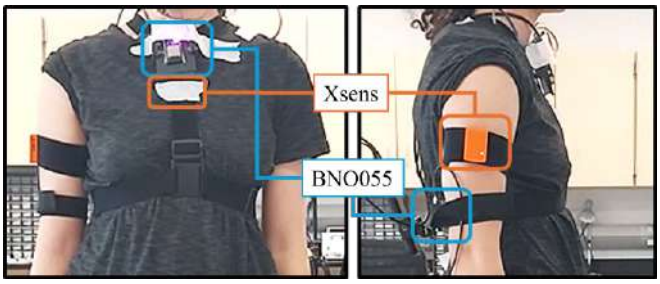

Figure 4. Placement of the inertial sensors from the two systems.

C. Data Recording

As shown in Fig. 4, one sensor of each system was placed on the sternum for tracking the thorax orientation and another sensor was used for tracking the upper arm, with the Xsens strapped to the lateral medial side and the BNO055 strapped to the posterior distal side. Orientation data were simultaneously collected by both systems while the participant stood in a static N-pose (shown in Fig. 2) for ten seconds, followed by ten functional movement repetitions of the thorax or upper arm. The thorax movements were forward flexions and lateral flexion–extensions; whereas, the upper arm movements were consequences of shoulder flexion–extensions and shoulder abduction–adductions.

IV. Results

The sensor-to-thorax and the sensor-to-upper arm calibrations were performed using the data collected during the experiment. The same methodology was applied to both systems (Xsens and BNO055). Then, the solutions for ${}^{WT}q_{WS1}$, ${}^{T}q_{S1}$, ${}^{WS1}q_{WS2}$, and ${}^{UA}q_{S2}$, were replaced into Equations 10 and 15 in order to calculate thorax and shoulder angles, as described in Section II-C. The root-mean-square error (RMSE) was used to report the differences in the resulting angles for the thorax and shoulder.

A. Thorax Motion

As shown in Fig. 5, patterns of thorax angles from both systems are comparable. The RMSEs were 3.88° in the forward flexion axis, 1.28° in the lateral flexion–extension axis, and 1.93° in the rotation axis.

B. Shoulder Motion

The results for the shoulder angles are shown in Fig. 6. It shows the decomposition of the shoulder orientation in flexion–extension, abduction, and internal–external rotations. As in the thorax, the patterns of the results from both systems are comparable. The RMSEs were 4.11° in the flexion–extension axis, 4.07° in the abduction axis, and 5.14° in the rotation axis.

V. Discussion

The sensor-to-segment alignment calibration presented in this paper was applied to the thorax and upper arm body segments to estimate the thorax and shoulder orientations. In this work, comparable results were obtained from angles estimated using the magnetometer-free system developed

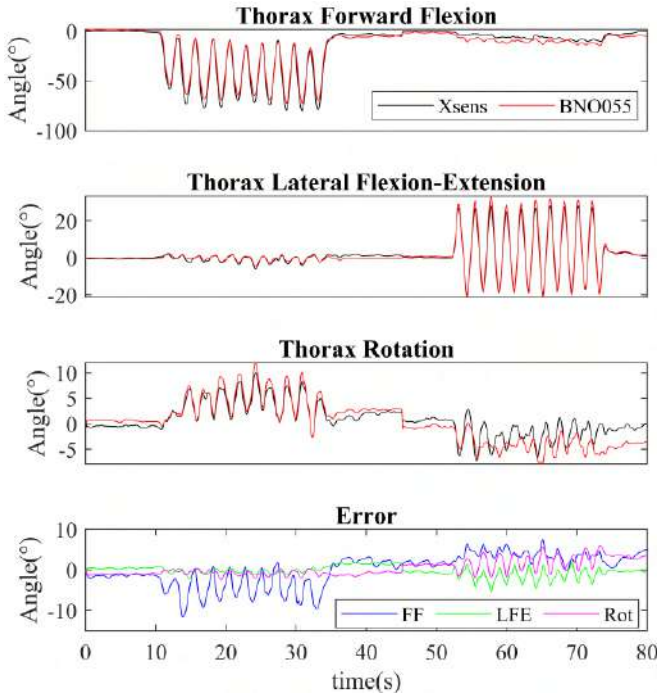

Figure 5. Comparison of the thorax motion angles obtained from both systems (Xsens and BNO055). FF: thorax forward flexion, LFE: thorax lateral flexion–extension, and Rot: thorax rotation.

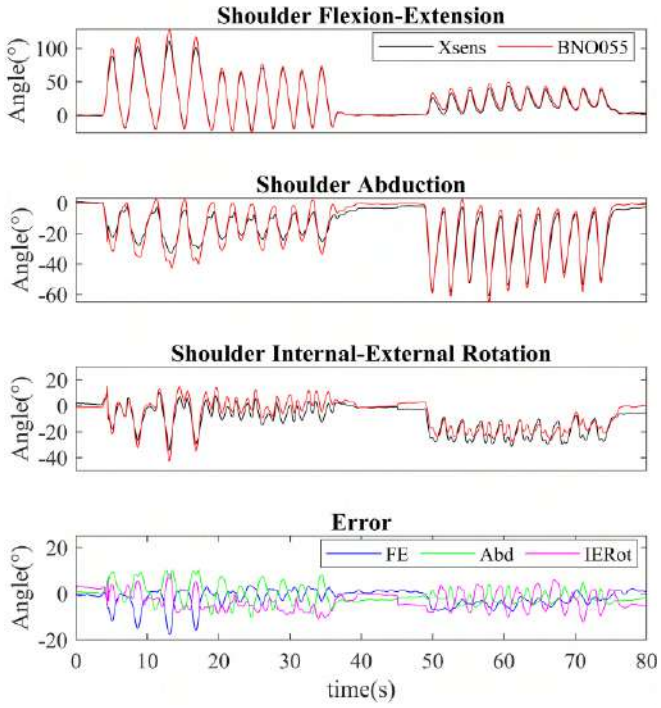

Figure 6. Comparison of the shoulder motion angles obtained from both systems (Xsens and BNO055). FE: shoulder flexion–extension, Abd: shoulder abduction, and IERot: shoulder internal–external rotation.

TABLE I

COMPARISON OF RMSE VALUES WITH SIMILAR STUDIES

	Thorax			Shoulder		
	FF	**LFE**	**Rot**	**FE**	**Abd**	**IERot**
Li. et. al. [18]	1.21°	0.76°	2.09°	3.5°	3.76°	5.44°
Zhu. et. al [7]	-	-	-	6.4°	3.8°	2.8°
This work	3.88°	1.28°	1.93°	4.11°	4.07°	5.14°

with BNO055 sensors and those obtained using the Xsens system, which included a magnetometer. Avoiding the use of the magnetometer is especially important when integrating sensors with wearable soft robots for rehabilitation applications, as the proximity of the sensor to the robot would cause interference with the orientation estimations.

A significant benefit of the proposed approach is that the methodology can be performed using only sensor orientation data. This is useful when the fusion algorithm integrated with the IMU sensors performs the sensor orientation estimations.

The estimated thorax and shoulder angles in this study were compared with other methodologies in the literature (summarized in Table I). Zhu et al. [7] utilized a third sensor on the forearm to estimate the humerus transverse axis during the functional movement of elbow flexion–extension. They used all three components of the IMU, assuming the readings were unaffected by magnetic disturbances. Compared to Zhu et al.'s methodology, the method proposed here achieved a similar RMSE for Abd estimation but had a 2° lower error in FE estimation. However, the method proposed in this paper showed a higher error in internal–external rotation (IERot) estimation. This higher error can be due to soft tissue artifacts [28], or that the wires from the BNO055 battery created variable torque, which was not present in the Xsens system.

Li et al. [18] excluded the magnetometer from their measurements and proposed a sensor-to-segment calibration combining one camera with IMUs to compensate for heading errors. The methodology proposed in this paper achieved comparable RMSE for all shoulder angle estimations, LFE, and thorax axial rotation (Rot). However, the error for FF was about 2° higher. This higher error was potentially caused by the BNO055 sensor moving during the FF, while the Xsens sensor remained stationary as it was taped directly to the skin.

VI. CONCLUSION

This study introduces a novel methodology for angle estimation using a magnetometer-free, low-cost system with two IMU sensors that measure thorax and shoulder angles. A significant advantage of this approach is its reliance solely on gyroscope and accelerometer data, making it more robust in environments with magnetic disturbances. The use of PCA for functional calibration ensures that the sensor coordinate system is accurately aligned with the anatomical reference frame of the body segment, thereby improving the accuracy of motion estimation.

The experimental results demonstrated that the proposed system could achieve comparable accuracy to a high-end

Xsens system, with RMSEs of 4.07°–5.14° for shoulder orientation and 1.28°–3.88° for thorax orientation. These results highlight the potential of the proposed methodology to provide reliable motion tracking without the need for magnetometers and based on only two sensor units.

Future work should focus on several key areas to further enhance the performance and applicability of the system. First, improving the attachment of IMU sensors to the body will help reduce movement artifacts and improve measurement accuracy. Also, expanding the experimental evaluation to include a larger and more diverse participant pool and adding more complex tasks, such as dynamic exercises and activities of daily living, will provide a more comprehensive assessment of the robustness and generalizability of the system. Additionally, comparing the estimated angles with the optical motion capture systems that are considered the "gold standard" will be essential. The next steps will be to integrate this system with wearable rehabilitation robots and conduct long-term studies.

The proposed magnetometer-free, quaternion-based functional sensor-to-segment calibration method represents a significant advancement in the field of wearable motion tracking. By providing accurate and reliable motion estimation with a low-cost and robust system, this methodology has the potential to enhance the development and deployment of upper-limb wearable rehabilitation robots, ultimately improving patient outcomes and advancing the area of rehabilitation technology.

ACKNOWLEDGEMENT

The authors thank Dr. Michael Naish and Niloufar Ahmadian for sharing some equipment used in the trials, as well as other members of the Wearable Biomechatronics Laboratory. Deep-Learning Control of Lower-Limb Exoskeletons via simplified Therapist Input

Lorenzo Vianello[1], Clément Lhoste[2], Emek Barış Küçüktabak[7], Matthew R. Short[1,4], Levi Hargrove[5,6], Jose L. Pons[1,3,4,6]

***Abstract*— Partial-assistance exoskeletons hold significant potential for gait rehabilitation by promoting active participation during (re)learning of "normal" walking patterns. Typically, the control of interaction torques in partial-assistance exoskeletons relies on a hierarchical control structure. These approaches require extensive calibration due to the complexity of the controller and user-specific parameter tuning, especially for activities like stair or ramp navigation. To address the limitations of hierarchical control in exoskeletons, this work proposes a three-step, data-driven approach: (1) using recent sensor data to probabilistically infer locomotion states (landing step length, landing step height, walking velocity, step clearance, gait phase), (2) allowing therapists to modify these features via a user interface, and (3) using the adjusted locomotion features to predict the desired joint posture and model stiffness in a spring-damper system based on prediction uncertainty. We evaluated the proposed approach with two healthy participants performing treadmill walking and stair ascent/descent at varying speeds, with and without external modification of the gait features through a user interface. Results showed a variation in kinematics according to the gait characteristics and a negative interaction power (-2.1 $\pm$ 1.6W for the hip and -0.6 $\pm$ 1.4W for the knee joints) suggesting exoskeleton assistance across the different conditions.**

I. Introduction

Lower-limb exoskeletons are valuable tools in rehabilitation for individuals with gait impairments. Clinically, these exoskeletons can be classified into two categories: full-assistance and partial-assistance [1]. Full-assistance exoskeletons are intended for patients with significant motor impairments who cannot ambulate independently, providing fully autonomous leg movement without requiring user input. They are usually controlled using position control strategies [2]. In contrast, partial-assistance exoskeletons are more appropriate for patients with mild to moderate impairments, as they support movement while still requiring the patient's active participation [3].

