HADAR Hand : 13-DoF Hybrid Actuation-based Dextrous Anthropomorphic Robotic Hand

Prashanth Jonna, Madhav Rao
IIIT Bangalore, prashanth.jonna@iiitb.ac.in, mr@iiitb.ac.in

***Abstract*— Dextrous robotic hand designs are pivotal in advancing the field of hand prosthetics, enabling users to perform robust grasping tasks essential for daily activities and improved quality of life. However, the widespread adoption of such dextrous hand prosthetics remains hindered by prohibitive costs that arise from the high number of actuators used to replicate natural human hand movements. This research seeks to address this challenge by critically evaluating the necessity of replicating many human hand DoFs and instead proposing a design that achieves 95% of human grasp configurations with a significantly reduced actuator count compared to conventional biomimetic robotic hands. We present the Hybrid-Actuated dextrous Anthropomorphic Robotic (HADAR) Hand, a novel 13-DoF robotic hand optimised for dextrous object grasping with a high degree of visual anthropomorphism. The HADAR Hand employs a hybrid actuation strategy, combining linkage-driven mechanisms for robust proximal joint control and tendon-based actuation for compliant distal joint movement, which is essential for delicate object handling. Utilizing insights from long-term occupational studies and Functional Range of Motion (FROM) data, rigid and elastomeric couplings were developed to bring down the actuator count to less than half the number of major tendons present in the human hand without compromising on the ability to perform human-like grasp configurations. Comprehensive performance evaluations validate the HADAR Hand's capabilities, with results demonstrating success in replicating hand grasps as per Cutkosky's taxonomy (14/15), Feix's GRASP taxonomy (31/33), and the Kapandji thumb opposability test (6/10). To promote accessibility and reproducibility, the HADAR Hand leverages cost-effective, widely available actuators, additive manufacturing techniques, and a compact, two-layer PCB capable of concurrently driving all 13 N20 DC motors that drive the HADAR Hand. This work represents a significant step in developing affordable, high-performance prosthetics and robotic hands.**

I. Introduction

Upper-limb prosthetics have evolved dramatically over the centuries, transitioning from rudimentary wooden limbs to sophisticated robotic systems designed to mimic human hand functionality [1]. Although a huge step forward, modern hand prosthetics still deal with the lack of dexterity [2]. As physical interfaces in human environments are inherently designed for the human hands, anthropomorphic robotic hands have emerged as a promising solution for achieving greater closure, dexterity, and manipulability [3]. But the complexity of the human hand, with over 100 tendons (27 of which are essential for motor functions), presents significant hurdles in replicating its structure and functionality within a compact form factor. Since the field of hand prosthetics significantly overlaps with that of robotic hands, we shall also look at robotic hand research to understand the design optimizations made to enhance dexterity with low actuator count. Biomimetic robotic hands like the Shadow Hand [4] that intend to closely replicate human dexterity typically rely on a high number of actuators, which dramatically increases the system's weight, footprint, and cost, limiting their widespread adoption. Conversely, simpler double four-bar linkage based designs commonly utilized in many prosthetic hands [5], [6] are relatively cost-effective but lack the fine-grained control necessary for precise manipulation tasks. This highlights a pressing need for a cost-effective yet dextrous robotic hand prosthetic.

The field of robotic hands was earlier dominated by high-DoF designs like the Shadow Hand, UB Hand IV, MPL v2 [4], [7]. These high-end robotic hands achieved exceptional dexterity using custom actuation mechanisms but are constrained by their high cost, weight, and reliance on custom components. On the other hand, there has also been the rise of simpler low-DoF robotic hands like InMoov [8], HRI Hand [9], and underactuated prosthetic hand designs like the Bebionic Hands [5], and Hannes [6], which prioritize affordability and durability but trade off dexterity and joint independence, limiting their application for high-dexterity demanding tasks. Direct drive-style robotic hands like ALLEGRO Hand [10] and LEAP Hand [11], although relatively cost-effective, are 30% larger than typical human hands, have higher inertia at joints due to the mass of embedded motors, and either lack critical movements like abduction/adduction or rely heavily on expensive actuators. Their lack of visual anthropomorphism also prevents them from being used as hand prosthetics.

Visual anthropomorphism has long been a priority in prosthetic design, but with the rise of humanoid robotics in the service and entertainment sectors, its importance has grown even further. The primary objective of this research with the development of the HADAR hand is to design a cost-effective, dextrous robotic hand that can achieve 95% human grasp configurations as defined by widely recognized grasp taxonomies while utilising a minimal number of actuators. Maintaining visual anthropomorphism and robust grasping capabilities were also priorities. By reducing actuator count and leveraging additive manufacturing, we aim to enhance functionality and minimize production costs and system weight. Recent advancements in additive manufacturing have led to more durable and affordable prosthetic solutions, as seen in designs like OpenBionics and the PSYONIC Ability Hand [12]. These developments highlight the growing potential of high-performance, low-cost 3D-printed prosthetics, reinforcing our decision to use 3D-printed components in the

HADAR Hand's fabrication. Moreover, because the HADAR Hand closely matches the size and proportions of a human hand and its digits, data from real-world human-hand object interactions can be used for imitation learning without any additional post-processing for prosthetic hand control at a later stage.

II. Design Considerations

Before we design the robotic hand, it is crucial to evaluate the functionality provided by the many degrees of freedom in human hands and their role in hand object interactions. There are many studies in literature that go in depth quantifying the utility of each DoF using measures like active range of motion (AROM), functional range of motion (FROM) and also look at the frequency of different hand grasps used by workers in real-world settings. Many robotic hand designs have also intelligently utilized such statistics to optimize for the number of DoFs in their design; therefore, we shall also look at the many robotic hand designs of the past to gain better insights on how we could reduce the number of actuators for the HADAR Hand.

A. AROM, FROM studies and Couplings

The active range of motion (AROM) that results from the constraints placed by ligaments on hand joints is a crucial metric to keep in mind while designing a robotic hand. However, it has also been noticed that the full active range of motion provided by our joints is not utilized during our day-to-day tasks and grasping activities. Hence, many scientific reviews focused on the topic of functional range of motion (FROM) have been published. This paper [13] notes that the FROM of MCP joints and palmar arch is highly dependent on hand size and gender since having a bigger hand would require one to flex more of his fingers and palm to grasp the same object. Although many robotic hands implement full-range MCP joints, palmer arch is often ignored, but is crucial in providing good closure while grasping objects. Abduction between fingers is found to have a high difference between AROM and FROM measures, with the abduction of the middle finger being quite low compared to other joint movements. Another study by Bain et al. [14], used electrical goniometry and made participants perform tasks as per the Sollerman test for hand grip function. They found out that 90% of the tasks could be completed with the utilization of only 48% of AROM at MCP, 59% at PIP, and 60% at DIP joints. To perform all the tasks as per the Sollerman test, a significant amount of extra movement at the MCP was required with not much difference in movement at the PIP and DIP joints. From this, we get to know that the movement at MCP is much more crucial than the ones at the PIP and DIP joints in the case of pre-grasp postures while performing precise manipulation tasks as stated in [5]. The work stated in [15] deals with reducing the number of DOFs in the hand by observing certain constraints present in our hands. It defines 1^{st}-degree constraints which are typical range of motion limits at each joint, and defines 2^{nd}-degree constraints as dynamic constraints like the PIP DIP motion constraint. Other dynamic constraints include how the range of abduction/adduction at an MCP joint of a digit is also limited by the flexion/extension at the MCP joint of the same digit. Certain observations have also mentioned that the abduction/adduction of the middle finger is close to zero.

B. DoF Design Strategies in Robotic Hands

Certain commonly used intra-finger couplings in many robotic designs are between the PIP and the DIP joints. The angle at the DIP is approximately $\frac{2}{3}^{rd}$ the angle at the PIP joint [15]. After observing the grasps present in most taxonomies, it is stated that the little finger plays a non-critical role in most grasps and hence is one of the less required DOFs. This is probably the reason behind assigning a minimal number of DOFs in the second version of Robonaut hand by NASA and the RoboRay hand by Samsung. In some cases, the little finger is completely removed, as seen in the ALLEGRO, LEAP hands. Another paper [15] focused on the hand joint couplings mentions the minimal movement of the middle finger in grasping different object geometries. Reduction of DoFs by eliminating the middle finger's abduction/adduction can be seen in the Schunk SVH 5-fingered robotic hand [16], which provides abduction/adduction movement for all digits except the middle finger. The CMC joint of the thumb is generally fixed in many prosthetics but has shown considerable movement in FROM studies, hence we will include all the major 4 DOFs of the thumb as seen in human hands. The 5^{th} DOF of the thumb involves changing the orientation of the thumb in order to provide appropriate opposition with other digits. This is generally fixed in most robotic hands at a particular orientation. We will adopt a similar architecture to the RoboRay Hand in terms of hybrid actuation to ensure that our robotic hand can be precisely manipulated, and also be compliant enough to handle delicate objects.

III. HADAR Hand system design

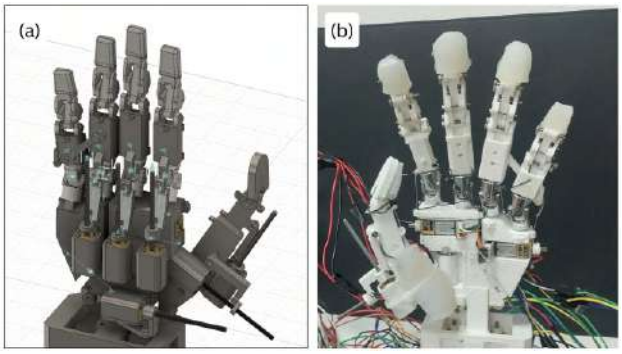

Fig. 1: (a) CAD model of the HADAR Hand in Fusion 360 (b) the fabricated HADAR Hand.

From the observations made in the previous section, we deduced certain design guidelines for the HADAR hand design. The PIP and DIP joints are coupled using four-bar linkages similar to the designs like the HRI hand [9]. Due to the comparatively lower involvement of the little finger in hand-object interactions, we constrain the MCP

joint of the little finger to the MCP joint of the ring finger. Although this decision can lead to a lack of imitation of certain possible human hand configurations, the effect of such a modification is minimal from a grasp point of view. One particular DOF typically overlooked by many robotic hand designs and crucial for better grasping is the mobility provided by the CMC joint below the ring and the little finger that provides palmar arching. We have modeled this DoF as a passive mechanism using elastomers. Abduction and adduction are some of the least utilized DOFs, but from a functional point of view, the abduction/adduction motion is crucial to performing power grasp, which is the most utilized grasp by household workers [17]. But the middle finger's MCP joint does not participate in the power grasp, and hence we eliminated it for the HADAR hand design. We use a set of tendon-driven actuation systems for the PIP-DIP-coupled movement for inherent compliance and use linkage-driven transmission for MCP joint movement to enhance precise control. The thumb plays the most important role in dextrous object grasping and in most cases acts as a single virtual finger by itself, therefore, we decided to use linkage-driven control at the CMC, MCP joints and tendon-driven control at the DIP joint. With the couplings decided and abstract actuation system design in place, our robotic hand will have 3 DOFs for the index finger (abd/add at MCP + flex/ext at MCP + flex/ext at PIP/DIP), 2 for the middle finger (flex/ext at MCP + flex/ext at PIP/DIP), 3 for the ring finger (abd/add at MCP + flex/ext at MCP + flex/ext at PIP/DIP) and 1 for the little finger (abd/add and flex/ext at MCP is coupled, only flex/ext at PIP/DIP is controllable). Here the notation abd stands for abduction, add represents adduction, $flex$ refers to flexion, and ext represents extension.

A. Components of the HADAR Hand

The HADAR Hand was designed in Fusion 360 as seen in Figure 1, with all the parts and linkages printed using a 0.1 mm layer height setting with an Ultimaker Cura S3 3D printer with PLA Pro material at 90% infill density. The MCP joints use a commonly available Stanley STMT86011-8B Chrome Vanadium Steel Universal Joint (1/4-inch), and the N20 motors used to drive the MCP flexion and extension are fitted with an M3 threaded rods and encoders. The N20 motors used for actuating the M3 leadscrew are the 6V 2000 rpm variant. The abduction of the index finger and the coupled ring-little finger is performed by 60 rpm 6V variant N20 motors embedded into the palm of the robotic hand. This is done instead of placing them in the forearm, as positioning them farther away increases tendon path, and concedes frictional losses, with degrading fine control of movement. The mobile CMC joint of the hand is introduced similar to the version 1 of InMoov Hand [8]; there are mechanical limits to ensure that the palmar arch does not cross 30°of inward rotation. Silicone finger pads and thumb tissue were designed to assist in the gripping of objects. All the fingertips were designed to replicate human fingertip's softness and elasticity. LSR-110 grade liquid silicone rubber was chosen for making fingertips as it is specifically rated to be used for mimicking the softness and elasticity of human upper limb parts and is generally used in prosthetic designs.

B. Kinematic Analysis of HADAR Hand

Fig. 2: Gradual flexion of index finger PIP-DIP joints.

1) Four-bar linkage kinematics for pip-dip coupling: The implemented four-bar linkage design follows exactly the same kinematics as described in the HRI hand paper [9] shown in Figure 2, since it mimics the natural human finger flexion and extension action. The mathematical equations that relates to the input and output angles are derived using loop closure and utilizes trigonometric identities, θ_b is the input at the PIP-DIP coupling, and θ_c is the output. Four bar linkages are quite popularly used and hence the widely available models are omitted in this paper for the sake of brevity. Figure 2 shows the four bar linkage in action.

2) Ring-little fingers abduction/adduction coupling: In Figure 3, we can see a barebones structural view of the proposed linkage mechanism in which a denotes the little finger, b denotes the ring finger, d represents the linkage and c is the grounded fixed distance between the MCP joints of the ring and little fingers. Using cosine and sine rules, we can easily compute the value of beta given the values of a, b, d and α.

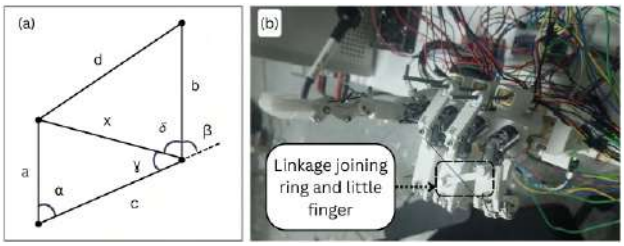

Fig. 3: (a) Mathematical representation of ring-little finger linkage (b) little-ring finger linkage of the HADAR Hand.

$$\alpha = \cos^{\propto 1}\left(\frac{a^2 + c^2 - x^2}{2ac}\right) \tag{1}$$

$$x = \sqrt{a^2 + c^2 - 2ac\cos(\alpha)} \tag{2}$$

$$\gamma = \sin^{\propto 1}\left(\frac{a\sin\alpha}{x}\right) \tag{3}$$

$$\delta = \cos^{\propto 1}\left(\frac{x^2 + b^2 - d^2}{2xb}\right) \tag{4}$$

$$\beta = 180 - \gamma - \delta \tag{5}$$

To optimize for the best coupling output, we set two conditions, when α is 68°, β should be in the range of $68° \pm m$, and when α is 118°, β should be in the range

of 88°± m, m refers to the margin. Setting up a python program configured to execute the mathematical model described above. The optimal a, b, and d parameters with least m was established. The optimal solution with m of β of 63.33°, α of 92.76 °, a of 14.0 mm, b of 27.2 mm, d of 29.8 mm for a given c of 20.6 mm was found.

3) MCP joint flexion/extension actuation mechanism: The Figure 4 is representative of the MCP flexion-extension movement produced using the lead screw mechanism actuated by N20 DC motors. The 'l2' side is the changing linear length actuated by the N20 lead screw mechanism, the 'l1' length is fixed and represents the parallel distance between the lead-screw attached to the N20 motor shaft and the vertical upward direction at the MCP joint. 'c' represents the length of the linkage used and 'r' represents the distance along the lower phalange from the MCP joint where the linkage is attached to the finger. Using trigonometric identities, one can easily derive the relation between the vertical actuation of the lead screw and the angle bent at the MCP joint, also expressed in the Equations 6, 7, and 8. By simulating the linkage mechanism, the effect of lengths 'r', 'c', 'l1' in the Figure 4 on 'l2' and θ was analyzed. Post optimization, we arrived at a solution for which around 25 mm actuation ('l2') would lead to a 0 to 90-°shift in θ. The range of motion at the MCP joint is 90 °and the linkage actuated motion derived from 'r', 'c', 'l1' parameters is demonstrated in Figure 4.

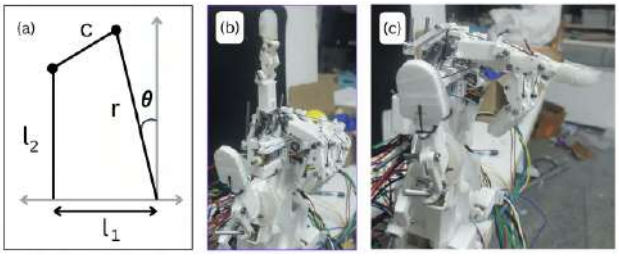

Fig. 4: (a) Mathematical diagram illustrating MCP flexion/extension model, (b) Snapshot of Index MCP joint fully extended, and (c) Snippet of Index MCP joint fully flexed.

$$(l_2 - r\cos\ \theta)^2 + (l_1 - r\ \sin\ \theta)^2 = c^2 \tag{6}$$

$$l_1 \sin\theta + l_2 \cos\ \theta = \frac{l_1^2 + l_2^2 + r^2 - c^2}{2r} \tag{7}$$

$$\sin\theta + \frac{l_2}{l_1}\cos\theta = \frac{l_1^2 + l_2^2 + r^2 - c^2}{2rl_1} \tag{8}$$

We take m = l_2/l_1 and the RHS of the above equation as k, shift the sin term to RHS and square the equation,

$$m^2 \cos^2\theta = k^2 + \sin^2\theta - 2k\sin\theta \tag{9}$$

$$(m^2+1)\sin^2\theta - 2k\sin\theta + (k^2 - m^2) = 0 \tag{10}$$

We now solve this quadratic equation by substituting a = m^2 + 1, b = -2k and c = k^2 - m^2 in the below standard quadratic equation solution to obtain the possible sin(θ) values and take inverse of sine to get the required θ values.

C. Electrical schematic

We use Teensy 4.0 as the main microcontroller for controlling the robotic hand. This choice has been influenced primarily by the 600 MHz clock speed of the ARM Cortex-M7 processor, which helps in managing sensor data in addition to high-density tactile sensor information. Controlling 13 N20 motors is a tedious task for any microcontroller, hence we designed a PCB that utilizes external IO pin extenders and PWM signal generators that continuously provide the required control signals to drive the N20 motors, significantly offloading processing from the microcontroller board. PCA9685 12-bit 16-channel PWM generator and PCF8575 16-bit digital IO expander were used for this purpose. This PCB is entirely controlled using an I2C bus, hence any microcontroller with an I2C bus can effectively control the speed and direction of 13 actuators concurrently. The encoder pins from the N20 motors are attached to Teensy directly and are programmed to trigger interrupts on the rising edge of the encoder signal. Due to the high clock speed of Teensy 4.0, multiple interrupts are generally triggered for one rising edge event, hence software debounce timers were implemented to resolve this issue.

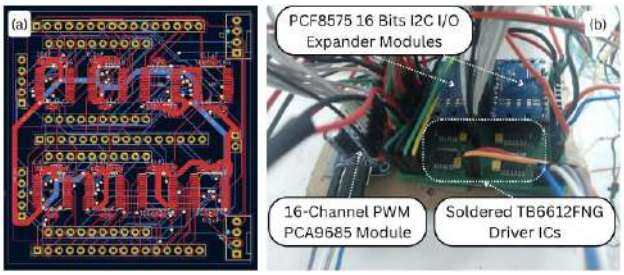

Fig. 5: (a) Designed PCB in KiCAD tool, (b) Manufactured and assembled PCB board that controls the HADAR Hand.

The PCB design for the 16-channel motor driver was done in KiCAD v7 as shown in Figure 5. A two-layer PCB was designed and SMD versions of TB6612FNG, tantalum capacitors and 0603 package resistors were used. Decoupling capacitors were placed near the motor driver ICs and the PCB by itself only contained 8 TB6612FNG and 2 PCF9685 digital IO extender modules that were used to stack on top of the TB6612FNG SMD components. This was established to make the design as compact as possible. The PCA9685 PWM module is connected to the PCB board externally and is wired again into the PCB's middle section using jumper wires to enable efficient track routing as in Figure 5. The routing was completed using auto-routing plugin in KiCAD. The track widths were chosen as per the total usual operation current load estimated to be drawn by 16 N20 motors concurrently when in operation. We did not include current during stall torque condition in our estimation as that would result in 16 A in the worst-case scenario, resulting in designing a very high track width that cannot be allowed in our 2-layered compact PCB due to routing issues caused by such high track width. The manufacturing cost of the developed HADAR hand system was under 300 USD.

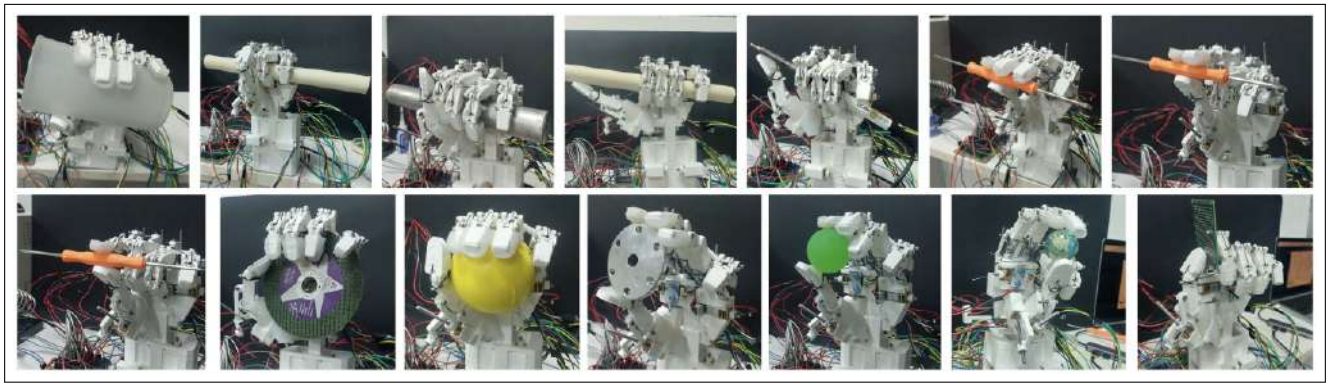

Fig. 6: The grasps imitated by the proposed HADAR hand as per the Cutkosky Taxonomy. The mentioned grasps are depicted in the order of left to right, top to bottom. The numbers assigned for each of the grasp motion matches the original Taxonomy: (1) Large Diameter, (2) Small Diameter, (3) Medium Wrap, (4) Abducted thumb, (5) Light tool, (6) Thumb 4 finger, (7) Thumb 3 finger, (8) Thumb 2 finger, (9) Thumb index finger, (10) Disk (Power), (11) Sphere (Power), (12) Disk (Precision), (13) Sphere (Precision), (14) Tripod, (16) Lateral Pinch. Score achieved: 14 out of 15, Prismatic 4-finger grasp was not robust enough.

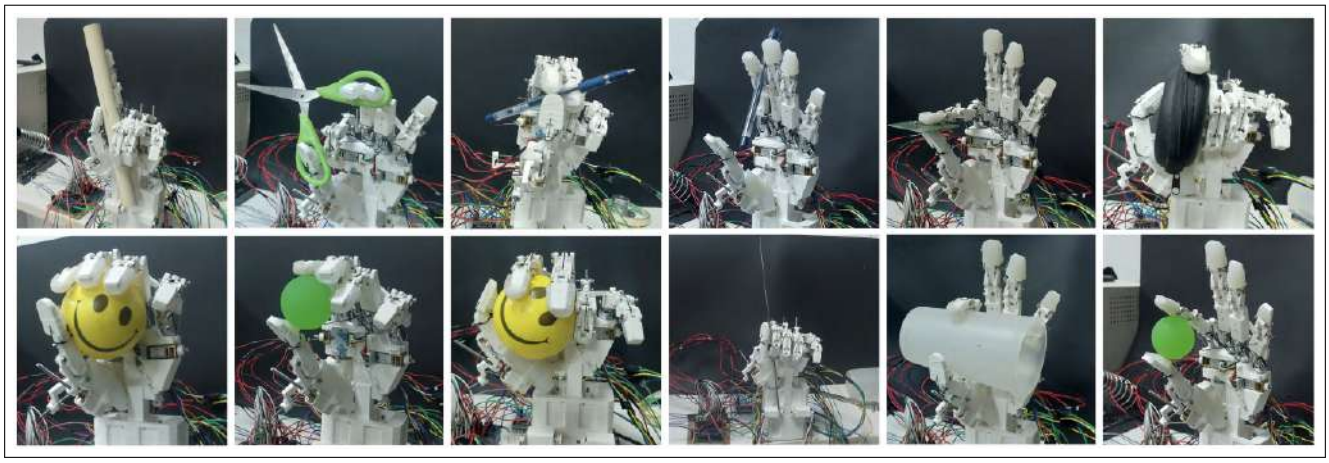

Fig. 7: Imitation of unique grasps from Feix's GRASP Taxonomy in the order of left to right, top to bottom (the numbers here are as per the number assigned to hand grasps in the original Feix taxonomy) : (17) Index finger extension, (19) Distal type, (20) Writing Tripod, (23) Adduction Grip, (24) Tip Pinch, (25) Lateral Tripod, (27) Quadpod, (28) Sphere - 3 finger, (29) Stick, (31) Ring, (33) Inferior Pincer. Score achieved: 31 out of 33, Prismatic 4 finger and Tripod variation grasps was not robust enough.

IV. Experiments and Results

Structuring and organizing hand grasps into a hierarchical taxonomy is useful to better understand the interaction of the hands with different objects as well as to advance and evaluate the graspability of prosthetics and biomimetic robotic hands that try to imitate human hands. Hand taxonomies are such systems used to classify and categorize various hand gestures, movements, and configurations. Hence we will look at the most popular hand taxonomies used in literature and evaluate our developed HADAR hand using them. The significant ones that are highly cited in this domain and well-accepted are Cutkosky's taxonomy [18], the grasp taxonomy [19], and kapandji's thumb opposibility test [20]. Cutkosky's Taxonomy is one of the first widely used taxonomies that aid the design of rehabilitation devices, prosthetics and robotic hands to this day. The cutkosky taxonomy is a rather highly discretized taxonomy and the author of this taxonomy admits that the taxonomy proposed is not complete and that many grasps are not covered individually in this categorization. The author calls them "children" of a particular described grasp type as these are typically slight modifications to one of the grasp types proposed in the taxonomy. Since many robotic hands have benchmarked using this taxonomy in literature, and hence for the sake of completeness, the same was used to benchmark our proposed HADAR hand. As can be seen in Figure 6, our designed HADAR Hand is able to perform 14 out of the 15 grasps present in Cutkosky taxonomy, unable to reproduce the prismatic 4 finger due to the little-ring coupling we introduced. We shall also evaluate our HADAR hand against Feix's grasp taxonomy, which is known to be the most extensive taxonomy incorporating all the grasps possible by human hand. The authors of this taxonomy state that the GRASP taxonomy is the product of a comparison of 22 wide-hand grasp taxonomies proposed

in the literature. The authors make a bold claim by stating that the proposed taxonomy is the most complete to date and they have never encountered a hand grasp that cannot fit into the taxonomy. As we can see in Figure 7, the HADAR hand is able to robustly mimic 31 of the 33 grasps. Hand grasps (18), (22), (30), and (31) from the Felix GRASP taxonomy are not displayed here as they are basic grasps performable by most under-actuated robotic hands and do not require even a mediocre amount of dexterity to imitate. (21) The Tripod variation was not replicated by the HADAR hand as it required precise force controls and hence was omitted. (29) Stick and (32) Ventral had very minimal difference and hence (32) was omitted for the sake of conciseness. The developed robotic hand was manually controlled to grasp different objects presented in Figures 6 and 7. A kapandji thumb opposibility score of 6 is attainable by the HADAR Hand as can be seen in Figure 8.

Fig. 8: Robotic hand grasp configurations that lead to Kapandji score of 6/10.

V. Conclusion and Future Work

This paper introduced the HADAR Hand, designed to achieve near human-like dexterity with a minimal number of actuators. We deeply questioned the necessity of replicating every joint of the human hand and employed couplings by analyzing the functional range of motion (FROM) statistics in literature to bring down the number of actuators required to drive the HADAR Hand. The system was rigorously assessed against established grasp taxonomies, such as those of Cutkosky and Feix, to quantitatively evaluate its versatility. Future work will focus on enhancing and quantitatively measuring grasp robustness and exploring synergy-based control strategies. Additionally, to advance its application as a prosthetic, we aim to integrate EMG signals with egocentric vision, high-density tactile sensing, and proprioceptive feedback for autonomous object grasping.

Muscle Synergy Analysis of Healthy Subjects Using a Soft Elbow Exosuit During Load-Carrying Tasks

Ali KhalilianMotamed Bonab[1*], Cristian Camardella[1], Antonio Frisoli[1], and Domenico Chiaradia[1]

***Abstract*—Soft assistive wearable robotics, or soft exosuits, have shown great potential in enhancing human motor function while preserving the user's natural movement. They are increasingly used to reduce fatigue and the risk of injury during physically demanding tasks and everyday activities. A deeper understanding of how assistive forces from soft exoskeletons influence muscle coordination during various tasks is crucial for developing optimized control and rehabilitation strategies for these devices. This study investigates muscle synergies in healthy participants carrying loads, as often performed in daily activities, over an extended period, both with and without the assistance of a soft elbow exosuit. Synergies similarity was analyzed by comparing the extracted patterns in both conditions, as well as their composition in terms of muscle contributions. The results show that, on average, in the with-exosuit condition fewer synergies are required to explain the performed movements. This suggests the idea that the assistive device "aggregates" motor primitives while reducing muscle activation. Furthermore, we found that synergies dominated by the wrist flexor, biceps, and infraspinatus were not altered by the exosuit assistance. However, the deltoid-dominated synergy observed during load carrying without the exosuit was altered by the exosuit assistance, shifting to a triceps-dominated synergy.**

I. Introduction

Soft assistive wearable robotics, or soft exosuits, have shown great potential in enhancing human motor function and are increasingly used to reduce fatigue [1], [2] and the risk of injury during physically demanding tasks [2], [3], as well as in everyday activities [4]. These devices provide mechanical assistance while preserving the natural movement patterns of the user. Understanding how humans adapt during assisted movements along with analyzing the individual muscle recruitment patterns is crucial for comprehensively assessing the impact of these devices on user performance and for optimizing their assistance strategies to develop more effective and generic support, and rehabilitation control strategies.

Muscle synergy analysis is a computational approach used to understand how the central nervous system (CNS) simplifies the control of muscles during complex movements [5]. According to the theory, rather than managing individual muscles, the CNS coordinates groups of functionally related muscles called muscle synergies, which act as motor primitives to perform tasks. This reduces the dimensionality of motor control, allowing for more efficient movement coordination despite the large number of muscles involved [5], [6].

Muscle synergies are typically extracted from electromyography (EMG) data by decomposing the muscle activation patterns into synergy vectors, representing the contribution of each muscle, and time-varying activation patterns, which reflect how these synergies are activated over time [7]. Methods such as non-negative matrix factorization (NNMF) [8] are commonly used for this decomposition [7]. The combination of these components helps reconstruct the original EMG signals, providing insights into the neuromuscular strategies used for movement.

Recent studies have emphasized the importance of muscle synergy analysis in developing effective control strategies, like myoelectric control [9], and gaining deeper insights into the performance of assistive robotics, particularly in the context of neurological impairments. In healthy individuals, research has shown that the constrained limb movements imposed by robotic rigid exoskeletons do not significantly alter muscle synergies, indicating that muscle coordination patterns remain stable under robotic assistance [10]. Similarly, studies have found that muscle synergies during lifting tasks remain consistent with and without the use of passive exoskeletons, suggesting that natural muscle recruitment strategies are preserved in non-pathological conditions [11]. However, during fatiguing stoop-lifting tasks with lumbar support exoskeletons, changes in muscle coordination were observed, particularly in the timing coefficients of synergy activation, highlighting how exoskeletons can influence the dynamics of muscle recruitment under more strenuous conditions [12]. Additionally, the use of ankle exoskeletons has been shown to modulate muscle recruitment patterns in healthy individuals, suggesting potential applications for rehabilitation by adapting muscle coordination strategies [13].

From a rehabilitation perspective, abnormal synergy patterns have been observed in patients with multiple sclerosis and stroke, revealing disrupted motor control that can be targeted for therapeutic interventions [14]. In stroke patients, robotic rehabilitation interventions have been shown either to modify muscle synergies to more closely resemble those of healthy individuals [14], improving motor control and upper limb function during activities of daily living (ADL) [15], or, mainly on chronic stroke patients, not to alter pre-existing compensation strategies, with muscle synergies resembling a new motor control [16]. In multiple sclerosis patients, exoskeleton-

assisted walking influenced muscle activation patterns without altering the existing synergy modules [17].

Despite extensive research on muscle synergies in various exoskeleton applications, no studies have specifically investigated how soft exosuits affect muscle synergy patterns in healthy individuals during load-carrying tasks. Understanding how assistive forces from soft exoskeletons influence muscle coordination in different tasks is crucial for developing optimized control and rehabilitation strategies [18] for soft wearable robotics. To bridge this gap, this study investigates muscle synergies in healthy participants while carrying loads within the range of daily activities over an extended period, both with and without the assistance of a soft elbow exosuit. By analyzing changes in muscle activation patterns, we aim to reveal how soft exosuit assistance modifies muscle coordination in isometric, load-bearing tasks. The insights gained will contribute to the design of more effective assistive strategies for wearable soft robotics, with applications in both everyday and occupational settings.

II. Methodology

A. Elbow Exosuit

The elbow exosuit, shown in Figure 1, used in this study is designed to support the extension and flexion movements of the elbow joint as a tendon-driven exosuit that delivers the assistive force to the elbow joint by pulling tendons wrapped around the joint. The actuation unit incorporates a brushless DC motor (Cubemars AK80-9) with an integrated 9:1 planetary gearbox, capable of producing a rated torque of 9 N·m. This motor is connected to a pulley that manages four stainless steel cables (AISI 316, 6 x 19 - WSC, PA -12 Coated, Carl Stahl) arranged in an antagonistic configuration—two cables facilitate elbow flexion while the other two assist with extension. These cables pass through Bowden sheaths (Jagwire, LEX-SL, ⌀4 mm) to connect to the proximal anchor points.

The exosuit body includes a back attachment, shoulder harness, upper-arm cuff, forearm cuff, and hand brace. The back attachment houses the actuation unit, electronics, and battery. The shoulder harness (Master-03, Reh4mat) secures the upper-arm cuff, which acts as the proximal anchor point and transfers reaction forces to the wearer's body. The upper-arm cuff contains four proximal anchor points that transmit force from the actuation unit to the elbow joint, along with a custom-designed board equipped with an inertial measurement unit (IMU, BNO 055) for data acquisition from load cells and the distal IMU (BNO 055), and transmitting them to the main control board. The forearm cuff secures the four distal anchor points, with two of the anchor points having loadcells (LSB201, Futek) linked to one flexion and one extension cable to measure tendon tension, complemented by another IMU (BNO 055) that works in conjunction with the upper-arm cuff's IMU to calculate elbow kinematics. The total weight of the exosuit is 4085 grams, including a 1400-gram battery.

The control system, adapted from Xiloyannis et al. [4], is designed to provide assistance by partially compensating for the gravitational load on the wearer's arm while minimizing interference with natural arm kinematics, thereby reducing interaction forces between the user and the exosuit. The control architecture employs a collocated admittance controller [19], featuring an outer-loop admittance control along with gravitational assistance and an inner-loop velocity controller. The main control board connects to an external laptop via Ethernet for command input and data transfer. Both the main control board and the upper-arm cuff board execute high-level control and communication at a frequency of 500 Hz.

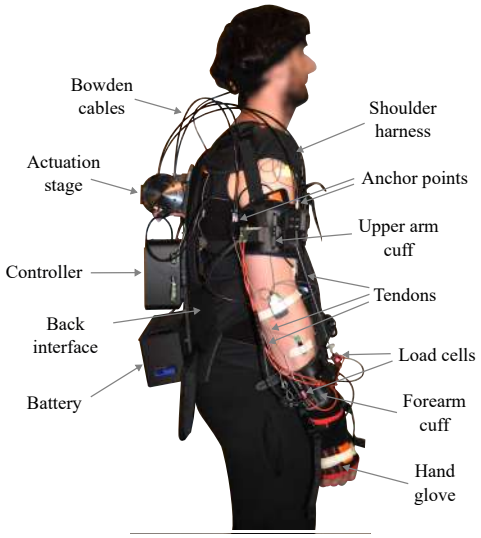

Fig. 1. Components of the soft elbow exosuit, with mechanical components, electronics, and sensing units.

B. Experimental Procedure

This study is aimed at characterizing the upper-limb muscle synergies in healthy participants while carrying a load with and without receiving assistance from an elbow soft exosuit. The experiments were conducted with 10 healthy participants (9 male and 1 female, age: 29.7 $\pm$ 2.75 years, height: 178 $\pm$ 6.32 cm, weight: 77.3 $\pm$ 10.01 kg, mean $\pm$ std). All subjects were right-handed and had no impairments that could affect them in performing the task. They were instructed to avoid fatiguing themselves prior to the experiments. Participants were briefed on the experimental procedures and provided informed consent. The experimental protocol and procedures were approved by the Scuola Superiore Sant'Anna Review Board.

To evaluate muscle coordination, participants walked on a treadmill while carrying a 3.5 kg weight, maintaining their elbow at a 90-degree angle. The experiment duration varied between 4 to 6 minutes, with all participants completing at least 4 minutes. If a participant was able to continue, the trial was extended up to a maximum of 6 minutes. This approach ensured that each participant could perform the task without excessive fatigue while maintaining a comparable effort level across subjects. The arm orientation was continuously monitored throughout the experiment. At the beginning of

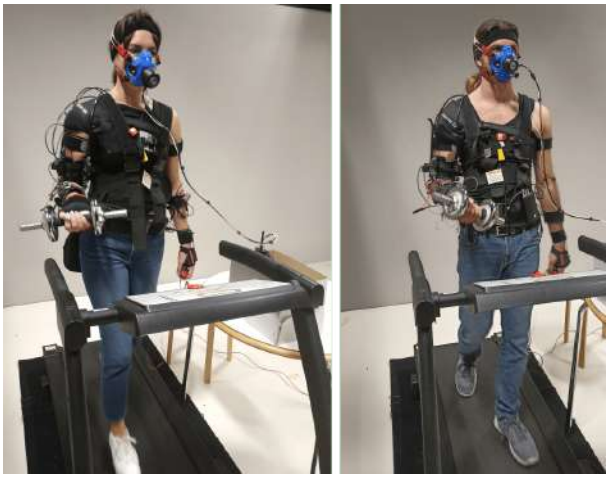

Fig. 2. The setup of the load-carrying experiment. The subjects in the figure wear the soft elbow exoskeleton while carrying a load on the right limb, also walking at a self-selected comfortable speed. Upper body kinematic, EMG, and calorimetry data were collected. Calorimetry data has not been used in this study.

the session, participants were familiarized with the task and determined their preferred walking speed.

Participants were then asked to walk under two conditions: (a) carrying the weight without wearing the exosuit, and (b) carrying the weight while receiving assistance from the elbow exosuit. The conditions were presented in a randomized order to minimize any learning effects, and participants were given at least 5 minutes of rest between the conditions to prevent fatigue effect on the experimental results. A sample experimental session is shown in Figure 2.

At the start of each experimental session, nine electromyography (EMG) sensors (Delsys, Trigno Quattro, and Trigno Avanti) were applied to the primary muscles involved in shoulder, elbow, and wrist movements, including the Deltoid (Anterior, Posterior, Middle), Infraspinatus, Triceps Long Head, Biceps Short Head, Brachioradialis, Extensor Carpi Ulnaris, and Flexor Carpi Radialis. EMG signals were captured with a sampling rate of 2148.1 Hz and the electrode placement was performed according to the guidelines in [20]. The acquired raw EMG data underwent post-processing, i.e. band-pass filtering (30–450 Hz), full-wave rectification, and low-pass filtering at 6 Hz using a zero-phase second-order Butterworth filter. For comparability across conditions and participants, the processed EMG envelopes were normalized to maximum voluntary contractions (MVC), which were measured at both the beginning and end of the session and then averaged to mitigate potential fatigue effects on the measurements. Finally, abnormal peaks and artifacts were manually removed to prevent distortions in metric calculations and statistical analyses.

C. Synergy Extraction

For each participant and condition, muscle synergies were derived from the normalized EMG envelopes of nine muscles using the non-negative matrix factorization (NNMF) algorithm [8], [21]. This algorithm decomposes the EMG envelope into a specified number of positive components, referred to as muscle synergies, as shown in Equation 1. The structure of each synergy is defined by the contribution (weight coefficient) of each muscle, represented in the weight matrix W, while the activation profile is given by the activation coefficients in matrix H. The residual error is represented by matrix E.

$$\mathrm{EMG}_{n\times m}(t) = W_{n\times r}H_{r\times m}(t) + E_{n\times m}(t) \tag{1}$$

To account for the potential of the iterative algorithm to converge on a local rather than a global minimum, the extraction process was repeated fifty times, and the solution with the highest overall explained variance was selected. The NNMF algorithm requires specifying the number of muscle synergies to extract; here, synergy extraction was performed with values ranging from two to seven, resulting in six sets of muscle synergies for each subject under each condition.