This paper focuses on partial-assistance exoskeletons, which have greater potential in rehabilitation settings as they consider the patient's volitional movements in the control loop. These exoskeletons use approaches like haptic guidance [4] or resistance through error augmentation [5] to promote the (re)learning of walking patterns, depending on the patient's functional ability.

Both of these strategies, assistance and resistance, depend significantly on the control of interaction torques between the user and the exoskeleton. This is typically achieved through a hierarchical structure comprising high-, mid-, and low-level controls [6]. High-level control determines desired interaction torques for specific activities, such as walking on flat surfaces, stairs, or ramps. Mid-level control estimates various states within an activity, like swing and stance phases during walking, and adjusts the desired interaction torque accordingly [7]. Finally, low-level control compensates for the exoskeleton's dynamics and generates motor commands based on the profiles selected in high- and mid-level control.

To provide patients partial-assistance during ambulatory activities, desired interaction torques are typically rendered using virtual springs and dampers, characterized by stiffness and damping parameters, which are attached to reference joint positions. This necessitates the identification of many control parameters specific to each activity and phase of locomotion. As many of these parameters are also user-dependent, this can result in lengthy calibration periods for a single session of therapy. This issue has been well-documented for active prosthetic devices [8], but few studies have quantified the time spent calibrating lower-limb exoskeleton controllers. This is likely due to a reliance on predefined trajectories for generating exoskeleton assistance profiles, which reduces the time and complexity of parameter selection, but limits the degree of parameter customization for individual users. Moreover, most research has concentrated on overground walking, with minimal investigation into scenarios involving stairs and ramps [1].

One potential solution to reduce controller complexity and calibration time is to employ data-driven methods that relate sensor readings with command outputs [9]–[11]. However, these approaches offer limited flexibility for personalization and adjustment of desired behaviors. For example, a therapist may require a progressive increase in foot clearance for a patient during a session of training. Additionally, therapists do not typically conceptualize adjustments in terms of gait cycle kinematics (e.g., trajectories or stiffness/damping parameters). Instead, they focus on clinically relevant features that are easier to interpret, such as step length, time, speed, or height.

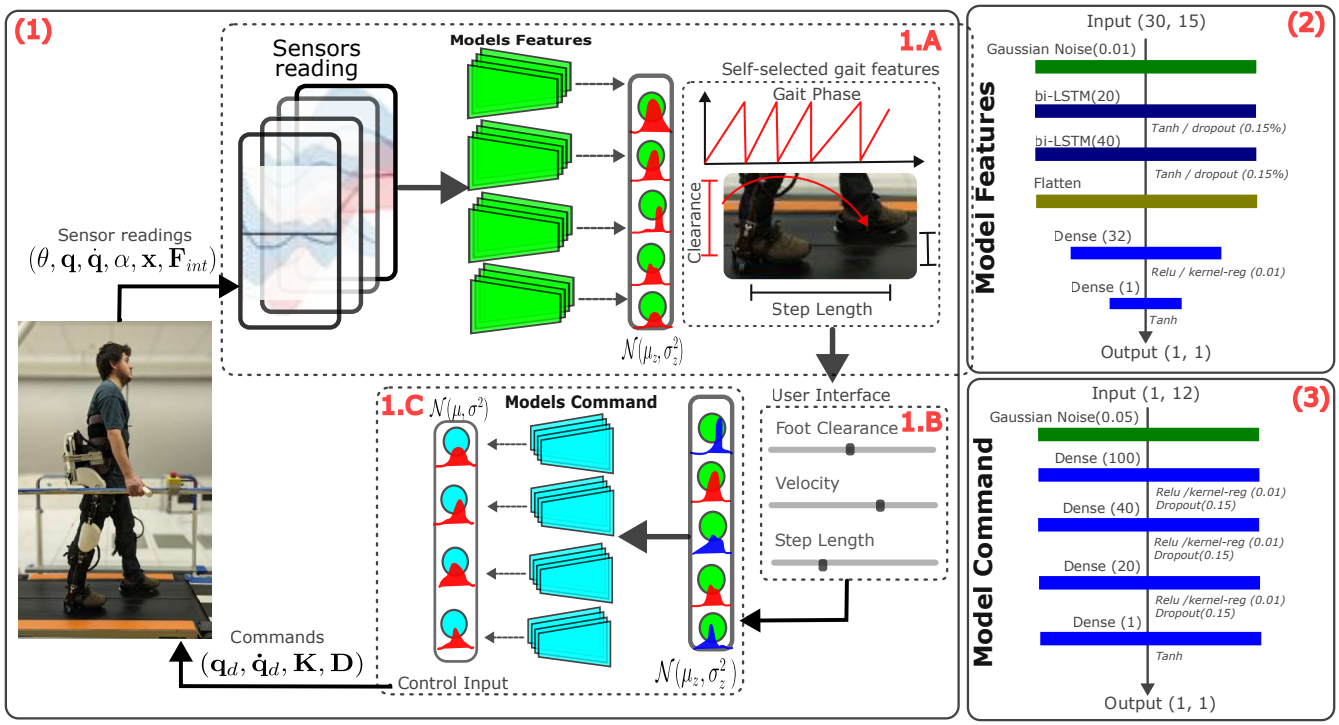

Fig. 1. (1) Data-driven controller:(1.A) Sensor readings are passed to multiple deep-learning models to estimate representative features of the walking pattern. Thes resulting features are fitted to a normal distribution to consider the uncertanty of the locomotion pattern; (1.B) User interface allows to modify the self-selected locomotion features to allow the therapist to adapt the locomotion depending on the needs of each patient; (1.C) The resulting modified features are passed to a combination of models to regress the desired joint configuration of the exoskeleton. At the same time, the uncertainty of the prediction is propagated and used to model the stiffness of the impedance controller of the exoskeleton. Impedance parameters are passed to the low-level controller of the exoskeleton as commanded input. (2) Structure of the feature extractors models. (3) Structure of the command predictor models.

For this reason, in this work, we propose a three-step data-driven approach to substitute the hierarchical structure of an exoskeleton controller (Fig. 1). In step (1) we probabilistically regress a short-term history of sensor readings (encoders, force sensors, foot-plate sensors) with a minimal set of clinically relevant gait features, namely step length, and height (to distinguish across ascending/descending surfaces), walking velocity, step clearance, gait phase; in step (2) we allow an operator (e.g., a physical therapist) to modify the self-selected gait features using a user interface and, finally in step (3) we probabilistically regress the current locomotion features to the desired joint posture of the exoskeleton, using prediction uncertainty to model the impedance in a spring-damper system connecting the user and exoskeleton.

II. METHODS

In this section, we present the structure of the proposed approach. In Sec.II-A, we present the hardware used. In Sec. II-B, we present how we collected data for training the deep-learning models. In Sec. II-C, we define the structure of the two consecutive models implemented to regress sensor readings and gait features and, subsequently, gait features with command inputs. Finally, Sec. II-D presents the real-time use of the proposed approach and the walking tests performed for validation.

A. Exoskeleton

We validated the proposed approach on a commercially available lower-limb exoskeleton (ExoMotus-X2, Fourier Intelligence, Singapore). The exoskeleton system has four active degrees of freedom (DoF) bilaterally at the hip and knee, and two passive DoFs at the ankle (Fig. 1). The following sensors are used to monitor both the exoskeleton's state and its interaction with the user [12]: joint encoders measure the positions of the knee and hip angles (θ) while strain gauges estimate interaction torque (τ_{int}) at each joint. An Inertial Measurement Unit (IMU) on the backpack measures the orientation of the trunk (θ_{bp}), while force-sensitive resistor (FSR) footplates measure ground reaction forces to quantify the weight distribution of the user (α). Communication between motors and sensors is achieved using CAN protocol. The controller is implemented on a ROS and C++ based open-source platform called the CANOpen Robot Controller (CORC) [13]; motor torque commands and sensor readings were updated at 333 Hz. The exoskeleton was controlled using an impedance controller that models the desired interaction torque passed to the exoskeleton internal controller, described in [12]:

$$\tau_{\text{int}}^{*} = K(\boldsymbol{\theta} - \boldsymbol{\theta}_d) + D(\dot{\boldsymbol{\theta}} - \dot{\boldsymbol{\theta}}_d), \tag{1}$$

where $K, D, \boldsymbol{\theta}_d, \dot{\boldsymbol{\theta}}_d$ are respectively the stiffness, damping, and the reference position and velocities returned by the data-

driven controller as discussed in Sec. II-D.

B. Data collection and processing

We collected data from nine healthy participants (5 males, 4 females, age 29.8±6.8, height 1.74±0.08 m, weight 70±10.6 kg) to train the deep-learning model. The Institutional Review Board of Northwestern University approved this study (STU00212684), and all procedures followed the Declaration of Helsinki. Participants performed various ambulatory activities while wearing the exoskeleton in two different controller conditions: haptic transparency (i.e., no assistance) [12] and state machine approach (i.e., non-zero assistance). In the state machine approach, the high-level controller was modeled using a remote (to switch between walking, ramps, or stairs). In the middle-level controller, the locomotion activities were split into four phases (early-stance, late-stance, early-swing, late-swing). For each of these phases, an equilibrium angle was selected and passed to an impedance controller. For each controller condition, participants performed five repetitions of overground walking (6 meters), three repetitions of stairs and ramps, both ascending and descending.

Data was processed offline to extract the *gait-phase* ($\boldsymbol{gp}$) for both legs, a continuous value from $[0, 100]$ indicating progression between consecutive heel strikes. To consider the periodicity of the gait phase, we transformed this value to its polar representation ($\boldsymbol{c}^{gp} = \cos(2\pi\frac{\boldsymbol{gp}}{100}), \boldsymbol{s}^{gp} = \sin(2\pi\frac{\boldsymbol{gp}}{100})$) [14]. The horizontal and vertical foot position relative to the stance foot ($x_k, z_k | k \in [0, 100]$) was calculated via forward kinematics and used to estimate descriptive features of the gait for each stride. The following features were extracted: landing step-height, landing step-length, step-clearance, and step-velocity. *Landing step-height* ($\boldsymbol{h}$) is the vertical position of the forward foot at the end of the stride ($\boldsymbol{h} = z_{100}$), this feature changes significantly when transitioning to a new locomotion mode (e.g. from overground walking to stairs) and is positive in the case of ascending and negative in descending strides. *Landing step-length* ($\boldsymbol{l}$) is the horizontal position of the forward foot at the end of the stride ($\boldsymbol{l} = x_{100}$) and represents the distance of the performed stride. *Step clearance* ($\boldsymbol{c}$) is the maximum vertical position reached from the feet during the stride $\boldsymbol{c} = \max_{[0,100]}(z_k)$. *Step-velocity* ($\boldsymbol{v}$) is the ratio between the step-length and the time required to execute the step ($\boldsymbol{v} = \frac{x_100}{\Delta t}$). All of these features were calculated for both the left and right gait phases. Robot state $\boldsymbol{q} = (\theta, \dot{\theta}, \theta_{bp}, \tau_{int}, \alpha, x_{l,r}, z_{l,r})$ and gait features $\boldsymbol{f} = (\boldsymbol{c}^{gp}_{l,r}, \boldsymbol{s}^{gp}_{l,r}, \mathbf{h}_{l,r}, \mathbf{l}_{l,r}, \mathbf{c}_{l,r}, \mathbf{v}_{l,r}) \in \mathbb{R}^{12}$ were normalized and sampled to convert from the data logging frequency to 100 Hz. Following these procedures, all data were divided in time windows of 300 ms [15] with a step size of 50ms.

C. Machine Learning Controller

In this section, we will present the two ML-based models designed to reduce the complexity of the hierarchical structure. The controller uses a data-driven approach to extract locomotion parameters representing a normative population without additional calibration procedures. Moreover, it allows therapists to modify movement execution in real-time, allowing safer and more structured adaptability to the specific needs of each patient.

Our approach is based on two consecutive neural networks (NN): (1) a Features Extractor Model (FEM), and (2) a Command Predictor Model (CPM). Both models provide probabilistic estimates of the output, enhancing the predictions with information about the associated uncertainty.

a) Features Extractor Model: Our FEM (Fig. 1.1.A) is based on two bidirectional Long Short-Term Memory (bi-LSTM) networks. The model uses a time window W of robot states ($x_1(t) = [\boldsymbol{q}_{t-T_W}, ..., \boldsymbol{q}_{t-t_1}, \boldsymbol{q}_t]$) as input and returns the current features representation of the step $y_1(t) = \hat{\boldsymbol{f}}_t$ as an output. These features represent the current locomotion intention of the user wearing the exoskeleton; we define them as *self-selected* to distinguish them from those selected by the therapist.

The architecture of the FEM is displayed in Fig. 1.A: the model receives a time-window W of dimension 30 of sensor readings and foot positions with a resulting dimension of the input $(30, 15)$. Gaussian noise (standard deviation of 0.01) is used in the first layer to introduce variability to the input data (x_t), allowing better generalization. Two bi-LSTM layers allow the model to learn dependencies between the different time steps in the window of data. The output of the second bi-LSTM model is flattened and passed to two consecutive dense layers that transform the features extracted from the bi-LSTMs to a single value representing each feature independently. A *Tanh* activation function is used to bound features in the range of $[-1, 1]$. Each feature is regressed using an independent model to avoid correlation across features. Hyperparameters were selected using a heuristic approach. The model was trained with the ADAM optimizer, employing the MSE loss function to quantify and minimize the difference between the predicted and actual values. Training proceeded for 100 epochs with early stopping, using batches of 256 samples.

b) Command Predictor Model: The second model (Fig. 1.1.C) receives as input the ground truth features extracted as described in Sec. II-B ($x_2(t) = \boldsymbol{f}_t$) and returns the expected joint kinematics $y_2(t) = (\hat{\boldsymbol{\theta}}_t, \hat{\dot{\boldsymbol{\theta}}}_t)$ as an output. Data augmentation was applied before training by weighted interpolation of both features and kinematics based on the features' Euclidean distances to create a more evenly distributed feature space. For example, we interpolated features from stair ascending and overground walking to generate intermediate feature values, such as moderate step heights.

The structure of the Command Predictor Model is displayed in Fig. 1.C. The model receives input of dimensionality $(1, 12)$ containing the current features and applies Gaussian noise (standard deviation of 0.01) in the first layer to introduce variability. Then, four consecutive dense layers with reduced dimensions, dropout, and kernel regularization transform the features to a single value representing either the joint position or velocity. Also, in this case, a *Tanh* activation function is used to bound the output in the range of $[-1, 1]$

and then rescaled in the same domain of the kinematics values. Each feature is regressed using an independent model to avoid correlation across features. Hyperparameters were selected using a heuristic approach. A training procedure similar to those of the Feature extraction models was applied.

c) Probabilistic estimation: To have a probabilistic estimation in both layers of the process, six independent NN were trained in parallel using six randomly selected subsets of users. This allows us to estimate and utilize the uncertainty of the predictions. For instance, in the early phases of the swing movement, there will be more uncertainty about the resulting foot placement, resulting in uncertainty in the joint kinematics. With a probabilistic estimation of the features followed by the kinematics, we can model this uncertainty. To propagate the uncertainty across the two phases, we used a Monte-Carlo approach similar to [16]: the normal distribution is used to randomly sample N values from the distribution which are passed to the model as a unique batch; the batch of output was fitted to a normal distribution and propagated to the next step of the framework.

All models presented were trained using TensorFlow (v2.15.0, Google) and converted to TensorFlow Lite (v2.13.0, Google) for real-time inference.

D. Real-time inference and validation

a) Real-time inference: The structure of the real-time inference is displayed in Fig. 1. A Python script performing these inferences runs in parallel to the exoskeleton controller running in C++; the two programs communicate through ROS. The script (python3 `concurrent.futures`) calls the multiple FEM Lite models in parallel. The outcome of this first phase (Fig. 1.1.A) is a batch of inferences of $\hat{\boldsymbol{f}}_i | i \in (0, 6)$. The mean and the standard deviation of the extracted features are calculated by fitting the prediction using a normal distribution ($\hat{\boldsymbol{f}} \sim \mathcal{N}(\mu_f, \sigma_f^2)$). At this point (Fig. 1.1.B), the operator (or therapist) can choose to manually change one of the features using a simplified interface designed using ROS `rqt`. This choice is implemented as the self-selected mean of the features (μ_f). Another parameter that can be manually adjusted is an increment δ, which is added to the mean of the gait phase. This adjustment results in an anticipation of the user's movement by δ instants, enabling the exoskeleton to deliver proactive assistance[1].

The distribution $\hat{\boldsymbol{f}} \sim \mathcal{N}(\mu_f, \sigma_f^2)$ is used to sample a normally distributed batch of features and passed to the CPM model. Also, in this case, the inference on multiple CPM Lite models is executed in parallel and the multiple outputs are fitted to a second normal distribution representing the expected δ future joint kinematic and its uncertainty $(\hat{\boldsymbol{\theta}}, \hat{\dot{\boldsymbol{\theta}}}) \sim \mathcal{N}(\mu_{\boldsymbol{\theta},\dot{\boldsymbol{\theta}}}, \sigma^2_{\boldsymbol{\theta},\dot{\boldsymbol{\theta}}})$. These values are passed as references to the exoskeleton controller (Eq. 1). In particular, the desired angle and velocity were chosen as equal to the mean of the prediction $\boldsymbol{\theta}_d, \dot{\boldsymbol{\theta}}_d = \mu_{\boldsymbol{\theta}}, \mu_{\dot{\boldsymbol{\theta}}}$, while stiffness and damping parameters were selected proportional to the inverse of the standard deviation similarly to [17]:

$$\boldsymbol{K} = \boldsymbol{K}_S(1 - \frac{\sigma_{\boldsymbol{\theta}}}{\sigma_{\max}}) \quad \text{with } \frac{\sigma_{\boldsymbol{\theta}}}{\sigma_{\max}} > 0, \tag{2}$$

$$\boldsymbol{D} = \boldsymbol{D}_S(1 - \frac{\sigma_{\dot{\boldsymbol{\theta}}}}{\sigma_{\max}}) \quad \text{with } \frac{\sigma_{\dot{\boldsymbol{\theta}}}}{\sigma_{\max}} > 0 \tag{3}$$

where $\sigma_{\max}$ was selected as the maximal uncertainty across the validation set while we assigned $K_S = [80, 60]$ Nm/rad, $D_S = [8, 6]$ Nm·s/rad for the hip and knee joints. These values were selected in line with previous work identifying impedance parameters during walking [9], [18]. The full inference process takes approximately 20ms, corresponding to a frequency of about 50Hz. The exoskeleton controller updates its reference whenever a new inference is available, while continuously streaming sensor readings at a frequency of approximately 333Hz.

b) Validation: The proposed framework was validated on two healthy participants external to the dataset used to train the two models. Participants gave informed consent for their participation. The study protocol was conducted in accordance with the Declaration of Helsinki and approved by the institutional review board of Northwestern University (STU00212684). The two users performed 15 minutes of treadmill walking and five iterations of stairs ascending and descending. We tested various parameters (i.e., changes in operator-selected features, changes in treadmill speed) to validate the proposed approach by manually changing these parameters during the 15 minutes of walking.

III. Results and Discussion

In this section, we present and discuss the results collected in this study. First, we evaluate the offline performance of the two models (FEM and CPM). Next, we present online results demonstrating the proposed controller's ability to assist user locomotion across different locomotion patterns. The results are evaluated using joint kinematics and interaction power metrics for two users.

Fig. 3 displays the prediction of gait features for two of the nine users used to develop the FEM and CPM model (seven users for training, two users for validation). The mean absolute error for the features is around a few centimeters (step height 3.1 ± 5.0cm, step length 2.6 ± 2.0cm, step velocity 1.6 ± 1.1cm/s, step clearance 2.7 ± 1.9cm). Nonetheless, as shown in Fig. 3, the prediction exhibits oscillations caused by uncertainty during the early-swing phase. Moreover, a limitation of the current approach is the need to identify a set of gait features that adequately capture the complexity of the walking pattern while maintaining clinical relevance. Walking patterns are highly subjective and can vary even for the same user, as shown by a moderate regression accuracy (R^2=0.68) between the predicted and desired joint kinematics on the validation set using the CPM. In preliminary tests, we included additional user characteristics (e.g., body weight and height) and features derived using auto-regressive techniques. However, these modifications did not result in additional variance explained (R^2=0.68). To

[1]It is important to note that δ is a-dimensional because it represents an increment of the gait phase and additional attention is needed to keep the resulting gait phase in the range [0, 100].