To assess the quality of synergy reconstruction, we employed the Variance Accounted For (VAF) metric [22], as defined in Equation 2. This metric quantifies the proportion of variance captured by comparing the sum of squared errors to the total squared sum of the EMG data. VAF values were calculated for each subject under each experimental condition.

$$\mathrm{VAF} \ = 1 - \frac{\mathrm{EMG}_{n\times m}\,(t) - W_{n\times r}H_{r\times m}\,(t)}{\mathrm{EMG}_{n\times m}\,(t) - \overline{\mathrm{EMG}}_{n\times 1}} \tag{2}$$

Here, EMG represents the recorded EMG signals, and $\overline{\mathrm{EMG}}$ denotes their mean values, while W and H correspond to the synergy weights and activation matrices, respectively. By comparing the sum of squared errors to the total squared sum of the EMG data, this method evaluates the quality of synergy reconstruction for each subject and condition. To determine the optimal number of muscle synergies, we applied two established criteria based on the Variance Accounted For (VAF) values across different synergy counts. The first criterion involves assessing the slope of the VAF curve: when the mean squared error of a linear fit to the remaining portion of the curve falls below a predefined threshold, indicating that adding more synergies results in negligible improvement, the current count is selected. The second criterion is based on a target VAF threshold; the smallest number of synergies whose median distribution exceeds this threshold is identified. The final choice of the optimal synergy count is the maximum between the two criteria, ensuring both adequate data representation and minimized redundancy.

In order to reorder the synergies of subjects and maximize the match between them, a random subject was selected as a reference. The similarity between the synergies of other subjects and those of the reference subject was calculated using cosine similarity, as expressed in Equation 3.

$$S = \frac{\mathbf{A}\cdot\mathbf{B}}{|\mathbf{A}|\,|\mathbf{B}|} \tag{3}$$

Here, $\mathbf{A}$ and $\mathbf{B}$ represent the synergy vectors for two different subjects, with $\mathbf{A}$ corresponding to the reference subject and $\mathbf{B}$ to another subject. The computed similarity

matrix was then used to reorder the synergies for each subject across both conditions.

D. Statistics

The Pearson correlation coefficient was used to compute the similarity between synergy in two different conditions. The Pearson correlation coefficient is defined as Equation 4.

$$R = \frac{1}{N-1} \sum_{i=1}^{N} \left(\frac{A_i - \mu_A}{\sigma_A} \right) \left(\frac{B_i - \mu_B}{\sigma_B} \right) \tag{4}$$

Here, $\mathbf{A}$ and $\mathbf{B}$ represent the two synergy vectors, N is the number of scalar observations, μ_A and σ_A are the mean and standard deviation of $\mathbf{A}$, respectively, and μ_B and σ_B are the mean and standard deviation of $\mathbf{B}$.

The computed R value for the correlation of synergies was then compared against the critical value from the Pearson correlation lookup table [23]. If the R value exceeded the threshold corresponding to $p = 0.05$, the null hypothesis was rejected, indicating that the two synergies were significantly correlated.

III. Results and Discussion

In this study, a VAF threshold of 90 % [22] and a slope threshold of 0.001 were applied to determine the optimal number of synergies. These criteria identified three synergies as optimal for the without-exosuit condition and four for the with-exosuit condition. However, four synergies were selected for both conditions, given both the wide distribution of values in the with-exosuit condition and to facilitate better matching and to enable a proper comparison. The VAF values across different synergy numbers are shown in Figure 3. As shown in this figure, the exosuit created an "aggregation" effect on synergies: given a certain number of synergies, the variability of the signal explained by them, i.e. the VAF distribution, is always higher than the without-exosuit counterpart, meaning that, for some of the involved subjects, less synergies are required to explain the performed movements and muscles are "aggregated" in fewer motor primitives. This behavior is comparable to other studies in literature: Tan et al. [12] showed that in stoop lifting task, under fatigue conditions, the VAF was higher in the with-exoskeleton (i.e. the HAL lower limb exoskeleton) condition. The same effect has been found by Ding et al. [11] in load lifting tasks with and without an upper limb exoskeleton.

The mean optimal muscle synergies for the with and without exosuit conditions, along with the Pearson correlation coefficient is presented in Figure 4. The analyses of similarities show that there are significant correlations between the first, second, and fourth synergies indicating that the assistance provided by the exosuit does not alter these synergies while carrying a load. Analyzing the shape of extracted common synergies, it is easy to find dominant muscles in each of them. The first synergy is easily explained by the particular hand pose subjects had to perform while holding the weight: having the up-oriented hand palm put the wrist flexor under the influence of gravity, thus, requiring it to be over-activated in a specific functional motor action. Looking at figure 5, it can be clearly visualized the influence of the FCU in driving the first synergy: the synergetic activation (Synergetic Activations, left) in the case of the with-exosuit condition progressively increases as the muscle activity increases (EMG activations, right) while it stays constant in the without-exosuit condition, reflecting the related FCU muscle activity. Other increasing muscle activity over time, like in the case of BRACH or ECU are distributed among multiple synergies, thus not constituting the main contribution of independent motor primitives. The second and fourth synergies are dominated respectively by the biceps and the infraspinatus, revealing typical lifting and arm supporting motor actions [24]. These synergies stay constantly activated in the case of the with-exosuit condition with a lower activation value compared to the without-exosuit revealing the contribution of the assistive device in the motor actions (see figure 5). The fourth synergy in particular, in the case of the without-exosuit condition, in its increasing behavior, reflects the increasing support of the infraspinatus in the load-carrying motion, given the absence of additional supports. A specific discussion is deserved for the third synergy which is a deltoid-dominated synergy during carrying the load without an exosuit was altered by the exosuit assistance shifting it to a triceps-dominated synergy.

This shift could be explained by considering the primary functions of the anterior deltoid and triceps muscles. The anterior deltoid plays a key role in shoulder flexion and stabilization during forward-reaching and load-carrying tasks, and it has been shown that external support, such as assistance to the forearm, can reduce the activity of this muscle [25]. With the exosuit providing active assistance during load carriage, the workload on the anterior deltoid, which helps stabilize the shoulder complex, may decrease. As a result, muscle activation may shift towards the triceps, which could become more involved in stabilizing the elbow joint, particularly during tasks that require both elbow flexion and extension.

The findings of this study are consistent with those reported in a simulation of an elbow-wrist exosuit used for lifting a similar load [26]. Both this study and similar simulation-based study [27] indicate that the human body optimizes muscle coordination across the entire muscle group, implying that

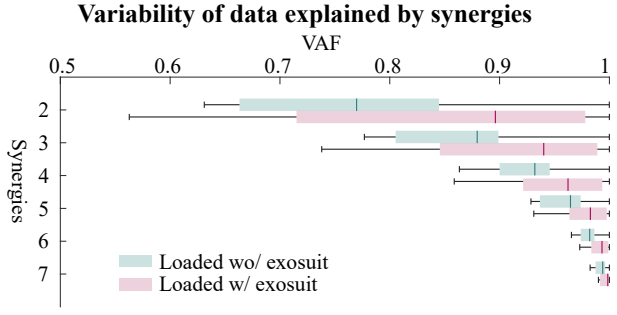

Fig. 3. The variability of data explained by synergies (i.e. VAF) in both experimental conditions, for an increasing number of synergies.

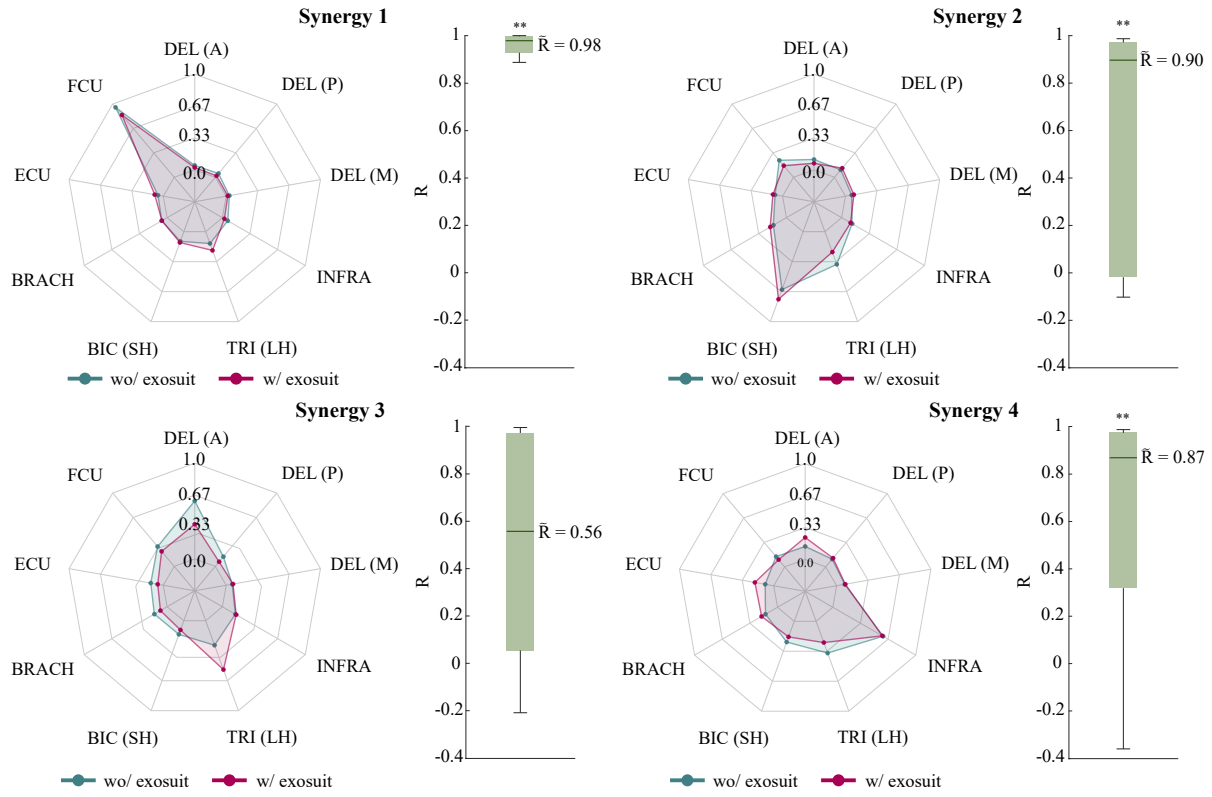

Fig. 4. The mean muscle synergies across two experimental conditions and their Pearson correlation. Radar plots show the synergy weights (W matrix in Equation 1) muscle by muscles, where the vertexes of the polygon represent a value equal to 1. The Pearson coefficient is computed through the comparison between synergy patterns (i.e. arrays) in without exosuit condition and with exosuit condition.

assistance at one joint can influence the activity of muscles that do not directly span that joint. Specifically, this study experimentally demonstrates that providing assistance at the elbow joint during a prolonged load-bearing task can decrease the involvement of the anterior deltoid, leading to a shift towards a triceps-dominant synergy.

IV. Conclusion

In this study, a muscle synergy analysis was performed on an elbow soft exosuit demonstrating that it allows for physiological load-carrying movements under an assistive control strategy, with the possibility to catch even little variations on physiological patterns and to reveal important improvements that can be applied to the device. This outcome supports the idea of using soft exoskeletons, such as the ones with cable actuation, both in clinical environments to perform upper limb rehabilitation sessions and to support activities of daily living. It also confirms the usefulness of muscle synergies as an assessment tool for detecting both patterns in motor coordination and potential alterations of these while wearing assistive devices.

It is important to note that the task analyzed in this study involved an isometric contraction of the elbow, thus these findings should not be directly generalized to other movement conditions. To address this limitation, future work will focus on gaining deeper insights into the effects of soft exosuits on muscle synergies by assessing functional movements. Such studies would provide a more comprehensive understanding of how exosuits influence arm motor function. This knowledge could guide the design of more effective soft exosuit-based therapy sessions, maximizing their therapeutic impact and improving outcomes for patients undergoing rehabilitation.

***Abstract*—Metabolic rate, the amount of energy expended over time, can be influenced by passive assistive devices like specialized footwear and exoskeletons. While most assistive device research has focused on elite athletes or recreational runners at a single speed, few studies have explored how these devices might affect metabolic rate across a range of running speeds. This study investigates the effect of a passive assistive device (exotendon), which connects a runner's legs, on metabolic rate in recreational runners across multiple speeds. In contrast to previous work, only 9 of 16 participants reduced metabolic rate with the device at 2.67 m/s, by an average of 7.6%. While all participants significantly increased stride frequency - a key factor identified in previous work for its influence on metabolic rate - the group that did not reduce metabolic rate exhibited greater variability in average stride frequency for both conditions. For those who reduced metabolic rate with the exotendon at 2.67 m/s, similar improvements extended across speeds from 1.68 to 4.36 m/s. These results indicate that the exotendon's effect on metabolic rate varies across individuals but can extend beyond a single running speed in those who respond to the device. This suggests that passive assistive devices may benefit some runners across a range of speeds, with potential applications for training and performance as well as rehabilitation, where reducing energy demand could aid recovery and mobility.**

***Index Terms*—metabolic rate, human running, assistive device**

I. Introduction

Techniques to reduce and understand metabolic rate (MR) have garnered the attention of numerous researchers, engineers, and athletes alike. If a product or technique could reduce the energy demand of running, would athletes use it? Here, we explore the use of an exotendon to influence MR and investigate its effects across a range of running speeds.

MR reflects the rate of energy expenditure during running and is assessed by analyzing oxygen consumption and carbon dioxide production [1]. MR demonstrates how energy is used at various speeds, with recreational runners showing a linear increase in MR as running speed increases from ∼2-4 m/s [2]–[4]. Comparing MR across populations or conditions can provide insight into the energy demands of running.

Various biomechanical factors, including gait patterns, kinematics, and kinetics, influence MR [5]–[7]. By optimizing these factors, runners can reduce their energy expenditure at various speeds [8]–[11]. As speed increases, the relative contribution of these factors shifts; for example, increasing stride length initially drives performance improvements, but eventually plateaus, necessitating further speed increases to come primarily from stride frequency [12]. This shift reflects the body's adaptation to maintain efficiency, conserving energy even as speed increases. Reducing MR is beneficial not only for improving running economy performance [13], [14] but also potentially for rehabilitation. Passive assistive devices, such as the exotendon, may facilitate recovery by minimizing MR, enabling injured runners to maintain activity and gradually reintegrate into training [15].

Specialized footwear is another factor that has been shown to reduce MR; however, most research has focused on elite athletes [16], [17], with only a few studies exploring benefits in recreational runners [14]. One notable example is the Nike Vaporfly 4% (VP4), which has demonstrated an average MR reduction of 3-4% compared to mass-normalized shoes, based on studies involving highly trained athletes at speeds of ∼4-5 m/s [18], [19]. Although research on recreational runners is limited, one study showed that at speeds of ∼3-4 m/s, recreational runners wearing the VP4 had a 4.3% reduction in MR compared to running in their habitual shoes [14]. Collectively, these findings highlight the ability of specialized footwear to reduce MR at varying speeds and levels of athletes.

Efforts to reduce MR have expanded beyond footwear to include passive assistive devices, such as lower-limb exoskeletons, which are designed to provide mechanical assistance at the hip, knee, and/or ankle joints [20]–[22]. These devices have demonstrated MR reductions in recreational runners when tested at fixed speeds of 2.5 and 2.67 m/s. For example, two recently developed devices focused on hip augmentation have shown MR reductions of 8-9% when running on a treadmill at 2.5 m/s [20], [21]. Another device, the exotendon, is a spring connecting a runner's legs that targets the metabolic energy

expended for leg swing. Their study demonstrated a 6.4% reduction in MR at 2.67 m/s, with the exotendon reducing MR by increasing the energy-optimal stride frequency [22]. While these advancements in assistive devices are notable, the focus on a single speed limits our understanding of their impact on MR across a broader range of speeds.

In this study, we first replicated the work of Simpson et al. [22] to determine whether running with the exotendon reduced MR at a fixed speed of 2.67 m/s. Expanding on this, we tested the hypothesis that MR would decrease across a range of speeds (between $\sim$2 and 4 m/s) when running with the exotendon, compared to without, for those who responded positively to the device at 2.67 m/s.

II. Methods

A. Participants

A total of 18 healthy young adults (9 female) with no known musculoskeletal or cardiopulmonary impairments participated in the first phase of this study. All participants were self-classified as recreational runners, with typical running speeds ranging from 2.67 to 3.35 m/s [23]. Two participants were excluded from data analysis due to missing data or discomfort interacting with the device. Additionally, seven participants were excluded from the primary analysis because they did not demonstrate a reduction in MR when running with the exotendon at 2.67 m/s (see details in section IIE). Therefore, nine participants are included in the primary analyses focused on MR outcomes across a range of speeds (5 female; age=28 ± 4.2 yrs.; mass=64.6 ± 8.6 kg; height=170.7 ± 9.9 cm; mean ± s.d.). The study protocol was approved by the University of Colorado Boulder's Institutional Review Board (Protocol #23-0292) and all participants provided written consent prior to participation in the study.

B. Experimental Protocol

Participants completed a three-day experimental protocol (Fig. 1A) involving running on a force-instrumented treadmill (Bertec, OH, USA) at both fixed and self-paced speeds. To allow participants to recover from fatigue while maintaining their familiarity with both the self-pacing treadmill and the exotendon, each experimental session was spaced 16-72 hours apart. During each session, participants ran one mile either with the exotendon ('exotendon running') or without ('natural running') in a randomized order, with at least a 5-minute rest between trials.

Consistent with the original work by Simpson et al., the exotendon was constructed from hollow cylindrical natural latex rubber surgical tubing (0.95 cm outer diameter, 0.64 cm inner diameter, 120 N/m stiffness). For each participant, the tubing was cut to 25% of their leg length (determined as the length between the lateral malleolus and anterior superior iliac crest) and attached to their shoelaces with two carabiners [22] (Fig. 1C). Participants were told that the exotendon was designed to improve running efficiency and were instructed to 'relax into running with the device' and to try to 'think about something else while running'.

C. Self-pacing Algorithm

During self-paced trials, participants were free to vary their speed naturally on the treadmill. We developed a self-paced controller based on previous work [24], [25]. Unlike previous control algorithms, our algorithm control is based on footstrike position rather than an estimated center of mass during double-stance. Importantly, this enables us to test self-paced running, which does not have a double-stance phase.

The controller is a linear-proportional controller using force plate data to estimate subject footstrike position on the treadmill, updating each time a footstrike is detected. If the subject speeds up, resulting in a footstrike further forward on the treadmill, the treadmill speeds up proportionally to the distance they moved forward, ultimately moving the subject back to the desired position. If the subject slows down, the opposite occurs. This approach allowed participants to self-select a comfortable pace during both exotendon and natural running.

D. Session 1 – Exotendon and self-paced treadmill training

The objective of session 1 was to expose participants to the exotendon and self-paced treadmill, allowing them to gain familiarity with both before the main experimental trials. Participants first completed three 1-mile exotendon runs at a fixed speed of 2.67 m/s, with rest periods in between. This pace is consistent with the preferred running speed of healthy recreational runners in previous treadmill studies [23], [26], as well as with the previous study by Simpson et al. [22]. The number of training runs was chosen based on prior work, where participants demonstrated reduced MR by the end of the fourth 1-mile exotendon run at 2.67 m/s [22]. However, in our study, we note that all three training runs occurred during a single session and did not alternate with natural runs in order to minimize the total miles run and to distribute the running distance more evenly across the three sessions.

Following the fixed speed runs, participants completed two 0.5-mile self-paced natural runs on the force-instrumented treadmill with the self-pacing algorithm. During the first trial, participants received real-time visual feedback of their relative speed in the form of a 2D speed versus time plot on a screen in front of them (Fig. 1B). This visual feedback helped participants quickly understand and adapt to the self-pacing algorithm. After a brief rest, participants completed a second 0.5-mile self-paced run without visual feedback to assess how well they could maintain their speed independently using the self-pacing treadmill. For the final 0.25 miles of this trial, participants were instructed to maintain a consistent speed, and speed variability was analyzed. Participants were required to keep speed variability within 5.5% of the standard deviation of their average speed, a threshold chosen to mimic variability during natural running [27], and were excluded from further participation in the study if they exceeded this variability.

E. Session 2 – MR qualification and self-paced testing

The goal of session 2 was to assess whether participants reduced MR when running with the exotendon at 2.67 m/s and to determine their self-paced running speeds in both natural

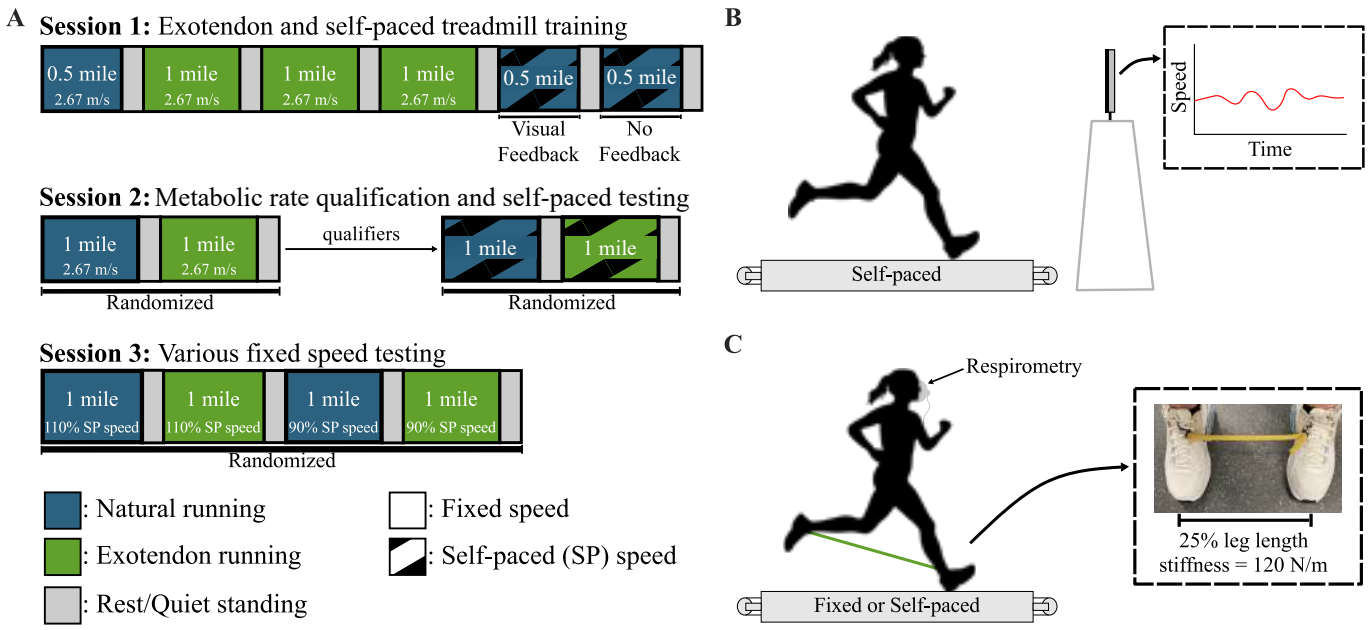

Fig. 1. **(A) Overall Protocol.** During session 1, participants trained with the exotendon at a fixed speed of 2.67 m/s and learned to use the self-pacing algorithm. Metabolic data were collected during all runs in sessions 2 and 3. Participants who showed a reduction in MR when running with the exotendon during the first two runs of session 2 ("qualifiers") proceeded with the remainder of the study. Self-paced runs in session 2 determined the participants' preferred speeds with and without the exotendon. During session 3, participants ran at fixed speeds based on the average of their session 2 self-paced speeds. The order of runs in sessions 2 and 3 was randomized, with at least 5 minutes of rest between trials. **(B) Self-paced Treadmill Acclimation.** During the first self-paced run of session 1, participants received visual feedback in the form of a relative speed versus time plot on a monitor placed in front of the treadmill. **(C) Exotendon Running Setup.** Participants completed both fixed and self-paced running trials with the exotendon, alternating with natural running trials.

and exotendon conditions. Participants were first instrumented with indirect calorimetry equipment (K5, COSMED, Rome, Italy) and completed a 5-minute quiet standing trial to measure baseline metabolic energy expenditure. Participants then completed two 1-mile runs at 2.67 m/s, one exotendon and one natural, with rest between. Net MR was compared between the natural and exotendon runs to determine whether participants reduced MR when running with the exotendon, compared to natural running. Participants who did not demonstrate a reduction in MR with the exotendon were excluded from further participation in the study.

Qualified participants then completed two 1-mile self-paced runs, one with the exotendon and one natural. Average speed was calculated over the whole trial for both runs to determine each participant's natural and exotendon self-paced running speeds. These values were then used to establish a comfortable range of running speeds for each participant.

F. Session 3 – Various fixed speed testing

The objective of session 3 was to assess the effect of the exotendon on MR across a range of running speeds, relative to each participants' self-selected speeds from session 2. Participants were again instrumented with indirect calorimetry equipment and completed a 5-minute quiet standing trial. Following that, participants completed four 1-mile fixed speed runs, two at 90% and two at 110% of their average self-paced speeds from session 2, with and without the exotendon. These speeds were chosen to evaluate the exotendon's performance across a wide range of fixed running speeds while ensuring participants ran at comfortable paces. Net MR was compared between the natural and exotendon running trials at the two tested speeds.

G. Data Analysis

1) Running speeds: For all trials, speed data were collected from the treadmill at a sampling frequency of 10 Hz. In session 1, treadmill speed was averaged over the final 0.25 miles of the second self-paced run, and variability was measured using the standard deviation of treadmill speed. In the second session, average running speed was calculated over the entire duration of each self-paced trial to determine natural and exotendon self-paced running speeds.

2) Stride Frequency: Ground reaction force (GRF) data were collected at a sampling frequency of 1000 Hz (Nexus 2.15.0) for the entirety of each running trial. Vertical GRF data were low-pass filtered using a 2nd order Butterworth filter with a cut-off frequency of 15 Hz. Foot contacts were identified using a threshold of 200 Newtons to determine the start of each stride. Stride frequency was calculated using the total number of strides recorded during the last minute of each trial, as in Simpson et al. [22].

3) Metabolics: For all fixed speed trials, gross MR was calculated from indirect calorimetry by averaging the time-normalized data from the last 2 minutes of each run [28]. Baseline MR, determined from the last two minutes of the quiet standing trial, was subtracted from the gross MR to

yield net MR for each run. The percentage change in net MR from natural running to exotendon running was calculated to determine participant qualification and results.

We analyzed net MR at both the previously studied speed (2.67 m/s) and across a range of speeds. First, we compared net MR between natural and exotendon running at all grouped speeds (2.67 m/s, 90% self-paced speed, and 110% self-paced speed). A Kolmogorov-Smirnov test indicated that the data were not normally distributed for all speeds (h=1, $p<0.001$), so we used a Wilcoxon signed-rank test for comparison. Next, we used two linear mixed effects models (LMMs) to evaluate net MR across speeds. In the first model, we incorporated fixed effects for speed and condition (natural versus exotendon) while accounting for individual subject variability as a random effect. This allowed us to isolate the effects of speed and running condition on net MR while controlling for individual differences. In a second model, we used speed as a fixed effect to analyze its influence on the percent different in net MR between conditions. We assessed the residuals of both models for normality using the Shapiro-Wilk test, which confirmed they were normally distributed (P=0.23).

III. Results

During the self-paced treadmill familiarization in session 1, all participants were able to mimic natural running variability with a standard deviation of 3.47 ± 1.25% of their average speed, below the designated threshold of 5.5% [27]. We found that running with the exotendon at 2.67 m/s led to a small reduction in MR of 2.44 ± 7.05% across all participants, but this was not significant (P=0.23, Wilcoxon signed-rank test; Fig.2A). Of the 16 participants, nine reduced MR when running with the exotendon at 2.67 m/s (”qualifiers”) and seven did not (”non-qualifiers”). All participants significantly increased stride frequency when running with the exotendon at 2.67 m/s. Non-qualifiers showed a larger range of average stride frequency values compared to qualifiers, despite having a smaller average percent change in stride frequency (5.94 ± 2.64%) compared to the qualifiers (4.73 ± 2.07% increase) (Fig. 2B).

The qualifiers had an average net MR reduction of 7.60 ± 4.36% when running with the exotendon at 2.67 m/s (P=0.004, Wilcoxon signed-rank test; Fig. 2C). For the qualifiers, we classified speeds as ”slow” (90% of each participants’ self-paced speed) and ”fast” (110% of each participants’ self-paced running speed). We found that participants significantly reduced their MR at both their slow speed (P=0.011, Wilcoxon signed-rank test) and their fast speed (P=0.004, Wilcoxon signed-rank test) when running with the exotendon. (Fig. 2C).

When compared across all speeds for the qualifiers, MR was significantly reduced by an average of 6.7% when running with the exotendon at speeds between 1.68 and 4.36 m/s ($P=1.03x10^{\propto 6}$, LMM; Fig. 3A). The percent change in MR was consistent across all speeds, as the slope of the line modeling this relationship was not statistically significant (slope=0.12, 95% CI=[-2.94, 3.18], P=0.94, LMM; Fig. 3B). Despite variability in individual speeds and MRs, nearly all participants reduced their MR when running with the exotendon at each tested speed (2.67 m/s, slow, and fast) (Fig. 4).

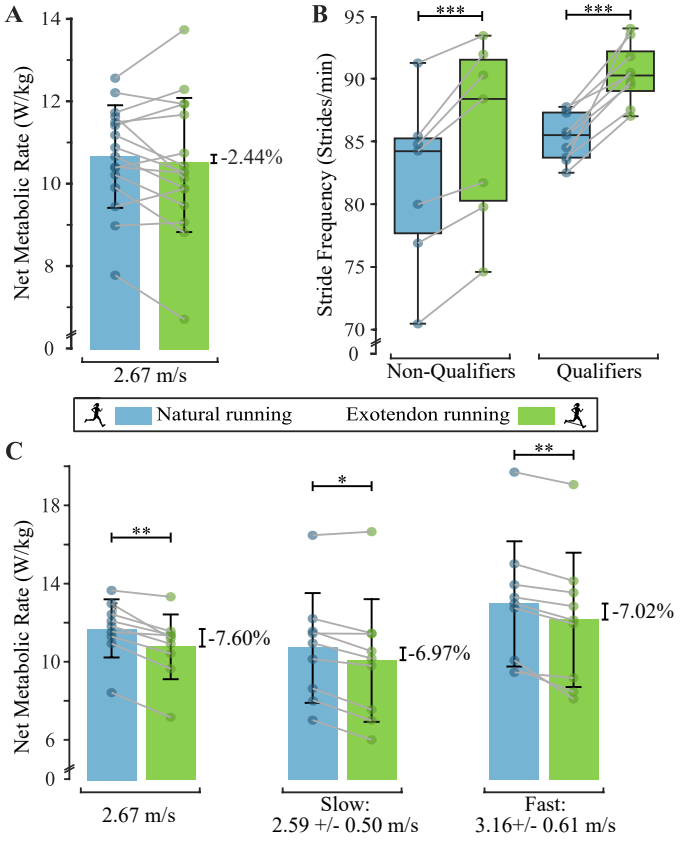

Fig. 2. **(A)** There was no significant change in net MR for all participants (P=0.23, Wilcoxon signed-rank test). **(B)** Both qualifiers and non-qualifiers significantly increased stride frequency when exotendon running, compared to natural running. **(C)** The qualifiers significantly reduced MR at 2.67 m/s (P=0.004, Wilcoxon signed-rank test). Additionally, they significantly reduced MR when running with the exotendon at speeds 10% above (“fast”) (P=0.011, Wilcoxon signed-rank test) and 10% below (“slow”) (P=0.004, Wilcoxon signed-rank test) their average self-paced speed. Error bars represent 1 standard deviation. Asterisks indicate statistical significance with confidence levels $p<0.05$ (*), $p<0.01$ (**), and $p<0.001$ (***).

IV. Discussion

This study examined whether running with an exotendon could reduce MR across a range of speeds. Across participants, we observed a smaller average reduction of 2.4% in MR when running with the exotendon at 2.67 m/s compared to that reported by Simpson et al. [22]. However, for those that did reduce MR, the average reduction was within one standard deviation of their reported value, suggesting that the exotendon has similar effects on MR in certain individuals [22]. Extending the analysis to a wider range of speeds (1.68 to 4.36 m/s), we found an average MR reduction of 6.7% at all speeds, which supports our hypothesis that the exotendon reduces MR beyond a single, fixed speed for those who responded positively to the device at 2.67 m/s.

Our findings contribute to a growing body of research suggesting that passive assistive devices can reduce MR [20]–

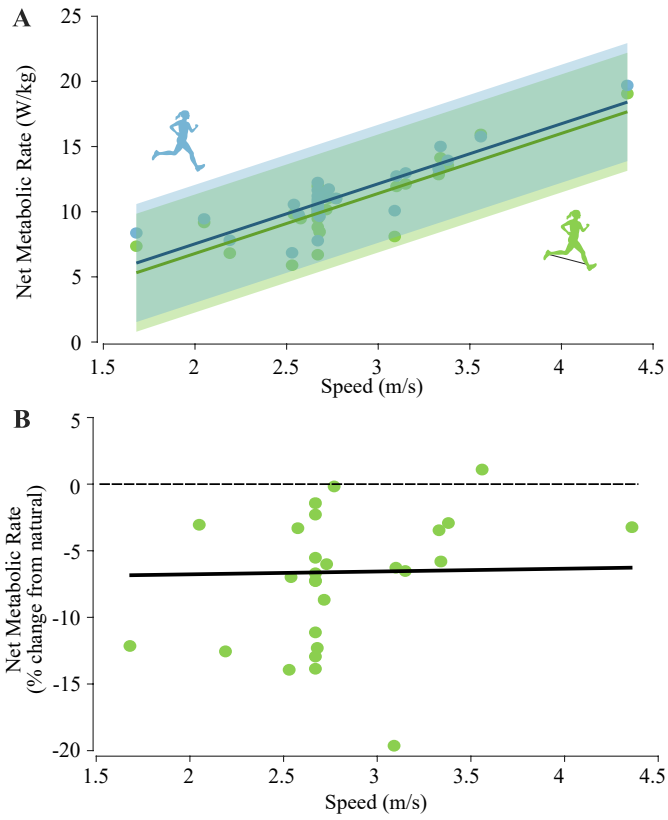

Fig. 3. **(A)** Net MR across speeds was significantly lower during exotendon running, compared to natural running (P=1.03x10^{-6}, LMM). There was a significant linear relationship between speed and MR (P=2.92x10^{-30}, LMM). Shaded regions show the 95% confidence interval of curve fits. **(B)** MR reductions were consistent across speeds, as the slope of the line modeling this relationship was not statistically significant (slope=0.12, 95% CI=[-2.94, 3.18], P=0.94, LMM).

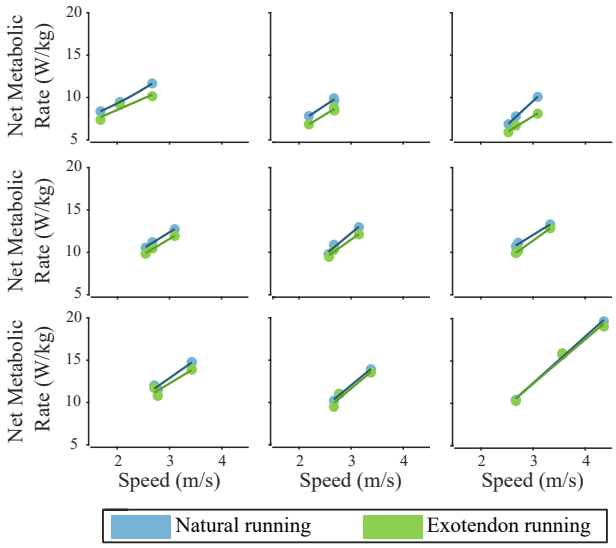

Fig. 4. There was considerable variation in net MR among subjects. Each subplot represents the net MR for an individual participant at 2.67 m/s, as well as at speeds 10% above and 10% below each of their average self-paced speeds. Based on previous findings of a linear relationship between MR and speed in both exotendon and natural conditions (Fig. 3), we enforced linearity for individual subject plots.

[22]. Unlike previous work with assistive devices, which often focus on singular speeds [20]–[22] or elite athletes [16], [17], our results show that the exotendon can benefit recreational runners across multiple running speeds. This broader applicability demonstrates the ability of the exotendon and other assistive devices to benefit a diverse range of athletes as well as individuals in rehabilitation, helping reduce MR across varying levels of performance.

In agreement with the literature regarding the relationship between speed and MR, our results displayed a linear relationship across all speeds for both exotendon and natural running [2]–[4]. However, our results differed slightly from those of Simpson et al., as only 9 of 16 participants achieved MR reductions at 2.67 m/s, compared to 100% in their study [22]. This discrepancy may be attributed to differences in training protocols. In our study, exotendon training sessions were held back-to-back during the first session, whereas Simpson et al. spaced their training across two sessions, alternating between natural and exotendon runs [22]. Prior work suggests that distributing training across multiple days can enhance retention of adaptations [29]. Thus, the timing and structure of training sessions may play a more critical role in maximizing the exotendon's effectiveness than anticipated.

The difference in subject populations may also contribute to the smaller MR reductions at 2.67 m/s found in our study, as compared to Simpson et al. [22]. Although all participants in our study met the pacing criteria for recreational runners (2.67 to 3.35 m/s), all but one were already running more than three hours per week. This amount of training time could contribute to biomechanical adaptations, such as improved movement efficiency or resistance to adaptations, that are often associated with higher running volumes [30]. As previous research suggests [31], assistive devices may be less effective for experienced runners due to their already optimized biomechanics, which may explain why our participants experienced smaller reductions in MR compared to those in Simpson et al.'s study [22].

Simpson et al. demonstrated that the exotendon reduced MR by increasing the energetically optimal stride frequency by approximately 8%, resulting in energy savings during both the swing and stance phases of running [22]. In our study, both the non-qualifiers and qualifiers significantly increased stride frequency when running with the exotendon, by 4.73% and 5.94%, respectively. We found that the non-qualifiers had greater variability in their average stride frequency, compared to the qualifiers. These differences may suggest that the non-qualifiers were unable to align their stride frequency with the energetically optimal frequency facilitated by the exotendon, which could explain why these individuals did not experience reductions in MR at 2.67 m/s. Preliminary analyses suggest that no single factor can fully predict whether a participant will reduce MR when running with the exotendon. Rather, a combination of factors likely influences its effectiveness, and

exploring this will be important for future research.

For the qualifier group, we expanded testing to both slower and faster speeds. The results confirmed that the MR reductions observed at 2.67 m/s extended to other paces. While the percent change in MR between natural and exotendon runs was consistent across speeds, additional data are necessary to confirm this trend.

Future work is necessary to better understand how individual factors influence MR. Investigating the differences between qualifiers and non-qualifiers could provide insights into the mechanisms underlying MR reductions when running with the exotendon. Additionally, studies examining how MR reductions influence self-paced running speeds could offer a deeper understanding of how these devices might affect performance.

V. Conclusion

Although not all runners reduced MR when running with the exotendon, those who did experienced reductions across multiple speeds. The exotendon's simplicity and versatility make it a promising tool for both training and performance, as well as a valuable option in rehabilitation settings, where aiding movement efficiency and reducing metabolic demand could be beneficial in return to sport post-injury. Further research is necessary to explore individual factors influencing the device's effectiveness and to determine the conditions under which it optimally enhances performance and rehabilitation outcomes.

***Abstract*—Dynamic balance in human locomotion relies on the regulation of whole-body angular momentum. Asymmetry in upper extremity body mass and motion that occurs from upper limb absence disrupts this regulation. Conventional transhumeral prostheses do not restore controlled arm swing, leaving this asymmetry unresolved. This project aimed to develop an actuated prosthetic elbow that mimics natural elbow rotations to restore arm swing during walking. Two prototypes with contrasting designs were fabricated and tested. Prototype 1, featuring a direct drive motor, tracked arm swing trajectories based on able-bodied data with less than 5% position error. It enabled evaluation of predicted elbow torque requirements, showing that a double-pendulum dynamic model overestimates torque needs. This finding supports using smaller, lighter direct drive motors for natural arm swing. While Prototype 1 performed well, its motor was too large for practical integration. Prototype 2 successfully fit the drive and control system into a standard prosthetic envelope for enhanced applicability. Testing revealed that gearbox friction hindered control, and successful operation required synchronizing elbow movement with natural arm swing frequency. Despite using the same control system, both prototypes produced notably different outcomes. These results highlight potential for future designs incorporating a small direct drive motor to match Prototype 1's performance while maintaining Prototype 2's compact form.**

I. Introduction

Reciprocal arm motion is essential for balancing leg momenta to minimize whole-body angular momentum that facilitates locomotor balance in bipedal human gait [1]. Recent evidence has revealed that individuals with unilateral upper limb absence experience bilateral asymmetry in both upper extremity body mass and motion [2]–[4], which affects the tight regulation of whole-body angular momentum during walking [5], [6]. This asymmetry and impact on dynamic balance may contribute to the high prevalence of falls in persons with upper limb absence, in which 67% of reported falls occur during walking [7]. While persons with unilateral transhumeral-level limb absence exhibit a small amount of affected limb arm swing during walking (nearly a third of the intact limb) [2]–[4] that gives rise to this asymmetry, conventional transhumeral prostheses are not designed to restore controlled arm swing and facilitate the inter-limb segment momenta cancellation required to minimize whole-body angular momentum [3], [6]. In fact, the limited arm swing of the affected side during walking remains the same whether or not a conventional arm prosthesis is being worn [2], [3].

Therefore, interventions are needed to restore the biomechanical symmetry of angular momentum and aid dynamic balance in persons with unilateral upper limb absence. This project aimed to develop a mechatronic prosthetic elbow that generates stereotypical elbow rotations to restore affected limb arm swing of persons with transhumeral-level limb absence during walking [8]. This paper describes steps for the design, development, and preliminary testing of two mechatronic systems that showcase contrasting design methods.