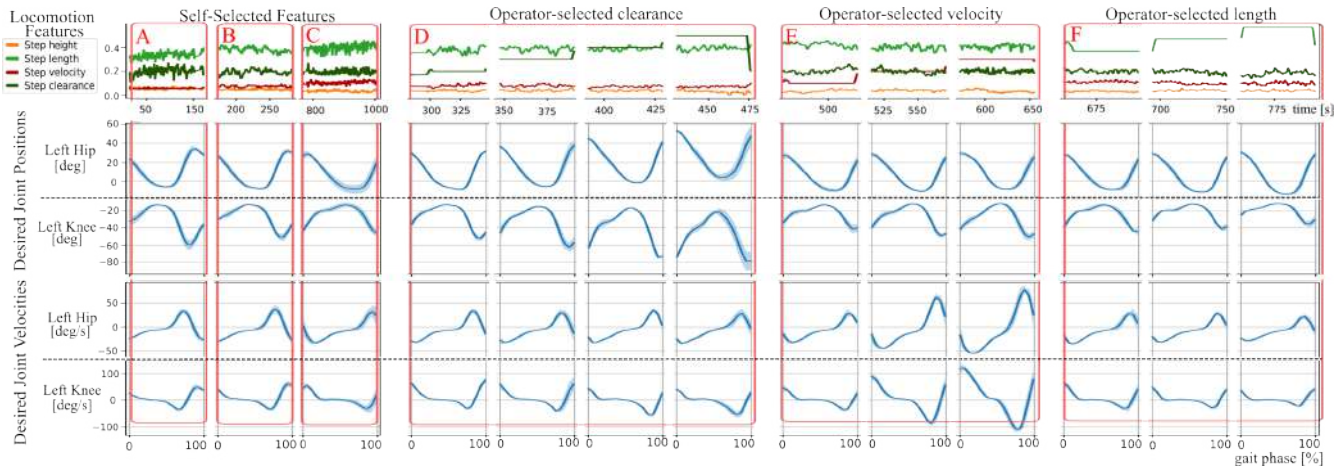

Fig. 2. Example of walking pattern for a single subject. In order, the five rows show: the implemented features (self-selected or operator-selected) over time [s], the reference position for the left hip and left knee, and the reference velocities for left hip, and left knee over the left stride percentage [%]. During the trial the user performed: (A) walking with exoskeleton controlled in transparency (self-selected features are not used to close the control loop) with treadmill velocity equal to 0.14 m/s; (B) Self-selected features used to close the loop of the controller; (C) walking with self-selected features on the treadmill at 0.19 m/s; (D) Operator-selected step clearance; (E) Operator-selected step velocity (at the same time increasing the treadmill velocity to 0.19 m/s); (F) Operator-selected step length.

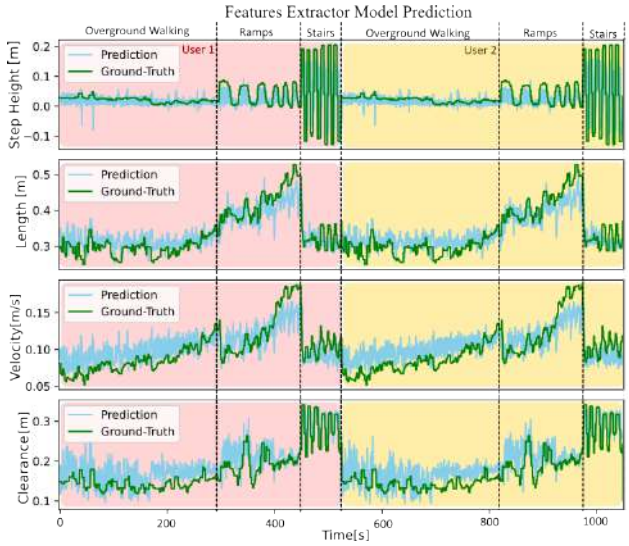

Fig. 3. Example of gait feature prediction. The plot displays the ground truth (in green) and the prediction of the Features Extractor Model (in blue) for two users in the training dataset over time (in seconds). Each user (user 1 in pink, user 2 in yellow) performed in order overground walking, ramps (both ascending and descending), and stairs(both ascending and descending). In order top-down the following features are displayed: step height, step length, step velocity, and step clearance.

address this, we adopted a probabilistic approach (II-C.0.c) for real-time prediction, which models the uncertainty in gait phases where variability is more prominent. This uncertainty was then used to adapt the compliance of the exoskeleton controller. Future research should focus on integrating additional locomotion features to further enhance the model's predictive capabilities.

Fig. 2 displays an example of a healthy user performing 15 minutes (for a total of 300 strides) of treadmill walking in different conditions. During the first three minutes (Fig.2.A), the user walked at a constant velocity of 0.14 m/s with their self-selected gait pattern while the exoskeleton was controlled in transparency. This first period of walking allows us to verify that the FEM can predict the gait features in an open loop. After predicting these self-selected gait features, we provide closed-loop control by using these features as input to the CPM (Fig.2.B). The user then walked for two minutes with exoskeleton assistance provided towards their self-selected features. We can observe that closing the loop of the controller (passing from A to B) resulted in an increased step-length (row 1 light-green plots) and step-velocity (row 1 red plot). This is likely due to the assistance the user receives during the movement. A similar trend can be observed in the following three minutes in which the velocity of the treadmill was increased to 0.19 m/s to validate its effect on the self selected features (Fig.2.C).

After testing the self-selected features, the operator manually selected the features to evaluate their effects on the participants' walking patterns. Shown in Fig.2.D, we observe how increasing the step-clearance results in a larger range of motion (ROM) in all kinematic trajectories (θ_d) for both the hip (second row) and the knee (third row). In a similar way, in Fig. 2.E, we observe the impact of increasing the step-speed, corresponding to an increase in the joint velocities ($\dot{\theta}_d$) both for the hip (fourth row) and the knee (fifth row). To account for the increased speed of the user, the velocity of the treadmill was increased from 0.14 m/s to 0.19 m/s and kept constant until the end of the experiment. Finally, in Fig. 2.F, the step length was increased. This resulted in an increased ROM for the hip joint angle (θ_d) and a smaller ROM for the knee angle, likely due to smaller knee flexion during swing movement to increase step-length.

Fig.4 shows the distribution of the joint configurations (hip and knee joint) of the two users across the different gait features. We observed that all features impact both the spatial

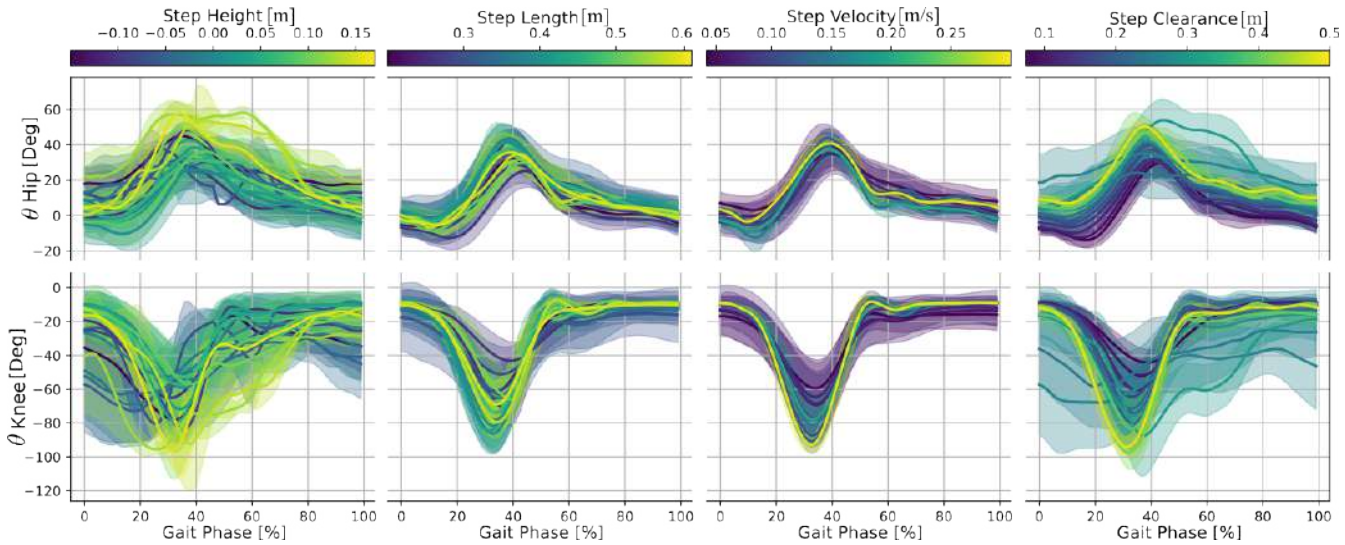

Fig. 4. Joint kinematic across gait features (both self-selected and operator-selected): The two rows display respectively the hip and knee joint angles (left and right grouped). Each column represents with a different color code the distribution of the joint kinematic for each gait feature (step-height, step-length, step-velocity, step-clearance). On the top of each column are displayed the color bars for each gait feature. The trend was grouped based on similarities in gait features and is presented using the mean and standard deviation.

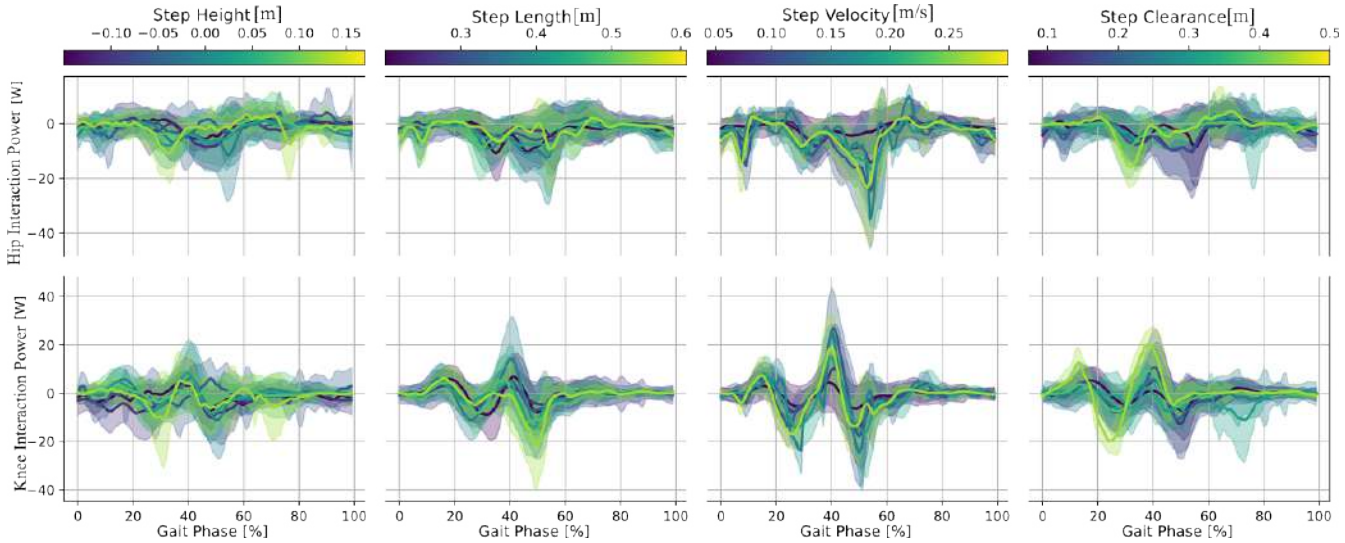

Fig. 5. Joint power across gait features (both self-selected and operator-selected): The two rows display the hip and knee joint power (left and right grouped). Each column display with a different color code the distribution of the desired joint kinematic for each gait feature (step-height, step-length, step-velocity, step-clearance).On the top of each column are displayed the color bars for each gait feature. The trend was grouped based on similarities in gait features and is presented using the mean and standard deviation. Negative joint power means exoskeleton assistance to the user while positive joint power represents resistance to the user.

and temporal aspects of the walking pattern. For instance, the step length highly influences the ROM (an increase to a step length of 0.34 m results in a increase of ROM of 20° for the hip and 40° for the knee). During these preliminary experiments, we observed an under-damped behavior of the exoskeleton during the early-stance phase (around 60% of the gait phase). This behavior could be due to two reasons: the impact of training data of stairs (after heel strike during stairs, the knee is more extended than in level-ground walking) or the independence in prediction across joint positions and velocities resulting in uncorrelated stiffness and damping parameters as they were calculated independently (Eq. 2). Further investigation is required to address these limitations.

Fig. 5 displays the interaction power ($\tau_{int} \cdot \dot{\theta}$), calculated as a product of the interaction torque and joint velocities. This metric represents the amount of assistance (negative values) or resistance (positive values) that the exoskeleton applied to the user. This metric is displayed for the two joints (hip and knee, grouped) across the two rows, and varying the gait features (across columns). For the hip joint, the interaction power is negative (assistive torque) in most conditions (mean interaction power ($\pm$ std) in all gait phases -2.05 $\pm$ 1.6W. For

the knee, the joint interaction power is also negative (-0.6 $\pm$ 1.39W) in most of the gait phase with two peaks of negative interaction power during the swing phase in knee flection (around 30% of the gait phase) and during both hip and knee extension (around 50-55% of the gait phase). This suggests that, during swing, the robot is actively assisting the user to execute the movement. On the other hand, two positive peaks were observed at the beginning of the early-swing and the beginning of the late-swing (respectively around 15% and 40% of the gait cycle). This can be due to several factors, but most importantly the users were blinded to the gait features manually selected by the operator and thus the nature of the assistance provided. Consequently, they were not aware of how much they should flex the knee during the swing phase. Moreover, they performed each activity for a few minutes, resulting in a limited time to adapt to each condition. Therefore, longer validation sessions are likely required to prove the efficacy of minimizing the interaction power across users.

IV. Conclusions

In this work, we present a three-step data-driven approach designed to replace the hierarchical structure of traditional exoskeleton controllers. The first step involves probabilistically mapping a short-term history of sensor data (including encoders, force sensors, and foot-plate sensors) to a minimal set of clinically relevant gait features: step length, height (to differentiate ascending and descending surfaces), walking velocity, step clearance, and gait phase. These features can either be applied directly or adjusted by an operator/therapist via a user interface to customize the user's locomotion. The final step uses probabilistic regression to map the current locomotion features to the desired joint posture of the exoskeleton, leveraging prediction uncertainty to adapt the impedance of a spring-damper system linking the user and the device. This adaptive compliance enhances safety, limiting large desired interaction torques when the prediction of the user's behavior is less accurate. Validation on two healthy users across diverse gait activities demonstrated the ability of the proposed approach to detect user intent and provide assistance accordingly, generating predominantly negative interaction power between the user and the exoskeleton. Future work will explore the selection of additional clinically relevant features in collaboration with therapists to ensure that they align with practical rehabilitation needs. Additionally, more extensive studies involving patient populations (e.g., stroke, spinal cord injury) are necessary to evaluate the impact of these assistive strategies on individuals with gait impairments.

Brain biomarkers for assessing practice of robotic arm reaching movements using a head-controlled interface

Anna L. Packy*, Isabelle M. Shuggi*, Hyuk Oh, Rodolphe J. Gentili
*Co-first author

Abstract—**Limited efforts have examined the cognitive-motor processes as individuals learn to operate upper-limb assistive devices that improve interactions in their environment (e.g., prostheses, head-controlled devices). Prior work mainly focused on performance without examining cerebral cortical dynamics via brain biomarkers to assess the level of practice during the learning of such assistive devices. Specifically, it was suggested that EEG biomarkers like low- and high-beta spectral power are related to learning as they assess memory formation and attentional mechanisms. Therefore, this work examines how sensorimotor performance, and low-/high-beta spectral power are influenced as individuals without disabilities practice reaching movements with a simulated robotic effector executed via a head-controlled interface. Results revealed faster and straighter reaching movements. Additionally, as individuals progressed from early to late practice, the movement planning stage revealed an elevation of frontal, central and parietal low-beta power and an attenuation of high-beta power in the temporal region. These spectral modulations may reflect an internal model memory encoding process of the novel sensorimotor mapping imposed by this interface throughout practice which ultimately enables improved reaching performance. This work could inform patients' cognitive-motor processes when learning to control assistive systems and provide biomarkers for monitoring practice during rehabilitation.**

I. Introduction

An important characteristic of the human cognitive-motor system is its ability to process information to learn new sensorimotor skills when facing changes in the body or environment [1]. As such, a large body of work has examined the underpinning cognitive-motor mechanisms of upper-extremity performance when individuals without disabilities practice a new motor task [2-4; for review see 5]. In contrast, a limited effort has investigated the cerebral cortical dynamics underlying performance changes in a rehabilitation context where individuals must learn to operate upper-limb assistive devices (e.g., prostheses, exoskeletons, head-controlled systems) [6-7]. In such a context, while prior efforts have examined cortical dynamics when individuals perform using assistive technologies, these studies did not focus on practice [8-10]. Furthermore, although previous work investigated performance when individuals learn to operate assistive devices such as upper-limb prostheses [11-13] or a head-controlled robotic device [14-18] the cerebral cortical dynamics were not analyzed. However, the assessment of both behavioral performance and cortical dynamics is important. For instance, while the performance can improve during practice, an absence of refinement of cortical dynamics would indicate that the brain is still engaging substantial resources to execute the task. Thus, the understanding of the cognitive-motor processes engaged during sensorimotor learning is a key element to identifying progress in patients operating assistive systems more comprehensively, beyond behavior analysis alone and, as such, their examinations are critical from both a theoretical and a practical standpoint [19-21].

A possible approach to examine the cerebral cortical dynamics underlying sensorimotor learning is to derive electroencephalography (EEG) biomarkers. In particular, multiple prior efforts revealed that the changes in spectral power in the beta frequency bandwidth could serve as a biomarker to index sensorimotor learning [19, 22-25]. Namely, it was suggested that a greater level of low-/high-beta or broadband beta power has been associated with improved performance during learning [19, 26-27]. Specifically, it was suggested that an elevation of beta power during practice indicates that: i) learning processes would take place through changes in cortical pathways resulting in memory formation [19, 22-23, 26] and ii) there is a refinement of attentional mechanisms, especially in the frontal regions [23, 27].

Although interesting, the examination of these EEG biomarkers in a context where individuals learn how to control assistive systems is limited. From a computational standpoint when individuals learn to operate an assistive device (e.g., upper-limb prosthesis; head-controlled robotic arm) they must encode a sensorimotor mapping via a human-body machine interface which involves body parts that are used differently from their traditional functions and thus are not well-suited to execute the tasks [14, 16, 28-29]. An example of such a human-body machine interface is a head-controlled robotic arm which requires individuals to encode a sensorimotor mapping between their limited angular head motion and the spatial displacements of the robotic end-effector. This unusual sensorimotor map requires the use of neck muscles which have a limited communication channel making them not naturally suited for executing accurate reaching movements [30-31]. As such, the encoding of this unnatural sensorimotor mapping to control the device requires, like many assistive systems, practice from participants [14-16, 32-34].

Therefore, by combining behavioral performance and EEG biomarkers, this study aimed to examine the cognitive-motor processes underlying practice of a novel sensorimotor

mapping by individuals to control a head-controlled robotic effector with limited head motion. We predicted that from early to late practice, individuals will exhibit improved reaching movement performance with the robotic effector along with an elevation of low-beta and high-beta power. This work has the potential to inform the cognitive-motor processes and provide biomarkers when individuals learn to use assistive robotic systems.

II. Methods and Materials

A. Participants

Eighteen individuals without disabilities, right-handed, participants (10 female, 8 male; age range: 18-35 years) with no prior experience of using head-motion controlled systems were recruited from the University of Maryland, College Park. All participants provided written informed consent before participation, in accordance with the Institutional Review Board of the University of Maryland.

B. Task

Participants used a human-body machine interface to complete a reaching task. The goal was to move the end-effector of a two-dimensional virtual robotic arm with two degrees of freedom to a spatial target by employing limited head motion. The effector and targets were displayed on a 21-inch screen approximately 24 inches away from the participants. An infrared sensor was placed on the participant's forehead and tracked head movements using a motion capture system captured at 100Hz (Optotrak™ 3020, NDI). The overall system was configured to operate at a sampling rate of 100 Hz. Participants were able to move their head in eight directions: vertical (pitch), horizontal (yaw), and combinations of these axes, to control the end-effector using a closed-loop inverse kinematic algorithm using a proportional integral control system. The movement velocity of the end-effector was proportional to the magnitude of the head displacement (Fig.1) (for further details, see [15]).

Each participant conducted a calibration phase to determine their range of head motion and a "dead zone" threshold below where no movement was registered. After calibration, participants completed a brief familiarization phase to become acquainted with the interface. Then, they practiced reaching movements by moving the robotic arm to 200 randomly appearing targets, equidistant to the pervious, as fast and as straight as possible [14,16]. After practice, participants executed a transfer task which, for clarity and conciseness, is not reported here.

For each reaching trial, a red target appeared in a random location within the workspace. Participants were required to maintain their head in the central position (i.e., within the dead zone) and take their time to plan the upcoming movement to reach this target. Unknown to the participants, this pre-movement period lasted at least two seconds, after which the target turned green when the participant initiated their movement. Upon reaching the green target, the participant was required to remain at the target for two seconds before the target disappeared and the next appeared. Due to the different mechanisms between planning and execution, if the participant moved outside of the central location before the two seconds elapsed, the target turned black and stayed black until the participant returned to the center position and restarted the trial [2]. Target onset, movement onset, and target reached events were tracked using MATLAB R2014a (The MathWorks, Inc.).