II. Methods

Two mechatronic designs of a robotic elbow were implemented to accommodate different motors for actuation. Prototype 1 is powered by a larger, brushless, direct-drive motor. Prototype 2 is powered by a small brushed motor with a high gear ratio, extracted from a servo motor, developed in response to the high cost and complexity required to use a brushless motor. Prototype 2 aimed to replicate Prototype 1 function with reduced complexity. Since Prototype 2 was developed after Prototype 1, it features a more compact design and prosthetic arm attached to the elbow, rather than a mock prosthesis that is weighted to mimic anatomical inertia (as seen in Prototype 1). These prototypes were developed

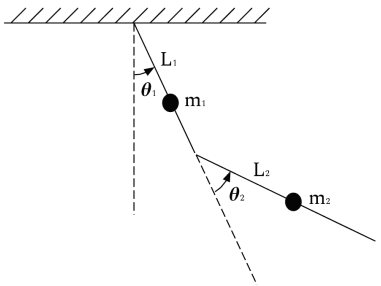

Fig. 1. Model representation of arm-body dynamics during walking as a double pendulum. System configuration is defined by shoulder angle θ_1 and elbow angle θ_2. The model predicts the required torque output at the elbow joint to generate desired swing trajectories.

only to assess the control and actuation platforms. This section contrasts the prototypes designs.

A. Prototype 1

1) Arm-Body Dynamics Simulation: The arm-body dynamics for arm swing during walking can be modeled as a double pendulum system as seen in Fig. 1. The system can be fully defined using the configuration $q = [\theta_1, \theta_2]$, the angles of shoulder and elbow flexion.

In this model, the arm is treated as a separate entity from the body, with energy input at the shoulder joint to simulate body-generated movement. The model calculates the torque required at the elbow joint to generate desired arm swing trajectories.

The Euler-Lagrange equations relate the system configuration q and its first and second derivative to the external forces acting on the system at a given time. This relationship can be used to forward integrate the behavior of the system and simulate its dynamics.. In this case, user data with trajectories (that is position, velocity, and accelerations) of the elbow are substituted into the Euler-Lagrange equations for a double pendulum to derive the required torque:

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{q}} - \frac{\partial L}{\partial q} = \tau \tag{1}$$

Here, τ is the joint torque vector and L is the Lagrangian defined as the difference between the kinetic and potential energy of the system.

2) Motor Selection: The power specifications for the motor can be estimated by the results from the Euler-Lagrange back-calculated torque. The motor specifications will be defined by the maximum output from the model. The arm swing trajectory that produces these maximum values is the most energetic arm swing. After examination of arm swing trajectory data collected from an able-bodied person, it was determined that the maximum speed at which data was collected, $1.4\frac{m}{s}$, was when the person produced the most energetic arm swing trajectory. Therefore, the largest torque output required from a motor was calculated from these configuration data. Fig. 2 displays the torque vs angular velocity profile, where the torque is the output from the Euler-Lagrange equations and the velocity is the time derivative of the angular position.

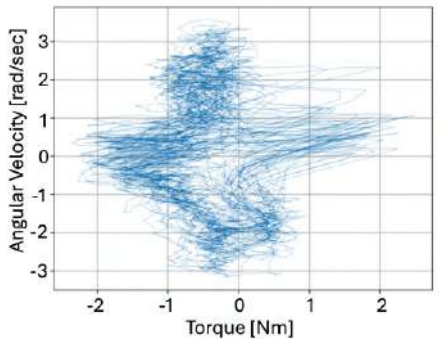

Fig. 2. Angular velocity versus torque landscape for an example user trajectory collected at walking speed $1.4\frac{m}{s}$ for 40s. The area of this curve represents the required power at the elbow. The maximum motor torque required nears $2.9\mathrm{Nm}$ and maximum velocity nears $3\frac{rad}{s}$.

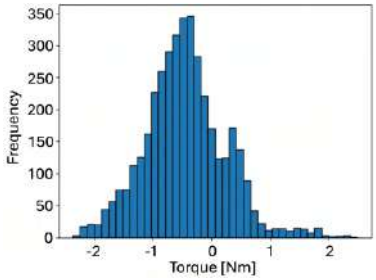

Fig. 3. Histogram of motor output torque over 40s trial collected at 100Hz with bucket size of $0.125\mathrm{Nm}$. Much less time was spent on torques outside $\pm 1\mathrm{Nm}$. This challenges the torque specifications required from the motor.

The motor power envelope should encompass the entire angular velocity-torque landscape such that it encompasses the largest entries of elbow torque and angular velocity. Approximately, the largest angular velocity required is $3\frac{\mathrm{rad}}{\mathrm{s}}$ while the peak torque required is $2.9\mathrm{Nm}$.

To enable the arm to swing according to the natural arm-swing trajectory while minimizing energy use, the elbow joint should have minimal friction. A direct drive brushless DC motor is relatively low friction because there is no transmission: the only friction involved is that in the bearings.

The size of the motor was constrained by its mechanical design and prosthesis design concerns. Excessive weight of an upper limb prosthesis is often cited as a comfort-related reason for device abandonment [9], so a design goal was to select a motor that minimized mass of the system.

To discover the true motor torque requirement, the calculated torque trajectory was decomposed into time spent at various torque output levels. This leads to Fig. 3 which shows the frequency at torque buckets of size $0.125\mathrm{Nm}$.

3) Control System: The most direct way to generate human arm swing during walking is to command the motor along predefined swing trajectories. However, motors take in current as their input. So, to use the desired positions as a set point for the motor we added a second layer to control the actual input into the motor. Each controller takes in an error determined by the difference between the desired and actual value. Then, the controller transforms the error and outputs it to the next step in the controller (Fig. 4). This describes a closed loop feedback system that drives the motor based on

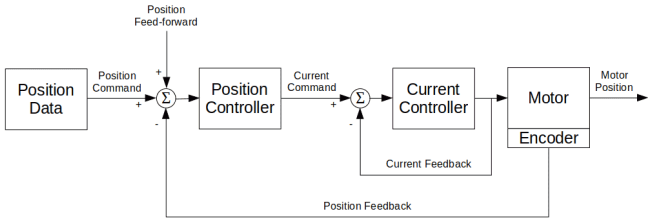

Fig. 4. Double nested closed loop feedback system. The Σ junctions represent the controllers.

the error generated. With control loops running fast enough and arm swing trajectories to follow this system will output arm swing trajectories.

4) Evaluation: Prototypes were tested to assess functionality as the device was carried on a person's arm while walking on a treadmill (qualified as development activity and *not human subjects research*). Prototype 1 was designed to validate arm swing trajectories at several fixed walking speeds that affected cadence: 0.7, 0.8, 1.0, 1.1, and $1.4\frac{m}{s}$. Torque trajectories for each speed were predefined from unpublished inertial measurement data walking at each of these speeds. Performance of the elbow was evaluated by the expected versus actual angle output, and current data was collected to analyze the actual output torque.

B. Prototype 2

1) Motor Selection: Prototype 2 uses a motor with internal gearing, enabling use of a smaller motor that can still produce sufficient torque to enable arm swing. Although a motor with power capable of reproducing a natural swing trajectory could be selected, there was concern that a motor would exhibit excess speed but insufficient torque to complete the swing task. This disparity means that a motor with minimal power, geared down significantly, can satisfy the torque and angular velocity requirements at a considerably lower weight than a motor with sufficient torque but no gearing.

2) Controller: Prototype 2 uses the same control system as Prototype 1. Although performance disadvantages are anticipated with a geared motor, some of these may be alleviated by the controller. The position controller should track arm trajectories regardless of the gearing of the motor because any response that is slowed by the transmission characteristics will generate more error that the controller will account for in its response.

3) Step Detection and Adaptive Control: People do not walk at a fixed cadence during community ambulation. Therefore, a usable prosthetic arm should be able to track the wearer's cadence and match arm swing trajectory to that cadence such that it is synchronized with contralateral leg swing. Cadence was estimated through registration of foot initial contact (i.e., collision) with the ground. This real-time registration was performed through data collected from an accelerometer attached to the prosthetic elbow and a peak signal detection algorithm, meaning that the control system should be able to adapt to a change of cadence and update its dynamics accordingly (with some reasonable lag).

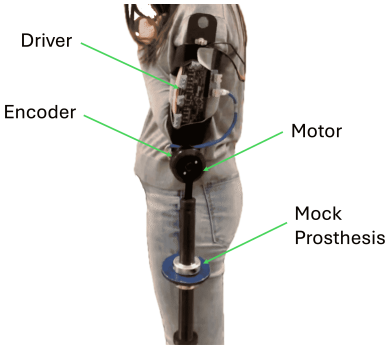

Fig. 5. The final Prototype 1 design features the motor and mock forearm that mimics the mass and inertia of a conventional prosthesis. The prototype is suitable for simulation based controller testing.

4) Evaluation: As with Prototype 1, Prototype 2 was tested as a person carried the prosthesis on their arm and walked on a treadmill. Arm swing trajectories of the wearer were collected at walking speeds of 0.7, 0.9, 1.1, and $1.3\frac{m}{s}$ to be used in the controller and tested during trials at the same speeds. Tests were conducted both at individual speeds to test the performance of the controller as well as at variable speed to test the step detection and adaptive control. The prototype was also tested on the bench without the prosthetic forearm and with the axis aligned with gravity, thus removing any external force on the motor.

III. Results

A. Prototype 1

1) Final Design Overview: The final design of Prototype 1 as seen in [10, Fig. 5] is composed of a driver, encoder, motor, and mock prosthesis. The motor selected is a direct drive system (R60, CubeMars, Jiangxi, China) with a peak torque of $2.3\mathrm{Nm}$, making it capable of outputting almost any torque required based on the Euler-Lagrange estimation. The mock prosthesis consisted of a plastic tube and disc weights that were positioned to simulate the length, mass, and center-of-mass position of a conventional prosthetics forearm/terminal device, which matched the forearm component in the arm-body dynamics model.

The prosthesis was controlled using a PIDF (proportional, integral, derivative, feed forward) controller to correct for error in position and current. The gains were tuned by hand during bench testing. The PIDF controller is simple and widely used, making it the first choice for this system. In addition to error generated response, the feed forward term generates output based on the desired value, resulting in a faster response.

2) Evaluation Results: The results from testing show that Prototype 1 performed well in tracking the desired trajectories. As seen in Fig. 6 the output position matches closely with the desired, and hovers between $\pm 5\%$ absolute position error.

When comparing the actual and theoretical torques as calculated previously, we discovered that the prosthesis does not require as much torque as was predicted to accurately track the trajectory. Fig. 7 shows that the actual torque output

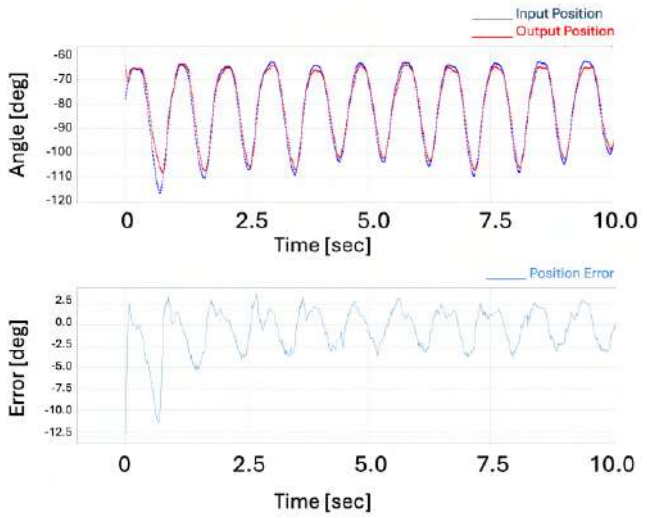

Fig. 6. Actual and desired position for Prototype 1 during testing (top), and error (bottom). The desired position was tracked with less than 5% error.

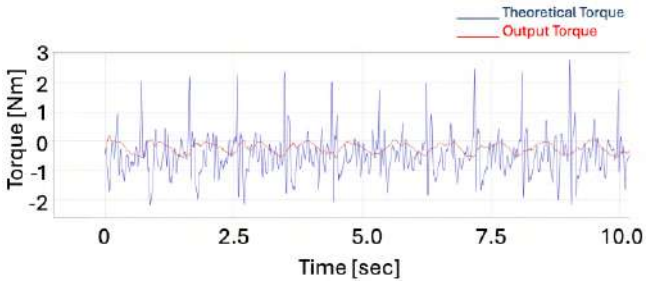

Fig. 7. Actual torque output superimposed on theoretical torque. The red signal displays the actual torque required to follow trajectories during testing, from its smallest to largest torques it ranges a total of 1Nm. This result suggests use smaller motors to achieve the same results achieved before.

varies at most 1Nm from the smallest to the largest actual torque outputs (compared to the simulations predicted range of 4.6Nm from smallest output torque to largest).

B. Prototype 2

1) Final Design Overview: Prototype 2 in Fig. 8 takes on a form similar to typical prosthetic arms, featuring an elbow that interfaces with a prosthetic socket, a prosthetic forearm with terminal device, and an external electronics center. The elbow joint motor interface and housing were designed around a commercial elbow joint (E400, Fillauer, Chattanooga, TN). Future iterations will condense the electronics such that it can be discretely fit inside a hollow forearm segment.

The motor selected for this iteration was a Coreless Servo (HiWonder, Shenzhen, China) with peak torque output of 3.4Nm. This high output torque from a smaller motor is achieved via its gearbox with a gear ratio of 1:342. Servo motors are typically controlled by a PWM signal that corresponds to a position. Instead of using this capability, which is sometimes inaccurate, the servo potentiometer was used as an encoder and the motor was controlled directly via its positive and negative terminals. Modifying the servo motor

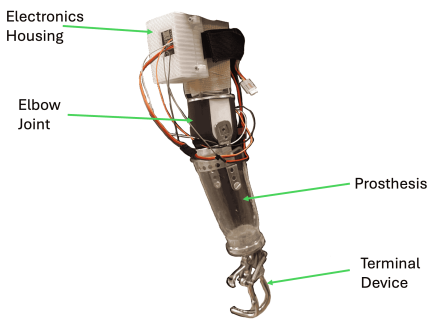

Fig. 8. Prototype 2 features an industry standard elbow envelope, conventional prosthetic socket and forearm/terminal device for universal application, as well as housed mechanical and electrical components.

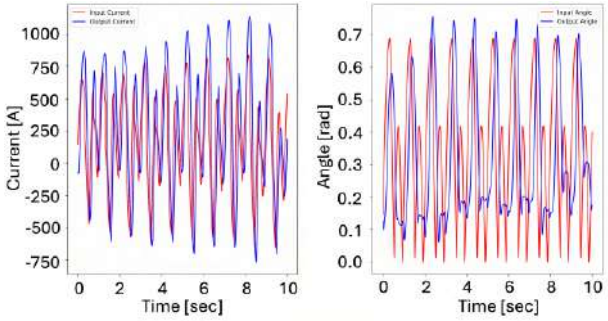

Fig. 9. Prototype 2 testing results with position control collected at $1.3\frac{m}{s}$ walking speed, displaying current (left) and position (right) output. There is deadband between the desired and actual output position. The controller tracks the desired trajectory with both overshoot and undershoot depending on the flexion or extension phase.

and incorporating current sensing allows for the same double nested control system as in Prototype 1 to be used for this motor (although the high gear ratio makes current sensing and torque control relatively inaccurate).

The controller for Prototype 2 uses a PIDF controller with a modified version of feed forward control to help overcome gearbox friction. Regular feed forward control is proportional to the desired output. However, the desired output is always nonnegative (since the elbow is restricted from hyperextension), so, it generates positive torque output from this term. Therefore, the feed forward coefficient was modified to be positive when the desired position was increasing (elbow flexion) and negative when the desired position was decreasing (elbow extension). This adjustment helps the motor overcome static gearbox friction when changing direction and kinetic gearbox friction during dynamic operations.

2) Evaluation Results: Exemplary results from testing with Prototype 2, displayed in Fig. 9, demonstrate success in tracking the shape of the arm swing trajectory. However, there is pronounced deadband between the desired and the actual trajectory, and the output does not track smaller arm swings presented in the desired trajectory.

Other results from Prototype 2 testing displayed less desirable behavior from the controller. In Fig. 10 the output position is overshooting and undershooting as it comes in and out of phase with the target arm swing frequency. The

phase difference was mitigated if the wearer aligned their cadence with the prosthesis output. However, if there was any discrepancy between the controller and the target arm swing trajectory, results like Fig. 10 were produced.

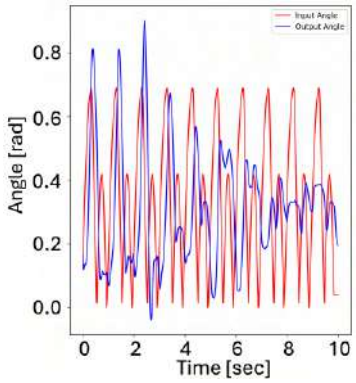

Fig. 10. Prototype 2 testing results with position control collected at $1.3\frac{m}{s}$ walking speed. The controller was unable to track the desired trajectory as it comes in and out of phase with the target arm swing.

The results in Fig. 11 are from testing with external forces removed from the motor to reveal the pure behavior of the motor within the control system.

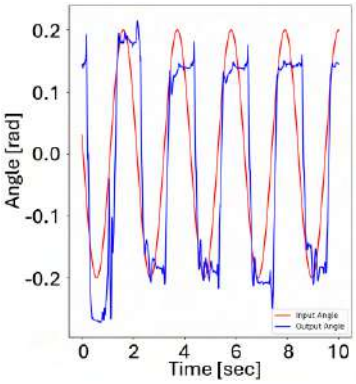

Fig. 11. Bench testing results on elbow joint tracking a sinusoidal trajectory with prosthesis and external forces due to gravity removed. The fast acceleration plateaus magnify the problems presented by gearbox friction that prevents the motor from moving at slow speeds from rest.

3) Adaptive Control and Step Detection: Initial results from testing of the step detection and adaptive control were promising. The step detection algorithm was able to accurately identify cadence when the wearer walked on solid ground, however, during treadmill walking the impact of footfalls was diminished and not registered by the automatic algorithm, thereby reducing its efficacy and challenging adaptive control. Future work will continue to refine this algorithm to enhance accuracy across different terrain.

IV. Discussion and Conclusion

1) Controller: The results of Prototypes 1 and 2 indicate that the same controller can have vastly different results depending on the prosthesis design. The promising results from Prototype 1 indicate that a double-nested position and current controller can work. The difficulties manifested in Prototype 2 are therefore likely resulting from the motor and transmission selection.

For Prototype 2, desynchronization with the wearer's cadence was likely due to the absence of control on the timing of the response. The desired arm swing trajectory was not aligned with any biomechanical marker such that the output phase is correctly timed. Issues with phase synchronization should be addressed in future iterations such that the arm auto-aligns its swing frequency with that of the user. This improvement would solve problems with undershooting the desired arm swing trajectory: phase alignment would prevent destructive interference between the elbow output torque and natural arm swing.

The overshoot of the desired arm swing trajectory during testing of Prototype 2 in Fig. 9 and Fig. 10 may be caused by the control system itself. The position control system should, in theory, be able to compensate for the additional energy added to the system by shoulder extension during walking as it monitors the position output in real time. However, the trajectory overshoot may be explained by the controller not anticipating extra energy added to the system by shoulder flexion/extension. When the torque output and arm momentum combine it generates a trajectory that overshoots the desired position. This interpretation is supported by the current output in Fig. 9. The motor current suddenly jumps during exaggerated arm swing, indicating that external forces drove the motor farther and required the controller to send more current through the motor to maintain the trajectory.

2) Motors: Prototype 2 testing demonstrated that use of a direct drive motor as in Prototype 1 has advantages. The sudden accelerations observed in Fig. 11 during bench testing likely resulted from internal gearbox friction. The controller is sending current to the motor proportional to the desired output, but the motor does not move until the torque output can overcome static friction. These jumps are then a manifestation of the limits of the motors operating torque from rest. If the motor was moving in one direction continuously, this characteristic would not be problematic. In this case the motor could not reflect the periodic flexion/extension of natural arm swing.

Sudden accelerations after plateaus did not appear during walking tests, likely due to the comparatively higher arm swing trajectory frequency. There was a deadband which manifested in the output difference between the desired and actual position. As observed in bench test results (Fig. 11) the motor is unable to track a sinusoidal trajectory without external forces. Since testing did not reveal firmware issues, we theorize that gearbox friction is the source of this deadband.

A. Future Work

1) Motor Selection: A direct-drive brushless motor has proven essential, offering significant advantages over geared motors. While direct-drive motors tend to be larger, Prototype 1 results suggest that a smaller, lighter brushless motor

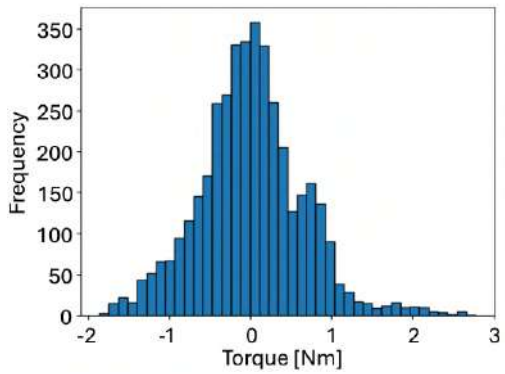

Fig. 12. Histogram of motor output torque over a 40s trial collected at 100Hz with a bucket size of $0.125\mathrm{Nm}$. These results incorporate a torsional spring with stiffness $k = 0.5\frac{\mathrm{Nm}}{\mathrm{rad}}$, which shifts the distribution's center toward zero, moving much of the torque output into the $\pm 1\mathrm{Nm}$ range. This design would allow use of a smaller motor.

could achieve similar torque output without compromising performance and still reduce device weight.

As seen in Fig. 3, the torque output was not centered at zero and the range is negative biased. Hence, a motor tasked with tracking the torque trajectory must output higher magnitudes than if the distribution was zero-centered. A design solution would be to add a torsional spring that reduces the maximum torque output required from the motor and allows a smaller motor to be used. The simulated histogram results from adding a spring with stiffness $k = 0.5\frac{\mathrm{Nm}}{\mathrm{rad}}$ to the arm-body model can be seen in Fig. 12, which is now shifted towards zero.

2) Control System: As for controlling the arm, there was success in using the existing control system. However, it has been shown that the controller output needs to be aligned with some wearer input such that its frequency matches the wearer's dynamics. Foot initial contact as estimated through data collected by the embedded accelerometer is a simple biomechanical marker to record and would correlate to desired time signatures in an arm swing trajectory.

3) Adaptive Response: Adapting the trajectory of the prosthetic arm to the user's walking cadence is a critical step to improve gait symmetry and natural movement. This adaptation can be achieved by reliably estimating the walking cadence through real-time measurement of the initial contact of the foot in different terrains and walking speeds. Consequently, the arm can dynamically adjust its trajectory to match the user's cadence, ensuring a smoother and more synchronized motion.

One possible approach to implementing this adaptive response is to use large datasets of arm swing trajectories collected from wearers at various walking speeds. The data would serve as a lookup table, such that the prosthesis would select the trajectory at a speed most similar to the user's walking speed. However, a library of generalized behavior would have to be generated that may not always map well to wearer dynamics, potentially requiring interpolation.

An alternative approach involves training a predictive model to generate arm swing trajectories based on the wearer's anthropometry (e.g. height, leg length, arm length). This model would generalize arm swing trajectories across users, and require easily measurable parameters to prepare (i.e., calibrate) the prosthesis for use. This solution reduces the need for extra data collection and enhances applicability of the prosthesis. Future work will implement these design approaches and conduct human subject trials to assess functionality of the prosthesis and its affect on user gait dynamics.

B. Conclusion

We have designed two embodiments of a mechatronic prosthetic elbow that has demonstrated the potential to restore symmetry in arm swing during walking for persons with transhumeral-level limb absence. The success of Prototype 1 demonstrated the viability of using a position-based controller with a brushless motor. Prototype 2 demonstrated the ability to integrate the elbow with a conventional prosthetic system and highlighted the potential for deeper user integration, paving the way for more intuitive and self-sufficient control systems. By combining insights from both prototypes, future iterations will focus on refining these features and conducting human subject trials to assess the impact of a motorized prosthetic arm on improving dynamic balance during walking and potentially reducing the risk of falls for upper limb prosthesis users.

An AI-Driven Telemonitoring System Exploiting Sensorized Glasses and Insoles to Correlate Cognitive Load and Mobility During ADLs

Giulia Bodo[*,1,4], Giulio Sciortino[*,2], Ludovico Pedullà[3], Erica Grange[3], Sara Giordanino[1,4], Gian Luca Bailo[2], Andrea Tacchino[3], Jessica Podda[3], Giampaolo Brichetto[3], Alexey Petrushin[1], Carlos Beltrán-González[2], Alessio Del Bue[+,2] and Matteo Laffranchi[+,1]

***Abstract*— Smart environments can play a crucial role in providing personalized assessment protocols for individuals. This study proposes a wearable telemonitoring system for non-invasively collecting and tracking mobility and mental effort parameters. The system consists of sensorized glasses, insoles, and AI algorithms for evaluating key metrics. To extract data, the activity "preparing coffee for two people" was performed by healthy participants. Preliminary results indicate that, on average, participants completed the task in 8 minutes. Mental workload, assessed through pupil diameter, showed a mean pupil diameter of $\mu = 5.19\ mm$ with a standard deviation of $\sigma = 0.99\ mm$. On average, participants took 340 steps during the task. Questionnaire responses demonstrated good system usability. The findings provide insights into user perceptions of the monitoring approach and highlight the system's potential for clinical adoption.**

I. Introduction

In clinical practice, independence in and performance of activities of daily living (ADLs) are usually assessed by occupational therapists using observation-based instruments that include actual performance analysis and take into account the complexity of daily activities [1], [2]. However, these methods have several limitations, including low sensitivity to mild impairments, difficulty detecting smaller and more specific changes over time, and potential influence from raters' sensitivity [3]. Limited attention has been dedicated to the quantitative assessment of ADLs through technological solutions, such as non-intrusive environmental or wearable sensors, home-testing biomarker-sensing devices, immersive virtual reality devices, and assistive robots that can operate in everyday life situations [4]. Recently, the use of technology and IoT device-based smart diagnosing assistance systems has been integrated into clinical research and practice to monitor and recognize specific ADLs performed by older adults in their home setting [5], [6]. However, no literature is currently available regarding the use of technological devices and wearables to assess the quality and independence of ADLs performance for people with neurological conditions. Moreover, despite the growing number of assessment and rehabilitation tools, greater efforts must be dedicated to personalizing these strategies, taking into account the complexity of each individual [7].

Telemonitoring is showing great promise as a non-invasive method for tracking health-related parameters [8], particularly through the use of wearable devices that do not interfere with ADLs [9], ensuring the ability to perform tasks while maintaining an ecological setting for the test environment [10]. Thus, smart environments equipped with advanced sensors and artificial intelligence algorithms offer the possibility to quantify motor and cognitive performances through continuous measurements [11]. Several studies highlight the use of sensorized insoles for monitoring and evaluating gait, enabling the recognition and identification of different walking phases [12]. Additionally, research demonstrates the potential of using gaze characteristics, such as pupil diameter variation, to study and understand the cognitive load associated with tasks requiring varying mental effort [13],[14], as well as to assess participant engagement [15].

This work presents the results of a collaboration between our research institute and clinical partners specialized in Multiple Sclerosis (MS), a chronic degenerative condition characterized by inflammation and damage to the central nervous system. MS leads to symptoms such as impaired mobility and cognitive decline [16]. The objective of this study is to design and evaluate a telemonitoring system for continuously assessing MS patients' performance. By leveraging collected data, the system aims to promptly detect changes in participants' abilities [17]. This paper describes the experimental setup of a smart monitoring system, which integrates wearable sensors, including sensor-equipped glasses (Tobii) and sensorized insoles, with AI-based algorithms. This combination enables the aggregation of data from multiple sources and the extraction of multidimensional metrics essential for assessing individuals' health status and activities. The study includes a pilot experiment involving six healthy participants performing a specific ADL, preparing coffee for two people, while wearing the wearable devices. This preliminary study is essential for evaluating the system's usability and functionality before introducing it to more vulnerable populations. It allows researchers to identify and address technical issues, design flaws, and user interface

challenges without the added complexity of managing health-related risks. Additionally, it facilitates the collection of an initial dataset of normative values for motor and cognitive metrics. These baseline values will later be compared with data from individuals with MS in a follow-up study planned for the next phase of the project.

II. Methods

A. Experimental protocol

As a daily living task, Preparing a coffee with a coffee maker and serving it for two people was chosen, based on the Assessment of Motor and Process Skills (AMPS) assessment tool [18]. This task requires the participant to focus on both motor and cognitive skills, allowing for a comprehensive evaluation of the participants' performance. The participants were asked to prepare the coffee for two people and serve it on a table. Before starting the task execution, a familiarization with the set-up of the environment, including the location of all needed tools and materials is provided. Participants were also asked to restore and return unneeded items to their original storage place, place dirty utensils in or besides the sink, wipe up any crumbs or spills. There were no specific rules regarding the coffee preparation process. The participants should proceed as they would at home. Ideally, the participant should not interact with the examiner, as they have all the information needed to complete the task independently. However, questions may be asked if necessary. The examiner will take notes as the participant performs the task. Before to start the task, sensorised glasses and insoles were worn by the participant as shown in Figure 1.

Fig. 1: Experimental Setup: (a) The wearable sensors are worn by the participant, with the insoles placed directly into their shoes. (b) Illustrates the glasses auto-calibration procedure, where the participant focuses on a fixed target to calibrate the gaze analysis. (c) Represents one participant wearing the devices during the test. (d) Shows the two devices adopted.

B. Sensorized glasses

The Tobii glasses are wearable devices equipped with a front-facing camera that records the surrounding environment and internal cameras that track the participant's eyes to analyze gaze and pupil behavior. Thanks to this device, it is possible to gather data on the cognitive load of the participant. Extensive literature highlights how pupillometry, particularly the assessment of variations in pupil diameter, is closely correlated with mental effort, as explained in [19], [13].

C. Sensorized insoles

The Sensing Tex sensorized insoles, fitted with 16 resistive pressure sensors, capture data on plantar pressure distribution through a 4×3 matrix of acquisition points located in the forefoot area and a 2×2 matrix in the rearfoot region. These flexible insoles are designed to fit comfortably inside regular shoes.

Both sensors communicate wireless with a central acquisition system, which manages the start and stop of data collection and gathers the recorded information at the end of each trial session.

III. Algorithms Design

The proposed analysis aims to collect a comprehensive dataset from wearable sensors to describe user activity at both cognitive and mobility levels. The algorithms are specifically designed to track: the participant's time spent in specific zones of the testing environment, the interactions with objects used during task preparation and mobility-related data (e.g., number of steps and average step cadence). Through the adoption of an analysis pipeline and evaluation of the results, the authors propose a correlation between cognitive load (assessed via pupillometric analysis) and the zones or phases of the test performed.

A. Object and QR code detection algorithm

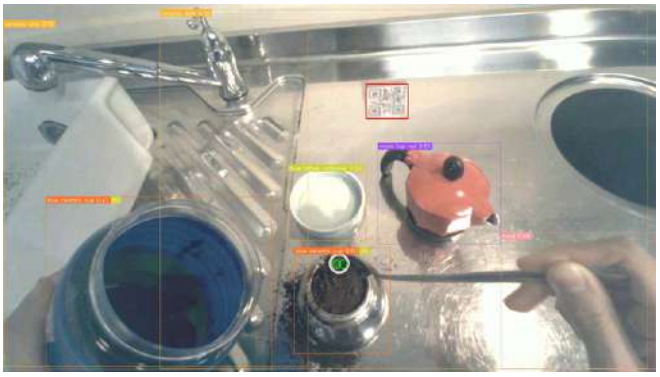

Fig. 2: Processing of a single frame from an experimental session. Bounding labeled boxes identify the recognized QR code zones and the detected objects.

The proposed system consists in a cascade of algorithms designed to perform object detection, QR code reading, and

hand-object interactions. For object detection, we employed YOLO World [20] a specialized version of YOLO v8 [21] fine-tuned on real-time open-vocabulary object detection, which demonstrated robust performance. YOLO World offers an easy way to detect a vast number of common-use objects without collecting and labeling an extensive dataset, resulting in a meaningful reduction of resources. Additionally, avoiding a manual fine-tuning process allowed us to quickly change setup during the first experimental phases and would not require any additional effort if the setting will change in the future. The ontology of the detected object is: coffee maker top red, coffee maker metallic bottom, hand, cup, coffee jar, spoon. As for the hand-object interaction, we selected frames in which the center of the bounding box of a detected object falls within that of a detected hand. When such situation occurs, it is interpreted as the hand holding the object.

The QR codes, stuck in the environment in their corresponding zone, were used to perform the detection of the zones involved in the scene during the execution of the task (an example of QR code and object detection is shown in Figure 2). The read QR codes correspond to shelf, stove area (coffee preparation area), living room and stock. The total time presence of these QR codes determines the presence of the user in the areas. The chosen python library was qreader.

B. Gait analysis pattern recognition: YOLO Model

The extraction of the useful metrics from the gait data was performed by first predicting the foot state in each time frame, then using a Python script we computed the total number of steps, where a step is a succession of detected $foot \rightarrow forefoot \rightarrow foot$ classes. Then a time frame of 250 to 2000 milliseconds was empirically chosen to exclude unrealistic data from the sample, for example, when the sensor or the model missed a foot or a forefoot. Regarding cadence calculations, only effective steps were considered during actual walking periods. The analysis of kinematic parameters includes step duration, step count, and cadence. For each participant, the evaluated metrics comprised:

- Number of steps (N_{steps}).
- Step duration: determined by taking the difference between the current contact time of one foot and the previous foot contact time of the same foot, whenever the pattern $foot \rightarrow forefoot \rightarrow foot$ occurs.
- Step cadence: it is calculated as the number of steps taken divided by the acquisition duration (in seconds), starting from the first step. The result is then converted to steps per minute.

$$Step_{cadence} = \left(\frac{N_{steps}}{\Delta T_{acquisition}(s)} \right) \cdot 60 \qquad (1)$$

Due to the variability of participants' foot size and body weight, interpreting the step phase numerically via pressure data is unfeasible. Therefore, we adopted YOLOv8m for detecting the step phase based on the shape of the pressure distribution on the sole. We chose version 8 due to our experience with it and compatibility with our environment,

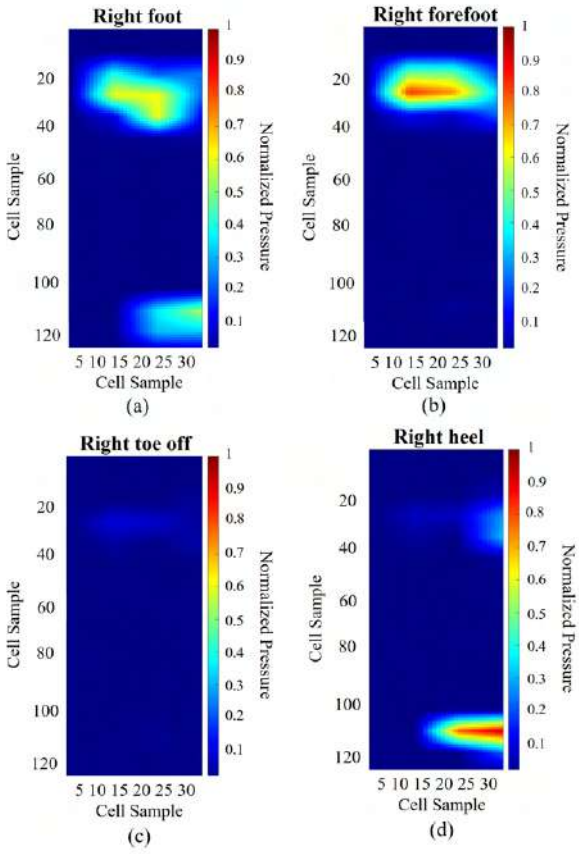

Fig. 3: Example of pressure maps captured from sensorized insoles for the right foot, illustrating different phases of gait: (a) stance, (b) push-off, (c) swing, and (d) heel strike.

specifically the medium model which offers a good balance between resources and precision. Object detection models offer an effective solution by assigning labels to pressure map configurations, and automatically recognize gait phases. This approach avoids manual analysis of individual sensor activations and uses labels to distinguish gait phases. Among the models considered for this purpose, YOLO was identified. The walking data over a distance of 6 meters were previously collected from 8 healthy participants and used to train the employed YOLO model. A MATLAB code was developed to convert the pressure maps, provided by the insoles, into jpeg images, by doing so we gathered a dataset of 2194 pressure map images for both feet (an example of the obtained pressure maps are shown in Figure 3). The dataset has been manually annotated. The following labels were used for the gait analysis:

- right_heel, left_heel: to identify heel strike
- right_foot, left_foot: to identify stance phase
- right_forefoot, left_forefoot: to identify the push-off
- right_toe_off, left_toe_off: to identify the swing phase

A total of 1123 samples were labeled for the left foot and 1071 for the right foot. The samples were then split into a training set and a validation set to train and validate the AI model. The split was randomized, assigning 20% of the

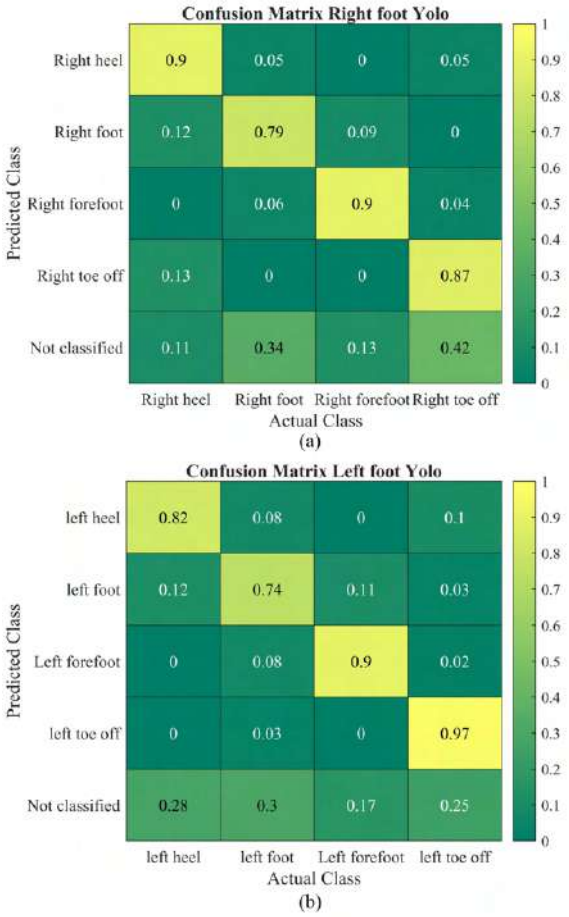

Fig. 4: Confusion matrices, related to the YOLO models for the right and left foot, evaluated on the validation set.

samples to the validation set: the training set contained 894 samples for the left foot and 854 for the right foot, while the validation set included 229 samples for the left foot and 217 for the right. Two distinct models were then trained, one for the right foot and one for the left foot. Each model was trained for 200 epochs and $lr0 = 0.1$, with results from the training process saved for further analysis. To evaluate the performance of the models, the confusion matrices for both left and right foot models are provided in Figure 4, and common metrics, as precision and recall are adopted to evaluate object detection models. Results as shown in Table I.

TABLE I: Precision and Recall for all classes in left and right foot YOLO model.

Class	**Left foot**		**Right foot**	
	p	***r***	***p***	***r***
Heel	67%	82%	71%	90%
Foot	60%	74%	64%	79%
Forefoot	76%	90%	80%	90%
Toe off	71%	97%	63%	87%

IV. Results

This section presents the results of monitoring the activities performed by the participants, reporting metrics related to both mobility and cognitive load. Due to hardware issues, the connection was lost with the sensors for two participants. As a result, sensor data are only available for four participants. The questionnaire responses were completed by all six participants.

A. Mobility and Cognitive metrics

1) Zone permanence timing: The different room areas were tagged with QR codes to track the participants' movements within the environment, without relying on additional external sensors (such as floor sensors or cameras to capture the participant's movements). The objective was to analyze the time participants spent in each of the four identified areas. The results show that, on average, the percentage of the total task duration spent in each area is as follows: 4.75% in the shelf area (where the coffee maker and cups are stored), 66% in the coffee area (where the coffee maker is prepared), 2% in the stock area (where coffee and spoons are kept), and 27% in the living room (where the coffee is consumed). The proportion of time each participant spent in each area, relative to the overall task duration, is represented in the bar charts in Figure 5.

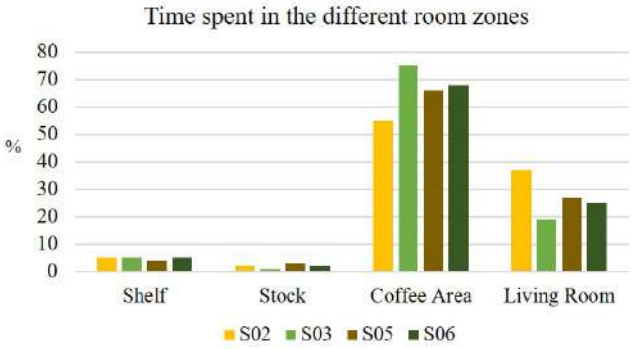

Fig. 5: The bar chart shows the proportion of total time each participant spent in four zones of the test area to complete the task. The zones are: the coffee preparation area (coffee area), the storage area for ingredients and spoons (stock), the coffee serving area (living room), and the shelf where the coffee maker and cups are stored (shelf). Results are provided for four participants.

2) Gait analysis: Insoles data were analyzed to compute the step numbers, cadence and mean duration as reported in Table II. Some anomalies were detected in participant S06's data, which can be attributed to manufacturing defects in the sensorized insole, whereas participants S03 and S02 exhibited a notably low cadence, attributed to frequent interruptions in their walking patterns.

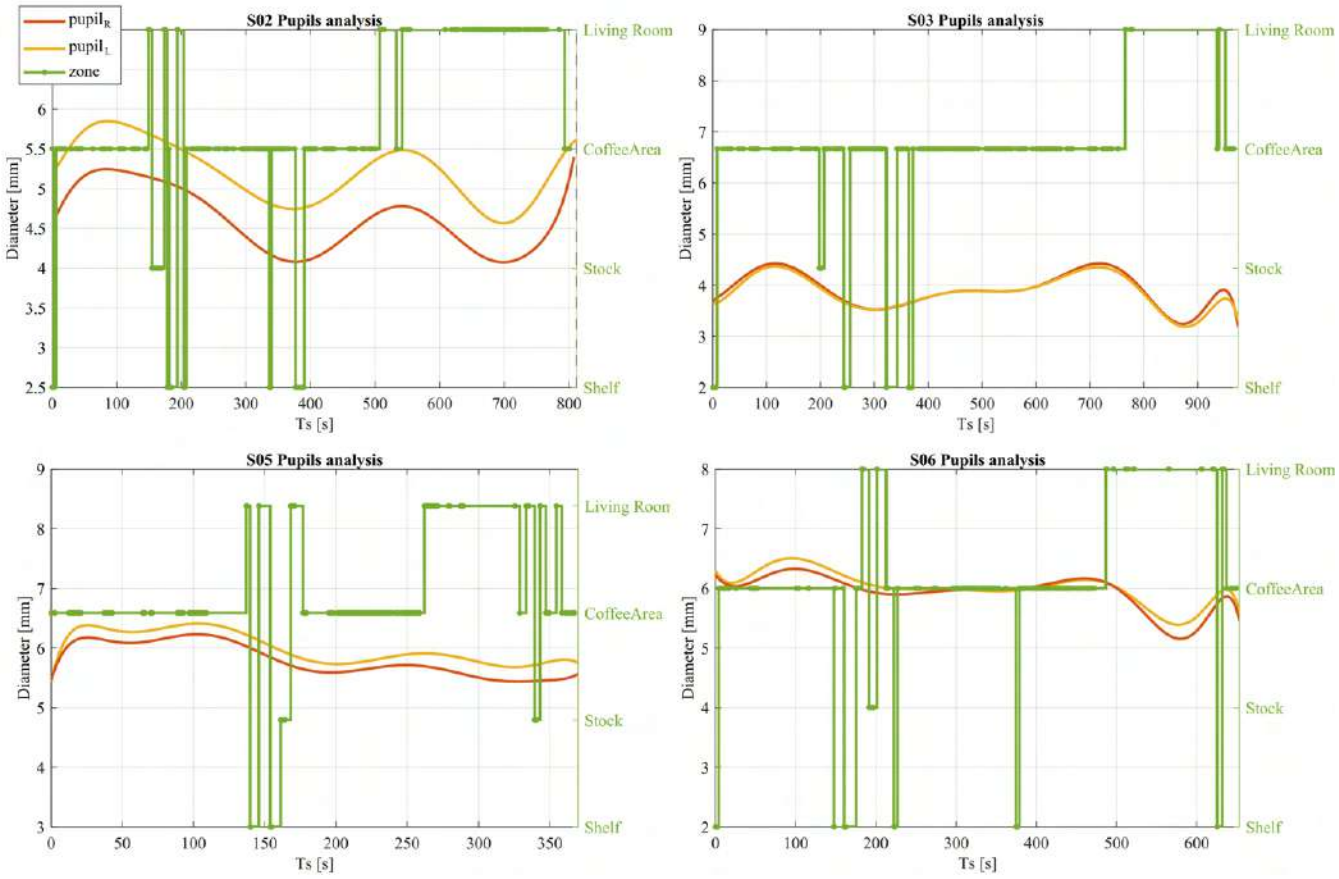

Fig. 6: The graphs show task duration, participant permanence in the different room zones (based on QR code data) and pupil diameter changes (left and right eyes). This allows for assessing mental effort during different task phases, with larger pupil dilation indicating greater mental effort.

TABLE II: Measured gait metrics.

id	N_{steps}	*Step Cadence* $[\frac{steps}{min}]$	Δt_{mean} $[ms]$
S02	529	54.7	448.5
S03	406	27.7	371.3
S05	343	85.1	320.7
S06	83	9.7	295.2

3) Pupillometry analysis: Table III lists, for each participant, the minimum and maximum pupil dilation values, along with the corresponding room zones where these measurements were taken and the pupil's coefficients of variation, computed as:

$$CV = \frac{\sigma}{\mu} \tag{2}$$

where μ is the signal mean and σ is the standard deviation. Statistical considerations can be done on the recorded pupils analysis, by aggregating both right and left pupils signals recorded it is possible to compute the overall weighted mean μ_{tot} of the n signals and the overall standard deviation σ_{tot}.

$$\mu_{\text{tot}} = \frac{1}{n}\sum_{i=1}^{n}\mu_i \tag{3}$$

$$\sigma^2_{\text{tot}} = \frac{\sum(\sigma_i^2 + \mu_i^2)}{n} - \mu^2_{\text{tot}},\ \sigma_{\text{tot}} = \sqrt{\sigma^2_{\text{tot}}} \tag{4}$$

Results indicate $\mu_{\text{tot}} = 5.187\ [mm]$ and $\sigma_{\text{tot}} = 0.992\ [mm]$. Figure 6 presents a correlation graph showing the relationship between cognitive load, as measured by pupil dilation, and the room zones where the participant was performing the task. With reference to Figure 6, in the case of S02, we can observe an increase in mental effort during the first part of the task, when the objects are retrieved and the coffee maker is prepared (from 0 to 200 seconds). Following this, as the participant waits for the coffee maker to be ready, pupil diameter decreases (from 200 to 450 seconds). The mental effort then increases again when the participant pours the coffee into the cups and brings them to the table (from 450 to 600 seconds). Finally, during the time spent in the living room, mental effort decreases once more. This analysis and interpretation are made easier by the availability of the video recorded with the Tobii system. Similar patterns can be observed in other participants, though the analysis is customizable for each participant.

4) Object interaction timing: The time participants spent interacting with key objects relevant to task completion was evaluated. The total interaction time with the coffee maker pot, cups, coffee jar, and spoon is summarized in Table IV. For all participants, the longest interaction time was with the coffee maker. This evaluation offers a useful

TABLE III: Pupillometry analysis includes maximum and minimum pupil dilation (right and left) associated with high and low cognitive effort zones, as well as the coefficients of variation for recorded pupil signals. The total task duration Δt is also reported, measured from the end of the experiment explanation to the completion of table tidying.

id	$\phi_{R_{min}}$ $[mm]$	$\phi_{L_{min}}$ $[mm]$	*Min. Eff. Zone*	$\phi_{R_{max}}$ $[mm]$	$\phi_{L_{max}}$ $[mm]$	*Max. Eff. Zone*	Δt *[min]*	CV_R	CV_L
S02	2.98	3.18	Coffee Area	6.59	6.88	Stock	13.36	0.115	0.104
S03	2.4	2.11	Living Room	6.43	6.08	Coffee Area	16.18	0.124	0.122
S05	4.28	3.83	Living Room	7.51	7.34	Coffee Area	6.23	0.086	0.0762
S06	3.42	3.38	Living Room	7.02	6.92	Living Room	10.96	0.063	0.062

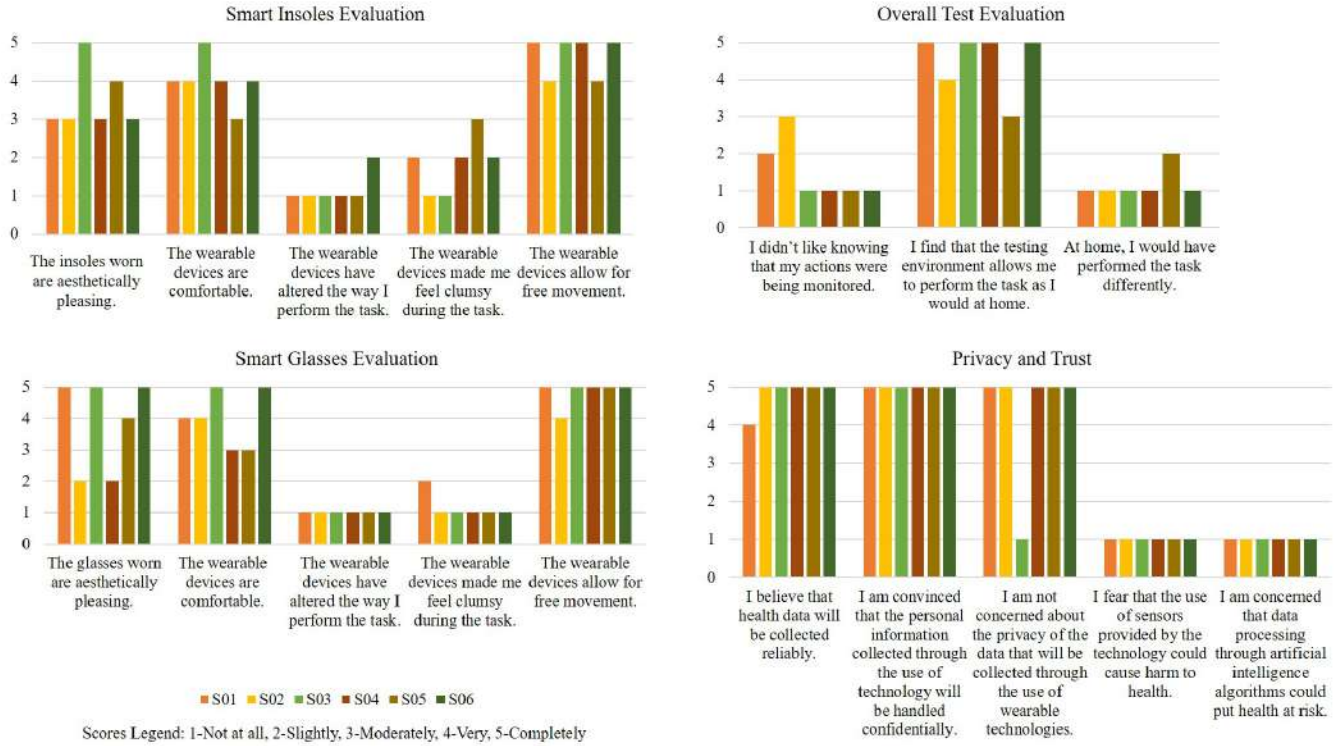

Fig. 7: The results of the questionnaires administered to participants at the end of the activities are presented. Participants were asked to evaluate various statements on a 1-5 scale (ranging from 'completely disagree' to 'strongly agree'). The investigation focused on both the usability and perception of the two wearables (insoles and glasses), as well as the overall impression of a telemonitoring AI-driven approach, including privacy-related concerns.

insight into the average coffee maker preparation time for a healthy participant that from this initial dataset, was found to be 7.93 minutes. Notably, participant S05 was particularly efficient, completing the task in a shorter time than the other participants (see Table III). The interaction time with the cups is also significant, especially in understanding the time required to "take the object and transport it" from the coffee preparation area to the living room and back. The average time for this action was about 48 seconds, consistent with the proximity of the two areas.

TABLE IV: Interaction time with various objects held by participants: the interaction duration is automatically computed using data derived from the YOLO processing algorithms for object detection. Four objects were considered for this analysis: a coffee maker pot, a cup, a coffee jar, and a spoon.

id	*Coffee maker* Δt $[min]$	*Cup* Δt $[min]$	*Coffee Jar* Δt $[min]$	*Spoon* Δt $[min]$
S02	8.22	1.13	3.00	0.77
S03	10.62	1.18	2.08	2.08
S05	4.17	0.57	1.25	0.14
S06	8.72	0.31	0.89	1.02

B. Questionnaires

The questionnaires results, shown in Figure 7, indicate that the proposed solution is user-friendly and highly acceptable to healthy participants. Both the insoles and the glasses were rated as aesthetically pleasing and comfortable, with minimal impact on task performance. Participants were able to move freely during the experiment, and notably, they reported that they would have performed the task in the same way at home. This suggests that the assessment provides a reliable reflection of daily-life performance. Additionally, no concerns regarding privacy or data collection were raised, indicating trust in the process.

V. Discussion and Conclusion

The results of this preliminary study offer valuable insights for future clinical applications. The extended interaction time with the coffee maker suggests that the chosen task is an effective proxy for assessing daily-life performance, reflecting challenges that may arise from cognitive or motor impairments (particularly manual dexterity), or a combination of both. Additionally, participants in this pilot study exhibited varying distributions of interaction times with objects and movement patterns across different areas of the room, indicating reliance on individualized strategies. This confirms that the task allows for personal planning, enabling participants to schedule activities freely while providing a quantitative and technologically robust assessment in a realistic, ecological environment. Pupil dilation data further highlight critical points in the task that may indicate increased effort, offering valuable insights into participants' specific challenges. Finally, gait analysis revealed that the participant who completed the task most quickly maintained the highest cadence, suggesting a correlation between lower-limb mobility, gait, balance and the achieved performance in completing the task. In future studies, it will be necessary to increase the sample size to 10–20 participants, as recommended for usability testing of eHealth devices [22]. Future acquisitions will be used to validate estimated interaction times and gait parameters, leveraging manual annotations of task phases and additional sensors such as a step counter. Additionally, correlations with individual characteristics, such as standard cognitive and motor assessments, will be examined. These analyses could help identify specific challenges faced by individuals with MS during this task and guide the development of personalized rehabilitative interventions. In conclusion, this study underscores the potential of task-based assessments in realistic settings to provide meaningful insights into the daily-life challenges. By integrating quantitative metrics, such as pupil dilation and gait parameters, with task performance analysis, authors believe that individual strategies and difficulties can be better understood. This approach lays the foundation for developing personalized, evidence-based interventions aimed at enhancing functional independence and quality of life for people with MS. The proposed solution holds also significant potential for extension to other conditions characterized by mobility impairments, fatigue, or cognitive challenges. By adapting the system's features to address condition-specific symptoms, it can be tailored to support elderly individuals or people with neurological disorders such as Parkinson's disease, stroke, or cerebral palsy, as well as other chronic conditions affecting functional independence.

Investigating Osseoperception in Distal Regions of the Upper Limb for Augmented Sensory Feedback

Cristian Felipe Blanco-Diaz, *Graduate Student Member, IEEE*, Mariateressa Pedone, Sophie Skach, Camilla Baselli, Leonardo Cappello, *Senior Member, IEEE*

***Abstract*— The somatosensory function is crucial for motor control, but is often deemed secondary in the design of assistive technologies for individuals with neuromotor impairments. This study investigates osseoperception—auditory and vibrotactile sensations evoked through bone stimulation—at the wrist pisiform bone (PB) and metacarpal head (MCH) of the index finger in 12 participants. Vibratory stimuli (100–6000 Hz) were applied during four psychophysical experiments: sensation discrimination, perception thresholds, sensory mapping, and loudness evaluation. Tactile sensations occurred below 940 Hz at the PB and 1000 Hz at the MCH, while auditory sensations predominated above these thresholds. Stimulation at 400 Hz expanded tactile zones, with PB sensations extending to the forearm and MCH sensations to carpal and interphalangeal joints. MCH stimulation had lower perception thresholds (0.14 N), while PB stimulation exhibited frequency-dependent loudness variations. These findings suggest the MCH and wrist as promising sites to elicit osseoperception, paving the way for the development of sensory feedback strategies to complement the effect of assistive technologies, especially those interfaced through osseointegration.**

I. Introduction

The loss of sensory feedback, resulting from neurological disorders, peripheral nerve damage, amputation, trauma, and degenerative diseases, may significantly impair the ability to perform fundamental movements for the activities of daily living (ADLs), such as grasping [1]. This because sensory information plays a crucial role in motor control, enabling precise adjustments through feedback and feedforward mechanisms [2]. The central nervous system (CNS) achieves this through internal models in the cerebellum: the inverse model predicts movements, while the forward model anticipates their sensory outcomes based on an efferent copy of the motor command [3]. Discrepancies between predicted and actual sensory feedback, known as sensory prediction errors, initiate corrective actions to reduce the error during motor performance, closing the control loop [4], [5].

Sensory information originates from mechanoreceptors embedded in the skin of the hand. These specialized sensory neurons detect and process tactile stimuli and are characterized by different properties such as spatial and temporal resolutions, and adaptability [5]. Superficial receptors, i.e., Merkel cells and Meissner corpuscles, enable fine-texture and shape detection, while deeper receptors, such as Pacinian corpuscles and Ruffini endings, detect vibrations and stretch. Loss of tactile, visual, or proprioceptive sensitivity disrupts fine motor control, grasp force, and prehension patterns, leading to significant functional impairments [6].

Sensory feedback can be intrinsic - arising naturally from sensory receptors in skin, muscles, tendons, and joints —, or extrinsic, artificially provided through external devices [6]. Extrinsic feedback, also referred as augmented feedback, is generally provided in the form of visual (through display monitors), auditory (through speakers, headphones), haptic cues (through robots, vibrotactile actuators), or a combination of them [7], [8]. Despite its importance, many assistive and rehabilitation technologies, such as robotic exoskeletons, focus primarily on motor assistance and overlook sensory feedback, possibly hindering their potential to restore natural and intuitive movements [9]. A reason could be the lack of optimal sensory modalities for providing effective augmented feedback, particularly with lightweight, fast-response, noninvasive devices.

Bone conduction has emerged as a promising approach for delivering augmented sensory feedback [10], [11]. By applying vibrational cues to the bones, it is possible to selectively elicit local vibrotactile sensations, stimulating the mechanoreceptors in the periosteum, or auditory sensations, when the vibrations reach the skull and stimulate the cochlea, i.e., osseoperception. This offers the advantage of conveying rich sensory information, using a single, lightweight, low-power transducer [10]. Previous studies have explored invasive applications, where bone transducers were attached to osseointegrated abutments in transhumeral amputees [10], and non-invasive applications, where the transducers were applied on the bone prominence of the elbow in healthy and amputee participants [11]. However, osseoperception in more distal upper-limb segments, such as the wrist or metacarpal bones, remains unexplored. Our preliminary explorations have focused on estimating the minimum perceivable stimulus on the wrist, limited to small sample sizes [12].

In this study, we investigated osseoperception by applying vibratory stimuli to the pisiform bone (PB) of the wrist and the Metacarpal Head (MCH) bone of the index finger. We conducted four psychometric tests to assess tactile, auditory, and combined sensory responses across different stimulation frequencies and forces. We used sensory mapping techniques

to delineate the vibration perception zones across the upper-limb and quantified auditory sensation loudness using a categorical scaling procedure. To the best of our knowledge, this approach has not been previously applied to the distal regions of the upper limb. By exploring osseoperception at these underexplored sites, our study contributes new insights into its potential application for restoring sensory feedback in individuals with neuromotor impairments. Furthermore, we believe that osseoperception as supplementary sensory feedback modality could be leveraged to facilitate controlling assistive technologies, such as osseointegrated prostheses (e.g., prosthetic hands or fingers), offering a promising avenue for enhancing prosthetic functionality.

II. Material and Methods

A. Participants

Twelve healthy participants (age between 24 and 35 yrs, equal number of male and female volunteers) were recruited for this study. Experiments were conducted under the Declaration of Helsinki and the guidelines of the Ethics Committee of the Scuola Superiore Sant'Anna (Approval No.10/2023). Participants were seated in front of a computer and given detailed instructions before the beginning of each experiment. Subsequently, they wore earplugs (35.5 dB, Tokelu, GE) and noise-canceling headphones (Peltor X5A, 3M, US), as recommended in prior studies [10], [11], [13]. These measures minimized external auditory interference, creating an isolated environment for our sensory assessments.

B. Experimental setup

The experimental setup, shown in Fig.1, included a Personal Computer (PC), a function generator, an audio amplifier, and a bone conduction transducer, detailed hereinafter. This design was inspired by previous studies in the literature [10], [11], [13]. A Graphical User Interface (GUI) was developed in MATLAB® (2021b, Mathworks, US) to adaptively set stimulation amplitudes and frequencies and record user responses. A multifunction DAQ module (PCI 6259, National Instruments, US) served as the function generator for sinusoidal signals with a 44.1 kHz sampling frequency. These signals were subsequently amplified and filtered (AK-170 Audio Amplifier, Hi-fi, CN) before being delivered to the bone transducer (B-81, Radioear, US). The bone transducer was positioned on the PB of the participant's wrist using a 3D-printed support, secured with adjustable elastic bands and Velcro straps to ensure stability [12]. The flat surface of the bone transducer was placed in direct contact with the target boney prominence, ensuring minimized contact with adjacent bones and hence unwanted vibrational effects, and a static force of 3-5 N was applied. This force range, determined based on prior studies, was sufficient to elicit bone conduction [10], [14]. The same experimental procedure was repeated with the transducer positioned on the metacarpal head (MCH) of the index finger (Fig. 1A). Prior to testing, the bone transducer was calibrated to ensure correct amplitude and frequency vibration using an artificial mastoid (4930, Bruel &Kjaer, DK).

C. Psycophysical experiments

1) Sensation Discrimination

This experiment aimed to evaluate what sensation was elicited by varying the parameters of the stimuli, i.e., frequency and amplitude. A single stimulus (1 s) was delivered to the participant, who was asked to report the elicited sensation among four options: tactile (T), auditory (A), both at the same time (T+A), or no perceived stimulus, by clicking on the corresponding button on the GUI (Fig. 1B). The stimulation frequency was randomly picked among seven values: 100, 200, 400, 750, 1500, 3000, 6000 Hz, based on values used in previous studies [10], [13]. Nine values of stimulation amplitude were randomly presented across the whole output range of the transducer (0-1 N of vibrational force). Each pair of parameters was presented to the participant twice, giving a total of 126 stimulations.

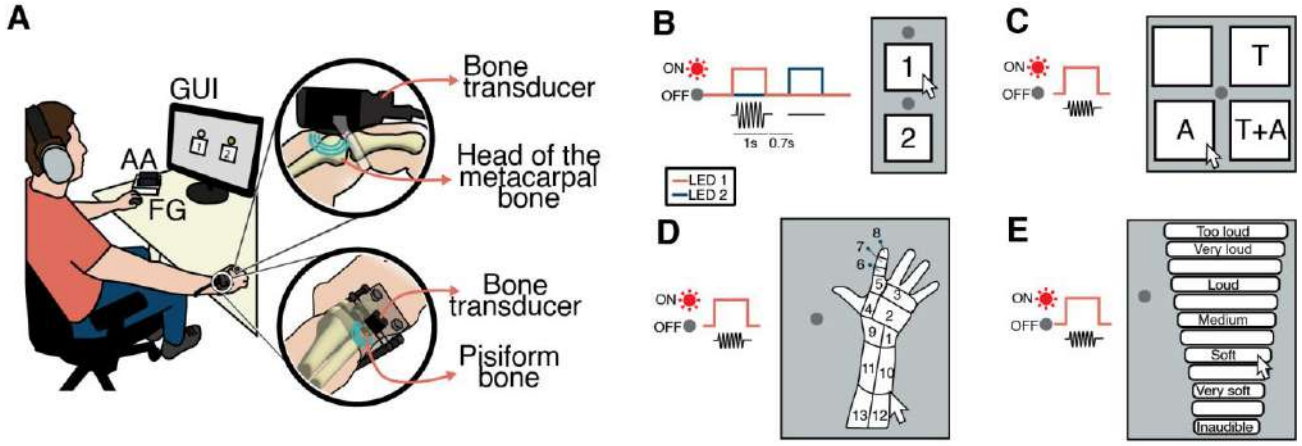

Fig. 1. (A) Experimental setup showing the PC running the GUI, connected to a Function Generator (FG), an Audio Amplifier (AA), and a bone transducer. The bone transducer was placed onto either the Pisiform Bone (PB) or the Metacarpal Head (MCH) of the index finger using two custom 3D-printed supports. A static force of 3–5 N was applied to ensure stable contact and effective vibration transmission. Timing of stimulation and user interface (gray background) for the four psychological experiments performed by the individuals: (B) Sensation discrimination, where the participants were asked to report which sensation (not perceived, tactile – T, auditory – A, or both – T+A); (C) Perception threshold, where the participants were asked to detect when a stimulus was delivered, discriminating against the null stimulus; (D) sensation zone, where the participants were asked to indicate the approximate zone were a tactile stimulus was elicited among 13 zones; (E) loudness evaluation, where the participants were asked to rate the auditory stimulus among 11 levels of loudness scaling.

For each participant, data were grouped by frequency. A logistic psychometric function was then fitted to each group of sensory responses, allowing to estimate the amplitude value corresponding to a 50% detection threshold (D50) for each sensation type. The D50 value indicates the sensitivity threshold for detecting each sensation, with lower D50 values signifying a higher sensitivity. The sensation with the lowest D50 at each frequency was classified as the predominant sensation. This methodology was based on the experimental procedures described in [10].

2) Perception threshold

The amplitude perception threshold (i.e., the minimum perceivable amplitude stimulus each participant could detect) was assessed upon stimulation at various frequencies. A single trial was administered, composed of a standard two-interval forced choice threshold procedure, in which participants discriminated between a target and a null stimulus (both 1 s in duration) in random order, separated by a retention interval of 0.7 s (Fig. 1C). The amplitude of the target stimulus was adjusted using a stochastic approximation staircase (SAS) method. If the participant's response to the previous trial was incorrect, the amplitude was increased; if correct, it was decreased. The step size of the SAS was calculated according to previous studies [10], [12]. Each SAS was stopped after 50 trials per frequency, and the value of the stimulus that would have been presented as the 51st trial was considered as the perception threshold. We selected 100, 400, and 750 Hz, since previous studies identified them to predominantly evoke tactile, combined tactile-auditory, and auditory responses, respectively [10], [11]. This methodology was based on the experimental procedures described in [10].

3) Sensory map

To assess the spatial distribution of tactile sensation, we conducted a test where a single vibrational stimulus (1 s) was delivered to the participant, who was asked to identify the approximate region where the tactile sensation was perceived. Then, the participant was asked to select one or more of 13 predefined regions displayed in the GUI (Fig. 1D). Since no prior studies have mapped the regions of tactile sensations elicited by bone-conducted vibrations on the upper-limb, we based the region layout on previous studies examining haptic points distribution [15], [16]. Stimulation frequencies were randomly selected between 100 and 400 Hz, known to elicit tactile sensations [10]. Nine stimulation amplitude levels were randomly presented across the whole output range of the transducer (0-1 N of vibrational force). Each frequency-amplitude combination was presented to the participant twice, for a total of 36 stimulations.

For each participant, responses were grouped by frequency and amplitude. The probability of stimulus perception in each zone was calculated as follows: 100% for consistent reports across the two stimuli, 50% for one report, and 0% for no reports.

4) Loudness evaluation

This experiment aimed to evaluate the loudness of sounds perceived by the participants, conveyed through bone conduction when their upper limb was stimulated. To achieve this, we used the categorical loudness scaling method following the recommendations of ISO:16832, similarly to [17]. The scaling procedure was presented through the GUI with 11 response options (Fig. 1E), each representing a 5-unit categorical increase in loudness, from 0-50 categorical units (cu).

The procedure consisted of delivering a single vibrational stimulus (1 s) to each participant at two frequencies, 1500 and 3000 Hz, chosen because they are known to convey auditory sensations only [9], [10]. The amplitude levels were calibrated using categorical loudness scaling with “Inaudible” (0 cu) and “Too loud” (50 cu) as reference points. We determined these levels with a staircase method, initially setting the bone transducer’s vibrational force to 0.6 N and incrementally increasing it by 0.05 N until the sound was rated as “Too loud”. Then, the amplitude was reduced by 0.10 N until the sound was rated “Inaudible”. If participants did not select the “Too loud” or “Inaudible” options, the vibrational force was limited between 0.2- 1 N to operate within the optimal range of the bone transducer (Fig. 1E). To obtain the loudness function for each participant, the following iterative procedure was employed.

i) **Initial Function Generation:** Using the stimulation forces at 0 and 50 cu, a linear interpolation function $F(L)$ was created to associate vibrational force L with the categorical loudness levels: “Very soft” (5 cu), “Soft” (15 cu), “Medium” (25 cu), “Loud” (35 cu), and “Very loud” (45 cu) (Fig. 1E). Variables k_{lo}, k_{hi}, and L_{cut} were initialized, with k_{lo} and k_{hi} representing the gradients of the interpolation (in cu/N), and L_{cut} representing the force associated with F(L)= 25.

ii) **Participant Ratings:** Five stimulation levels, corresponding to each loudness category (Fig.1E), were presented, and participants rated their perceived loudness using the GUI.

iii) **Updating the Function:** For each stimulation level, the perceived loudness c might differ from the function $F(L)$ prediction. Thus, the actual function $F_p(L)$ was computed using a piecewise approach:

   a) $Fp(L)=k_{lo}(L-L_{cut})+25$ for $c\leq 15$ cu
   b) $Fp(L)=k_{hi}(L-L_{cut})+25$ for $c\geq 35$ cu
   c) $Fp(L)=bezier(L,k_{lo},k_{hi},L_{cut})$ for 15 cu < c <35 cu

iv) **Function Refinement:** The variables k_{lo}, k_{hi}, and L_{cut} were iteratively updated by minimizing the mean squared error between the initial function F(L) and the estimated function Fp(L).

v) **Recalculation of Forces:** New stimulation forces L were calculated using the inverse function $F^{-1}(L)$ and the updated parameters, corresponding to the five intermediate loudness levels: 5, 15, 25, 35, and 45 cu.

vi) **Iteration:** Steps **ii** through **v** were repeated three times

The final function F(L), derived after three iterations, provided the best-fit loudness function for each participant. This methodology was based on the experimental procedures described in [17].

D. Statistical Analysis

For the sensation discrimination test, D50 values were grouped by sensation type and frequency across all participants. The normality and homogeneity of variances were assessed using the Kolmogorov-Smirnov and Levene tests, respectively. A one-way ANOVA was conducted to evaluate whether the D50 for one sensation was significantly lower than for the other two sensations at each frequency (α=0.05). Subsequently, post hoc comparisons were applied using the Tukey-Kramer method. The null hypothesis posited no significant differences among the sensations, while the alternative hypothesis suggested that one sensation was better perceived (lower D50) than the others [10].

For threshold perception, data from all participants were grouped by frequency (100, 400 and 750 Hz) and stimulation zone (i.e., PB and MCH). Normality and variance uniformity were confirmed using the same methodology as in the sensation discrimination test. A paired t-test was then employed to compare the minimum thresholds between the PB and MCH zones for each frequency. The null hypothesis stated no significant differences between zones, while the alternative hypothesis suggested statistically different thresholds (α=0.05).

For the loudness experiment, data were grouped by frequency (1500 Hz and 3000 Hz) and stimulation zone (PB and MCH). Normality and homogeneity of variances were assessed as before, and a paired t-test was applied to determine whether perceived loudness significantly differed by frequency or stimulation zone. The null hypothesis suggested no significant differences, while the alternative hypothesis posited that perceived loudness varied significantly. Results are presented as [mean ± standard deviation].

III. Results

A. Sensation Discrimination

Tactile D50 values were significantly lower than auditory D50 values at 100 Hz ($p<0.05$), 200 Hz ($p<0.05$), and 400 Hz for both wrist and MCH stimulation (Fig. 2). In contrast, auditory D50 values were significantly lower than tactile D50 values at 750 Hz and above, including 1500 Hz ($p<0.05$), 3000 Hz ($p<0.05$), and 6000 Hz ($p<0.05$). However, participants P01 and P12 did not perceive stimuli at 6000 Hz during wrist stimulation, and participants P02 and P12 failed to perceive stimuli at this frequency during MCH stimulation.

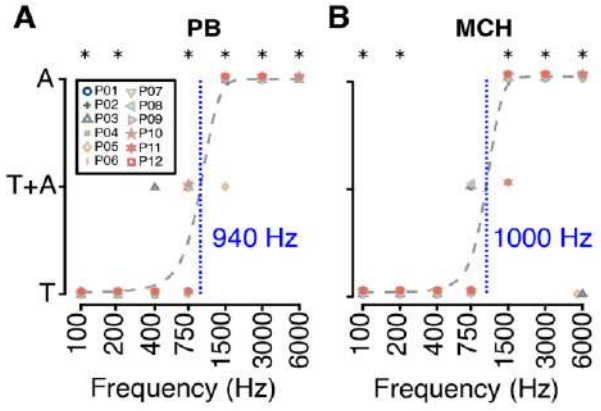

Fig. 2. Comparison of 50% of detection level (D50) for tactile (T), auditory (A), and combined tactile-auditory (T+A) sensations, measured across all participants. A) D50 values during stimulation of the PB of the wrist and (B) D50 values during stimulation of the MCH bone of the index finger. (*) Indicates statistically significant difference ($p<0.05$)

Some participants experienced combined tactile and auditory sensations. For instance, at 400 Hz, participant P03 reported both sensations during wrist stimulation, while at 750 Hz, this combined sensation was reported by participants P01, P02, P01, P02, P03, P05, P08, and P10. During MCH stimulation, combined sensations were reported by participants P01, P03, P04, and P08 at 750 Hz, and by participant P11 at 1500 Hz. Psychometric logistic functions revealed that the frequency threshold separating tactile and auditory sensations was approximately 940 Hz for wrist stimulation and 1000 Hz for MCH stimulation.

B. Perception threshold

On average, across all evaluated frequencies, the perception threshold was lower during MCH stimulation compared to wrist stimulation, although the difference is not statistically significant ($p>0.05$). The lowest average threshold was observed at 400 Hz during MCH stimulation (0.14±0.15 N), while the highest average threshold was recorded at 100 Hz during wrist stimulation (0.35±0.08 N) (see Fig. 3). At 400 Hz, the lowest perception thresholds were observed for the wrist (0.06 N, participant P08) and MCH (0.06 N, participant P06). In contrast, the highest perception thresholds were observed during wrist stimulation at 750 Hz (0.50 N, participant P05) and MCH stimulation at 100 Hz (0.51 N, participant P01).

C. Sensory map

Across all participants, the probability of detecting tactile sensations was higher during MCH stimulation than wrist stimulation (Fig. 4). At 100 Hz, the highest detection probabilities for wrist stimulation were in zones 1 (62% at 0.8 N) and 2 (38% at 0.9 N), while for MCH stimulation, zones 5 (77% at 0.4 N) and 6 (54% at 0.6 N) showed the highest probabilities (Figs. 4B, 4D). At 400 Hz, tactile sensations were perceived across additional zones compared to 100 Hz. For wrist stimulation, these included zones 3, 9, and 10, while for MCH stimulation, they expanded to zones 3, 4, 7, and 8. Furthermore, the probability of detecting tactile stimuli at lower vibration force amplitudes increased with frequency (e.g., from 100 Hz to 400 Hz), aligning with the trends observed in perception thresholds (Figs. 4C, 4E).

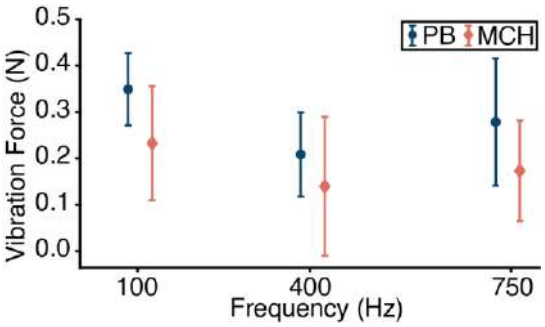

Fig. 3. Averaged perception thresholds across all participants per frequency using SAS technique. Error bars represent standard deviations.

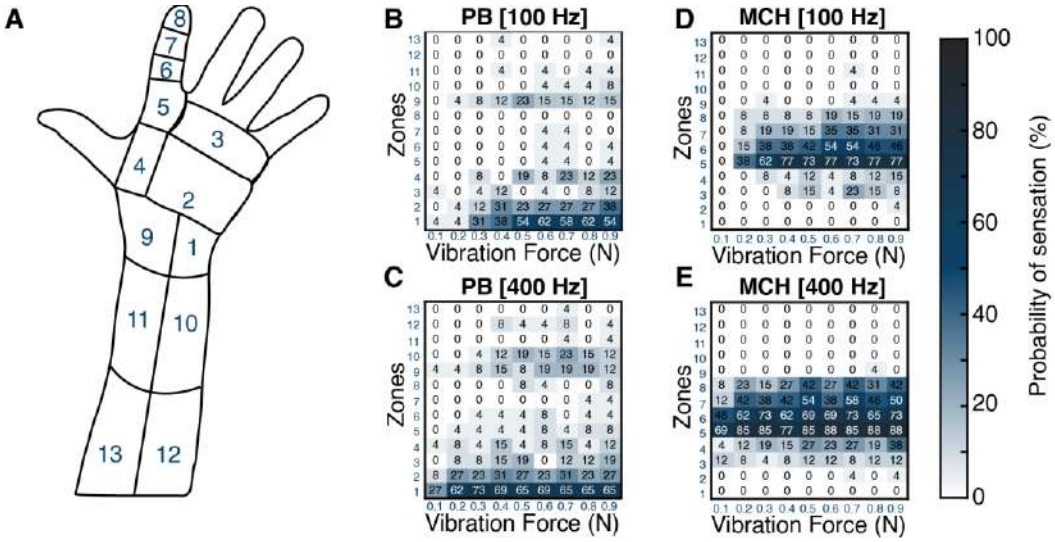

Fig. 4. (A) Reference image displayed in the GUI, showing the 13 perceptual zones that can be selected after stimulation. (B, C) Average probability of tactile perception across all participants in each zone during PB of the wrist (B) and MCH bone of the index finger (C) stimulation at 100 Hz. (D, E) Average probability of tactile perception during PB of the wrist (D) and MCH bone of the index finger (E) stimulation at 400 Hz. Results are shown for all vibration force amplitudes.

D. Loudness evaluation

The estimated loudness functions for 3000 Hz and 6000 Hz showed an approximately linear relationship between perceived loudness and stimulation force (Fig. 5). In general, higher vibration forces were required to achieve the same loudness perception at the wrist compared to the MCH. Additionally, a significant variation in vibration force (Δ) was observed between the two frequencies (3000 Hz and 6000 Hz) during wrist stimulation, indicating a frequency-dependent effect on loudness perception ($p<0.05$). However, this variation was almost null during MCH stimulation.

IV. Discussion and Conclusion

This study investigated evoking osseoperception in humans by stimulating with vibrotactile transducers two anatomical sites, i.e., the PB of the wrist and the MCH of the index finger. Four psychophysical experiments were carried out with healthy participants to assess their sensations.

All participants perceived vibrotactile sensations between 100 and 750 Hz and auditory sensations between 1500 and 3000 Hz for both PB and MCH stimulation, which is consistent with prior findings [10], [13]. However, the stimulation site influenced the threshold frequency distinguishing tactile and auditory sensations. Psychometric analysis suggested that this threshold frequency was approximately 940 Hz for PB stimulation and 1000 Hz for MCH stimulation. Previous studies reported different thresholds depending on the stimulation site: Clemente *et al.*[10] found a threshold near 309 Hz using an invasive interface on transhumeral amputees, while Mayer *et al.* reported thresholds between 400 and 750 Hz when stimulating the elbow of healthy participants [13]. These results suggest that the frequency required to evoke tactile, auditory, or combined sensations depends on the stimulation site. Furthermore, there may be a proportional relationship between the distance of the stimulation site from the mastoid bone and the required frequency, indicating that more distal sites require higher frequencies to convey auditory sensations [10]. However, further investigation is required to confirm this trend and identify its underlying mechanisms.

Our study found that the minimum perception thresholds occur during the stimulation of MCH at 400 Hz with a force of approximately 0.14 N. While Clemente *et al.* [10] reported the lowest thresholds at 100 Hz, our findings align more closely with Mayer *et al.*[13], who observed no consistent pattern in thresholds at frequencies above 200 Hz. This variability may be influenced by factors such as population sensitivity or the invasiveness of stimulation. Furthermore, the difference between the minimum thresholds during MCH and PB stimulation was not significant. This can be associated with the limited statistical power due to the sample size in this study.

Vibration strength and frequency significantly influenced the zones where tactile sensations are perceived. For instance, stimulating the pisiform bone elicited sensations around the wrist and forearm, particularly towards the ulnar side. In contrast, stimulation of the MCH produced sensations

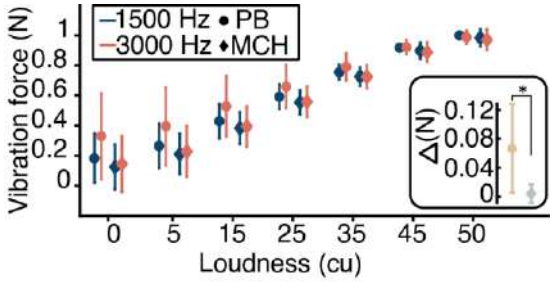

Fig. 5. Averaged loudness functions derived from the categorical loudness scaling procedure across all participants, plotted against varying vibration force and frequency for PB of the wrist and MCH bone of the index finger. (Δ) represents the difference in vibration force between frequencies, highlighting variations in categorical loudness scaling at each stimulation site. (*) indicates statistically significant differences ($p<0.05$). Error bars represent standard deviations.

extending to the carpal bones and the interphalangeal joints. These effects were intensified when the stimulation frequency was 400 Hz. Due to the rigid nature of the bone, mechanical waves, i.e., vibrations, can travel across it [18]. Consequently, these waves can stimulate the mechanoreceptors in the periosteum [9] and, possibly, the nearby innervated areas, potentially leading to sensations perceived in different regions in proximity of the bone [2], [10], [14].

The iterative scaling procedure provided accurate measures of loudness perception for each frequency. Our results suggest that higher loudness is perceived when vibration force increases, consistent with findings by Stenfelt *et al.* [17]. They found a proportional relationship between loudness and vibration force using bone transducers placed on the mastoid. However, the loudness ranges found when the transducer was placed on the mastoid were higher than those observed in this study. This can be associated with the attenuation of mechanical waves caused by the distance between the transducer and the cochlea [9]. Additionally, we observed that when the stimulation point was the PB, perceived loudness varied significantly with frequency (e.g., between 1500 Hz and 3000 Hz), which was not observed when stimulating the MCH.

To conclude, this study investigated psychophysical responses to vibrational stimuli applied to distal upper-limb bones for the first time [10], [11], [13], expanding the current understanding of osseoperception. However, it is important to note that our knowledge of osseoperception is still limited and further research is required before its clinical application. A potential limitation may be the perceivable sound generated by the mechanical waves applied by the transducers during auditory tests, particularly pronounced at high stimulation forces. Although measures were taken to minimize this effect—such as verifying the transducer's range and equipping participants with earplugs and noise-canceling headphones—sounds exceeding 35 dB are sometimes generated, possibly influencing psychophysical responses [10], [11], [13]. Future studies should implement stricter noise isolation measures or alternative calibration methods to enhance reliability of auditory perception data. Additionally, the relatively small sample size and the limited age range of participants may restrict the generalizability of our findings. Future approaches should include a more diverse sample to better understand individual differences and their impact on osseoperception.