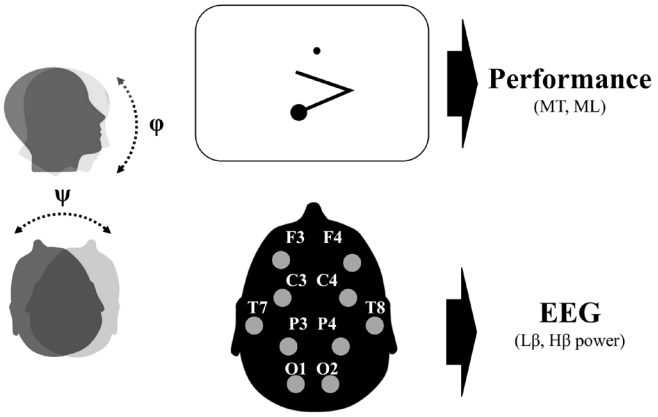

Figure 1. Experimental set-up to study cognitive-motor processes as individuals practice reaching movements with the robotic end-effector in 2D (X,Y) controlled via limited head motions (pitch (φ) and yaw (ψ)). During practice the EEG was collected to derive the low-beta (Lβ) and high-beta (Hβ) spectral power along with performance. MT: Movement Time; ML: Movement Length.

Both the kinematics of the end-effector and EEG signals were continuously recorded throughout the task. EEG signals were sampled at 1000 Hz using a 64-electrode 10-10 actiCAP (Brain Products GmbH). A 10 degrees of freedom inertial measurement unit (IMU), MTw (Xsens Technologies B.V.), was placed on the participant's forehead to capture head movements at 100 Hz for EEG movement artifact removal. For all trials, events were marked within the EEG signals to identify the start (movement onset) and end (target was reached) of the robotic arm movement for subsequent EEG analysis during both the late portion of the movement planning (-1 to 0 sec before movement onset) as well as execution (movement onset to target reached) [2]. The practice period (200 trials) lasted approximately one hour.

C. Data Processing

All data were processed using MATLAB R2014a. The movement time (MT) and length (ML) assessed motor performance of the robotic end-effector and were averaged for the early (50 first trials) and late (50 last trials) practice period [14-16]. The MT was defined as the time elapsed between the movement onset and the reaching of the target. The ML was calculated as the path travelled by the robotic end-effector during the movement.

The EEG signals were processed using EEGLAB v13 [35]. First, EEG signals were band-pass filtered between 3 and 40 Hz with an eighth-order Butterworth filter. EEG channels were manually inspected to reject and interpolate any bad channels. Following interpolation, the signals were down-sampled to 500 Hz (to compare to the up-sampled IMU data; see later). A second-order blind identification (SOBI) independent component analysis (ICA) was performed [36]. Artifacts related to eye, muscle, and channel noise were identified and removed by manual inspection. Head motion artifacts during the execution stage were removed using an ICA approach informed by the IMU data in line with

previous work [36-38]. The infrared system was employed only to control the end effector. In addition to the linear acceleration and angular velocity acquired by the IMU, linear velocity and angular acceleration were employed to identify motion artifacts. These four kinematic signals were filtered using a band-pass eighth-order Butterworth filter between 1 and 10 Hz. This filtered IMU data was up-sampled to 500 Hz to match the down-sampled EEG data and then decomposed into independent components with the SOBI ICA. The EEG components correlated with the IMU components within the lag range from -10 to 10 milliseconds were identified as motion artifacts and removed.

Power spectra in the low-beta (14-22 Hz) and high-beta (23-35 Hz) bands were computed from the Welch's power spectral density for channels over the left and right frontal (F3, F4), central (C3, C4), temporal (T7, T8), parietal (P3, P4), and occipital (O1, O2) regions for both the movement planning and execution stages. The average power values were computed for early and late practice periods. Spectral EEG metrics were naturally log-transformed before conducting statistical analysis.

D. Statistical Analysis

The performance metrics MT and ML were compared between early and late practice periods by means of paired t-test or Wilcoxon signed-rank test depending on whether the data were normally distributed or not, respectively, in which normality was assessed using the Shapiro-Wilk test.

The changes of EEG power from the early to the late practice period during both the movement planning and execution stages were examined using a 2 PERIOD (Early Practice, Late Practice) × 2 HEMISPHERE (Left, Right) × 5 REGION (Frontal, Central, Temporal, Parietal, Occipital) repeated measure ANOVAs conducted separately for the low-beta and high-beta frequency bandwidth. If the sphericity (assessed with the Mauchly test) was violated, the Greenhouse-Geisser correction was applied, and the p-value was reported with the corrected degrees of freedom. Whenever necessary, the Tukey's HSD test was employed for post-hoc analysis. Whenever appropriate the partial-eta squared (η_P^2) and Cohen's d effect sizes were reported. All criterion alpha levels were set to $p < 0.05$.

III. RESULTS

A. Motor Performance

The results revealed that MT ($z = 2.678$; $p = 0.007$; $d = 0.522$) and ML ($t(17) = 3.027$; $p = 0.008$; $d = 0.705$) decreased as practice progressed (Fig. 2).

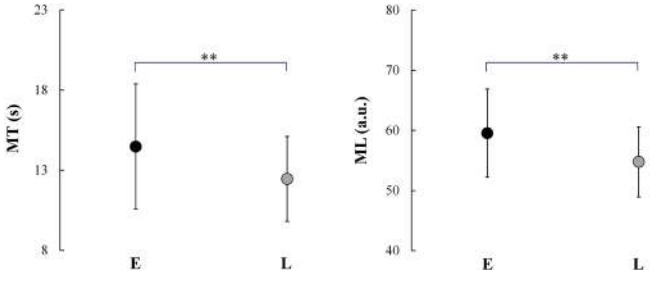

Figure 2. Changes in performance from the early (black filled circles) and late (gray filled circles) practice period. MT: Movement time; ML: Movement length; E: Early practice period; L: Late practice period; ***: $p<0.001$; **: $p<0.01$; *: $p<0.05$.

B. Spectral Power in the low- and high- beta band

For the movement planning stage, the results revealed a PERIOD × REGION interaction effect for the low-beta ($F(1.502, 25.533) = 6.414$, $p = 0.010$, $\eta_P^2 = 0.274$) as well as the high-beta ($F(1875, 31.877) = 7.351$, $p = 0.003$, $\eta_P^2 = 0.302$) power. No other effects were detected ($p > 0.050$).

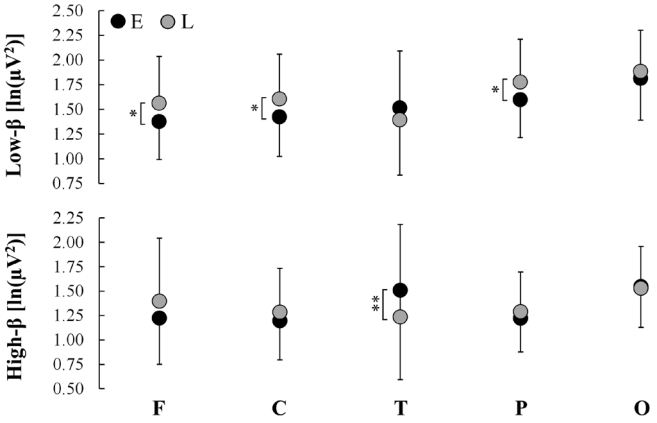

Figure 3. Changes in EEG low-beta (top row) and high-beta (bottom row) power from early (black filled circles) to late (gray filled circles) practice period during the planning stage and for each cortical region (average of left and right hemispheres of each region). ***: $p<0.001$; **: $p<0.01$; *: $p<0.05$. F: Frontal, C: Central, T: Temporal, P: Parietal, O: Occipital.

The post-hoc analysis revealed that, from the early to the late practice period, the low-beta power increased in the frontal ($p = 0.022$; $d = 0.442$), central ($p = 0.028$; $d = 0.419$) and parietal ($p = 0.034$; $d = 0.424$) regions during the movement planning stage (Fig. 3, top). In addition, the same post-hoc analysis revealed that the high-beta power in the temporal region was attenuated from early to late practice period in the planning stage ($p = 0.002$; $d = 0.315$) (Fig. 3, bottom). For the movement execution stage, the results did not reveal any main or interaction effect for both the low-beta and high-beta power ($p > 0.05$ for all comparisons) (Fig. 4).

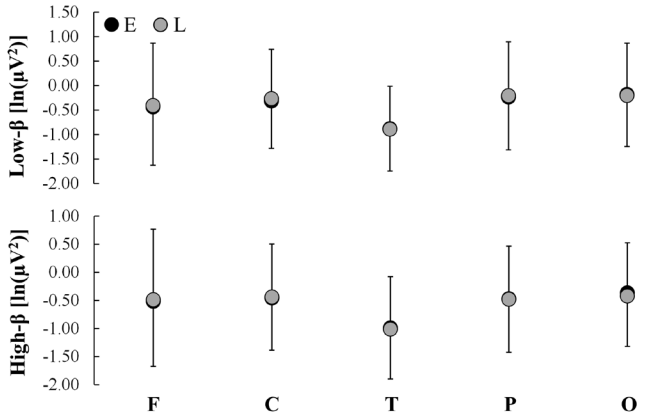

Figure 4. Changes in EEG low-beta (top row) and high-beta (bottom row) power from the early (black filled circles) to the late (gray filled circles) practice period during the movement execution stage and for each cortical region (average left and right hemispheres of each region). F: Frontal, C: Central, T: Temporal, P: Parietal, O: Occipital. ***: $p<0.001$; **: $p<0.01$; *: $p<0.05$.

IV. Discussion

This study investigated the neural correlates underlying practice reaching movements through a head-controlled virtual robotic arm. Overall, participants exhibited improved performance, with faster and straighter reaching movements, from the early to the late practice period. These behavioral improvements were accompanied by an elevation of low-beta power in the frontal, central and parietal regions along with an attenuation of high-beta power in the temporal region during the movement planning stage.

The observation that practice led individuals to produce faster and straighter reaching movements with the robotic end-effector is consistent with prior studies which revealed enhanced performance when individuals were trained to control assistive systems such as upper-limb prostheses [11-12] and head-controlled devices [14-16]. Importantly, performance enhancements were also accompanied by an elevation of low-beta power in the frontal, central and parietal regions. These changes are consistent with the notion that the increased power in this frequency range suggests a successful encoding in memory of sensorimotor information and a reduction of attention [19, 22-23, 26-27, 39]. Thus, a possible mechanism is that throughout practice, individuals have encoded in their memory an internal model of the new sensorimotor map imposed by the assistive device, resulting in an elevation of the low-beta power in the central and parietal regions [24, 40-41]. These central and parietal regions are well-known to be involved in sensorimotor processing and sensory integration contributing to the formation of internal representations [42-44]. In addition, the elevation of frontal low-beta power may suggest that, as individuals progress through practice, attentional mechanisms are being refined [23, 27, 45].

Although other interpretations could be considered, the decrease in high-beta power in the temporal regions over practice could be associated with the enhanced engagement of memory systems in the early stages of learning [46-48]. It is likely that further training would be needed for the individuals to reach a more advanced skill level [47]. While previous work in adaptation of reaching tasks identified an increase of beta power during movement execution (e.g., [49]), this was not observed here. This difference may be explained by the novel and unusual nature of the sensorimotor mapping imposed by the head-controlled system which may require a longer practice time to observe the emergence of cortical changes during the execution stage.