The findings of this work indicate that the MCH region is more effective for eliciting tactile sensations, as evidenced by lower perception thresholds and more distinct sensory maps. In contrast, the wrist showed greater efficacy for auditory sensations, as shown by results from the sensation discrimination experiment and loudness scaling. These differences may be attributed to anatomical and physiological factors: the high density of mechanoreceptors in the hand likely contributes to the superior tactile sensitivity in the MCH [2], [10], [14], while the wrist's proximity to the cochlea may justify enhanced auditory perception [10], [18]. These findings emphasize the importance of both the stimulation site and frequency on the phenomenon of osseoperception. We aim at conducting other studies involving both healthy individuals and people with neuromotor impairments, focusing on functional tasks and possibly exploring its application to deliver augmented sensory feedback in assistive devices. This will allow us to explore the potential of osseoperception for enhancing tactile and auditory perception, and eventually extending the reach of assistive technologies.

***Abstract*—This paper presents a flexible software with a Graphical User Interface (GUI) designed to assist clinicians in upper limb robotic rehabilitation sessions. The flexibility comes from the fact that, since it relies on the Robot Operating System 2 (ROS2) framework, it is potentially compatible with any collaborative industrial robot, with relatively low integration effort. The software collects and analyzes data related to each session to identify critical movement directions for each patient, detecting improvements or regressions through statistical tests, thus reducing subjectivity. Moreover, it suggests personalized physical and cognitive rehabilitation exercises focusing on the most critical movement directions. Results are visualized through intuitive graphs, allowing clinicians to design custom trajectories tailored to each patient's needs. The software has been tested in combination with a Franka Emika Panda robot proving its seamless integration and ability to process data in real time.**

***Index Terms*—robotic rehabilitation, evaluation methods, interfaces for rehabilitation**

I. Introduction

Each year, millions of people are affected by chronic neurological diseases [1]–[3]. A prompt intervention with motor and cognitive rehabilitation therapies is crucial to mitigate the disease effects in chronic cases or to help recover lost functions in acute cases [4]. The variability in a patient's abilities from session to session creates the need for personalized therapies [5]. Robotics has proven to be an effective tool in rehabilitation, helping the therapists in performing repetitive movements with the patient. Moreover, it allows objective assessments of patient abilities using sensor-based evaluations.

The Center Out Point To Point (CO-PTP) exercise, commonly used in upper limb rehabilitation robotics, involves moving the robot end-effector from a central point to targets around a circle [6]. In the meantime, kinematic and dynamic data are collected and employed in the computation of Quality Metrics (QMs) such as the smoothness, the precision error, the mean velocity, and the duration. Such QMs have been proven to correlate with established clinical scales (e.g., Medical Research Council Muscle Power Scale and Fugl Meyer Assessment Scale [7]), commonly used for the assessment of the upper-limb function in post-stroke patients [8], [9]. A peculiarity of CO-PTP is that it can identify movements that require more effort by the patient [6], being an ideal exercise in the treatment of neurological patients.

An ideal automated system should interpret data and adjust rehabilitation exercises to maximize their benefit on the patient. However, learning the relationship between a patient's condition and optimal actions is challenging due to limited data, patient variability, complex setups, and legal and safety constraints [10]. While relying on therapists circumvents data issues, it introduces inefficiencies, interrupting sessions and reducing therapy time. To address this, therapists must quickly interpret data and intuitively adjust robotic settings [11]. Graphical data visualization enhances data accessibility, while a safe, user-friendly interface facilitates interaction. In particular, a recent study demonstrated that the teaching by demonstration of a trajectory is a very appreciated functionality in the physiotherapy realm [11]. Such a tool allows to manually move the robot, record the trajectory, and enable the robot to automatically replay it to guide the patient's hand in tracking the end-effector path accomplishing the Trajectory Tracking (TT) exercise.

Various technologies have been developed to achieve these goals, using mechanical devices specifically designed for medical purposes and user-friendly GUIs [12]–[15]. However, while these devices offer tailored solutions, they often come with high development and manufacturing costs and limited scalability making them less accessible and adaptable. A recent and cost-effective solution proposed is the use of industrial collaborative robots for rehabilitation purposes (e.g. [16]–[18]). The adoption of industrial robots in the recovery realm offers advantages such as lower cost due to mass production, versatility and scalability, as well as established maintenance and technical support. However, they are still rarely used in rehabilitation practice [17]. Moreover, only a few of this kind of systems feature software with GUIs that allow for intuitive reading, processing, and visualization of results and, to our knowledge, no system offers a software that can be used with different robotic models. Recently, however, a dashboard has been developed to process and visualize dynamic data from multiple robotic rehabilitation sessions, conducted with any rehabilitation system capable of collecting such data [19].

The work has been supported by the Italian Ministry for University and Research in the framework of the Fit4MedRob project - PNC0000007.

However, this software only allows for result visualization and does not enable the programming of new exercises.

In this article, we propose a new software designed for clinicians who are responsible for managing multiple patients during various rehabilitation sessions based on the use of a generic industrial collaborative manipulator. The software is equipped with an intuitive GUI and is capable of exchanging information with the robot by means of the Robot Operating System 2 (ROS2) communication framework, collecting data while the patient is performing the rehabilitation exercises. Such data are employed to identify the movement directions that are most critical for the patient and, through statistical tests, detect improvements or regressions. This allows the software to tailor the rehabilitation sessions, customizing standard rehabilitation exercises such as the CO-PTP, to promote movements in the most critical directions. In addition, by visualizing the data using intuitive graphs, clinicians can design custom trajectories for the TT exercise that best suit the needs of each patient, relying on objective information. The compatibility of the proposed software with collaborative industrial manipulators was assessed by testing it in combination with the Franka Emika Panda robot.

The rest of the paper is organized as follows. Section II describes the complete flexible rehabilitation framework, Section III presents the modes of operation of the robotic system, Section IV describes in details the proposed intuitive GUI. Finally, in Section V the experimental test is described, while some conclusions are drawn in Section VI.

II. Flexible Rehabilitation Framework

This section presents the proposed flexible robotic rehabilitation framework, depicted in Fig. 1, and its components.

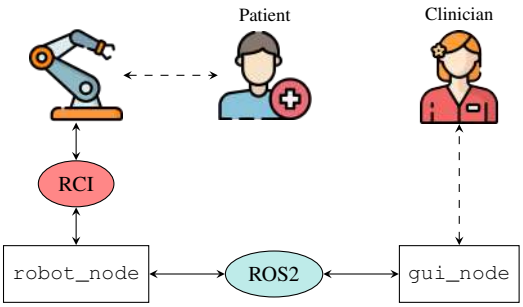

Fig. 1: Graphical representation of the flexible rehabilitation framework. The red ellipse represents the communication via the robot robot control interface (RCI), while the blue one the communication via ROS2. The dashed lines represent physical access.

To be compatible with the interface presented in this work, the robot must be a torque-controlled collaborative robot manipulator compliant with the safety requirements specified in the ISO/TS 15066:2016, and should allow the installation of a custom end-effector that facilitates the interaction with the patient.

In general, manipulators are characterized by $n \in \mathbb{N}_{>0}$ revolute joints, whose positions, expressed in radians, are collected in the joint variable vector $q \in \mathbb{R}^n$ [20]. The dynamics of the robot is modeled according the Euler-Lagrange formulation as

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + g(q) + F(q,\dot{q}) = \tau + J \quad (q) f_h, \quad (1)$$

where $M : \mathbb{R}^n \to \mathbb{R}^{n\times n}$ is the inertia matrix, $C : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^{n\times n}$ is the matrix of Coriolis and centripetal effects, $g : \mathbb{R}^n \to \mathbb{R}^n$ is the gravitational torque, $F : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^n$ is the vector of frictions, $\tau \in \mathbb{R}^n$ is the control input torque, $J : \mathbb{R}^n \to \mathbb{R}^{6\times n}$ is the geometric Jacobian, while $f_h \in \mathbb{R}^6$ is the force applied by the patient or the clinician to the end-effector of the robot through the handle.

In general, the control of the robot is carried out by means of a software that interacts with the low level controllers via an application program interface provided by the robot manufacturer. In the rest of the paper, this last one will be referred to as robot control interface (RCI). In the majority of cases, RCIs are interfaced with external software components by means of network communication protocols such as TCP/IP or UDP. Despite the effectiveness of this approach, it lacks of flexibility since it requires significant integration work in order to synchronize the transmission of information.

In the proposed rehabilitation framework, the robot should communicate with a rehabilitation interface, which is a GUI that allows to program, monitor, and analyze rehabilitation sessions. Due to the articulated nature of this last one (more details in Section IV), implementing a robust communication with the robot may require significant integration effort. Hence, both the control software and the rehabilitation interface are programmed as ROS2 nodes, denoted respectively as `robot_node` and `gui_node`, which share information about the robot state an the control actions by means of the ROS2 topics in Table I. The objective of the `robot_node`, which embeds the RCI, is to broadcast information about the state of the robot and, at the same time, receive a new control torque reference τ by the `gui_node` and send it to the low-level controllers through the RCI. It is important to note that while the `gui_node` is already implemented in Python programming language and requires no modifications (making the system "flexible"), the `robot_node` varies depending on the robot and must be implemented by the user to integrate the GUI with a new robot. However, this node is designed to be simple to develop and should be implemented following the flowchart shown in Fig. 2. More details are provided later in Section III.

TABLE I: ROS2 topics used to exchange information between the robot control software and the rehabilitation interface.

Topic name	Description
`/r/state/joints/pos`	Joints position vector
`/r/state/joints/vel`	Joints velocity vector
`/r/state/ee/pose`	End-effector pose
`/r/state/ee/vel`	End-effector velocity
`/r/ctrl/torques`	Input torque
`/r/ctrl/hg/start`	Start the robot handguide mode
`/r/ctrl/tc/start`	Start the robot torque control mode
`/r/ctrl/stop`	Stops the control of the robot

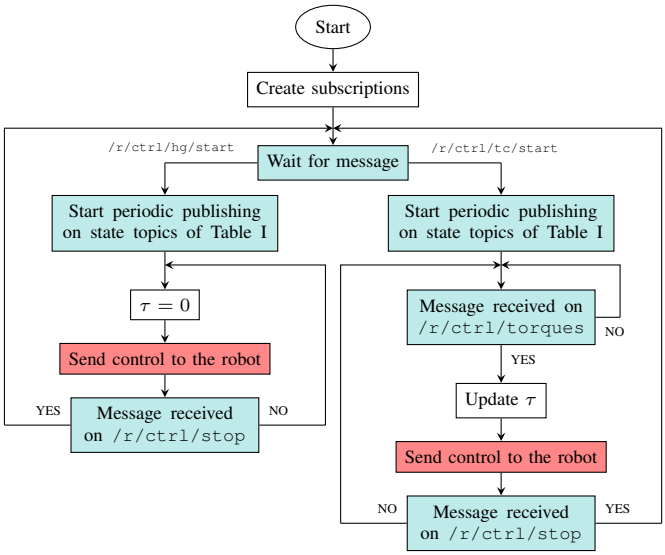

Fig. 2: Flowchart of the `robot_node` structure: red blocks indicate RCI communication, blue blocks indicate ROS2 communication.

III. Modes of Operation

The aim of this section is to provide a brief description of the modes of operation of the proposed robotics rehabilitation system, i.e., CO-PTP, trajectory recording, and TT, and how the robot is controlled in each of these modes.

A. Center Out Point To Point

In this mode of operation, the patient performs the CO-PTP exercise. In particular, the patient is asked to grasp the robot end-effector using the handle and move it from a starting point, toward one of the targets placed along a circle whose center coincides with the starting point, as depicted in Fig. 3, and reach back the center. The exercise can be performed in Traditional Mode (TM) and Cognitive Exercise Mode (CEM) that requires a mnemonic effort and consequently serves as both a physical and neurological training.

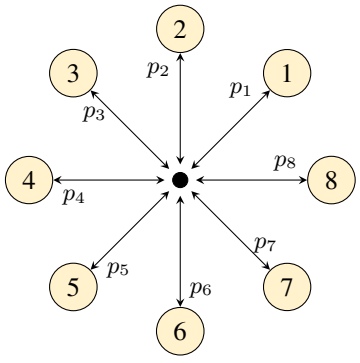

Fig. 3: Targets in the CO-PTP exercise with the associated ideal movement directions and selection probabilities.

In TM, the patient is simply instructed to perform a Reaching Movement (RM) on a specific target $i \in \{1, 2, \ldots, 8\}$. A RM is defined as the composition of two movements, the Center To Point (CTP) movement which starts from the center and ends in the target, and, vice versa, the Point To Center (PTC) movement which starts from the target and ends in the center. The system automatically detects when a RM is completed and the patient is instructed to perform another RM on target $i+1$. In particular, the RM is considered completed when both the velocity of the end effector and its distance from the central point are lower than 0.0005 m/s and 0.03 m, respectively. Once the operation is repeated for all the targets, the exercise is completed.

On the other hand, when the exercise is executed in CEM, the patient is asked to perform RMs on a sequence of the targets, in an order that is shown before the beginning of the exercise. The length of the sequence depends on the results of previous exercise iterations, while the speed with which the sequence is displayed depends on a parameter chosen by the clinician, and described in Section IV. The sequence depends on the past results and this is required since some patients, especially those affected by stroke, may have difficulties moving in specific directions. Therefore, the choice of targets in the sequence is not random but is designed to prioritize directions that require more effort from the patient, as described in the following.

Let $n_i \in \mathbb{N}_{>0}$ be the number of RMs carried out in the last rehabilitation session toward the i-th target, with $i \in \{1, 2, \ldots, 8\}$. Then, let $S_i \in \mathbb{R}_{>0}$ be a penalty score related to the i-th target defined as

$$S_i = \frac{\bar{s}_i + \bar{v}_i}{\bar{d}_i + \bar{e}_i} \tag{2}$$

where $\bar{d}_i, \bar{e}_i, \bar{s}_i, \bar{v}_i \in \mathbb{R}_{>0}$ are the sum of the normalized QMs described in Table II. In particular, let $x_i \in \{e_i, s_i, v_i, d_i\}$, then

$$\bar{x}_i = \sum_{j=1}^{n_i} \frac{x_{i,j} - \min_j x_{i,j}}{\max_j x_{i,j} - \min_j x_{i,j}}, \tag{3}$$

where $x_{i,j}$ is the QM associated with the j-th RM toward the i-th target.

TABLE II: Quality Metrics associated with the i-th target.

QM	Name	Description
e_i	Precision error	Distance between the endpoint of the CTP movement and the target
s_i	Smoothness	Ratio between the average speed and the maximum speed of the end-effector in a RM
v_i	Mean speed	Average speed of the end-effector in a RM
d_i	Duration	Time taken to complete a RM

Finally, the probability of the i-th target of being selected during the computation of the sequence can be defined as

$$p_i(\alpha_{\text{IOP}}) = \gamma(\alpha_{\text{IOP}}) + \sigma_i(\alpha_{\text{IOP}}), \tag{4}$$

with $p_i \in [0, 1]$ and $\sum_{i=1}^{8} p_i = 1$, and where $\alpha_{\text{IOP}} \in [0, 0.8]$ is a constant related to the Impact Of the Performance (IOP) of the previous sessions, and it is chosen by the clinician via the GUI, as detailed in Section IV. The first term of (4) is the same for all targets and it is defined as

$$\gamma = \frac{(1 - \alpha_{\text{IOP}})}{8}, \tag{5}$$

while the second one depends on the previous performance obtained by the patient moving toward the i-th target and is defined as

$$\sigma_i = \alpha_{\text{IOP}} \frac{S_i}{\sum_{i=1}^{n} S_i}. \tag{6}$$

To perform the CO-PTP exercise, the robot should be put in handguide mode. This can be done by the clinician which, by simply pressing a button of the GUI, publishes a message on the associated topic (see Table I). Since the patient, which, as detailed in (1), exerts a force f_h on the robot, should be able to move the end-effector effortlessly, the robot must be controlled so that it compensates the gravitational torque g. Since in the majority of the industrial robots gravity is compensated directly by internal controllers, it is sufficient that `robot_node` controls the manipulator setting $\tau = 0$.

B. Trajectory Recording

In this mode of operation, the clinician defines a three dimensional trajectory which is recorded and stored, along with the associated trajectory in the joint space.

During the recording phase, the robot is set into the handguide mode as described at the end of Section III-A, and the clinician is supposed to instruct the robot using a teaching by demonstration approach. In particular they need to grasp the end-effector and move it in the three dimensional space along a trajectory that the patient should follow with their hand afterwards in the TT mode. The value of the joint positions is stored locally to construct a trajectory $q^\star(t) \in \mathbb{R}^n$.

C. Trajectory Tracking

In this mode of use, the patient is required to grip the handle placed on the end effector and allow themselves to be guided by the robot, as it follows a prerecorded trajectory. The start of this exercise, and thus the beginning of the robot movement, is triggered by the clinician through the GUI, and involves the activation of torque control on the robot by means of the publication of a message on the associated topic (see Table I). Then, the `gui_node` computes the control signal as

$$\tau = K_P \Big] q - q^\star \big) + K_I \int_0^t \Big] q - q^\star \big) dy + \tau_r, \tag{7}$$

where $K_P, K_I \in \mathbb{R}^{n \times n}$ are diagonal gain matrices, while τ_r is a robust control component which aims to compensate the force f_h that the patient exerts on the robot while being carried by this last one. In particular, since f_h acts as a bounded matched disturbance, τ_r can be designed according to the *Sliding Mode Control* [21], widely adopted in the domain of robot control [22], [23], having

$$\tau_r = -\rho \frac{C_1(q - q^\star) + C_2(\dot{q} - \dot{q}^\star)}{||C_1(q - q^\star) + C_2(\dot{q} - \dot{q}^\star) + \varepsilon||}, \tag{8}$$

where $\rho \in \mathbb{R}_{>0}$ is a control gain, $C_1, C_2 \in \mathbb{R}^{n \times n}$ are diagonal design matrices with positive entries, while $\varepsilon \in \mathbb{R}_{>0}$ is a small design constant.

IV. The Proposed Graphical User Interface

The GUI, programmed in the `gui_node` and designed through Qt Designer, is structured as in Fig. 4, identifying three sections: the Trajectory Recording Section (TRS), the Patients Management Section (PMS), and the Individual Monitoring and Therapy Section (IMTS).

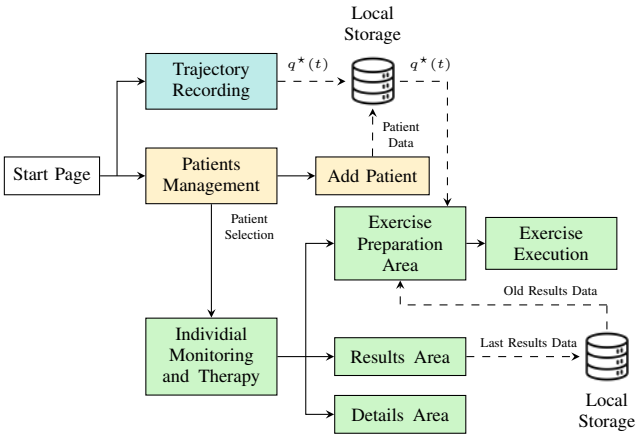

Fig. 4: Diagram of the GUI structure. The dashed lines represent interactions with the local storage.

The TRS is composed by a page from which the clinician can start the recording, then move the robot, defining a three dimensional trajectory for the end-effector from which the associated joints position trajectory $q^\star(t)$ is computed. Once the recording is completed, the user can choose to save both the end-effector and the joint position trajectory. In particular, this last one will be employed in the TT exercise, as detailed in Section III-C.

In the PMS, which can always be accessed by the user from a navigation bar placed on the top of the GUI, the clinician has access to information about patients that have been already registered in the system. From the same page, it is possible to register a new patient entering details that include first name, last name, the neurological condition and, optionally, a note with relevant information about the therapy. From the PMS page the clinician can enter the IMTS page for a patient.

In the IMTS, the clinician can monitor the patient's status by observing the results achieved in completed rehabilitation sessions and prepare and start exercises for the patient in a new rehabilitation session. The section is further divided into three areas, accessible through a sidebar: the Details Area (DA), the Exercise Preparation Area (EPA), and the Results Area (RA). In the DA the clinician can view and edit all the patient's details entered during the registration procedure. In the EPA, depicted in Fig. 5 the clinician can select the exercise for the patient and, if needed, adjust parameters governing how the exercise is conducted. Specifically, the user can choose between TT and CO-PTP as exercises to administer to the patient. The TT exercise, described in Section III-C, has only one mode of execution. Hence, the clinician is only required to select from a drop-down menu a trajectory among the ones that have been already recorded and ask the patient to grasp

the robot end-effector. Then, by pressing a button, the robot starts reproducing the trajectory. As for the CO-PTP exercise, described in Section III-A, it can be performed in TM or CEM. Hence, the clinician is asked to choose between the TM and CEM modes. If CEM is selected, the clinician is prompted to adjust the velocity and the parameter α_{IOP} in (4), by means of two sliders.

Independently from the mode, during the CO-PTP exercise the patient is provided with visual feedback on a screen, by means of a real-time plot that shows the actual path the patient is following, overlapped to the desired straight line trajectories connecting the center and the targets in Fig. 3.

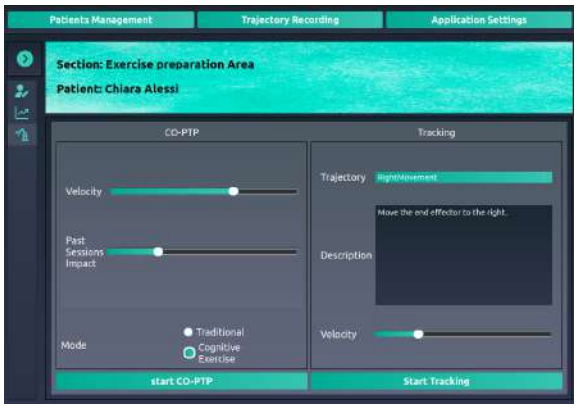

Fig. 5: Screenshot of the EPA, in which the clinician can setup the parameters of the exercises.

In the RA, the clinician can review the results obtained by the patient during the CO-PTP exercise. These results, based on the QMs in Table II, are presented in three different formats, *single session*, *statistical comparison*, and *progress*.

As for the results of a single session associated with a specific QM, they are displayed using a radar plot, in which each vertex is related to one of the CO-PTP targets. Given a specific movement direction, the distance between the center and the associated vertex depends on the value of the selected QM achieved by the patient while moving the end-effector during the session. An example is presented in Fig. 6.

As for the progress format, it allows the clinician to select a QM and a target index $i \in \{1, 2, \ldots, 8\}$, identified by an angle. Then, it generates a plot depicting the trend over time of the mean value of the QM computed during the movement accomplished toward the selected target.

Finally, it is possible to see the results associated with a specific QM in the statistical comparison format. In particular, the QM scores obtained during all the RMs that have been carried out by the patient, are divided by session and by target, and stored in a dataset. The two ways Friedman test is then used to check whether there exists at least one session in which the selected QMs scores are statistically different from the ones of the other sessions. In case there is no significant difference, the clinician is informed via text message; otherwise, a heat map like the one in Fig. 7 is presented. This heatmap, which represents the results of a Nemenyi post hoc test for multiple

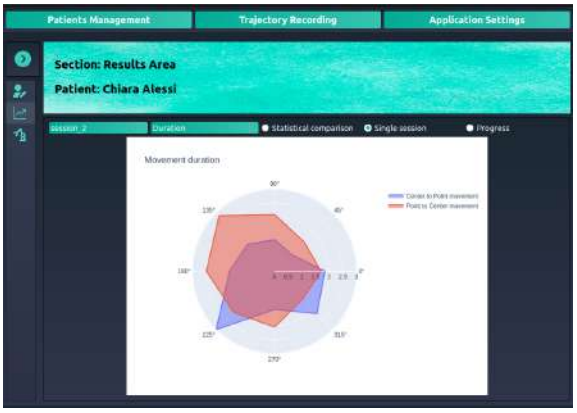

Fig. 6: Example of a radar plot to show the results of a single session related to CO-PTP duration d_i, including the results obtained in the CTP motion (blue) and the PTC motion (red)

comparisons, consists of a matrix in which each element is associated with a couple of sessions. If the difference between such sessions is significant, the color of that element of the heatmap is darker and the p-value of the post hoc test for multiple comparison, written in the center of the element, is lower than 0.05.

Fig. 7: Example of heatmap showing presence of statistical differences between sessions.

V. Case Study

In order to assess the effectiveness of the software and its compatibility with industrial robots, it was tested in combination with Franka Emika Panda, a collaborative robot characterized by 7 degrees of freedom. A customized 3D-printed handle was attached to the end effector, to allow the user to move it. The software was installed on a workstation running Ubuntu 22.04 with ROS2 Foxy. Communication with the Franka Emika Panda was managed through the dedicated `robot_node`, implemented in C++ following the workflow illustrated in Figure 2. The Robot Control Interface (RCI) was based on the *libfranka* library, which provides low-level access to the robot's control and state information. Several key functionalities were tested, including the recording of a new trajectory for TT exercises as described in Section III-B, the

configuration and execution of rehabilitation exercises and the visualization of results data provided by the GUI. The robot demonstrated full compatibility with the software, successfully enabling real-time data visualization and collection during the CO-PTP exercise and the trajectory recording.

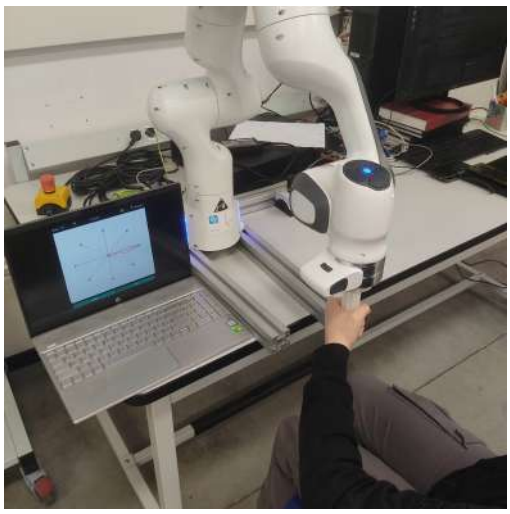

Fig. 8: Experimental testing of the compatibility of the software with the Franka Emika Panda robot: real-time feedback visualization during CO-PTP exercise

VI. Conclusions

In this paper, a software equipped with GUI for a flexible upper limb robotic rehabilitation via industrial manipulator has been proposed. The main purpose of such a software is to help the clinician in the evaluation phase, allowing them to monitor the condition of the patient through sessions via intuitive graphs, and design new exercises via simple interaction with the robot. Unlike other GUI-based software, the proposed one can be interfaced seamlessly with any industrial collaborative manipulator, making it an easily adaptable solution which allows for robotics rehabilitation sessions which do not require any customized technology. The software has been assessed in combination with the Franka Emika Panda robot, demonstrating its full compatibility and real-time data processing capabilities. In future studies, we aim to evaluate the system's usability and effectiveness in a clinical environment. Additionally, we plan to expand the graphical interface by integrating exergames to enhance patient engagement.

Adaptive Motor Unit Decomposition During Walking: Towards Systematic Validation

Antonio Gogeascoechea*, Nathan van Dieren*, Utku S. Yavuz, and Massimo Sartori

***Abstract*— Understanding motor unit (MU) behavior during locomotion is essential for uncovering the neural control of human movement and advancing the development of assistive technologies. Although high-density electromyography (HD-EMG) allows for the extraction of individual MU firing activity, conventional methods are typically restricted to isometric or slow dynamic contractions. Additionally, accurate characterization of MU twitch responses is essential for decoding the mechanical output of muscle contractions. In this study, we present an adaptive online-capable methodology for decoding soleus' MU firing events and MU-specific activation dynamics along with a conservative validation during locomotion. Our proposed framework incorporates advanced blind source separation techniques, adapted for the detection of low-threshold MUs and capable of addressing non-stationary MU action potential variations. The framework is built on three main components: (1) an offline process to derive decomposition parameters and optimal twitch characteristics from isometric and walking trials, (2) an online approach that includes both static and adaptive decomposition strategies to refine MU firing event estimation and apply derived twitch properties for real-time MU-specific activation, and (3) a validation of the decoded MU spike trains against those derived from intramuscular EMG, as well as a comparison of MU-specific activation against ankle joint moments. Experimental results demonstrated that the adaptive approach improved the agreement with intramuscular EMG-derived spike trains and provided strong correlations between MU-specific activation and ankle joint moments.**

This work holds significant promise for future real-time applications in assistive devices that can more effectively adapt to individual patient needs and track their progress over time.

I. Introduction

Interfacing with motor units (MUs) *in vivo* provides a unique window into the neural commands that drive human movement. Each MU, comprising an α-motor neuron and the muscle fibers it innervates, represents the smallest functional unit of force generation, making it essential for understanding both healthy and impaired motor function (*e.g.* [1]–[3]). Decoding MU activity can therefore play a pivotal role in advancing mobility restoration and enhancing rehabilitation outcomes for individuals with motor impairments.

High-density electromyography (HD-EMG) combined with blind source separation (BSS) has become a promising approach for decoding MU behavior, with significant potential for advancing rehabilitation technologies. BSS techniques allow for the identification of MU discharge patterns without *a priori* knowledge of MU action potential (MUAP) shapes, relying solely on the statistical properties of MU discharges [4]. This approach has enabled the non-invasive characterization of α-motor neuron discharge patterns in both healthy and neurologically impaired individuals [1]–[3].

Despite their promise, BSS techniques face two significant limitations. First, they typically assume stationary conditions [4], [5], restricting their application to isometric or slow dynamic contractions. This assumption poses challenges for more complex, real-world scenarios such as walking, where MUAPs vary continuously and muscle activations are rapid and high in amplitude. Second, BSS is susceptible to MU amplitude cancellation [6], a phenomenon that complicates the accurate decomposition of low-threshold MUs during high-force activities. Overcoming these challenges is essential for reliable MU analysis during locomotion. Additionally, decoding actual joint moments requires more than just MU firing patterns; it needs linking these patterns to their corresponding twitch contractile responses to translate neural commands into force production effectively.

In this context, our previous work [7] laid the foundation for real-time decoding of both MU firing events and their corresponding twitch responses during locomotion. Specifically, our proposed MU-specific formulations [7], [8] provided activation patterns that better described ankle joint moments compared to conventional EMG envelopes. To achieve this, we integrated state-of-the-art methodologies aimed at reducing amplitude cancellation effects, including peel-off approaches [9], [10], and decomposing MUs online using offline-estimated separation vectors (MU Filters) [11]–[13]. Additionally, we focused on the soleus muscle, which experiences minimal fiber length variation during the push-off phase of the gait cycle [14], [15], making it well-suited for decoding MUs during walking. However, the non-stationary nature of MUAPs remained a challenge, as MUAPs can vary even in isometric conditions (*e.g.* contraction intensity [16])). Furthermore, validation at the MU firing level is still required. While our findings indicated that the decoded MUs produced activation profiles closely correlated with joint moments, we lacked ground truth data to confirm the accuracy of the decoded firings.

In this study, we focus on extending our methodology to address variations in MUAP shapes during locomotion and validating its accuracy using intramuscular EMG (iEMG) as a benchmark for MU decomposition. These enhancements improve the robustness of our framework and allow for more precise muscle activation estimates. Our validated method-

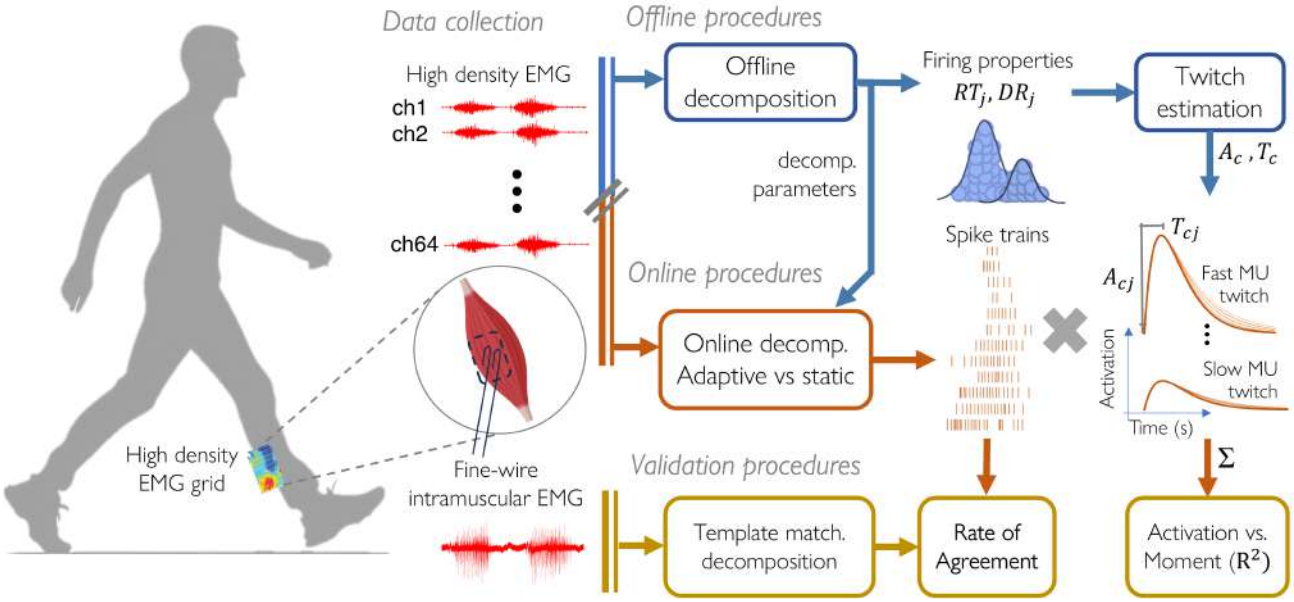

Fig. 1. Study overview. HD-EMG and iEMG are recorded from the soleus muscle during walking and low-force isometric trials. The HD-EMG data are split for offline and (pseudo-)online decomposition of motor unit (MU) firing events. The offline processes provide decomposition parameters and MU twitch properties. These are then used online for decoding MU spike train and activation using adaptive and static approaches. HD-EMG-derived MU spike trains are validated against spike trains obtained from iEMG (via template-matching). Muscle activations are assessed against ankle joint moments derived from inverse dynamics. RT, DR, A_c, and T_c represent recruitment threshold, discharge rate, twitch amplitude, and contraction time, respectively.

ology has the potential to transform the control of assistive devices, allowing real-time adaptability and feedback that seamlessly integrate with the user's neuro-musculoskeletal system, ultimately promoting a more natural and effective rehabilitation experience.

II. Methods

Overview of our framework

Our framework comprises three main components (Fig. 1). First, an offline procedure for extracting decomposition parameters and optimal twitch characteristics from a training dataset including isometric and walking trials (Section II-B). Second, two online decomposition approaches: a static approach that reuses the pre-determined decomposition parameters and an adaptive approach that updates them to improve the estimation of MU firing events. Both approaches use the derived twitch characteristics to produce MU-specific activation dynamics (Section II-C). Third, a validation step involving the comparison of HD-EMG-decoded firing events with those obtained from iEMG, as well as an assessment of the activation profiles against ankle moments (Section II-D). All procedures were approved by the ethical committee CMO region Arnhem-Nijmegen (protocol ID: NL73230.091.20).

A. Data Collection

Kinematic, kinetic, iEMG, and HD-EMG data were collected from a healthy participant during isometric and walking trials. The experimental protocol included walking for a minute at three different speeds (preferred, slow, and fast), along with a sustained push-off trial at a sub-maximal force levels (∼30% MVC).

Motion capture data and ground reaction forces (GRFs) were synchronously recorded using a motion tracking system (Qualisys, Goteborg, Sweden, 100 Hz) and a force plate (Bertec Co., Columbus, OH, USA, 2000 Hz). Reference ankle angles and moments were derived from marker trajectories and GRFs via inverse kinematics and inverse dynamics.

EMG recordings were performed using TMSi amplifiers (TMS International B.V., Oldenzaal, The Netherlands). IEMG signals were recorded with a 16-channel EMG amplifier at 17295 Hz (TMSi Refa). A bipolar fine-wire electrode was inserted diagonally at a shallow depth (∼1 cm) into the medial part of the soleus to record from superficial fibers. For HD-EMG recordings, an 8x8 electrode grid (4.5mm of inter-electrode distance) was placed over the intramuscular electrode. HD-EMG data were collected using a 64-channel EMG amplifier at a sampling rate of 4000 Hz (TMSi SAGA).

The HD-EMG data were split into sets for estimating and refining MU filters (offline procedures), and for (pseudo) online decomposition. For the offline decomposition, we employed the low-force push-off trial and half of the walking cycles. For the pseudo-online decomposition, we used the remaining walking data. HD-EMGs were band-pass filtered between 10-500 Hz with a fourth-order Butterworth filter, and poor-quality channels (low signal-to-noise) were excluded. IEMGs were high-pass filtered at 1000 Hz with a first-order Butterworth filter [17].

B. Offline procedures

1) Decomposition parameter estimation: To estimate decomposition parameters offline, which are subsequently utilized for online procedures (Section II-C), we employed a de-convolutive blind source separation (BSS) approach [4], [5] as follows (1):

$$s_j = c_{s_j z}^T C_{zz}^{-1} z, \tag{1}$$

where $w_j = c_{s_j z}^T C_{zz}^{-1}$ is the separation vector of the j_{th} MU, $c_{s_j z}$ is the cross-correlation vector between the source s_j and

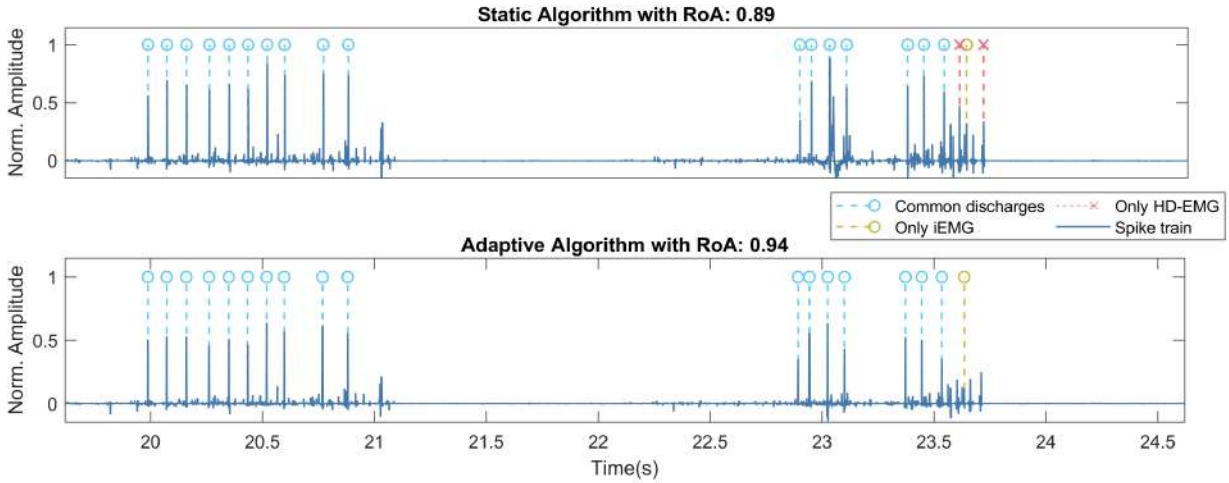

Fig. 2. Validation of HD-EMG-decoded spike trains against reference derived from iEMG (representative example, walking speed: 0.4 m/s)

the whitened extended signals z, and C_{zz} is the covariance matrix of the whitened extended signals.

The extension of the signals was computed by incorporating their delayed versions by a factor of 16. The extended signals were subsequently whitened using singular value decomposition. A fixed-point algorithm [5] was then applied to increase the sparsity of each source (s_j). For each iteration, the separation vector (w_j) was initialized as the vector with the maximum squared summation of the extended signals (z) across all time points, which indicates the instance with the highest signal activity potentially representing one or more MU discharges [4]. We then maximized the level of the sparsity of each source (contrast function: log cosh) until convergence (tolerance: 10^{-4}). For obtaining MU spike trains, the resulting source was squared to identify peaks with a minimum separation of 20 ms. The peaks were classified as spikes or noise using K-means classification [5], [18].

A refinement algorithm was then employed to enhance the estimation of MU spike trains by iteratively recalculating the separation vector (w_j) and updating the source estimation process (squaring, peak detection, and classification) until the maximum silhouette value was achieved [7], [19]. Separation vectors were selected and considered MU filters if their corresponding MU spike train estimation yielded silhouette values exceeding 0.87 (indicating high-quality separability).

To decode low-threshold MUs in walking data, the MU filters derived from isometric trials were further refined. The refinement algorithm was initialized with MU filters obtained from the sub-maximal isometric contraction trial [7], and these were adjusted using walking data. The resulting spike trains from the refined MU filters were compared against those detected in the walking trials, and duplicates were removed (common discharges $> 30\%$).

This step yielded MU filters, classification centroids, covariance matrix, extension factor, EMG mask (with good-quality channels), and normalization factors.

2) MU twitch properties estimation: Each MU twitch response (a) was modeled as the impulse response of a second-order system [20] defined by two twitch properties: peak amplitude and contraction time. In prior work, we characterized these properties by identifying a wide range of MU types [8], [21] and assigning specific twitch responses to individual MU spike trains based on this characterization. In this work, we applied the firing-to-twitch property transformations established in [8] to generate initial estimates for MU twitch properties and activation dynamics.

These initial estimates were further optimized through an iterative calibration process to minimize the delay and enhance the correlation between the resulting MU-specific activation profiles and the ankle moment [7]. Specifically, contraction times and peak amplitudes were iteratively adjusted provided that the delay decreased and the correlation improved. This approach was chosen to enhance the responsiveness of the activation model [20] while preserving its congruence with the resulting force.

C. Online procedures

We simulated an online setting by segmenting the EMGs of the test cycles in batches of several sizes.

1) Adaptive decomposition: To adapt to the non-stationarities in the signals, we propose an adaptive algorithm that only updates the separation vectors every time new spikes are detected. It uses the non-whitened equivalent of the CKC algorithm:

$$s_j = c_{s_j x}^T C_{xx}^{-1} x. \tag{2}$$

In every batch, the covariance matrix was updated with [19] (3):

$$C_{\bar{x}\bar{x}} = (1-\lambda) \cdot C_{\bar{x}\bar{x}} + \lambda \cdot C_{\Delta\Delta x}. \tag{3}$$

in which λ is the learning rate and $\Delta\bar{x}$ the extended EMG signals in the new batch. A new source estimation was made Eq. 2 and if any spikes (Ψ_i) were found, the filter was updated with (4):

$$c_{s_j x} = (1-\lambda) \cdot c_{s_j,x} + \lambda \cdot \frac{1}{\text{card}(\Psi_i)} \sum_{n_k \in \Psi_i} \bar{x}(n_k). \tag{4}$$

Unlike Chen et al. [10], we used a weighted average to update the $c_{s_j x}$ with the newfound spikes. The centroids

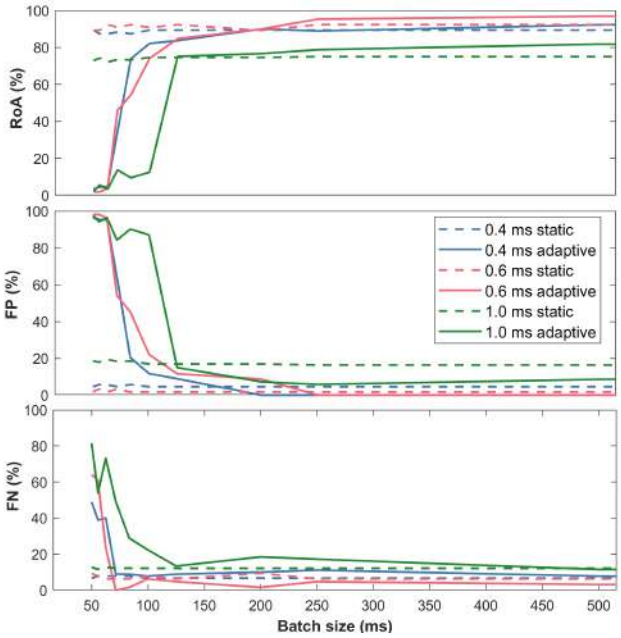

Fig. 3. Accuracy (RoA, FP, FN) across batch sizes

were updated with the following weighted average calculation [10](5):

$$T_{ij} = \frac{w_1 T_{ij} + w_2 T_{ij}^{'}}{w_1 + w_2}, \quad i = 1, 2, \tag{5}$$

where T_{ij} is the previous centroid of spikes (i = 1) and noise (i = 2) for the j_{th} spike train, T'_{ij} is the mean of the newfound spikes. $w1$ and $w2$ are the weighting factor of the centroids. $w1$ was set to 5 empirically, $w2$ was determined as the number of newfound spikes in a batch. λ was set at 0.05 empirically.

2) Static decomposition: To compare the adaptive method with traditional static approaches (*e.g.*, [18]), we re-used the offline identified MU filters to estimate the sources using Eq. (1). Similarly, spike classification was performed by re-applying the derived centroids and normalization factors.

3) MU-specific activation dynamics: To compute MU activation profiles online, the activation was discretized [22] to filter each spike train with its offline-estimated twitch model. The combined contributions of all MUs were summed to define the overall muscle activation.

D. Validation procedures

1) iEMG template matching: A reference decomposition was performed through template matching of iEMG [17]. All identified spikes and templates were thoroughly inspected and validated by an expert to ensure accuracy.

2) MU firing validation: Both decompositions (iEMG and HD-EMG) were compared by calculating the rate of agreement (RoA) for the static and adaptive algorithm (6):

$$RoA = \frac{C}{C + I + O} \cdot 100\%, \tag{6}$$

where C is the number of common discharges between iEMG and HD-EMG decomposition (tolerance window $\pm$ 0.5 ms),

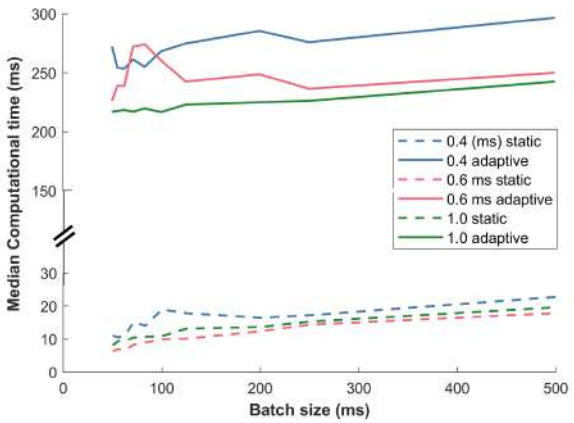

Fig. 4. Computational time (ms) across batch sizes

I the number of spikes only identified in iEMG, and O the number of spikes only identified in HD-EMG decomposition. Two spike trains were classified as originating from the same MU if the common discharges (C) were larger than 30% [4], [5]. Also, both false positive and false negative rates were calculated as (7,8):

$$FN = \frac{I}{I + C} \cdot 100\%, \tag{7}$$

$$FP = \frac{O}{O + C} \cdot 100\%, \tag{8}$$

3) MU-specific activation assessment: The coefficients of determination (R^2) between the estimates of muscle activation (static and dynamic approaches, and EMG envelopes) and moments were computed per gait cycle as the square of the maximum normalized correlation. Statistical significant differences were tested using the Wilcoxon signed-rank test.

4) Real-time assessment: To test the real-time capabilities of our methodology, the median values of the computational times were calculated for the pseudo-online algorithms. All the procedures were executed on a computer with an Intel Core i7-9750H CPU (2.60 GHz) with 16 GB RAM.

III. Results

In offline decomposition, 9, 10, and 9 MUs were identified in 0.4, 0.6, and 1.0 m/s walking trials, respectively, with 4, 1, and 2 extra MUs refined from low-force isometric MUs. One common MU was found between decompositions at each speed. Figure 2 presents a representative example (slow walking speed), comparing spike trains derived from HD-EMG using both adaptive and static approaches against the ground truth spike trains obtained from iEMG. Figure 3 summarizes the overall results of these comparisons across batch sizes, highlighting the RoA, FN, and FP. The validation of our framework at the MU firing level demonstrated superior performance of the adaptive approach compared to the static approach, particularly for windows larger than 200 ms. For slow speeds ($\leq$ 0.6 m/s), RoAs $>$ 90% were found for both static and adaptive algorithms. Fig. 4 shows the median computational times for the online procedures across batch sizes. Figure 5 illustrates a comparison between the

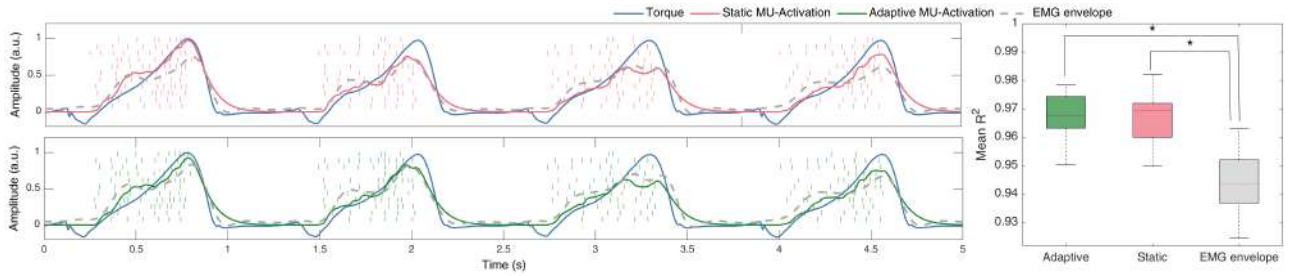

Fig. 5. Comparison between normalized activation estimates and ankle moments. Left panel: Calculated activation versus joint moment for 1.0 ms speed. Right panel: Coefficients of determination between activation estimates and ankle moments per gait cycle. * indicates significant differences (P<0.001).

MU activation estimates and the joint ankle moment, along with the R^2 values for the test trial (1.0 m/s speed). The R^2 values of the adaptive and static algorithms were higher than those of the EMG envelope ($P < 0.001$).

IV. Discussion

We proposed and validated an online-capable adaptive methodology for decoding MU firing events and their associated MU-specific activation dynamics during locomotion, yielding preliminary results in a healthy participant. Our approach offered three key contributions: first, we adapted advanced decomposition algorithms [5], [18] to facilitate the identification of low-threshold MUs [7] and to account for variations in MUAPs [10], [19] during locomotion. Second, we incorporated our established methodology [7], [8] for decoding MU twitch responses and deriving muscle activation. Third, we validated our methodology at both the MU firing level, using iEMG, and the activation level, through comparison with joint moments.

The validation of our framework at the MU firing level demonstrated superior performance of the adaptive approach compared to the static approach, particularly over longer observation windows (Fig. 3). Although the static approach is computationally faster and could be advantageous for real-time applications, its reliance on pre-defined MU filters limits its adaptability. A potential strategy could combine the strengths of both approaches, using the static method to deliver rapid estimates while the adaptive algorithm runs in parallel to refine the MU filters approximately every 200 ms (Figure 4). This integrated approach balances real-time performance with enhanced accuracy, offering a practical solution for continuous decoding during locomotion.

The assessment of our framework against joint moment predictions revealed comparable results for both the adaptive and static approaches (Fig. 5). This similarity may arise from several factors. One potential explanation is that the twitch models act as low-pass filters, which may reduce resolution and mask differences between the methods. Another contributing factor might be the fact of comparing activation profiles with joint torque, which does not capture nonlinearities in resulting musculoskeletal function. To enhance joint-level assessments, future work should integrate our framework with personalized neuro-musculoskeletal (NMS) models [8], [23], [24] to generate muscle force and joint moment predictions. These models can generate detailed predictions of muscle force and joint moments, allowing for a more precise and direct comparison of predicted joint moments with actual measurements. Such integration would not only enhance the validation but also establish a robust NMS tool, serving as a digital twin to simultaneously decode MU, muscle-tendon unit, and joint-level functions.

Moreover, to further improve the accuracy of the twitch models, future work should consider incorporating an adaptive approach that accounts for time-dependent properties of MU twitches, such as potentiation and fatigue [25], [26]. These features are crucial for capturing the full range of MU behavior during sustained and repetitive movements, and could potentially improve the activation accuracy. Furthermore, a significant challenge remains in validating twitch models in vivo due to the complexities of capturing real-time muscle responses. In this regard, recent advancements in imaging techniques, such as ultra-fast ultrasound imaging [27] and microendoscopy [28], present promising alternatives for in vivo validation. These emerging technologies have the potential to offer the resolution and temporal accuracy required to assess twitch dynamics and validate their integration into our adaptive framework, ultimately improving the realism and applicability of MU-driven models in clinical and rehabilitation contexts.

Once coupled with personalized NMS models, our framework could serve as a tool for driving neuro-robotic devices, enabling MU-driven control strategies for rehabilitation applications. Specifically, it was designed to assist with push-off during the gait cycle in individuals with neurological impairments. This methodology could facilitate real-time parameter adjustments, dynamically adapting to the patients immediate needs. Beyond in-session adjustments, our framework may offer clinicians valuable insights into longer-term rehabilitation progress, such as changes in MU behavior and remodeling [29], [30]. This information could be used to fine-tune rehabilitation strategies across multi-week sessions, ensuring personalized and progressive adaptation to the patients evolving motor function.

A key limitation of this study is its validation on a single able-bodied participant. Before translating our methodology into practical MU-driven control of neuro-modulatory devices, future research should prioritize evaluating its robustness across a broader and more diverse cohort, particularly individuals with neurological impairments. Pathological conditions often involve altered MU behavior, such as increased persistent inward currents (PICs) and abnormal synergies [31], [32]. Differentiating between healthy and pathological

MU behavior is crucial for ensuring that the framework can accurately identify desired MU activity and provide clinically relevant insights, such as tracking MU remodeling over time. Expanding the participant pool will not only help validate the frameworks adaptability to diverse clinical scenarios but also ensure its potential for tailoring interventions to address individual variations in MU behavior.

In conclusion, we presented a validated, online-capable framework for decoding MU firing events and their corresponding activation dynamics during locomotion. Our methodology demonstrated the potential to provide insights into MU-specific contributions to joint moments and to inform the design of neuro-rehabilitation devices. With further validation in a broader and more diverse population, this framework could enable real-time adjustments to device parameters while providing clinicians with detailed information on long-term adaptations at the MU, muscle, and joint levels, ultimately supporting more personalized and effective neuro-rehabilitation strategies.

***Abstract*— The thumb has been called a "hallmark of humanity", and yet, in stroke rehabilitation, there are few studies that have examined thumb function and even fewer that have focused specifically on thumb sensory function. Here we describe a novel robotic technique to assess thumb proprioception and apply it to quantify the relationship between thumb proprioception and hand function after stroke. Based on a video game, "SomatoCircleJump" challenges participants to "jump" to radial targets presented on a screen as their thumb rotates around a circle, driven by a robot. Proprioceptive ability is quantified by radial jump error. We evaluated 35 individuals in the chronic phase post-stroke as part of a randomized controlled trial of robotic finger training. Compared to an age-matched control group, people with stroke had significantly increased jump error ($p < 0.001$). Thumb proprioception ability predicted hand function, as measured by the Box and Block Test score ($\rho = -0.44$, $p = 0.01$) and the Nine-Hole Peg Test time ($\rho = 0.49$, $p = 0.006$). Jump error was also correlated with an independent robotic measure of finger proprioception ($\rho = 0.54$, $p = 0.003$). These results validate a novel robotic method to quantify thumb proprioception and indicate thumb proprioception deficits are common after stroke, co-occur with finger proprioception deficits, and relate to functional hand ability.**

Keywords—neurorehabilitation, proprioception, serious games, stroke, thumb

I. Introduction

Despite extensive therapeutic efforts during rehabilitation, the chances of regaining full use of the affected hand after a stroke are low. Three months after a stroke, only 12% of survivors experience no issues with hand function, whereas 38% report substantial difficulties in hand use [1]. Given the importance of the hand for activities of daily living, it is surprising that relatively little emphasis is placed on a critical aspect of hand function after stroke: proprioception. Proprioceptive impairments greatly affect an individual's capacity to sense and control limb position, leading to challenges in motor coordination and performing functional tasks [2]. Proprioceptive impairments are common in the fingers after stroke [3], [4], [5] and predict potential for recovery [6]. Yet only 1% of therapists assess proprioception after stroke [7]. Recent research studies have highlighted the importance of objective and reliable methods for assessing hand proprioception, particularly in clinical populations with neurological impairments. Robotic assessments have been increasingly used to quantify proprioceptive deficits in the index finger [8], [9], but they have not yet been widely adopted in clinical settings.

This gap in proprioceptive assessment is particularly severe for the thumb. Evolution of the opposable thumb conveyed key survival advantages to humans, making it a "hallmark of humanity" because of its association with increased tool use [10], [11], [12]. The importance of thumb sensation for hand function is evidenced by the large somatosensory cortex representation of the thumb [13]. Despite the critical role of thumb sensation, traditional assessments of thumb proprioception focus on coarse indicators such as identifying the direction of a movement that is externally imposed on the thumb by a clinician [14]. To our knowledge, beyond these coarse clinical methods, no other clinical assessment methods specifically focused on thumb proprioception have been developed. This limits our understanding of the role thumb proprioception impairment plays in hand function recovery after stroke.

To tackle this challenge, we developed a novel robotic assessment of thumb proprioception called SomatoCircleJump. The assessment quantifies a person's ability to estimate the location of their thumb as a robot moves it in a circle. We embedded the assessment in a computer game that requires participants to indicate when they feel their moving thumb align with a target shown on a visual display, in order to "jump" to the target. We hypothesized that proprioceptive deficits quantified by jump error would predict hand function after stroke, as quantified by standard clinical assessments.

II. Methodology

A. Design of the thumb proprioception assessment task

We established four design criteria for the novel thumb proprioception assessment. First, we desired a high resolution measure of thumb localization ability. The test we settled on provides a continuous measure of error. Second, we desired that the task be engaging so as to maintain attention. Thus, we embedded the task in a popular phone game, Super Circle Jump [15]. Third, we desired that people with severe thumb motor impairment could still participate in the test. The resulting test does not require active thumb movement ability. Lastly, we desired that the test be safe and simple to implement. The movement we selected is a circle, which is a comfortable movement for the thumb and can be implemented with a single motor.

Super Circle Jump involves the player triggering a jump when a ball, rotating around a centralized circle, aligns with a visual target, represented by another circle (Fig. 1 Right). This game can also be viewed as shooting an orbiting ball at a target. For SomatoCircleJump, we modified the game so that a robot moves the player's visually hidden thumb in a circular motion in a vertical plane parallel to the screen to represent the ball's rotation around the circle. The player must press a button with their other hand to make the ball jump to the target, relying on sensing their thumb location to determine when to press the button. This strategy is an example of a "Propriopixels" gaming strategy, in which a game element is presented proprioceptively rather than visually [16], [17]. In this case, the location of the orbiting ball is presented by moving the thumb in a circle.

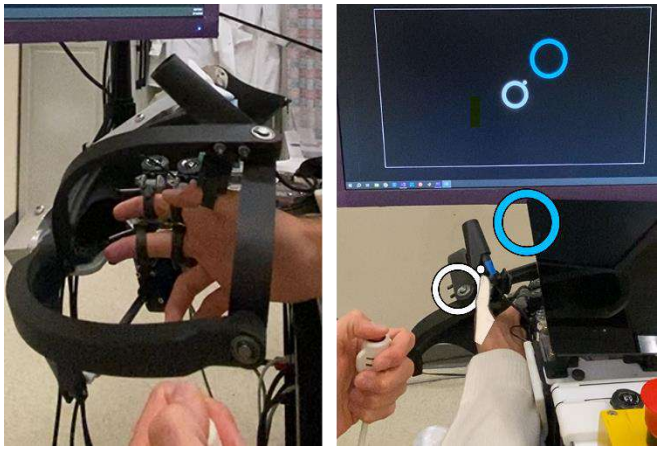

Fig. 1. Left: Side view of thumb exoskeleton of the FINGER robot used for the proprioception assessment. A spherical mechanism controls the thumb in 2 DOFs. Right: Participant's view of the SomatoCircleJump game with graphics overlaid in hand space (drawn thumb, white ball, and center and target circles) to illustrate game play. The robot guides the thumb in a circular path (orbiting a ~5 cm diameter circle in thumb space, shown by the overlaid white circle) following the position of the white ball, and the participant must press a button with their other hand when the thumb is closest to the blue target circle. After each press, the blue circle shifts to a new position. During task familiarization, a white cursor (ball) represents the thumb's position, but this visual aid is removed for the proprioceptive assessment and vision of the hand is blocked with a movable screen.

Thumb movement was applied using the thumb module of the Finger INdividuation Grasp Exercise Robot (FINGER), which uses a 2-degree-of-freedom (2-DOF) spherical 5-bar thumb exoskeleton (Fig. 1 Left) actuated by two high bandwidth, low-friction, linear, electric actuators [18], [19].

We quantified thumb localization ability using the "jump error" between the angle of the ball when the button is pressed and the optimal jump angle, defined by the line connecting the centers of the white orbit and the colored target circles (**Error! Reference source not found.** 1 Right). Following the button press, the SomatoCircleJump game instantaneously displays a small ball that jumps from the current thumb location along a path radially outward toward the target. The ball turns green if it collides with the target circle, denoting a successful shot, and red otherwise. The test also provides numerical feedback going from 0 to 10 depending on how close they were to a perfect jump, with 10 being a perfect jump. Total score is shown at the top of the screen.

B. Experimental design

We conducted an experiment to assess thumb proprioception ability after stroke using SomatoCircleJump as part of a randomized controlled trial (RCT) of robotic finger training. The Institutional Review Board of UC Irvine approved the protocol and participants provided informed consent.

Subjects: Thirty-five individuals with single or multiple ischemic or hemorrhagic stroke, confirmed through radiological imaging, showing residual weakness in one hand, and being at least 6 months post-stroke, were recruited for the study. Additional inclusion criteria required participants to score at least 3 blocks on the Box and Block Test (BBT), with their score on the affected arm being at least 20% lower than that of the unaffected arm. Exclusion criteria included severe muscle tone in the upper extremity (score > 3 on the Modified Ashworth Spasticity Scale), severe aphasia (score of 3 on the NIH Stroke Scale, question 9), concurrent participation in another study related to stroke recovery, and evidence of major depression, as defined by DSM V criteria or a score on the Geriatric Depression Scale > 10.

SomatoCircleJump protocol: We assessed the participants' thumb proprioception using the SomatoCircleJump game in a single visit at the beginning of the RCT. During the session, participants played four games, all of them at a speed of ~60 deg/s, a workspace of 5 cm in diameter, and in the clockwise direction of rotation. The first game was played with vision of the white ball and their thumb. For the second game, the graphical image of the ball was removed from the game so the participants could not see the ball but still had vision of their thumb. The last two games were without vision of either the ball or their thumb. The first two games were used to teach them how to play the game, while the last two games were the assessments that we analyzed to quantify proprioception. Training games were played with 10 jumps, although some participants were allowed more practice if needed. Assessment games were comprised of 20 jumps.

Control group: Additionally, a group of 24 age-matched, unimpaired older adults (50+ years old, mean = 63.8 ± 10.1 years old, 14 females, 4 left-hand dominant) performed one SomatoCircleJump game with 20 jumps under the same

conditions as the post-stroke group as a control for quantifying intact thumb proprioception ability.

Clinically accepted hand dexterity tests: Besides the thumb proprioception assessment, we measured upper extremity impairment with the Fugl-Meyer Assessment for Upper Extremity (FMA-UE) [20], hand/arm function with the Box and Block Test (BBT) [21], and fine dexterity with the Nine-Hole Peg Test (NHPT) [22]. BBT performance was quantified as the total number of blocks transferred in one minute by the affected limb. NHPT performance was scored as the total time required to place and remove 9 pegs with the affected hand, with an upper limit of 1 minute. On the FMA-UE, items are scored on a 3-point ordinal scale (0 = cannot perform, 1 = performs partially, 2 = performs fully). Out of the 4 motor function sections of the assessment (Upper Extremity, Wrist, Hand, and Coordination/Speed), the most relevant to this study is the third one, related to the function of the hand. Inside the hand section, there are four tasks that involve the active use of the thumb:

1. Thumb adduction: grasp a sheet of paper with pure thumb adduction.
2. Pincer grasp, opposition: oppose thumb pad against pad of index finger with a pencil interposed.
3. Cylinder grasp: grasp cylinder-shaped object, e.g. small can, with volar surface of thumb and index finger wrapped around object.
4. Spherical grasp: grasp a tennis ball with all 5 fingers.

For these four tasks, a score was given based on the established criteria: 0 points if the participant could not perform the action, 1 point if they could keep the object in place but not against a tug, and 2 points if the object held well against a tug. Participants scored from 0 to 8 in total for this selection of the FMA-UE.

Independent robotic test of finger proprioception: Finally, we conducted a finger proprioception test called Crisscross for all stroke participants using the FINGER robot. The goal was to assess the correlation between the finger proprioception errors obtained in this validated research test and the thumb proprioception errors obtained in SomatoCircleJump. In the Crisscross test [23], the FINGER robot moves the participant's affected index and middle fingers in a crossing pattern, with the hand occluded from view. They are instructed to press a button with their non-affected hand when they perceive their fingers are aligned, without visual feedback. Proprioceptive error is measured as the mean absolute crossing error. Previous studies have shown that Crisscross is sensitive to aging [23], detects the presence of stroke [4], and can predict the functional benefit of robotic hand movement training after a stroke [24].

C. Data analysis

We performed correlation analyses between thumb proprioception error and all the different clinical and robotic assessments previously mentioned. We checked the normality of the data by visually inspecting all variables using a histogram and a Q-Q plot, and then performed the Shapiro-Wilk test [25]. Since all the data was assumed to be monotonic but was non-normally distributed, we used Spearman's rank correlation.

III. Results

We measured thumb proprioceptive ability of people in the chronic phase post-stroke (mean days post-stroke = 1645 ± 1354) using a novel technique called SomatoCircleJump (SCJ). Their mean age was 56 ± 15 years old, and there were 25 males and 10 females, 9 right-side impaired and 26 left-side impaired. Their mean Box and Block score was 23.3 ± 15.7. We instructed participants to indicate by pushing a button with their unaffected hand when their affected thumb was pointing at a target located radially around a central circle as a robotic device moved their thumb in a circular motion. We quantified proprioceptive ability by "jump error", i.e., the difference between thumb and target angular location at button press.

A. Jump error was increased after stroke

The mean of the absolute value of jump error was 52.3º ± 24.5º, indicating substantial levels of error at the task. The older unimpaired group had a mean absolute error of 26.8º ± 10.6º, which was significantly lower than that obtained for the individuals post-stroke (unpaired t-test, $p < 0.001$).

B. Jump error predicted clinical scores of UE function

The Spearman's rank correlation between thumb proprioception error and the total FMA-UE score approached significance (Fig. 2, $\rho = -0.33$, $p = 0.07$). The correlation between thumb proprioception error and the sum of the scores of the four selected FMA-UE tasks related to thumb function also approached significance (Fig. 3, $\rho = -0.33$, $p = 0.07$). Although the correlations did not reach statistical significance at the 0.05 level, they suggested a weak-to-moderate negative association that may warrant further investigation.

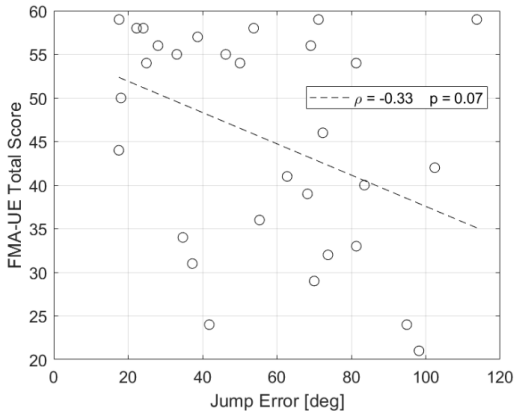

Fig. 2. Relationship between the total score of the FMA-UE and the thumb jump error obtained in SomatoCircleJump. Dashed line shows robust fit, and statistics show result of correlation using Spearman's Rank correlation.

We conducted a Spearman's rank correlation analysis on the non-normally distributed BBT data. Thumb proprioception error and BBT score were significantly correlated (Fig. 4, $\rho = -0.44$, $p = 0.01$).

We conducted a Spearman's rank correlation analysis on the non-normally distributed NHPT data. Thumb proprioception error was significantly correlated to NHPT score (Fig. 5, $\rho = 0.49$, $p = 0.006$).

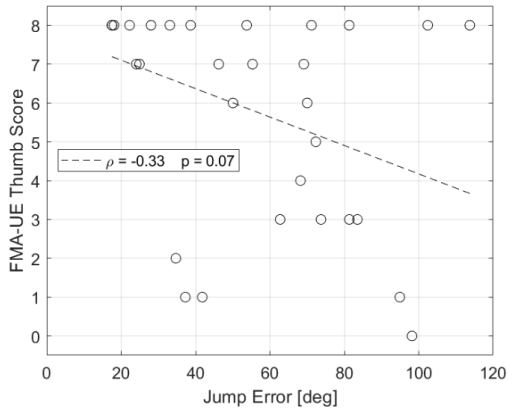

Fig. 3. Relationship between the sum of the scores obtained on four FMA-UE tasks related to the thumb total score of the FMA-UE and the thumb jump error obtained in SomatoCircleJump. Dashed line shows robust fit, and statistics show result of correlation using Spearman's Rank correlation.

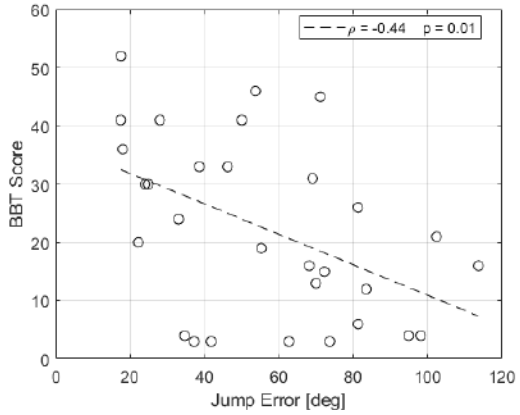

Fig. 4. Relationship between BBT score and thumb proprioception ability measured by jump error during game play of SomatoCircleJump. Dashed line shows robust fit, and statistics show result of correlation using Spearman's Rank correlation.

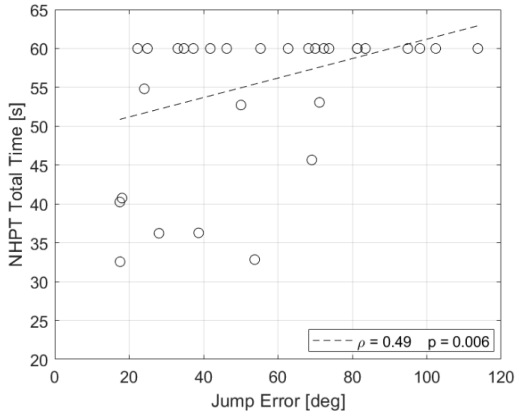

Fig. 5. Relationship between the time taken to perform the NHPT compared to the jump error for SomatoCircleJump. Dashed line shows robust fit, and statistics show result of correlation using Spearman's Rank correlation.

C. *Thumb localization error was related to finger proprioception ability*

We compared thumb jump error with finger proprioception error measured with the Crisscross test. Thumb and finger errors were significantly correlated (Fig. 6, $\rho = 0.54$, $p = 0.003$).

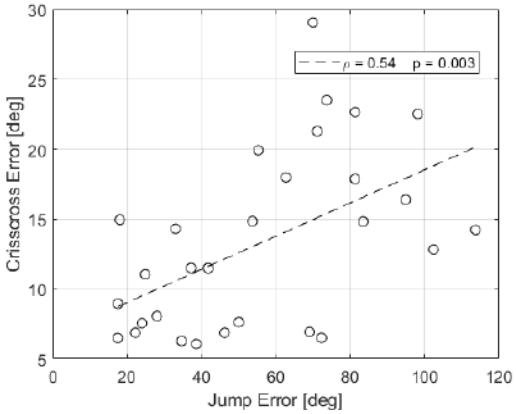

Fig. 6. Relationship between finger proprioception crossing errors obtained using the Crisscross assessment and thumb jump errors in SomatoCircleJump. Dashed line shows robust fit, and statistics show result of correlation using Spearman's Rank correlation.

IV. Discussion

In this study we developed a novel robotic thumb proprioception test in which participants had to sense the position of their thumb in order to "shoot" (or "jump") an orbiting ball at different targets. We used it to measure thumb proprioception ability, quantified as jump error, in persons with chronic stroke and found that: 1) thumb proprioceptive error was, on average, significantly increased after stroke and approximately double that of age-matched controls; 2) hand function on two clinical tests was significantly correlated with thumb proprioception error; and 3) finger and thumb proprioception errors were correlated. These results are further discussed below, followed by limitations and future directions.

A. *Development of a novel thumb proprioception test*

Despite the importance of the thumb for human hand function, there is a lack of rehabilitation technology for assessing a key aspect of the thumb – its proprioceptive ability. Clinical assessments of thumb proprioception, such as the *joint movement and movement direction discrimination* test, part of the Rivermead Assessment of Somatosensory Performance [26], [27], are simple and quick to apply, but provide only a coarse indication, focusing on the ability of the patient to gauge the direction of a movement that is externally imposed on the thumb by a clinician [14]. And, even with its simplicity, this assessment is rarely applied in stroke rehabilitation [7]. Few other methods have been developed to quantify thumb proprioception. One study positioned the fingers and thumb of one hand and asked unimpaired people to indicate their locations with a mouse pointer [28]. They found that finger and thumb

proprioception were surprisingly inaccurate, with average errors up to several centimeters. A limitation of this test is that it only measured static proprioception. We are not aware of previous studies that have measured dynamic thumb proprioception, or thumb proprioception after stroke.

Accurate performance on the test described here requires a complex set of proprio-visual-motor processes to occur. SomatoCircleJump is a dynamic test, so the brain must proprioceptively sense not only the position but also the speed of the thumb in order to anticipate the correct moment to push the button (this could be considered "internal model #1" for this task). The brain must also build into its estimate of the button press moment the fact that it must initiate the motor command to push the button sufficiently in advance of the thumb/target crossing moment so that the command has time to descend, activate hand muscles, and cause the force of the button press at the right time (call this internal model #2). Finally, a visual-proprio mapping is required (internal model #3), as SomatoCircleJump presents the target visually on a screen, and the brain must map the thumb location into screen coordinates (or vice versa). So, a seemingly simple proprioceptive test is probing at least three types of internal models, as well as the ability to sense thumb location and speed as inputs to those models. The finger proprioception test that we used as a basis for comparison, Crisscross, also relies on two similar internal models: #1 for predicting the position and speed of both the index and middle finger, and #2 to send the command for the non-assessed hand to press the button [23]. This reliance on similar types of internal models may help explain why SomatoCircleJump error was correlated with Crisscross error.

B. Stroke impairs thumb proprioception ability

We found that stroke increased thumb proprioception error. Several studies of the fingers [4], [6], [24], as well as studies of the arm [29], have found that proprioceptive error is increased in the upper extremity after stroke. It would be odd if stroke did not also affect the thumb, given the thumb's large cortical representation that is integrated with the representations of the fingers [30], [31]. Indeed, we found that if people tended to have more severe finger proprioception impairment, they also tended to have more severe thumb proprioception error, consistent with the overlap of thumb and finger proprioception representations in somatosensory cortex [13].

A recent systematic review of over 1,350 proprioception assessment methods found that results of different proprioceptive tests are mostly uncorrelated in unimpaired individuals, demonstrating no associations between joints, highlighting the site- and method-specific nature of proprioceptive ability [27]. In the present study, thumb proprioception error assessed in stroke participants using SomatoCircleJump showed a moderately strong correlation with the finger proprioception crossing error measured by Crisscross, an independent technique performed with the same robot (FINGER) [19], [24]. This suggests site specificity within the hand breaks down when there are lesions due to stroke.

C. Thumb proprioceptive deficits predicted hand dexterity

Our motivation for this study was the idea that quantifying thumb proprioception would be valuable for stroke rehabilitation because of the importance of the thumb for hand function. As we hypothesized, we found that proprioceptive errors quantified by SomatoCircleJump were moderately correlated with two common clinical measures of hand function: BBT and NHPT. This is consistent with the idea that the thumb and its sensory feedback are important in performing fine motor tasks. The correlation with the total FMA-UE score only approached significance, likely due to the broad nature of the FMA-UE that is aimed at coarse characterization of upper limb movement impairment. Another explanation could be that the hand-related components of the FMA-UE mainly assess motor execution and grip strength rather than proprioceptive function.

D. Future directions

The mean thumb proprioception errors were large after stroke: participants misestimated their thumb location by over 50 degrees. An interesting question for future research is how to partition this error into impairments in the various proprioceptive sensing and neural modeling processes outlined in subsection IV.A. Another interesting question is whether some of the error is due to disuse of the hand after stroke, as it is well established that proprioceptive ability is modifiable with activity, as well as training and exercise [32], [33]. A questionnaire like the Motor Activity Log could be used to categorize individuals with varying levels of hand use post-stroke and SomatoCircleJump could be used to compare their proprioception accuracy.

We would like to make SomatoCircleJump clinically practical to use as a thumb proprioception assessment. Although we used a sophisticated thumb robot to implement SomatoCircleJump in this study, the circular thumb movement could be implemented by a low-cost rotary motor in a hand-held device. The test itself only takes 2-3 minutes to implement with 20 jumps. The SomatoCircleJump paradigm is also potentially translatable to other joints (e.g. finger, wrist, elbow, shoulder, hip, ankle), as all of these joints can move in circles. An interesting question is whether proprioceptive ability varies at these different joints.

We would also like to explore use of SomatoCircleJump as a proprioceptive training tool, capitalizing on its engaging and entertaining video game structure. There are currently only a few gamified proprioception training techniques [16], [34].

Interesting rehabilitation science questions that SomatoCircleJump could help answer are: "Does thumb proprioception ability predict the ability to respond to hand rehabilitation therapies?"; "To what extent is thumb proprioception ability modifiable after stroke with training?"; and "Does improving thumb proprioception improve functional hand outcomes?"

***Abstract*—Predicting grip force and wrist angle during dynamic hand movements is crucial for advancing upper-limb prosthetic systems, enabling simultaneous and proportional control of multiple degrees of freedom (DOFs). This study introduces a novel wearable ultrasound-based system that leverages M-mode data from four single-element transducers placed on the forearm to capture muscle activity for the concurrent prediction of grip force and wrist angle. A multi-layer perceptron (MLP) regressor was utilized for the simultaneous prediction of both parameters, and a comparative analysis was conducted using a Gaussian process regressor (GPR), which is commonly adopted previously in similar studies. The system was validated on unseen data from five participants without limb loss. The MLP demonstrated superior performance compared to GPR, achieving R^2 values of 0.85±0.06 for wrist angle prediction and 0.74±0.07 for grip force. These findings underscore the challenges of predicting simultaneous grip force and wrist angle during dynamic hand movements and highlight the need to address these issues for intuitive and practical prosthetic control in real-world scenarios.**

***Index Terms*—simultaneous and proportional control, wearable ultrasound, dynamic movements, multi-layer perceptron regressor, gaussian process regressor.**

I. Introduction

The ability to predict grip force and wrist angle during dynamic hand movements is critical for advancing the control of upper-limb prosthetics. These systems are essential for rehabilitation, providing individuals with limb loss the ability to regain functional independence and perform everyday tasks with greater efficiency [1], [2]. Simultaneous and proportional control (SPC) of grip force and wrist angle is especially important for tasks requiring seamless coordination, such as manipulating objects in a reachable workspace. Despite its importance, current prosthetic systems often fall short of offering intuitive and natural control during dynamic and combined motions, limiting their effectiveness in real-world applications [3].

While significant progress has been made in prosthetic control, most prior studies have relied on surface electromyography (sEMG) signals to achieve SPC across multiple degrees of freedom (DoFs) [4]–[7]. Data-driven methods, including non-negative matrix factorization (NMF) [8], linear regression (LR) [9], support vector regression (SVR) [10], and neural network-based approaches, have been employed to map sEMG signals to joint kinematics. However, these methods are often limited by the stochastic and nonstationary nature of sEMG, low spatial resolution, and susceptibility to crosstalk effects. Advanced machine learning techniques [11]–[13], such as bidirectional long short-term memory (Bi-LSTM) networks [14], recurrent neural networks (RNNs), and transformer architectures, have demonstrated improved performance [11], [15], [16] yet these methods require extensive calibration and lack transferability across tasks, which limits their practicality in real-world scenarios.

Sonomyography (SMG) has emerged as a promising alternative to sEMG, offering higher spatial and temporal resolution and robustness by capturing muscle morphology and tissue deformation using ultrasound [3], [17]. SMG has been shown to outperform sEMG in gesture classification and joint kinematics prediction, particularly when employing B-mode ultrasound imaging systems [18]. However, such methods have primarily focused on static or isolated motions [5], [6], [19]–[22], and these systems have large footprint making them unsuitable for incorporating inside a prosthetic socket. Recent advancements, including the use of single-element transducers [21], have enabled SMG-based systems to classify hand gestures and estimate finger movements with reduced complexity, making them suitable for wearable applications. Despite these

advances, a critical gap persists in extending SMG-based systems to achieve seamless, simultaneous control of wrist and grip motions during dynamic reaching, and miniaturizing the systems for further translation towards incorporation inside a socket. Addressing this limitation is essential to fully realize the potential of SMG-based systems and make them truly wearable for real-life, dynamic applications.

Time Delay Spectrometry (TDS), an ultrasound imaging technique, offers a promising solution to this challenge. TDS uses continuous, frequency-modulated signals to capture tissue properties with high spatial and temporal resolution [23]. Unlike traditional pulse-echo ultrasound methods, which rely on high excitation voltages and complex hardware, TDS operates at low excitation voltages and requires significantly simplified instrumentation. These features make it particularly well-suited for wearable applications. In our previous work, we introduced a wearable ultrasound system developed based on TDS, incorporating only four small single-element ultrasound transducers and front end electronics that is no more complicated than a frequency-modulated radio, and demonstrated its capability for dynamic imaging of muscle activity [24].

The aim of this study is to leverage a compact wearable system with four ultrasound sensors to evaluate SPC predictions for natural, reachable workspace movements. Our approach overcomes the limitations of static-position studies, advancing toward real-world prosthetic applications. Additionally, we highlight the impact of muscle fatigue, a critical factor that affects the accuracy of grip force predictions over time.

II. Problem Formulation

In this study, we aim to establish a mapping between M-mode ultrasound data collected over a time period T and the biomechanical outputs of grip force (f) and wrist angle (ω). Our dataset consists of m trials from N participants, totaling mN observations. For each trial i (where $i = 1, 2, \ldots, mN$), the ultrasound data is captured as depth-wise measurements over time. By discretizing the time period T into K time points $\{t_1, t_2, \ldots, t_K\}$, we represent the ultrasound data for trial i as a matrix:

$$\mathbf{X}_i = \begin{bmatrix} \mathbf{x}_i(t_1) \\ \mathbf{x}_i(t_2) \\ \vdots \\ \mathbf{x}_i(t_K) \end{bmatrix} \in \mathbb{R}^{K \times D},$$

where $\mathbf{x}_i(t_k) \in \mathbb{R}^D$ is the ultrasound measurement at time t_k, and D is the depth dimension.