Therefore, this work confirms and extends prior work by suggesting that the changes in low- and high-beta power could serve as possible brain biomarkers in a clinical context to assess the practice level of individuals when they learn to control an assistive device. For example, in the cases of a high-level spinal cord injury, the cortical dynamics of patients could be assessed whenever possible to monitor their brain activity as they practice head motion to control end-effectors or more generally various assistive systems (e.g., robotic arms, computer cursors, wheelchair joysticks). Such cortical monitoring along with behavioral assessment can more comprehensively inform the training approach deployed by the therapists as their patients learn to operate the assistive device to (re-)engage with their environment for regaining autonomy.

V. Conclusion

This work suggests that the modulation of low-beta and high-beta power would reflect the advancement of the encoding in memory of an internal model of a novel sensorimotor map while individuals practice reaching movements using a head-controlled robotic effector. Thus, these spectral power dynamics could possibly provide brain biomarkers to track the changes in cerebral cortical dynamics along with performance as sensorimotor learning progresses. Beyond these findings, this work has limitations. First, the participants involved in this work were individuals without disabilities and as such this work should be extended by considering a clinical population (e.g., patients with high-level spinal cord injury). Also, while the regional activity as employed here is informative, future work should also consider cerebral cortical connectivity to capture neural network communication which could further inform the cognitive-motor processes when individuals learn to control an assistive device. In addition, the efficacy index combining performance and cortical dynamics as well as the effect of a prolonged practice period on cortical dynamics should also be examined [15,16]. Despite these limitations, this work has the potential to contribute and to inform the monitoring and retraining of individuals with disabilities who must learn to control assistive technology devices to be able to interact again with their environment using the underlying neural mechanisms for targeted biomarkers.

A Task-Agnostic Knee Exoskeleton for Reducing Osteoarthritis Pain Across Activities of Daily Life: A Pilot Study

Nikhil V. Divekar*, Ernesto Hernandez Hinojosa*, Jiefu Zhang, and Robert D. Gregg

***Abstract*— Patellofemoral osteoarthritis is a prevalent musculoskeletal disorder characterized by knee pain during physically demanding activities like stair climbing and sit-to-stand transitions. These movements require high knee extension torques, leading to increased quadriceps activation and patellofemoral joint compression, which aggravates pain. While external torque assistance at the knee joint could theoretically reduce joint loads, traditional exoskeletons have not proven effective in managing osteoarthritis due to their rigid actuation, cumbersome attachments, and inadequate control systems. We address these limitations by modifying a commercial post-operative knee brace with a highly-backdrivable actuator and adapting a task-agnostic torque-assist controller, originally designed for lifting and carrying tasks, to accommodate osteoarthritis patients. In pilot trials with four participants with patellofemoral osteoarthritis, our device facilitated substantial reductions in both pain and perceived difficulty across daily activities including stair/ramp navigation, walking, and sit-to-stand transitions. Across all participants and tasks, pain and difficulty were reduced by 0.82 and 0.57 points, respectively (on a scale of 0 to 4). Electromyography revealed decreased quadriceps activation, varying by participant and task. These preliminary findings motivate future research on backdrivable knee exoskeletons as a novel conservative treatment for patellofemoral osteoarthritis.**

I. Introduction

Knee osteoarthritis (OA) is a highly prevalent musculoskeletal disorder affecting ∼14% of American adults [1]. OA can afflict one or more of the three knee joint compartments (medial, lateral, and patellofemoral), with over 24% of knee OA cases being isolated patellofemoral and 40-59% being multi-compartmental [2]–[4]. Physical therapies focus on strengthening the quadriceps to address knee instability and muscle force imbalances between the medial and lateral quadriceps heads [5], [6]. However, pain often limits patients to low joint torque activities like walking, causing them to avoid more demanding tasks such as stair climbing. This restricts general mobility and perpetuates a negative cycle of inactivity, muscle weakness, and OA progression [7].

Conventional unloader knee braces help realign tibiofemoral joint spaces by balancing force distribution between medial and lateral sides. While this alleviates pain in these compartments, these braces cannot address pain from quadriceps muscle action. This muscle action increases compressive forces primarily at the patellofemoral joint [8], [9]. Patellofemoral pain therefore intensifies during activities like stair/ramp climbing and sit-stand [10], which require high knee extension torques and thereby high quadriceps forces. This source of pain inspired the recent design of tri-compartmental unloading knee braces that use springs to help reduce forces and torques in the knee [11]. However, these devices cannot add or remove net energy during human locomotion, making them inadequate for challenging daily activities like climbing up or down stairs [12]. Moreover, the spring can cause a hindrance during swing knee flexion. These limitations highlight the need for a new class of *powered* knee unloaders that can provide a small fraction of biological torque to reduce patellar and quadriceps tendon forces across various activities of daily living (ADLs).

Recent attempts at using knee exoskeletons to relieve pain and increase physical performance in OA patients have shown promise but still face significant challenges. Both the Keeogo and ROAM Ascend exoskeletons require large backpacks and have usability issues related to comfort, weight, and noise [13], [14]. The pneumatically powered Ascend [14] is bulky and, similar to spring-based knee unloaders, does not support knee flexion during late stance and early swing. Moreover, the highly-geared Keeogo [13] was unable to induce acute benefits for knee osteoarthritis patients, likely due to the lengthy user adaptation needed for the task recognition-based controller.

We previously developed a task-agnostic knee exoskeleton to support the quadriceps during lifting-lowering and multi-terrain carrying tasks [15]. This design integrates a backdrivable, quasi-direct drive actuator with a post-operative knee brace, providing high control bandwidth, precise current-based torque control, energy regeneration, quiet operation, and impact compliance [16]–[19]. The exoskeleton features a task-agnostic controller that automatically modulates virtual springs, dampers, and gravity and inertia compensation to assist various activities. Unlike end-to-end neural networks, our controller uses predictable, bounded components with interpretable parameters that can be optimized for biomimetic assistance and fine-tuned for specific applications like OA. This approach also enables seamless task transitions while maintaining natural movement patterns. The exoskeleton reduced quadriceps effort in unimpaired individuals across six key activities: level walking, ramp and stair ascent/descent, and lifting-lowering tasks. These results suggest this technology could similarly reduce quadriceps-induced loads on the patellofemoral compartment to relieve knee OA pain.

This paper presents the deployment and pilot evaluation of our task-agnostic knee exoskeleton for relieving knee

OA pain across the primary activities of daily life. Firstly, we refined our prior controller [15] to support sit-stand transitions rather than lifting-lowering tasks. Secondly, we simplified the brace setup used in [15] by removing the medial thigh plate to prevent unwanted knee forces from strap tightening. Finally, we evaluated the exoskeleton's effectiveness in reducing pain and difficulty across various activities in four participants with patellofemoral-dominant knee OA. Results showed *acute* reductions in both perceived pain and task difficulty, along with participant- and task-dependent reductions in peak and mean quadriceps activation. By providing targeted, backdrivable assistance when needed, this exoskeleton represents a potentially significant advance in non-invasive knee OA management, with implications for improving mobility and patient quality of life.

II. Methods

A. Controller Modifications

Fig. 1 shows a high-level summary of the task-agnostic bilateral knee controller, which was originally developed for lifting-lowering and multi-terrain carrying in [15] and adapted here for supporting knee OA participants. Briefly, the controller consists of core torque bases that are heuristically modified to form task-specific stance torque bases and general (task-invariant) swing torque bases. Next, for stance, task sensitization or multiplication with functions sensitive to certain task characteristics (such as terrain slope) provide task-adaptive stance torque functions. Last, taking the convex sum of the stance and swing torque bases based on the ground reaction force (GRF) unifies them into the final task-adaptive knee torque function.

Here, the "lifting-lowering spring", which was designed to generally support symmetric closed chain squat-like motions, was modified to support sit-stand transitions ("Sit-Stand spring" in Fig. 1). Based on user feedback, the modification essentially involved suppressing the spring torque more for small knee flexion angles. Furthermore, compared to [15], we have an additional basis function for assisting leg clearance ("Swing boost" in Fig. 1). This function supplements the gravity compensation basis by applying knee flexion torques based on the sagittal thigh angle (a commonly used signal for phase-based controllers [20]).

B. Hardware Implementation

The controller was implemented on modified bilateral knee modules of the modular lower-limb exoskeleton system M-BLUE [15], [19]—see Fig. 2. Briefly, this bilateral exoskeleton configuration uses two highly-backdrivable commercial actuators (T-Motor AK80-9, DEPHY driver), each comprising a high-torque pancake motor and an internal 9:1 planetary gearset resulting in a very low reflected friction and inertia (92.1 kg·cm^2). We bypassed the motor driver's default thermal limits and implemented a thermal model-based torque limiter [21], allowing short (1-2 s) bursts of higher peak torques (limited to 25 Nm). We also implemented a ground reaction force sensor (IEE Sense) based on a matrix of force sensitive resistors. An inertial measurement unit (3DM-GX5

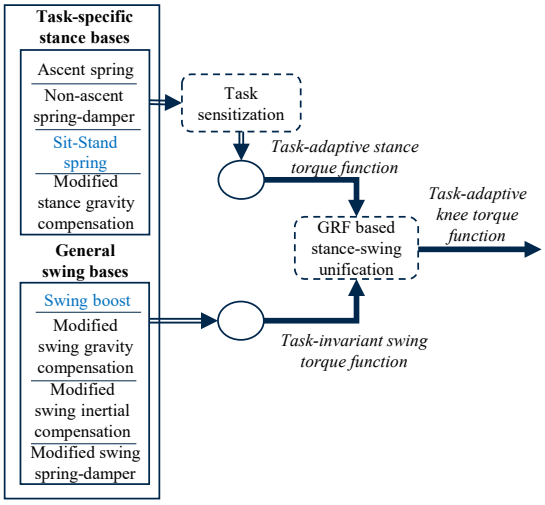

Fig. 1. High-level summary of the task-adaptive knee controller—adapted from [15]. Basis functions that were added or modified are shown in blue.

Fig. 2. Modified bilateral knee exoskeleton for knee OA users.

AHRS, Microstrain) is directly attached to each leg segment (four total) to measure the orientation and angular velocity of both thighs and shanks. The controller for each leg runs on a single board computer (Raspberry Pi 5 8GB, Raspberry Pi Foundation) at 300 Hz with wireless communication to share sensor feedback between legs. The system is powered by two 24 V, 2 Ah powertool battery (Kobalt 24-V Lithium Battery, Kobalt). The total mass of the system is 4.6 kg.

Each actuator is mounted on an off-the-shelf knee brace (T Scope Knee, Breg). We modified the brace setup used in [15] to better suit knee OA participants. Essentially, we removed the medial thigh beam of the brace to allow tightening of the thigh and shank straps with minimal stress on the knee joint in the frontal plane. While this modification makes torque transfer to the human slightly less efficient, it greatly improved comfort of our participants. For user safety, a remote emergency stop switch was implemented to cut off battery power to the motor.