The corresponding biomechanical outputs for trial i are represented as a vector:

$$\mathbf{y}_i = \begin{bmatrix} \omega_i \\ f_i \end{bmatrix} \in \mathbb{R}^2,$$

where ω_i is the wrist angle and f_i is the grip force. Our objective is to learn a function $h_{\text{MLP}} : \mathbb{R}^{K \times D} \to \mathbb{R}^2$ using a Multi-Layer Perceptron (MLP) that maps the ultrasound data $\mathbf{X}_i$ to the biomechanical outputs $\mathbf{y}_i$:

$$\mathbf{y}_i = h_{\text{MLP}}(\mathbf{X}_i) + \boldsymbol{\varepsilon}_i,$$

TABLE I
Demographics of the Study Participants

Participant ID	Age	Gender	Dominant Arm
AB01	33	Female	Right
AB02	34	Female	Left
AB03	29	Female	Left
AB04	30	Male	Right
AB05	27	Male	Right

where $\boldsymbol{\varepsilon}_i \in \mathbb{R}^2$ represents the residual error vector for trial i. By formulating the problem as a regression task that maps high-dimensional temporal data $\mathbf{X}_i$ to low-dimensional outputs $\mathbf{y}_i$, we aim to predict simultaneous grip force and wrist angle from M-mode ultrasound data, advancing towards real-world prosthetic applications by focusing on natural, dynamic movements within a reachable workspace.

III. Materials and Methods

A. Participants

Five participants without limb loss (mean age: 30 ± 5 years) were recruited for this study. The demographic details of the participants are presented in Table I. Written informed consent was obtained from all participants prior to their involvement in the research. Ethical approval for the study was granted by the Institutional Review Board (IRB) at George Mason University.

B. Experimental Procedure

For the experimental setup, the sensors were placed on the marked forearm location after palpation and volitional movement assessment. An IMU was positioned on the wrist, and participants held a hand dynamometer. Participants performed dynamic hand movements within a reachable workspace while seated comfortably. Their dominant arm was positioned to allow natural wrist and hand motions throughout the experiment. Participants were instructed to perform dynamic hand movements across three positions: a neutral position, a shoulder-level position, and a position crossing the midline of the body illustrated in Fig. 1 . These positions were chosen to simulate real-world hand and arm movements while maintaining consistency in the experimental setup. During the tasks, participants

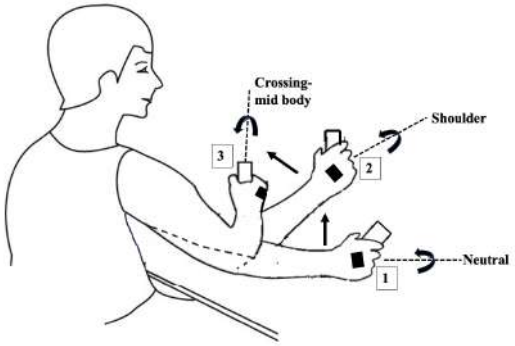

Fig. 1. Different arm positions with dynamic movements.

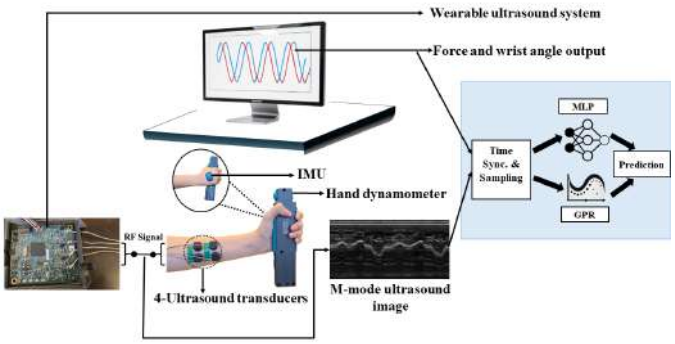

Fig. 2. Experimental setup illustrating the wearable ultrasound system attached to the participant's forearm, the hand dynamometer used to measure grip forces, and the IMU sensor used to measure wrist angles. The monitor displays the force and wrist angle trajectories, while M-mode ultrasound data is collected for simultaneous grip force and wrist angle prediction.

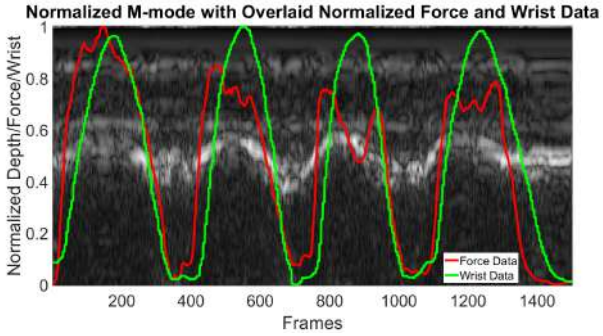

Fig. 3. Normalized m-mode with overlaid normalized force and wrist data from one of the participants.

were instructed to increase their grip force progressively to their maximum capacity while simultaneously rotating their wrist. Once the maximum grip force was achieved, they were guided to release their grip force back to zero while returning their wrist to a neutral angle. A wearable ultrasound system, developed for sonomyography (SMG) analysis, was secured on the forearm using a custom-designed holder. The system utilized four ultrasound transducers in 3D printed housing (each measuring 15×15×6 cm) driven by a 12-bit frequency sweeper (AD5930, Analog Devices, Burlington, USA) to generate linearly swept sinusoidal chirps between 3 MHz and 5 MHz with a sweep time of 10 ms and a peak-to-peak amplitude of 5 V. The echoes from the muscle tissues were processed by a specially constructed analog front-end, where the signals were amplified and digitized using independent 16-bit analog-to-digital converters (TMS320F28379D, Texas Instruments, Dallas, USA), sampled simultaneously at 40 kSa/s. To reduce the computational load, the M-mode ultrasound signals were processed using a 1024-point fast Fourier transform (FFT), and the relevant depth of 4 cm was retained for analysis [24]. This design ensured reliable and efficient collection of SMG data for simultaneous grip force and wrist angle prediction.

Ground truth data included synchronized grip force and wrist angle measurements. Grip force was recorded using a hand dynamometer (Vernier, Beaverton, OR, USA), and wrist angle trajectories were captured using an IMU sensor (WitMotion, Shenzhen, China) attached to the wrist. Participants were tasked with gripping and rotating their wrist while dynamically transitioning through the specified arm positions (neutral, shoulder-level, and midline-crossing). The tasks required participants to modulate their grip force—progressively increasing to their maximum force while rotating their wrist to its extreme position, and then decreasing the force to zero while rotating the wrist back to a neutral angle. A screen placed in front of the participants displayed real-time feedback on their grip force and wrist angle trajectories, aiding in maintaining consistency and accuracy during the experiment.

Fig. 2 depicts the experimental setup, showcasing the wearable ultrasound system positioned on the participant's forearm, the dynamometer used for grip force measurement, and the IMU sensor for wrist angle tracking.

Three trials of data were collected from each participant, with each trial lasting 30 seconds. During each trial, participants performed grip force tasks and wrist rotations while dynamically transitioning between the neutral, shoulder-level, and midline-crossing positions. SMG signals from the wearable ultrasound system, grip force from the dynamometer, and wrist angle from the IMU sensor were recorded via a Python interface for visualization and analysis, enabling the evaluation of the system's ability to predict grip force and wrist angle during dynamic movements across varied arm positions.

C. Data Processing and Model Optimization

Data processing was conducted using three trials collected during each data collection paradigm. To ensure unbiased evaluation, a leave-one-trial-out validation strategy was employed. In this approach, one trial was reserved for validation, while the remaining two were used for training the model. This process was repeated for all three trials, ensuring that each trial served as the validation set once. By rotating the validation trial in this manner, any potential bias caused by good or poor data quality in a particular trial was minimized. The average validation performance across the three iterations was calculated, providing a reliable and robust measure of the model's generalization capability.

All data, including ultrasound signals, grip force, and wrist angle measurements, were synchronized and sampled at 50 Hz to ensure temporal alignment for predicting grip force and wrist angle. Fig. 3 illustrates a representative example of one of the four M-mode ultrasound channels (each channel having a Y-axis size of 130), overlaid with normalized force and wrist angle data obtained from the dynamometer and IMU, respectively. Each 30-second trial generates 520 spatial samples across four channels, with all data time synchronized and min-max normalized to maintain consistency and support robust model training.

We employed both Multi-Layer Perceptron (MLP) and Gaussian Process Regressor (GPR) for estimating wrist angle

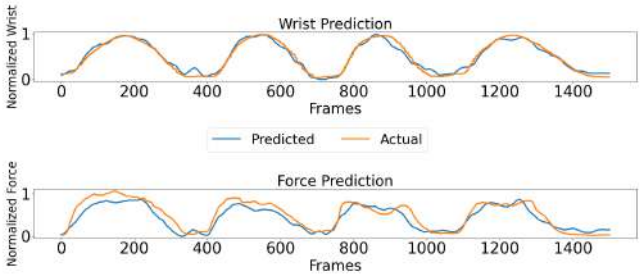

Fig. 4. Validation data wrist angle and grip force prediction from one of the participants.

and grip force, allowing for a comprehensive comparative analysis of their performance on both biomechanical outputs. For the MLP model [25], we utilized a neural network architecture with two hidden layers, each incorporating rectified linear unit (ReLU) activation functions [26]. The ReLU activation introduced non-linearity while mitigating the vanishing gradient problem, enhancing the model's ability to learn complex relationships within the data. Training was conducted over 500 iterations to balance computational efficiency with predictive accuracy. The MLP effectively captured non-linear dependencies in the M-mode ultrasound signals, providing robust predictions for both wrist angle and grip force.

For the GPR model [27], we applied principal component analysis (PCA) [28] to the M-mode ultrasound data to reduce dimensionality. PCA retained the most significant features, eliminating redundant or noisy information, which improved computational efficiency and focused the model on meaningful patterns within the data. The GPR model employed a combination of a radial basis function (RBF) kernel and a white noise kernel [27]. The RBF kernel captured smooth, continuous variations, while the white noise kernel accounted for residual variability and noise, ensuring robust predictions for both grip force and wrist angle despite potential inconsistencies in the input data.

The integration of data synchronization, feature normalization, and advanced modeling techniques enabled reliable training and validation for simultaneous grip force and wrist angle prediction.

D. Evaluation Metric

The performance of the proposed system was assessed using two evaluation metrics: mean squared error (MSE) and the coefficient of determination (R^2), to evaluate both wrist angle and grip force predictions.

a) Mean Squared Error (MSE): The MSE quantified the average squared difference between the predicted values and the ground truth, measuring prediction accuracy:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \tag{1}$$

where y_i represents the true value, $\hat{y}_i$ is the predicted value, and N is the number of data points.

b) Coefficient of Determination (R^2): The R^2 value measured the proportion of variance in the ground truth that was captured by the model's predictions:

$$R^2 = 1 - \frac{\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{N}(y_i - \bar{y})^2} \tag{2}$$

where $\bar{y}$ is the mean of the true values. An R^2 value closer to 1 indicates a better fit between the predicted and true values.

By leveraging these metrics, the effectiveness of the proposed method was validated across dynamic hand movements and varied arm positions.

IV. Result

The wearable ultrasound-based system was evaluated for its ability to simultaneously predict grip force and wrist angle during dynamic hand movements across three arm positions: neutral, shoulder-level, and midline-crossing. Fig. 4 shows the predicted wrist angle and grip force for validation data from one participant. The Multi-Layer Perceptron (MLP) model consistently outperformed the Gaussian Process Regressor (GPR) in predicting both biomechanical outputs. For wrist angle prediction, the MLP achieved an average R^2 of 0.85 ± 0.06 and a mean squared error (MSE) of 0.018 ± 0.006, reflecting strong predictive accuracy and consistent performance across participants. Similarly, for grip force prediction, the MLP attained an average R^2 of 0.74 ± 0.07 and an MSE of 0.026 ± 0.005, outperforming the GPR model, which achieved an average R^2 of 0.70 ± 0.05 and an MSE of 0.030 ± 0.005.

Performance metrics for individual participants, as summarized in Table II and showed across the the trials in Fig. 5, reveal that wrist angle predictions using the MLP were highly consistent, with all participants achieving R^2 values above 0.80. For grip force predictions, the MLP also outperformed the GPR but exhibited greater variability among participants, with R^2 values ranging from 0.65 (AB03) to 0.77 (AB01). The higher variability in grip force prediction can be attributed to differences in individual muscle behavior and fatigue effects during extended trials. Despite the observed variability in grip force predictions, the system effectively captured simultaneous wrist angle and grip force during dynamic, multi-positional tasks, highlighting the potential of the wearable ultrasound-based system for real-world upper-limb prosthetic applications.

V. Discussion

This study demonstrates the feasibility of a wearable ultrasound-based system for the simultaneous prediction of grip force and wrist angle during dynamic hand movements across varied arm positions. Unlike previous work, which evaluated SPC with the arm static in neutral positions, this study focused on dynamic, reaching movements likely encountered in daily living.

The current dataset, consisting of gradual, simultaneous increases and decreases in wrist angle and grip force, proved effective for initial evaluation but limited the model's generalizability to more complex tasks. This limitation likely

contributed to PCA's inability to effectively separate wrist angle and grip force, as observed in prior studies [19], [21]. Expanding the dataset to include diverse dynamic movement patterns, such as non-linear or abrupt transitions, remains a priority for future work to enhance dimensional separation and robustness. Prediction models based on raw ultrasound echo envelopes were employed in this study, with the Gaussian Process Regressor (GPR) using RBF and white noise kernels outperforming default configurations, but proving computationally intensive. The Multi-Layer Perceptron (MLP) model demonstrated superior accuracy and computational efficiency, making it better suited for real-time implementation.

The MLP consistently outperformed the GPR, achieving higher R^2 values and lower MSE across participants, as shown in Table II and Fig. 5. For wrist angle, the MLP achieved R^2 values above 0.80, demonstrating its ability to model complex relationships. For grip force, the MLP also outperformed the GPR, though greater variability was observed due to differences in muscle activation patterns across participants. While the MLP effectively captured non-linear dependencies, future research will explore recurrent networks (RNNs or LSTMs) to better leverage the sequential nature of M-mode ultrasound data.

The system's computational efficiency makes the MLP suitable for real-time applications, unlike the computationally intensive GPR. Ongoing work is focused on validating the system in individuals with limb differences and integrating the MLP into a real-time prosthetic control system. To train models without direct ground truth data for individuals with limb difference, a cursor control task or a mirrored movement

approach using the intact limb will be utilized to generate training data for the affected limb.

VI. Conclusion

This study introduces a wearable ultrasound system for the simultaneous prediction of grip force and wrist angle during dynamic hand movements, effectively addressing challenges in proportional control for real-world applications. By using M-mode ultrasound data and the MLP model, which outperformed GPR in both accuracy and computational efficiency, this work establishes a foundation for dynamic prosthetic control. However, the dataset's limited movement diversity may restrict generalizability. Expanding the dataset with diverse dynamic movements and exploring recurrent models (RNNs/LSTMs) will be key to enhancing the system's robustness. These advancements will further enable the development of intuitive, real-time prosthetic control systems for individuals with limb differences.

Accuracy of IMUs and monocular human pose estimation at measuring elbow flexion

David Rode[1,*], Alessandro Ceccarelli[2], Adrian Esser[1], Peter Wolf[1], Robert Riener[1,3]

***Abstract*—Markerless human pose estimation and inertial measurement units are two common methods for human movement analysis. They are cost-effective and easy to use, but their accuracy compared to established optical motion capture methods is yet to be determined for some movements. This study compared the accuracy of IMUs and BlazePose, a markerless monocular 3D human pose estimator, against a marker-based optical system for measuring elbow flexion angles. After performing a static offset calibration to account for differences in anatomical coordinate systems, these were reduced to a mean absolute error of 4.2° and a root mean square error of 6.0°. The accuracy of markerless pose estimation was significantly influenced by the orientation of the participants to the camera. The optimal camera orientation was achieved when participants performed the movement fully within the image plane, with a mean absolute error of 10.5° and a root mean square error of 14.7° after performing a static offset calibration. Bland-Altman analysis indicated mostly constant deviations for the IMUs but non-constant deviations for HPE, which underestimated large elbow flexion angles. The findings of this study underscore the importance of camera orientation for monocular HPE accuracy. IMUs display much higher accuracy at measuring elbow flexion than monocular HPE. Further improvements in the accuracy of HPE independent of orientation might broaden its applications in motion analysis.**

***Index Terms*—Inertial measurement units, markerless pose estimation, optical motion capturing, elbow flexion, joint angles**

I. Introduction

Measurement of joint angles is of significant interest in a multitude of fields, including clinical diagnoses, movement science, and home-based applications, such as gamified home therapy [1]. Optical motion capturing (OMC) with passive reflective markers is considered a state-of-the-art method among non-invasive measurement techniques. This method requires the attachment of markers that reflect infrared light to specific anatomical landmarks on the human body. Infrared cameras are capable of detecting the reflections off these markers with a high degree of accuracy. The orientations of body segments and joint angles can be reconstructed from the marker positions by means of kinematic models. However, the use of OMC in clinical or home settings is limited by several factors. These include the time-consuming setup and calibration processes, the high hardware requirements, the substantial financial investments, and the expertise required for marker attachment and system operation.

Recent technological advances have led to the emergence of novel, user-friendly, and cost-effective measurement techniques capable of tracking joint motion. Two notable examples of this include the analysis of human motion by inertial measurement units (IMUs) [2], and markerless human pose estimation (HPE) [3]. These methods can track human motion with significantly lower hardware requirements, faster setup and calibration times, and higher ease of use than with OMC. Furthermore, because they do not require expert knowledge to prepare and operate, they could be used in home applications, such as remote clinical assessments, gamified therapy, and the control of rehabilitation devices.

IMUs are wearable sensors that utilize gyroscopes and accelerometers to quantify the angular velocity and specific force experienced by the sensor. Additionally, some IMUs include magnetometers to measure the magnetic field of the Earth, but these sensors are often sensitive to external electromagnetic noise and can cause significant drift over time [4], [5].

Markerless human pose estimation aims to detect human joints and poses from images or videos. Most current HPE methods rely on learning-based methods to identify humans within image frames and determine the location of anatomical landmarks within these frames. Monocular pose estimators require only one camera, which makes them particularly appealing for applications with strict time requirements, such as home applications. The straightforward setup and calibration process reduces the overall time required for data acquisition. The absence of markers or sensors which have to be attached to anatomical landmarks makes them suitable for use by non-expert users.

It is evident that both IMUs and HPE-based methods are user-friendly, require minimal setup time, and have low hardware requirements. However, the accuracy of these methods must be evaluated in comparison with established techniques to determine their suitability for specific applications. This study evaluated the accuracy and precision of IMUs and HPE in determining the flexion angle of the elbow joint by comparing them with marker-based OMC on a dataset of five participants performing five repetitions of isolated elbow flexion and extension.

II. Methods

A. Participants and Tasks

A total of five participants were recruited for this study and each provided their written informed consent. The study was reviewed and approved by the ETH Zurich Ethics Committee, with the approval number 24 ETHICS-294.

TABLE I
Overview over the participants included in this study. The values represent the mean and values within square brackets indicate the range of values.

Gender	Age (years)	Height (cm)	Weight (kg)
Female (n = 4)	27 [24 - 30]	166 [158 - 180]	53 [43 - 64]
Male (n = 1)	29	173	67
Overall (n = 5)	28 [24 - 30]	167 [158 - 180]	56 [43 - 67]

Participants were instructed to maintain a fixed standing position during each test and only move their dominant forearm, which was the right side for all participants. They performed a flexion movement of the elbow from a fully extended starting configuration with their arms at their side and their palms facing forward. They were instructed to flex their elbow to approximately 90° and fully extend it again afterwards for a total of five repetitions for each condition. This movement was repeated for three conditions with different orientations of the participants towards a RGB camera. One condition of this movement was performed fully within the image plane at an angle of 0°, one was performed facing the camera at an angle of 45°, and one was performed fully facing the camera at an angle of 90°.

B. Optical Motion Capturing

A passive marker OMC system was employed as a ground truth reference method. The OMC system consisted of eight infrared motion capturing cameras (Miqus M3, Qualisys, Sweden). An RGB camera (Miqus Video Plus, Qualisys, Sweden) was connected to the OMC measurement system, thereby ensuring simultaneous measurements and identical start and stop times. The RGB camera was placed 3 m from the participants at a height of 1.12 m. The OMC cameras ran at a sampling frequency of 100 frames per second (FPS).

The videos recorded by the RGB camera were used as visual inputs for the subsequent markerless pose estimation process. The OMC measurements and RGB video recordings were conducted within the same software program (Qualisys Track Manager, Qualisys, Sweden). A commonly used kinematic model (Upper Limb Model, Vicon, United Kingdom) was selected and processed in another processing software program (Nexus 2.15, Vicon, United Kingdom). This kinematic model requires a set of 15 markers attached to defined anatomical landmarks of the upper body (see Fig. 1). Throughout all trials, the markers and IMUs were placed by the same expert.

The kinematic model outputs the joint center locations and joint angles for the dominant side of the upper body. Capturing a static calibration is necessary for this model to return accurate joint angles. During this static calibration trial, participants stood in a stationary position with their hands on their sides and their palms pointing anterior. After this calibration, the participants performed the three conditions in succession. The selected kinematic model treated the elbow joint as a universal joint with two degrees of freedom: flexion and pronation-supination. As this study compared the accuracy of different methods at measuring elbow flexion, the pronation-supination angle was not considered after processing the kinematic model.

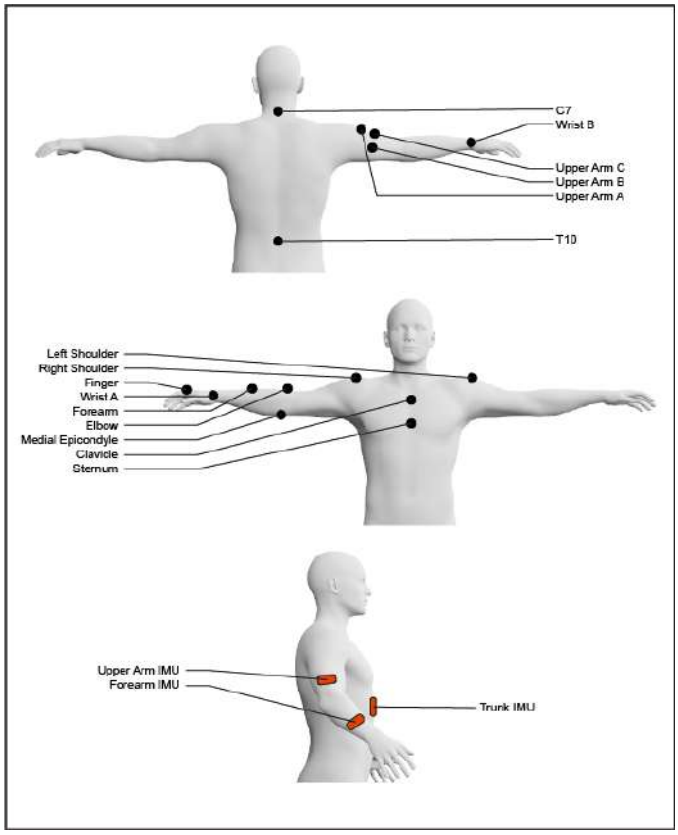

Fig. 1. Overview over the placement of markers and IMUs on the participants. The Upper Limb Model (Vicon, United Kingdom) marker set required attaching 15 reflective markers (black). Three IMUs were attached to the torso, upper arm and forearm (red). The IMUs and markers were placed by the same trained expert during the entire study and were worn simultaneously throughout all measurements.

C. Markerless Pose Estimation

Due to its accuracy, user-friendliness and high processing speed, BlazePose (Mediapipe Version 1.09, Google, USA) was selected for this study [6]. BlazePose is a markerless monocular human pose estimator that is capable of direct three-dimensional pose estimation [7]. We used the "Global" operating mode of BlazePose which returned coordinates in metric units with the "Heavy" model, which is the most accurate among the available models.

As the RGB camera was connected to the OMC system, their signals were already synchronized. The RGB camera captured frames at a sampling frequency of 50 FPS. BlazePose returned a set of 33 three-dimensional landmark locations of the human body for each frame in which a pose was detected. Some of these landmarks represent joint center locations, whereas others represent characteristic features of the face,

hands, and feet. The elbow flexion angle was computed by the scalar product formula, using a three-dimensional vector constructed from the shoulder joint to the elbow joint and a three-dimensional vector pointing from the elbow joint to the wrist joint.

D. Inertial Measurement Units

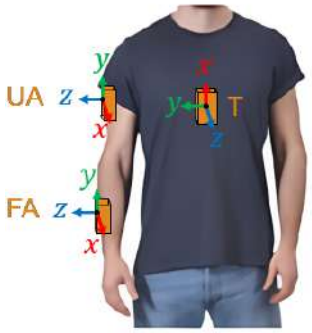

Fig. 2. The locations and orientations of the trunk (T), upper arm (UA), and forearm (FA) IMUs during the static calibration pose.

Three IMUs (NGIMU, x-io Technologies, United Kingdom) were attached to the participants (see Fig. 2). To determine the angles of the upper body joint in the dominant arm for subsequent comparison, an IMU was placed on the trunk, another on the dominant upper arm, and a third on the dominant lower arm [8]. All were worn simultaneously with the marker set. The recording of the three IMUS occurred synchronously in the same software program (Synchronized Network Manager version 1.18, x-io Technologies, United Kingdom) at a sampling frequency of 50 Hz. As IMU recordings were started from a different program than OMC and HPE measurements, the raw IMU signals were not synchronized with OMC and HPE. The IMUs ran an onboard Attitude and Heading Reference System (AHRS) fusion algorithm, fusing the accelerometer and gyroscope data to provide an estimate of the global orientation of each IMU relative to the world frame. The magnetometers were disabled, and prior to the trial of each subject, the three IMUs were aligned and reset to calibrate their headings.

The following reference frames were considered:

- The World reference frame (W)
- The IMU reference frames ($\mathrm{I_i}$, $i \in \{T, UA, FA\}$)
- The Body reference frames ($\mathrm{B_i}$, $i \in \{T, UA, FA\}$)

The attached IMUs did not directly measure the orientations of the segment frames. Therefore, a calibration procedure was used to calibrate the measured IMU orientations [9]. Before each trial, participants stood upright for five seconds, with their palms facing their hips and elbows fully extended (see Fig. 2). The elbow flexion angle was assumed to be zero during this calibration procedure.

The calibration procedure resulted in a rotation that defines the orientation change from the world frame to the IMU frame while in the calibration pose: ${}_{W}\mathbf{R}_{I,i,0}$ This matrix was assumed to be time-invariant. If the IMU sensors are moved relative to the body of the wearer, this calibration procedure should be repeated.

The time-varying rotations between the world frame and the IMU frames (during motion) were defined as ${}_{W}\mathbf{R}_{I,i}(t)$

Thus, the rotation from the IMU orientation at static calibration towards the IMU orientation in any posture was given by:

$$ {}_{I,i,0}\mathbf{R}_{I,i}(t) = ({}_{W}\mathbf{R}_{I,i,0})^{-1} \cdot {}_{W}\mathbf{R}_{I,i}(t) \tag{1}$$

We assumed that the IMUs and the body frames moved together rigidly, thus:

$$ {}_{B,i,0}\mathbf{R}_{B,i}(t) = {}_{I,i,0}\mathbf{R}_{I,i}(t) \tag{2}$$

Finally, the orientation of the body frames relative to the world frame was found from the following:

$$ {}_{W}\mathbf{R}_{B,i}(t) = {}_{W}\mathbf{R}_{B,i,0} \cdot {}_{B,i,0}\mathbf{R}_{B,i}(t) \tag{3}$$

$$ = {}_{W}\mathbf{R}_{B,i,0} \cdot ({}_{W}\mathbf{R}_{I,i,0})^{-1} \cdot {}_{W}\mathbf{R}_{I,i}(t) \tag{4}$$

The rotation matrix ${}_{W}\mathbf{R}_{B,i,0}$ represents the rotation from the world frame to the body frame during the calibration pose. These rotations are time-invariant and depend on the orientation by which the IMUs were attached to the participant. These rotations are defined intrinsically as:

$$ {}_{W}\mathbf{R}_{B,T,0} = \mathbf{R}_x(\pi) \cdot \mathbf{R}_y(\frac{\pi}{2}) \tag{5}$$

and

$$ {}_{W}\mathbf{R}_{B,UA,0} = {}_{W}\mathbf{R}_{B,FA,0} = \mathbf{R}_x(\frac{\pi}{2}) \tag{6}$$

where $\mathbf{R}_x(\cdot)$ and $\mathbf{R}_y(\cdot)$ represent principle rotations about the x and y axes, respectively.

With ${}_{W}\mathbf{R}_{B,UA}(t)$ and ${}_{W}\mathbf{R}_{B,FA}(t)$, the elbow angle is the angle between the y-axes of these two frames in the world frame. Defining:

$$ \overrightarrow{y}_{UA} = {}_{W}\mathbf{R}_{B,UA}(t) \cdot \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} \tag{7}$$

$$ \overrightarrow{y}_{FA} = {}_{W}\mathbf{R}_{B,FA}(t) \cdot \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} \tag{8}$$

We defined the elbow flexion angle at time t as α_t^{IMU}, which is given by:

$$ \alpha_t^{IMU} = \arccos\left(\frac{\overrightarrow{y}_{UA,\ t} \cdot \overrightarrow{y}_{FA,\ t}^{T}}{\| \overrightarrow{y}_{UA,\ t} \| \cdot \| \overrightarrow{y}_{FA,\ t} \|} \right) \tag{9}$$

This elbow flexion angle corresponds to the first angle in the ISB joint coordinate system, which prescribes a Z-X-Y order of rotations, with the first angle being elbow flexion-extension, the second angle being elbow pronation-supination, and the third angle being the passive carrying angle, which is often not reported [10].

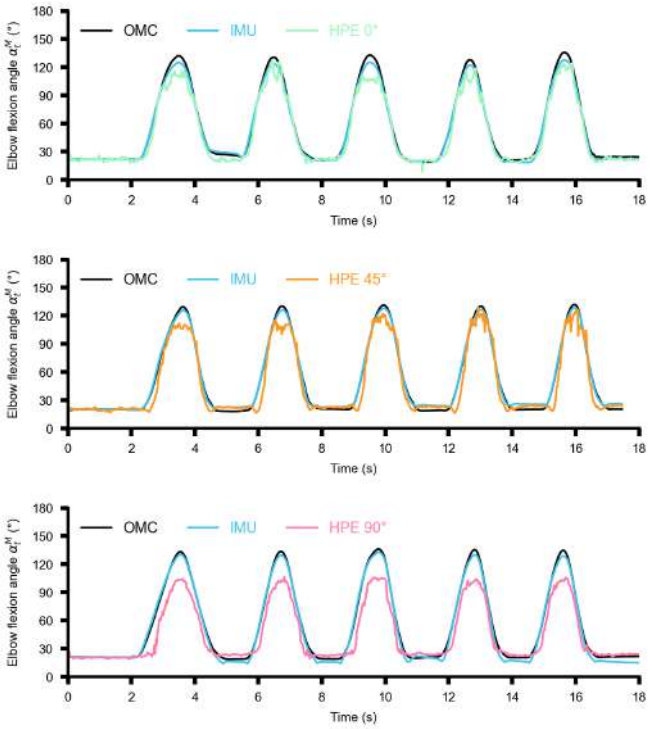

Fig. 3. The elbow flexion angle as captured by passive marker optical motion capturing, inertial measurement units, and markerless human pose estimation with different camera orientations for one exemplary participant. Note that a static offset calibration has been performed on these IMU and HPE flexion angles to account for differences in anatomical coordinate systems. At an orientation of 0°, participants performed elbow flexion within the image plane, while at an orientation of 90°, they faced the camera frontally.

E. Metrics

To compute the differences between the measured angles, we first synchronized all signals from the different measurement methods and transformed them to a common sampling frequency. First, the OMC measurements were downsampled to 50 FPS by dropping every second frame to have the same frequency as the HPE and IMU measurements. As the OMC measurements and the RGB videos for HPE were recorded from the same system, they were already synchronized. The IMU measurements were synchronized with the OMC measurements by maximizing the cross-correlation of the flexion angles for each trial. Then we applied a static offset calibration to the HPE and IMU flexion angles to account for different definitions of the anatomical coordinate systems between the different measurement methods (see Fig. 3). The constant offset factor was determined by comparing the average OMC flexion angle to the average of each measurement method during the first second of each test for each participant and condition. We then applied this constant offset factor to the entire trial.

The mean absolute error (MAE) and the root mean square error ($RMSE$) were the primary metrics investigated for the accuracy. Defining the elbow flexion angle at time t measured by method M as α_t^M, these are:

$$MAE^M = \frac{1}{N_{timestamps}} \cdot \sum_{t=1}^{N_{timestamps}} |\alpha_t^M - \alpha_t^{OMC}| \quad (10)$$

$$RMSE^M = \sqrt{\frac{1}{N_{timestamps}} \cdot \sum_{t=1}^{N_{timestamps}} (\alpha_t^M - \alpha_t^{OMC})^2} \quad (11)$$

These values were computed by averaging over all timestamps in the dataset, including all participants and repetitions.

III. Results

A. Accuracy of IMUs and HPE

Before performing a static offset calibration, the elbow flexion angles were measured by IMU with a MAE of 13.8 ° and a RMSE of 15.2 ° when averaged over all participants and conditions (see Fig. 4). The same elbow flexion angles were measured by HPE with a MAE of 18.7° and RMSE of 23.8° when averaged over all participants and all orientations.

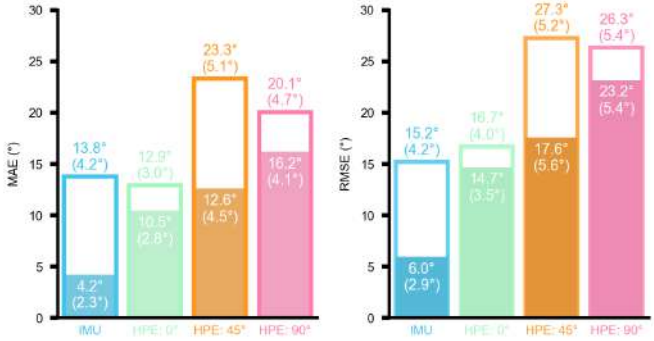

Fig. 4. Overview of root mean square errors and mean absolute errors before and after performing static offset calibration. The hollow bars and colored values represent the accuracy before calibration, whereas the filled bars and white values indicate the accuracy after calibration. The values in brackets represent the inter-participant variability as standard deviation. Static offset calibration accounted for the differences in anatomical coordinate systems and led to a great increase of accuracy for the IMUs. Notice the higher overall accuracy demonstrated by the IMUs and the large effect of participant orientation on HPE accuracy. Movements performed fully within the image plane at an orientation angle of 0° led to the highest accuracy for HPE.

The static offset calibration reduced the MAE of the IMUs to 4.2° and the RMSE to 6.0°.

Overall, markerless HPE using BlazePose "Global" with the "Heavy" model showed a MAE of 13.05° and a $RMSE$ of 18.75° after performing static offset calibration and when averaging over all participants and all orientations. When participants performed the elbow flexion movement fully within the image plane at an orientation of 0°, the MAE was 10.5° and $RMSE$ was 14.7° over all participants. When participants faced the camera at an angle of 45°, the MAE was 12.6° and the $RMSE$ was 17.6° over all participants. Lastly, when the participants were facing the camera frontally at an angle of 90° with respect to the image plane, the MAE was 16.2° and the $RMSE$ was 23.2° over all participants.

B. Bland-Altman analysis of HPE

When comparing the different conditions in a Bland-Altman plot, non-constant deviations are observable for all three orientation angles (see Fig. 5). The mean differences and limits of agreement increased with an increasing angle of the participants towards the image plane.

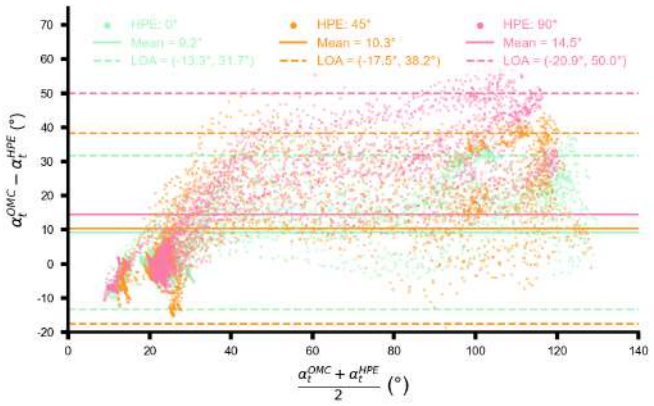

Fig. 5. Bland-Altman plot of markerless pose estimation for all camera orientation angles after performing static offset calibration. The mean deviations to optical motion capturing and the limits of agreement are indicated for each orientation. Observe the non-constant behavior of the deviations for all orientation angles. Performing the movement fully within the image plane at an angle of 0° resulted in the tightest LOAs, whereas facing the camera frontally at 90° led to the largest LOAs. HPE tends to underestimate large elbow flexion angles irrespective of the orientation towards the camera.

C. Bland-Altman analysis of IMUs

The Bland-Altman plot of the IMU measurements shows mainly constant deviations (see Fig. 6). The three conditions of participant six are highlighted to exemplify this behavior. These constant deviations varied by participant and, at times, even showed considerable changes between conditions.

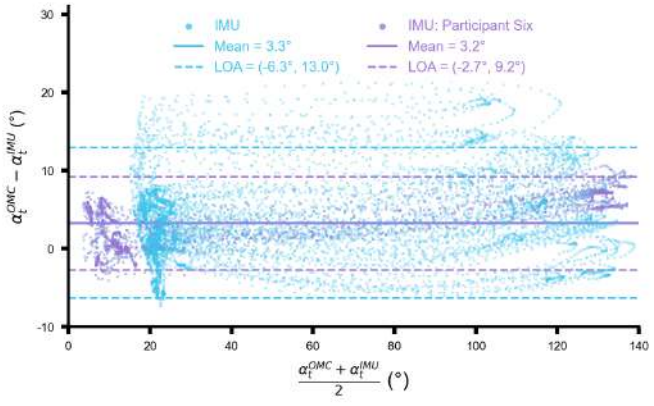

Fig. 6. Bland-Altman plot of all IMU measurements after performing static offset calibration. The mean deviation to optical motion capturing and the limits of agreement are indicated. The IMU measurements of participant six are highlighted to emphasize the behavior of the IMU deviations. Observe the more constant behavior of the deviations when compared to HPE.

IV. Discussion

The Bland-Altman analysis of the calibrated flexion angles reveal that the IMUs showed more constant deviations than BlazePose for all orientations (see Figs. 5 and 6). BlazePose showed non-constant behavior of the deviations for all orientations, as it underestimated large flexion angles when compared to OMC (see Fig. 5). This non-constant behavior did not allow for a simple static offset calibration to greatly reduce the deviations (see Fig. 4).

In contrast, the Bland-Altman plot of the IMU measurements shows more constant deviations throughout the measured range of elbow flexion angles (see Fig. 6). The constant deviations are likely caused by different definitions of the anatomical coordinate systems and can be accounted for by applying a static offset calibration, which greatly reduced the errors for IMUs. After static offset calibration was performed, the IMUs clearly demonstrated higher accuracy than BlazePose for any orientation (see Fig. 4).

When comparing the accuracy of the calibrated HPE data, a clear dependence of the measurement accuracy on the orientation of the participant is visible (see Fig. 4). The most accurate measurements were achieved when participants performed the flexion movement fully within the image plane. The accuracy decreased greatly when increasing the angle towards the image plane and was lowest when participants stood perpendicular to the image plane and faced the camera frontally at an angle of 90° towards the image plane. This is likely due to the greater errors in depth estimation than within the image plane for monocular HPE methods. Therefore, when using these methods, great attention should be paid to the orientation of participants towards the camera and the plane in which movement occurs. HPE could be an alternative to IMUs and OMC for non-critical applications like home therapy or remote assessments when the measured movement is fully within the image plane. If the movement is three-dimensional or cannot be captured purely within the image plane, IMUs will display much greater accuracy than HPE and are preferable if the application allows them.

The accuracy values after performing a static offset calibration align with reported values. An assessment of IMU accuracy at measuring elbow flexion with anthropomorphic robotic arms found an RMSE of up to 5.7° [11]. Another study compared the elbow flexion angle during swimming motions measured by IMUs to an OMC system and found a RMSE between 2.23 and 5.84° [12].

Currently, there is a lack of information on the accuracy of markerless HPE methods at measuring upper body joint kinematics [13]. A study comparing the accuracy of markerless multi-view HPE found an RMSE of up to 7.4° in elbow flexion compared to OMC [13]. Another multi-view HPE method showed an MAE of 6.8 ° in elbow flexion compared to OMC [14]. Therefore, the errors found in this study for a monocular 3D HPE method are reasonable, as the lacking multi-view information results in lower accuracies.

This study solely investigated BlazePose, so these insights may

not extend to other pose estimators due to different training data and model architectures. Furthermore, the IMUs in this study were calibrated before each measurement condition to correct for drift and integration errors, so the reported accuracy may not be achievable in practical applications. Lastly, the choice of reference measurement system and kinematic model affect the resulting accuracy of the tested methods. In this study, we chose passive marker OMC as a reference, which is known to suffer from marker displacements due to soft tissue deformations [15]. Furthermore, upper body kinematic models lack the amount of validation that gait models have had [16]. Nevertheless, we chose passive marker OMC as reference due to its wide-place adoption in research and very high accuracy compared with other non-intrusive methods.

Future studies in this domain might determine the accuracy of HPE methods for other joint angles of the upper body. Increasing the accuracy of monocular HPE methods irrespective of the orientation of users towards the capturing camera could increase their usability and allow for more use cases. This could be accomplished by using different model architectures and collecting training data with diverse poses using established systems to obtain accurate joint locations.

V. Conclusion

This study compared the accuracy of IMUs and BlazePose, a monocular markerless human pose estimator, to passive marker optical motion capturing at measuring elbow flexion angles. IMUs consistently outperformed BlazePose in accuracy across all orientations, with lower errors and tighter limits of agreement. The accuracy of BlazePose varied strongly with the orientation of the participants to the camera, achieving the best results when elbow flexion was completely within the image plane. It underestimated the larger elbow flexion angles for all investigated orientations of the participants. Whereas a static offset calibration showed great results on the accuracy of the IMUs, this could not be achieved for BlazePose. Selecting the optimal camera orientation is crucial for accurate motion analysis when using HPE methods. Future research might investigate the accuracy of both methods for other joint angles of the upper body. Enhancing the accuracy of monocular HPE methods across all orientations could lead to a broader range of use cases.