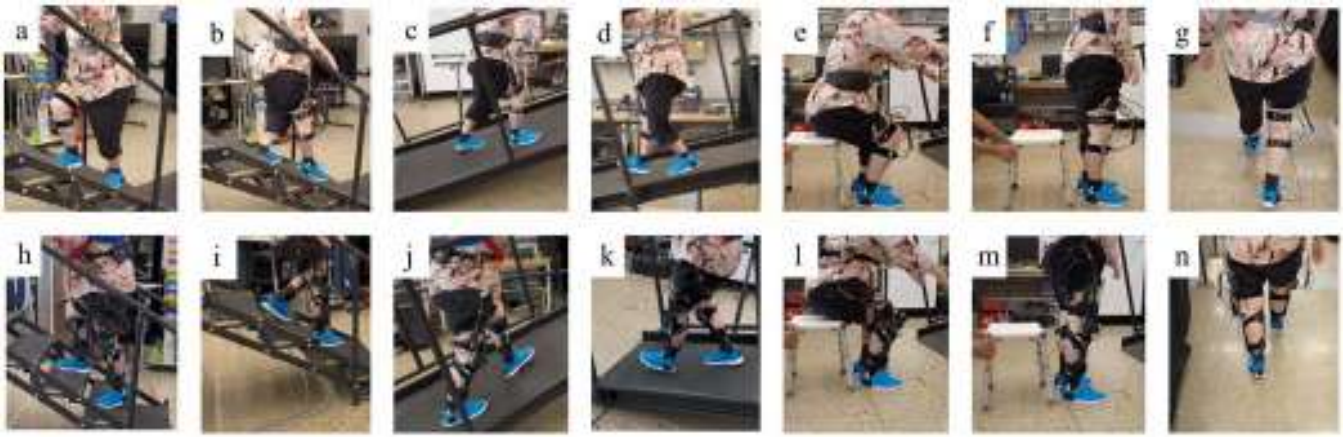

Fig. 3. Participant performing the seven different tasks with both conditions: (a-g) depict the participant without exoskeleton assistance (Bare condition), while (h-m) show the participant performing the same tasks with exoskeleton assistance (Exo condition). The tasks include: (a, h) stair ascent, (b, i) stair descent, (c, j) ramp ascent, (d, k) ramp descent, (e, l) sit-to-stand descent, (f, m) sit-to-stand ascent, and (g, n) level walking.

C. Experimental Design

TABLE I
SUBJECT INFORMATION

	Sex	Age	Weight (kg)	Height (m)
Subj. 1	F	70	94	1.6
Subj. 2	M	81	83	1.83
Subj. 3	F	65	73	1.57
Subj. 4	F	53	52	1.63

The study was approved by the University of Michigan's Institutional Review Board (HUM00201957). We enrolled four participants with pre-eminent pain at the patellofemoral joint—assessed via a questionnaire, sometimes including their x-ray reports. Participants were selected based on self-reported regular pain during walking, which worsened during stair climbing, ensuring they met the study's criteria for patellofemoral OA-related symptoms. The participant information is provided in Table I. All participants gave written consent before participating.

The study involved assessing the effect of our controller/exoskeleton on pain, difficulty, and quadriceps activation levels in a multi-activity test. The activities comprised level ground walking (LW), ramp ascent (RA), ramp descent (RD), stairs ascent (SA), stairs descent (SD), sit-to-stand (STS-A), and stand-to-sit (STS-D); performed on a multi-terrain circuit composed of a level 10 m level walkway, a 3.7-m ramp inclined at 15°, a five-step staircase with a 7 inches (18 cm) step height, and a height adjustable stool.

Before the test, participants attended a separate acclimation session lasting approximately 2-3 hours. During this session, they performed different tasks with the exoskeleton under different levels of assistance (LoA), until they were confident with the device. After acclimation we acquired important gait parameters without the exoskeleton for each activity in our multi-terrain circuit (Fig. 3) for the purpose of applying experimental controls. We acquired the maximum knee extension velocity in stance for ascent (ramp and stairs) and sit-stand transitions, resembling the protocol in [15]. Because OA participants exhibit high intra-subject variance in peak knee velocity during descent tasks (ramp and stairs) and level-ground walking, we instead acquired the time to complete these activities—resembling the average speed for each activity. These parameters served as experimental controls for both the Bare and Exo conditions during the subsequent test visit.

The test visit, which lasted approximately 3-4 hours, was conducted in two conditions: no exoskeleton (Bare) and active exoskeleton (Exo), with the order of the conditions alternated between subsequent participants. In the Exo condition, the level of assistance was kept the same for all participants to fully utilize the peak torque of the actuators. Subjects performed each activity multiple times until obtaining at least 10 gait/task cycles with peak velocities/average speeds within $\pm 10\%$ of their baseline values.

D. Data Collection and Analysis

Pain and difficulty were assessed for each activity using a modified Western Ontario and McMaster Universities Arthritis Index (WOMAC) questionnaire [22], in which participants rate their perceived pain and difficulty on a scale of 0-4, corresponding to "None", "Slight", "Moderate", "Very", and "Extremely". Participants completed the questionnaire at the end of each task trial, following all repetitions of a specific task under a given condition (e.g., after all Exo stair climbing repetitions, all Bare ramp descent repetitions, etc.).

Quadriceps effort was assessed using surface electromyography (EMG). After appropriate skin preparation, we taped three wireless electrodes (Delsys, Massachusetts, USA) onto the participant's right lower limb over the vastus medials oblique (VM), vastus lateralis (VL), and rectus femoris (RF) to assess muscle activation. EMG data was parsed into individual task/gait cycles using the knee angle for sit-stand activities and the FSR for gait activities. Each muscle's EMG was demeaned, bandpass filtered (20 - 200 Hz), and smoothed with a moving 125 ms window RMS filter with 50% overlap. EMG was normalized to the maximum muscle activation level observed during the test.

We then calculated the mean and peak muscle activation for each muscle, taking the difference between the Exo and Bare conditions. Specifically, the peak EMG difference for each muscle/activity was calculated by normalizing the peak EMG of each trial in the Exo condition relative to the Bare condition, using the formula

$$\text{Normalized Peak EMG} = \frac{\text{Exo Peak} - \text{Bare Peak}}{\text{Bare Peak}}$$

Finally, per our previous work [15], the three muscles were lumped together using a weighted average based on each muscle's cross-sectional area to acquire the overall quadriceps mean and peak activations for each activity.

III. Results

Participants reported an average pain reduction of 0.82 points across all tasks and conditions when using the exoskeleton (Fig. 4, Table II). Subject 1 reported a single-point reduction in pain for the stairs and ramp tasks. No changes were observed for other tasks. Subject 2 experienced pain reductions across all tasks except LW and STS-A, where pain remained unchanged. Subject 3 noted relief in all tasks except SD in which pain increased by one point. Subject 4 reported no change in SA, SD, and RA, but observed pain reductions in all other tasks, with the largest reduction of 2 points in STS-D.

TABLE II
PAIN DIFFERENCE (EXO MINUS BARE)

	SA	SD	RA	RD	STS-D	STS-A	LW	Avg.
Subj. 1	-1	-1	-1	-2	0	0	0	-0.71
Subj. 2	-1	-1	-1	-2	-1	-2	0	-1.14
Subj. 3	-2	1	-1	-2	-1	0	0	-0.71
Subj. 4	0	0	0	-1	-2	-1	-1	-0.71
Avg.	-1	-0.25	-0.75	-1.75	-1	-0.75	-0.25	-0.82

Task difficulty decreased by an average of 0.57 points with exoskeleton use (Fig. 4, Table III). Subject 1 reported single-point decreases in difficulty for SA, RA, RD, and STS-A, but found STS-D more difficult with a single-point increase. Other tasks remained unchanged. Subject 2 found all tasks easier except level walking, which became slightly more difficult (single-point increase)—notably this participant had the highest reduction in difficulty of 3 points for STS-A. Subject 3 observed the greatest reduction in difficulty for SA of 2 points, followed by single-point reductions for RA and RD. Sit-to-stand and level walking tasks showed no change, while SD became slightly harder with a single-point increase. Subject 4 reported single-point decreases in SA, STS-D, and level, while RD was slightly more difficult (1 point increase).

The ensemble-averaged EMG activity and torque applied by the exoskeleton (normalized to the task cycle percentage) are presented for each of the seven locomotor tasks in Fig. 5. The plots illustrate how muscle activation patterns differ between the Bare (red) and Exo (blue) conditions and highlight the timing and magnitude of exoskeleton assistance torque (black) throughout the task cycle. Table IV presents

TABLE III
DIFFICULTY DIFFERENCE (EXO MINUS BARE)

	SA	SD	RA	RD	STS-D	STS-A	LW	Avg.
Subj. 1	-1	0	-1	-1	1	-1	0	-0.43
Subj. 2	-1	-1	-2	-1	-1	-3	1	-1.14
Subj. 3	-2	1	-1	-1	0	0	0	-0.43
Subj. 4	-1	0	0	1	-1	0	-1	-0.29
Avg.	-1.25	0	-1	-0.5	-0.25	-1	0	-0.57

the mean EMG differences between the Bare and Exo conditions, where negative values indicate reduced muscle activation with the exoskeleton. Subject 1 experienced decreased activation in most tasks (the across task average change was -1.7%), especially in STS-A having the highest change of -6.8%. Subject 2 showed mixed responses, with slight reductions in RA and STS-A, but slight increases in all other tasks—the across task average change was 1.1%. Subject 3 consistently showed reductions, most notably in STS-A, with only level showing an increase—the across task average change was -3.1%. In contrast, Subject 4 exhibited increased activation across all tasks (3.9% change on average). Overall, the data suggests that the exoskeleton may provide benefits in reducing the mean activation during activities that involve greater muscle exertion, like sit-to-stand transitions with an average reduction of -3.1% across all participants.

TABLE IV
MEAN EMG DIFFERENCE (% CHANGE RELATIVE TO BARE)

	SA	SD	RA	RD	STS-D	STS-A	LW	Avg.
Subj. 1	**-3.2**	**-0.4**	**-0.8**	0.2	**-3.4**	**-6.8**	2.4	**-1.7**

Avg.	0.4	0.9	0.7	0.0	0.1	**-3.1**	5.0	0.6

Table V highlights changes in peak EMG activation. Subject 1 exhibited the highest peak EMG change of -13.8% observed in STS-A—the across task average change was -2.2%. Subject 2 exhibited peak EMG increase in all tasks except STS-A—the across task average change was 2.2%. Subject 3 exhibited peak EMG reductions in all tasks except level—the across task average change was -3.3%. Subject 4 exhibited peak EMG reductions in SA and STS-A, but increases in all other tasks—the across task average change was was 5.5%. Overall, there were peak EMG reductions for SA, RD, and STS-A. Notably, STS-A had the highest and most consistent change with -8.5%.

TABLE V
PEAK EMG DIFFERENCE (% CHANGE RELATIVE TO BARE).