***Abstract*—Sensory deficits caused by neurological disorders, *i.e.*, loss of tactile sensitivity and/or limb proprioception, hinder object manipulation and precise movements, and ultimately lead to a significant slow-down in motor rehabilitation. Although sensory rehabilitation has been catching on more and more, current procedures for evaluating tactile sensitivity are still inefficient in terms of equipment portability, test execution time, and specific training required for healthcare personnel. While some automated tactile stimulation platforms have been developed for other applications, robotic systems designed to evaluate residual tactile sensitivity are still largely under-explored. Here we propose a hand-wearable, pneumatically-driven device, which exploits an air chamber to transmit contact forces to the user's fingertip by means of sliding pin, which can then be used to assess tactile sensitivity in a quantitative and reproducible manner. We tested the proposed platform on five healthy participants, and obtained pressure perception thresholds in the order of 0.01 bar, with a median of ~ 0.03 bar, which showed a good correlation ($\rho = 0.8441$) with the Semmes-Weinstein test. Although these results are preliminary, they suggest the potential of the proposed device as a complementary assessment tool of tactile sensitivity.**

I. Introduction

Neurological disorders, such as stroke, spinal cord injury, multiple sclerosis, and other neurodegenerative diseases, lead to motor impairments: reduction in voluntary motor control, anomalous muscular contractions, worsening of motor coordination, muscle weakness, and longer reaction times, among the others [1]. However, sensory deficits, *i.e.*, loss of tactile sensitivity and/or limb proprioception, may also arise. For instance, 85% of post-stroke patients suffer from some form of reduced tactile or proprioceptive sensitivity [2].

In turn, a chronic loss of sensitivity hinders the execution of fine and complex movements [3], such as object manipulation and precision movements [1, 2, 3], thus significantly hampering the overall progress in motor rehabilitation [4]. While restoration of muscle strength and motor coordination is paramount, rehabilitation strategies should then also focus on somatosensory recovery. In this regard, next to motor rehabilitation therapy, also sensory rehabilitation – where patient's discrimination of tactile stimulations is evaluated and trained – has been catching on more and more in recent years [3]. However, following clinical focus groups, we believe that current procedures for evaluating tactile function – Semmes-Weinstein monofilament test, two-points acuity, JVP domes – are not optimized. Although they are virtually widespread, limited equipment portability, long test execution time, and specific training required for healthcare personnel hamper their efficiency and thus their application. While some automated tactile stimulation platforms have been developed for other applications (such as tactile stimulation during MRI studies [5, 6] and augmented feedback in virtual reality [7, 8]), robotic systems designed to evaluate residual tactile sensitivity after a brain lesion still lay uncharted.

In this study, we report on the development of a hand-wearable, pneumatically-driven device (shown in Fig. 1a), designed to evaluate residual tactile sensitivity in a streamlined fashion. The system is made of a fabric glove endowed with a fingertip stimulation module, which hosts a pneumatic

Fig. 1. a) The developed fingertip module, mounted on a fabric glove and worn by a user. b) Upper view of the fingertip module: a custom support hosts an air chamber, which is attached to a sliding pin.

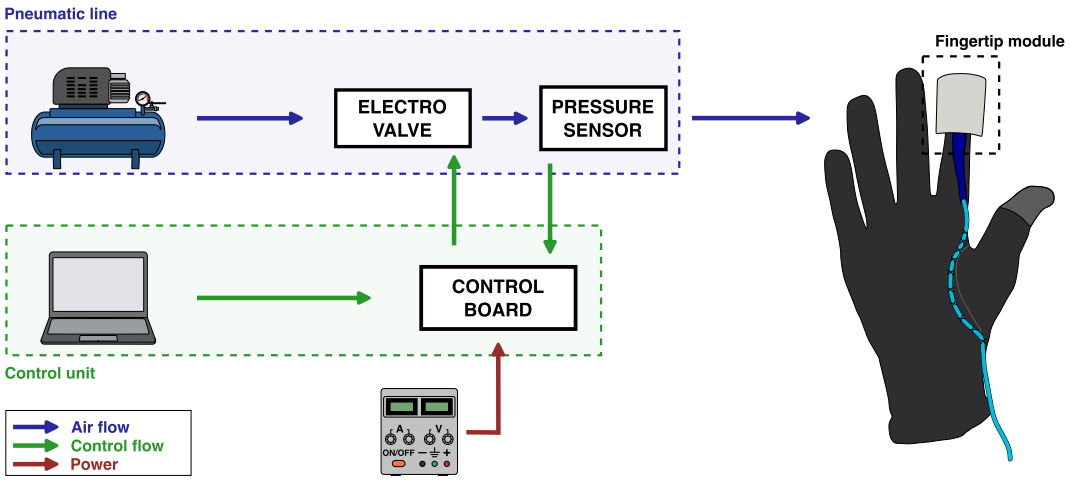

Fig. 2. Schematic of the proposed platform. A PC sends control inputs to a control board, powered by an external supply, which operates the inlet electrovalve connected to an external air compressor. According to the set target, the control board regulates the pressure of the fingertip module by controlling in closed loop the air flow from the inlet electrovalve.

chamber that, upon pressurization, transmits a contact force to the user by means of a sliding pin (Fig. 1b), which can be used to assess their tactile sensitivity in a quantitative and reproducible manner. After a characterization of the relationship between chamber's pressure and exerted force, we tested the proposed platform on five healthy participants to compare its performances against the Semmes-Weinstein monofilament test, which is regarded as the gold standard in assessing tactile sensitivity [9, 10].

The remainder of this paper is organized as follows. In Section 2, we outline the architecture of the device and report its manufacturing steps. In Section 3, we describe the workbench characterization procedure of the device as well as the experimental protocol for tests on healthy participants. In Section 4, we report the device characterization curve and discuss the results of tactile sensitivity tests, comparing them with the Semmes-Weinstein test. Finally, in Section 5 we draw our conclusions, highlighting some limitations of the proposed device and outlining possible future directions.

II. Device Architecture

Our device consists of a wearable fabric glove endowed with a fingertip stimulation module, which is composed of an inflatable air chamber, a retractable sliding pin placed on top of it, and a 3D-printed custom support to house them (see Fig. 1b). Upon pressurization, the air chamber inflates and pushes the pin in contact with the user's fingertip, thus transmitting a contact force that can be controlled by modulating the pressure of the system. In this way, it is possible to administer a reproducible stimulation to infer the tactile sensitivity of the user.

The full system is composed of a pneumatic line (from an air source to the chamber), the fingertip stimulation module (support, chamber and sliding pin), and a control unit (a microcontroller and a PC) connected to an external power supply (see Fig. 2). A detailed description is given in the remaining part of this section.

A. Pneumatic Line

The pneumatic line comprises a commercial air compressor integrated with a pressurized air reservoir, two solenoidal electrovalves to regulate inlet and outlet flows, a custom air chamber and a pressure sensor. We used a proportional valve (PVQ13-5L-08-M5-A, SMC, Japan), controlled in pulse-width modulation (PWM), to regulate the inlet air flow and in turn the inner pressure in a continuous way, while we adopted an ON/OFF valve (VZ110-5MOZ-M5-Q, SMC, Japan) for the exhaust line.

B. Fingertip Stimulation Module

The air chamber was designed with an oval shape, to better adapt to a fingertip, and realized using a commercial polyester fabric coated in thermoplastic polyurethane (TPU), to have an airtight yet flexible material that allows quick inflation-deflation, while minimizing distal encumbrance and weight. Two layers of the TPU-coated fabric, spaced by an insulation layer cut in the desired chamber profile, were heat-sealed using a heat-press (TC7 SMART, Secabo, Germany), running at 140 °C for 20 seconds, in order to form an airtight bladder (see Fig. 3a). The excess material was then cut out, and a plastic tube of 2 mm in diameter was inserted in the chamber and fixed using superglue and sodium bicarbonate.

The chamber was then embedded in a commercial fabric glove at the level of the right index fingertip, by means of a custom 3D-printed support fastened with an elastic band: the air chamber is housed inside the support, and a custom-made pin is placed on top of it (see Fig. 3b). The side of the support in contact with the skin presents a central through-hole, which allows sliding motion of the pin: upon actuation of the chamber, the pin slides through the hole and comes into contact with the user's skin. Finally, to avoid pre-stressing the target skin area with a continuous contact pressure, the surface of the support was grooved around the through-hole and, to allow a direct contact between the skin and the pin, a portion of the glove fabric was cut out.

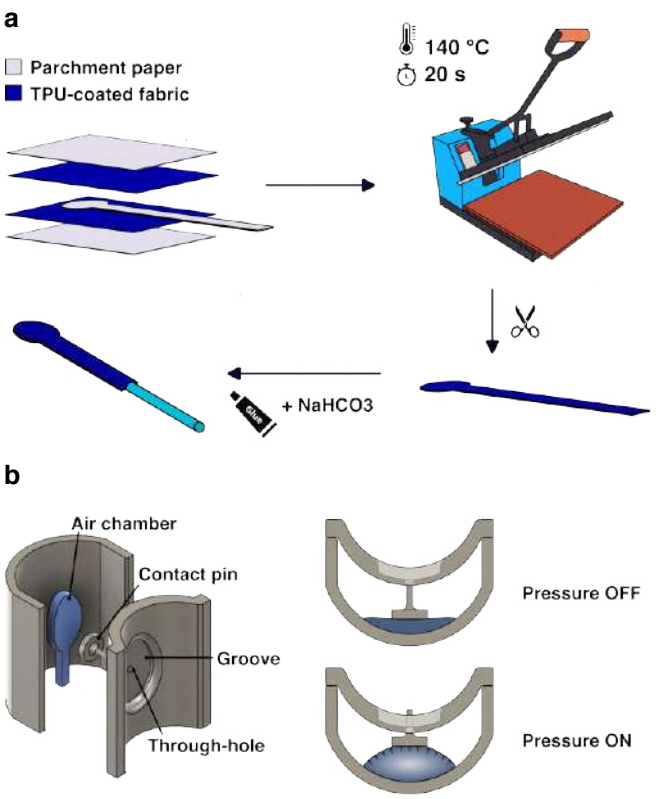

Fig. 3. a) Schematic of the fabrication process of the air chamber. Layers in the heat-press were arranged as follows: parchment paper as an insulation layer, first TPU-coated fabric layer, a piece of parchment paper shaped like the chamber profile, second TPU-coated fabric layer, and a last layer of parchment paper. After the heat treatment, the desired profile was cut from the bonded layers. Finally, a plastic tube was inserted and glued into the elongated portion of the chamber. b) CAD of the custom support, printed in a photoresistive resin. Upon pressurization, the air chamber pushes the pin that slides through the support and comes into contact with the skin.

C. Control Unit

A commercial board (UNO R3, Arduino, Italy) was used to monitor and control the inner pressure of the air chamber in closed-loop, implementing a PID controller. The chamber pressure is read with an absolute pressure sensor (ELVH-150A-HAND, Amphenol All Sensors, US) and the difference between the read value and a target one, set via software, is fed to a PID function; finally, the output of the PID is used as the duty cycle value of the PWM voltage signal that drives the inlet proportional valve, thus closing the control loop.

Based on the literature [11], we modeled the air chamber with a third-order transfer function and fitted its parameters according to the system's response to a chirp signal. Specifically, the proportional inlet valve received as input a PWM signal with duty cycle D given by

$$D(t) = 0.5 + 0.5 \sin\left(2\pi\left(f_0 + \frac{f_1 - f_0}{T}t\right)t\right), \quad (1)$$

that is, an up-chirp where $f_0 = 0.001\,\text{Hz}$ is the initial frequency, $f_1 = 50\,\text{Hz}$ is the final one, and $T = 30\,\text{s}$ is the duration of the signal. The pressure output corresponding to the chirp input was then imported in MATLAB 2023a (The MathWorks, US), and the System Identification Toolbox was used to determine a third-order transfer function. Finally, using the obtained model for the air chamber, PID parameters were tuned by means of the PID Tuner app in MATLAB ($P = 149.28$, $I = 300$, $D = 9.17$).

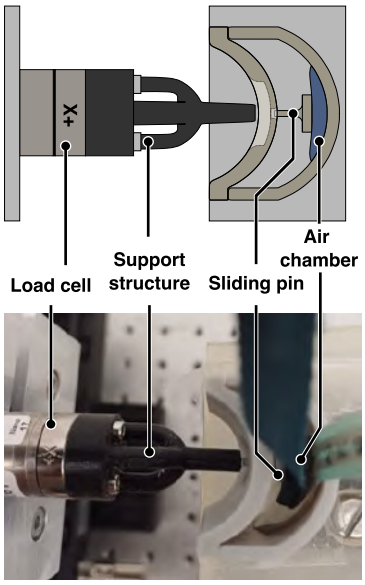

Fig. 4. Experimental setup for the pressure-force characterization of the system. A 3D-printed support was mounted on a load cell and interfaced with the sliding pin in order to measure the force exerted upon pressurization.

III. Experimental Validation

A. Device Characterization

We characterized the relationship between the air chamber's inner pressure and the contact force exerted by the pin using a load cell (Nano17, ATI Industrial Automation, US). The fingertip module was positioned in front of the load cell, so that the through-hole was centered with it. Upon pressurization of the air chamber, the pin slid and came into contact with a custom 3D support mounted on the load cell, which read the exerted force (see Fig. 4). We measured this force 5 times for each of 20 inner pressures, ranging from 0.1 to 1.3 bar.

B. Tests on Healthy Participants

To have a preliminary validation of our device, we recruited five healthy participants (24-29 yrs, 4 males and 1 female). Experiments were conducted under the Declaration of Helsinki and the guidelines of the Ethics Committee of the Scuola Superiore Sant'Anna (Approval No. 10/2023).

At the beginning of the experimental session, we assessed the participant's tactile sensitivity at the right index fingertip by administering the Semmes-Weinstein monofilament test, expressed in gram-force (gf) [9, 10]. We then used our platform to measure their tactile sensitivity in terms of amplitude perception threshold, that is, the minimum perceivable stimulus upon indentation of their fingertip, according to the following experimental protocol.

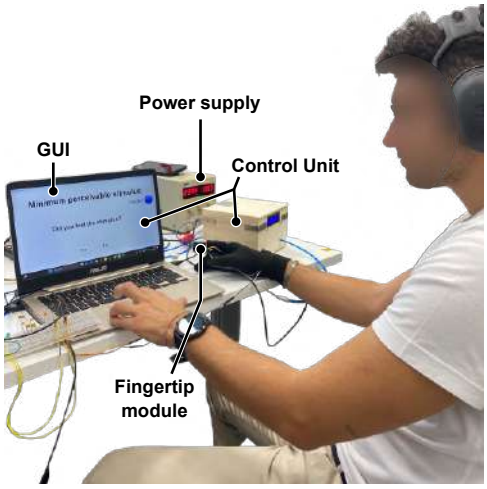

Fig. 5. Example of an experimental session with the proposed device.

Experimental Protocol: Participants were asked to wear the device on their right hand, and the fingertip module was mounted on their index. Additionally, participants were asked to wear a noise-canceling headset during the experiments, to avoid biases due to the noise produced by electrovalves. Tests followed a Two-Interval Forced Choice (2-IFC) procedure. Each trial was made of three phases: a first stimulation window, a short interval, and a second stimulation window. Participants received an actual tactile stimulus in one of the two windows, randomly chosen, and no stimulation (null stimulus) in the other one; they were then asked to indicate in which of the two windows they had perceived a tactile event (see Fig. 5), by means of a custom MATLAB GUI adapted from [12]. The amplitude of the following stimulation was then adaptively modified by means of a Stochastic Approximation Staircase (SAS) algorithm. After 50 trials, the perception threshold was selected as the stimulus amplitude adjusted for the hypothetical 51^{st} trial [13].

IV. Results and Discussion

A. Force-Pressure Calibration Curve

The force-pressure curve obtained from the load cell characterization (see Fig. 6) was highly linear ($\rho = 0.9986$) and had low variability (average IQR $= 0.0116$). This result suggests that the device is capable of exerting a normal contact force in a reliable manner without noticeable non-linearities, despite the presence of the soft air chamber, a characteristic that is particularly desirable for the automatic control of the system.

B. Comparison of Sensitivity Thresholds

Sensitivities measured with the monofilament test ranged from 0.02 to 0.07 gf, with a median of 0.04 gf (IQR 0.04-0.04); pressure perception thresholds obtained with our device were in the order of 0.01 bar, with a median of 0.034 bar (IQR 0.031-0.068) (see Table I and Fig. 7 for complete results). Although not statistically significant ($p > 0.07$), results of the two tests showed a high correlation

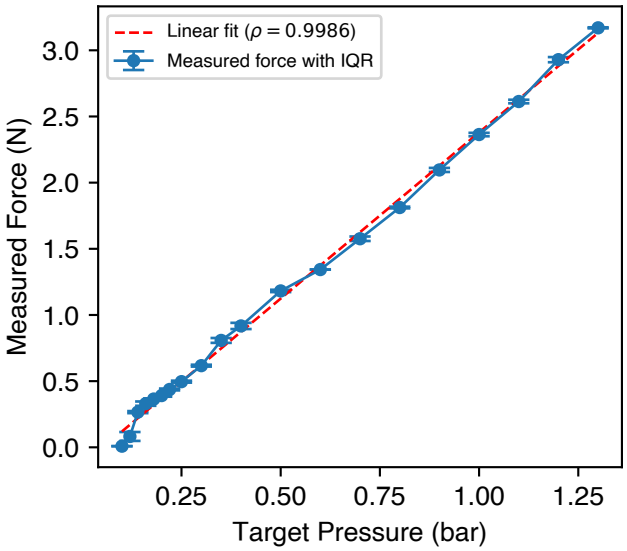

Fig. 6. Pressure-force characterization curve (median with interquartile range, IQR, blue curve) with its linear fitting ($\rho = 0.9986$, red dashed curve).

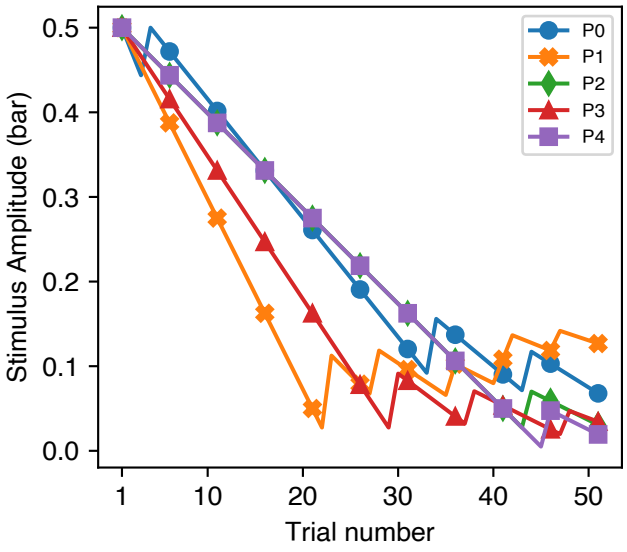

Fig. 7. Staircase stimulation curves of the five participants, where the amplitude adjusted for the hypothetical 51^{st} stimulus is selected as the threshold.

TABLE I
Sensitivity Thresholds Comparison

Participant	Semmes-Weinstein (gf)	Device (bar)
P0	0.04	0.07
P1	0.07	0.13
P2	0.02	0.03
P3	0.04	0.03
P4	0.04	0.02
Median	**0.04**	**0.03**

($\rho = 0.8441$); the unexplained variance could be due to the intrinsic differences in their psychophysics. Specifically, the monofilament test involves a single ascending method of limits where, for the lowest-force filaments ($< 1.4\,\mathrm{gf}$), it is possible to perform up to three stimulations before proceeding to the next filament. Therefore, it is sufficient to perceive only one out of three consecutive stimulations to declare the investigated force as the sensitivity threshold. On the other hand, we implemented an adaptive staircase method to estimate the threshold above which the user has a probability to correctly identify the stimulus ≥ 0.85 [13].

Additionally, the monofilament test has an intrinsic subjective component: to leverage the buckling of the filament, the examiner should approach its critical load in a quasi-static fashion. Since it is not possible to accurately control the speed of indentation, the level of exerted force could cross the critical load, effectively exerting a force higher than intended. Moreover, a higher stimulation rate could elicit different recruitments of mechanoreceptors: the Semmes-Weinstein test, which consists in tapping the participant's fingertip, could excite mainly "fast-adapting" mechanoreceptors, while our device, based on a pneumatic actuation system that exhibits a slower dynamics, could recruit mainly "slow-adapting" ones, characterized by a lower sensitivity [14].

Finally, the prototype nature of the device plays a role, too: at low inner pressures, friction could hamper sliding motion of the pin, making it fail to properly contact the user's skin.

V. Conclusions and Outlook

We developed a wearable pneumatically-driven device for the assessment of tactile sensitivity, which exploits a small air chamber to transmit a indentation force to the user's fingertip. The proposed platform can be used to assess the tactile perception threshold of the user in an automated and repeatable fashion, at a controllable rate and intensity.

Experimental results on five healthy participants showed an overall satisfying performance and suggested the potential of the device as a complementary clinical assessment tool. However, this preliminary investigation also highlighted some limitations to be addressed in future work: increasing the portability of the system, optimizing the fingertip module, and using a direct force measurement as a feedback signal.

In future studies, we aim to increase the number of participants, the number of stimulation modules to target other areas of the hand that can be addressed with the monofilament test, as well as to adapt the device to assess tactile acuity, possibly increasing the number of pins on the same location.

***Abstract*—The global trend of population aging has increased demand for healthcare professionals, particularly those assisting individuals with mobility impairments. To aid these people, rehabilitation robotics, such as smart walkers (SW), can be used to enhance motor capabilities. However, repetitive and painful tasks in rehabilitation can reduce patient engagement and motivation. To help enhance motivation during rehabilitation, tools such as augmented reality (AR) and virtual reality (VR) can be used. In this way, this paper presents a study aimed at evaluating the differences between using AR and VR in locomotion assisted by a SW. Fourteen healthy volunteers were recruited to perform a 3-minute walk, collecting items while assisted by an SW in both AR and VR environments. The results showed a slight increase of 6.2% more items collected in the AR environment. In terms of enjoyment, volunteers reported greater enjoyment using AR, with Physical Activity Enjoyment Scale (PACES) questionnaire scores increasing by 5.6% points in AR compared to VR, with a statistically significant difference (p-value = 0.03). These findings suggest that while both AR and VR provide enjoyment during the task, AR may offer a more enjoyable experience and promote greater confidence using the SW. This paper highlights the potential of AR as a valuable tool to improve user engagement in robotic rehabilitation, suggesting that integrating AR with robotic systems could enhance rehabilitation outcomes.**

***Index Terms*—Augmented Reality, Rehabilitation Robotics, Smart Walker, Virtual Reality.**

I. Introduction

Population aging, once a common process observed only in high-income countries, is now becoming a global trend across others nations [1]. This demographic shift has significantly increased the demand on healthcare professionals, particularly for those caring for individuals with mobility impairments, whose quality of life is deeply impacted by the decline in motor abilities [2], [3].

To mitigate the effects of motor ability decline, rehabilitation robotics devices, such as exoskeleton, instrumented treadmill and smart walkers (SW), are becoming increasingly prominent in clinics and hospitals [4]. SW provide physical support during overground locomotion, aiding in the recovery of muscle strength, balance, and coordination throughout the rehabilitation process, while also offering sensory and cognitive assistance [5].

Nevertheless, a common challenge in rehabilitation is the frustration among patients to perform repetitive and often painful tasks, which demands significant attention from healthcare professionals to maintain patient motivation and prevent dropouts [6]. To address this challenge, augmented reality (AR) and virtual reality (VR) are technologies that can be used to enhance patient engagement, transforming rehabilitation into a more interactive and enjoyable experience [7].

AR overlays virtual elements onto the real world, offering guidance and visual feedback that simplify and enhance the interactivity of real-world tasks [8]. Meanwhile, VR creates a virtual environment that offers a similar set of guidance and feedback as AR, but in a complete virtual world, where users interact with virtual environments and elements [8].

Both technologies have limitations that can impact user experience. For instance, they can induce motion sickness symptoms, such as nausea and headaches, particularly during extended use [9], [10]. AR may also contribute to cognitive overload due to the constant flow of information presented to the user [11]. On the other hand, VR, being fully immersive, lacks real-time tracking of the user's body in the physical environment, which can lead to a disconnect from the user's surroundings and potentially diminish situational awareness

Financial support received from FAPES (PROAPEX, 2023-XDHHW, 2022-D48XB, 2022-C5K3H, 2022-NGKM5, 2021-GL6OJ, 2021-07KJ2), CNPq (308155/2023-8, 403753/2021-0), FINEP (0036/21, 2784/20) and CAPES (Funding Code 001).

[10]. For example, in the study performed by [12], nearly 90% of volunteers assessed the use of VR as having good potential in walking settings. However, they experienced some side effects during VR walking, including a 7.3% reduction in walking speed in the VR condition.

Despite these limitations, AR and VR remain promising tools for gait rehabilitation [13], [14], especially when integrated with overground walking robots, such exoskeletons and SWs. These robotic devices enable users to move freely on a mobile base, supporting the practice of a more natural gait without restrictions, which can enhance the outcomes of rehabilitation programs [15], [16]. Therefore, understanding the differences between AR and VR in similar rehabilitation tasks is important to identify their respective benefits and challenges. This insight can guide the optimization of rehabilitation programs, maximizing their effectiveness while minimizing potential drawbacks.

To assess the efficacy of AR and VR tools in gait rehabilitation, an approach combining both quantitative and qualitative methods should be employed. This evaluation should include metrics such as walking speed, physical activity enjoyment, incidence of motion sickness, heart rate, and cognitive load, among others [15], [17]. These diverse measures will provide a thorough understanding of the pros and cons of these technologies and how they impact rehabilitation outcomes.

Our research group has been working with SW over the last decade, developing strategies for autonomous navigation, human-robot interaction, and cloud-based data processing systems [18]. More recent works have focused on integrating SW with VR to combine overground walking robots with interactive rehabilitation scenarios. In general, the results show good acceptance of the SW combined with VR by the elderly population, promoting engagement without compromising other aspects, such as kinematic parameters and the presence of motion sickness [15], [19]. Furthermore, advancements in Head-Mounted Display (HMD) technology have enabled the development of these same scenarios for AR.

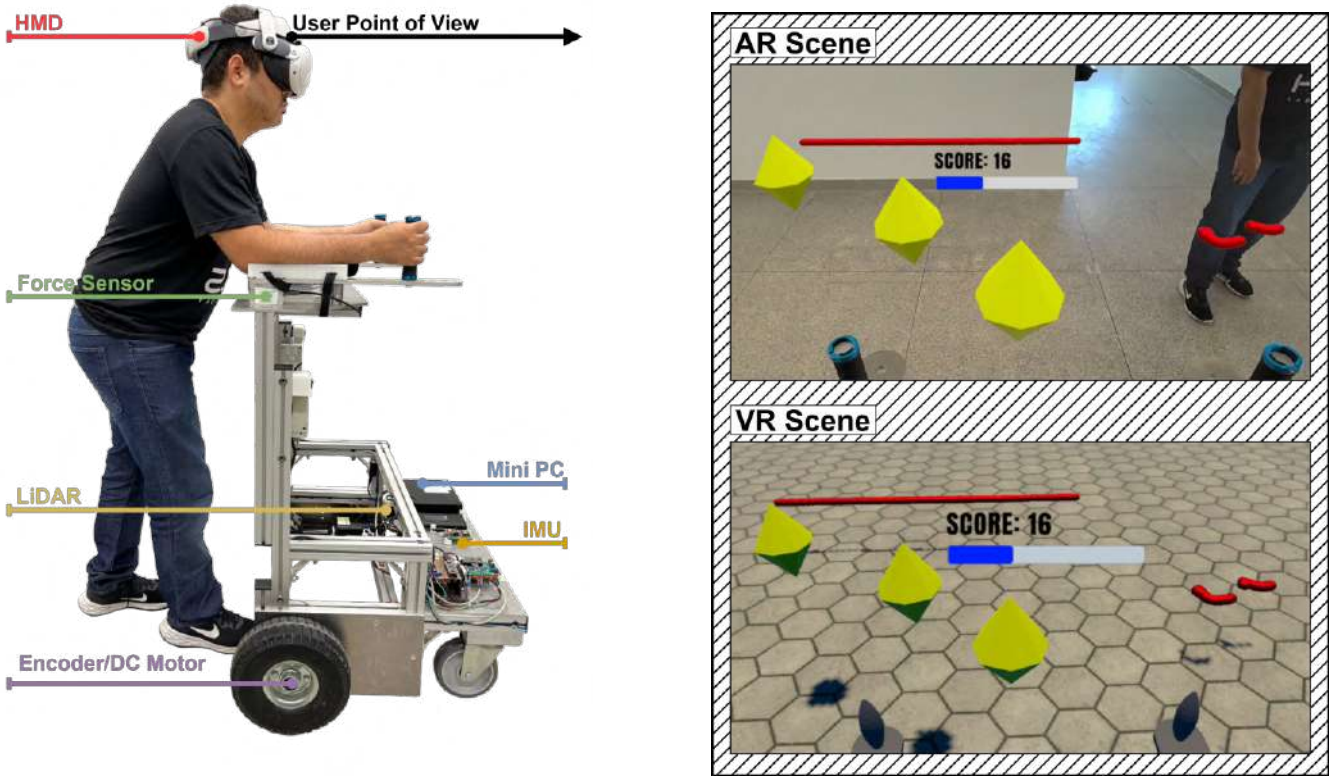
In this context, this paper presents a study aimed at evaluating the differences between the use of AR and VR in smart walker-assisted locomotion. The objective is to compare user performance and experience when performing the same task in different reality-based environments. The paper is structured as follows. Section 2 present the methodology employed for the system's development, Section 3 shows the results and discussion, and Section 4 concludes with the findings and future researches.

II. Methodology

A. Materials

The materials used in this study were the UFES WalkerXR, a robotic assistive device developed at the Human Centered Systems (HCS) research group, and a HMD, the Meta Quest 3 (Meta, USA). This robotic device is an enhanced version of the UFES vWalker [20], which initially featured VR feedback interfaces to aid user navigation. Building on this, the UFES WalkerXR incorporates AR capabilities, enabling the creation of extended reality (XR) environments. This integration combines real-world and virtual elements to provide interactive feedback, enhancing both user safety and navigation support.

As shown in Fig. 1a, the UFES WalkerXR is equipped with two DC motors (Imobras, Brazil), two encoders (Autonics, South Korea), an IMU (Movella, Netherlands), a LiDAR (SLAMTEC, China), two biaxial force sensors (ProCal, Brazil), and a mini PC (DELL, USA). The IMU and encoders work together for odometry and localization, while the motorized and castor wheels assist with propulsion and stability. The LiDAR is responsible not only for obstacle detection and environmental mapping, but it also monitors the distance between the user's legs and the WalkerXR, ensuring safe interaction during movement. The biaxial force sensors capture the user's motion intentions, converting them into linear and angular reference velocities via an admittance controller [21].



Sensor data from these components are processed by a microcontroller (STM32), which handles low-level control functions. The data is then transmitted to the mini PC, running the Robot Operating System middleware (ROS, Version: Humble), to control the UFES WalkerXR's behavior. These components are depicted in Fig. 1a.

B. Augmented and Virtual Reality Environments

The AR and VR environments were developed using Unity, a powerful engine designed for creating games and other applications. Two plugins were utilized within Unity: the Meta XR All-in-One SDK, which offers essential tools for developing immersive experiences in both AR and VR, and the Rosbridge package alongside the ROS# plugin, which enables communication between Unity and the robot's sensor data. The interaction between the UFES WalkerXR and Unity is bidirectional, facilitated by WebSocket protocols from the Rosbridge package. These protocols convert JSON strings to ROS calls and vice versa. Messages received in Unity are converted from JSON format into Unity-readable data, while messages sent from Unity to the UFES WalkerXR are converted back into JSON format before transmission. This setup enables real-time data exchange, enhancing interaction and ensuring enhanced integration between the virtual and physical environments.

By utilizing ROS#, the displacement and sensor readings from the UFES WalkerXR are replicated in Unity through a digital twin, allowing users wearing an HMD to immerse themselves in both AR and VR environments. Fig. 1b presents a comparison of the user's point of view at corresponding moments, recreated across both realities, highlighting the transition between the two experiences.

The UFES WalkerXR displacement occurs by combining its odometry data with a pre-mapped environment created before the experiments. Probabilistic localization is then applied using the Monte Carlo localization approach, implemented via the ROS2 navigation stack [22]. The experiments were also conducted in a well-lit environment to ensure good tracking performance of the HMD, in line with the manufacturer's

(a) (b)

Fig. 1: The UFES WalkerXR and his sensor in (a) and the point of view of the user in the AR and VR environments in (b).

recommendations. These configurations were implemented to avoid tracking issues during the experiments.

The AR environment in Fig. 1b depicts the user collecting yellow virtual items to increase their score, which is represented by the blue bar and the text in the center of the screen. Physical obstacles within a 2-meter radius, such as walls, chairs and people, detected by the LiDAR sensor, are highlighted by red spheres, alerting the user to nearby surroundings. On the other hand, in the VR environment, the environment is completely virtual. The physical device is replaced by its digital twin, while physical obstacles continue to be indicated by red spheres to maintain the user's awareness of the physical world. The virtual items and scoring system remain the same.

The yellow virtual items were evenly distributed in both environments to define a Bernoulli lemniscate path with a α = 2.0, determining the size of the lemniscate. This path is divided into two phases: the first phase consists of a leftward circle, and the second phase is a full circle to the right.

C. Experimental Protocol

To assess the differences between the AR and VR environments using the UFES WalkerXR, fourteen healthy volunteers (20.8 ± 2.6 years) were recruited for the experiment. The volunteers were university students with no prior experience using AR, VR, or the robotic device, and they were unaware of the experiment's objectives. The experiment was approved by the Research Ethics Committee of the Federal University of Espírito Santo under registration number 6.294.101 and all participants provided written informed consent.

Prior to the experiment, all volunteers underwent a familiarization session to learn how to operate the UFES WalkerXR before perform the AR and VR tasks. The volunteers were then randomly assigned to two groups. In the first group (AR-VR), volunteers began by walking for 3 minutes in the AR environment, collecting as many yellow items as possible while following a lemniscate path. After a 15-minute rest, they repeated the task in the VR environment. In the second group (VR-AR), volunteers performed the same tasks but in the reverse order, starting with the VR environment and then the AR environment.

Before and after completing the tasks in both the AR and VR environments, volunteers completed the Virtual Reality Sickness Questionnaire (VRSQ) [23] to assess any symptoms of motion sickness. Also, at the end of each task, the volunteers had to fill out the Physical Activity Enjoyment Scale (PACES), an 18-item questionnaire designed to measure the level of enjoyment during the activity, with scores ranging from 0 to 126 [24]. When the experiment was concluded, the volunteers answered an open-ended question regarding which environment (AR or VR) they preferred and to provide an explanation for their choice.

The focus of this paper was to evaluate the differences between AR and VR across different variables during similar tasks: the presence of motion sickness symptoms (measured by the VRSQ), enjoyment of the activity (measured by PACES), volunteers' self-perception of the preferred environment (through an open-ended question), and distance traveled during the 3-minute session (indicated by the number of yellow items collected).

D. Statistical Analysis

A statistical analysis was conducted to assess whether significant differences existed in the PACES questionnaire scores and in the number of items collected for four categories of comparison. The first and second comparisons were between the AR-VR group and the VR-AR group. The third comparison was between the AR and VR environments (AR vs. VR), regardless of which task was performed first. Lastly, the fourth comparison was between the first and second tasks (T1 vs. T2), independent of whether AR or VR was performed first.

The data from the seven volunteers in both the AR-VR and VR-AR groups were analyzed to determine if transitioning between environments (AR to VR or VR to AR) influenced participant performance or enjoyment. The results from all 14 volunteers were compared in the AR vs. VR analysis to assess overall differences between the two environments. Additionally, the T1 vs. T2 comparison was used to explore potential learning effects and examine how task order might have influenced participant outcomes.

For the statistical analysis, the Shapiro-Wilk test was first applied to assess the normality of the data, and Levene's test was used to verify the homogeneity of variances. Based on these results, a paired t-test was used to compare the means between conditions when the assumptions of normality and homogeneity were met. In cases where the data did not meet the assumptions for parametric tests, the Wilcoxon signed-rank test was used as a non-parametric alternative.

III. Results and Discussions

Analyzing the results in the VRSQ questionnaire, no motion sickness symptoms were detected either before or after the experiment in both AR and VR environments. The reason that may have prevented the presence of these symptoms is the support provided by the UFES WalkerXR during the tasks, which offered increased stability and safety for the volunteers during use. Additionally, the displacement of the volunteers, the UFES WalkerXR, and its digital twin in a synchronized manner within the VR/AR environments, may contribute to the absence of symptoms.

Regarding the number of items collected, only slight variations in the means were observed across the AR-VR, VR-AR, AR vs. VR, and T1 vs. T2 comparisons, as indicated in Fig. 2. Despite these differences, no statistically significant results were found, as shown in Table I.

In the AR-VR group, volunteers collected an average of 69.14 items in the AR task, which decreased by 1.7 items in the VR task. In the VR-AR group, the average number of items collected increased by 6 items when volunteers performed the task in the AR environment. Overall, in the AR vs. VR comparison, volunteers collected an average of 3.9 more items in the AR environment than in the VR environment, though this difference was not statistically significant.

One potential factor contributing to the absence of a statistically significant difference in the increased number of items collected is the limited speed of the UFES WalkerXR. This limitation was intentional, as the device - and smart walkers in general - is specifically designed for individuals with mobility impairments [15]. The restricted speed may have prevented participants from walking faster, which could explain the slight but non-significant increase in items collected in the AR environment compared to the VR environment.

A similar explanation may account for the lack of a statistically significant difference when comparing task order, regardless of the reality environment (T1 vs. T2). Participants collected only 2.1 more items in the second trial (T2), suggesting minimal evidence of a learning effect during the experiment.

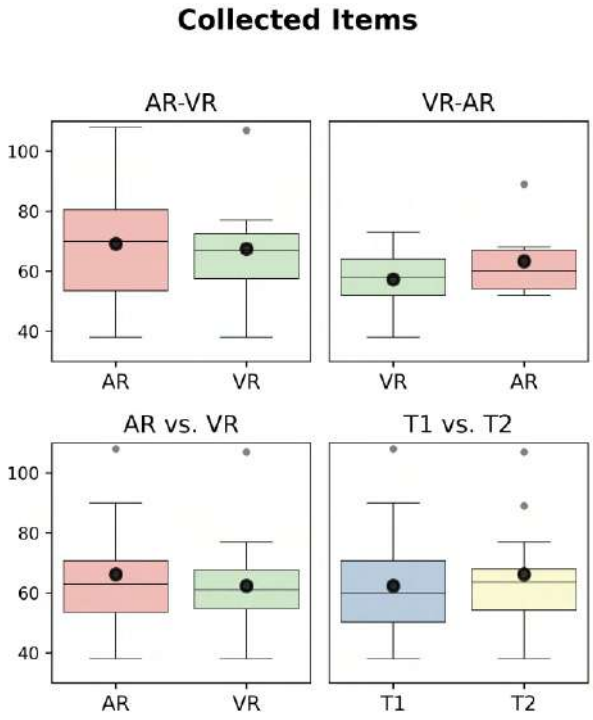


Fig. 2: Boxplots of items collected in the four comparisons. The first and second boxplots represent the AR-VR and VR-AR groups, respectively. The third boxplot shows data from AR and VR, regardless of task order. The fourth boxplot compares the first and second tasks. The red, green, blue, and yellow boxes represent AR, VR, first task, and second task, respectively. The black circle in the middle indicates the mean value.

In the PACES questionnaire scores, larger variations in the

	VR	67.42	38	107	
VR-AR	VR	57.28	38	73	0.24
	AR	63.28	52	89	
AR vs. VR	AR	66.21	38	108	0.22
	VR	62.35	38	107	
T1 vs. T2	T1	63.21	38	108	0.51
	T2	65.35	38	107	

means were observed across the AR-VR, VR-AR, AR vs. VR, and T1 vs. T2 comparisons, as indicated in Fig. 3. Statistically significant differences were found in the VR-AR and AR vs. VR comparisons, as shown in Table II.

In the VR-AR group, volunteers reported an average score of 91.14 in the VR task, which increased by 9.57 points in the AR task, a statistically significant difference. When comparing AR vs. VR, the AR environment received an average score of 99.14, significantly higher than the VR environment's score of 93.85 ($p = 0.03$). These results suggest that volunteers experienced greater enjoyment not only when transitioning from VR to AR but also in the AR environment in general.

The AR-VR group reported an average score of 97.57 for the AR task, which slightly decreased by 1.0 point to 96.57 in the VR task. Although the AR environment received a higher score in this comparison, the difference was not statistically significant. A similar result was observed in the T1 vs. T2 comparison, where the score increased by 3.5 points in T2, but no significant difference was found. This suggests that task order did not significantly affect volunteers' overall enjoyment, measured by the PACES questionnaire.

The results of this experiment suggest that both tasks (AR and VR) provided a high level of enjoyment, as reflected in the PACES scores (mean 99.14 out of 126 for AR and mean 93.85 out of 126 for VR). However, the paired t-test indicate that volunteers had a more favorable experience in AR compared to VR, especially when the AR task followed the VR task.

From the open-ended question, 10 volunteers preferred the AR environment over the VR environment (5 from the AR-VR group and 5 from the VR-AR group). These results align with the higher PACES scores for the AR environment. Participants explained their preferences, with many highlighting that the visibility of the real world in the AR environment offered increased confidence and a stronger sense of safety while operating the UFES WalkerXR. This perception may also account for the slightly higher number of items collected in the AR environment, as participants felt more at ease while walking. On the other hand, those who favored the VR environment often cited the immersive experience of being transported to an entirely different world, which they found particularly enjoyable.

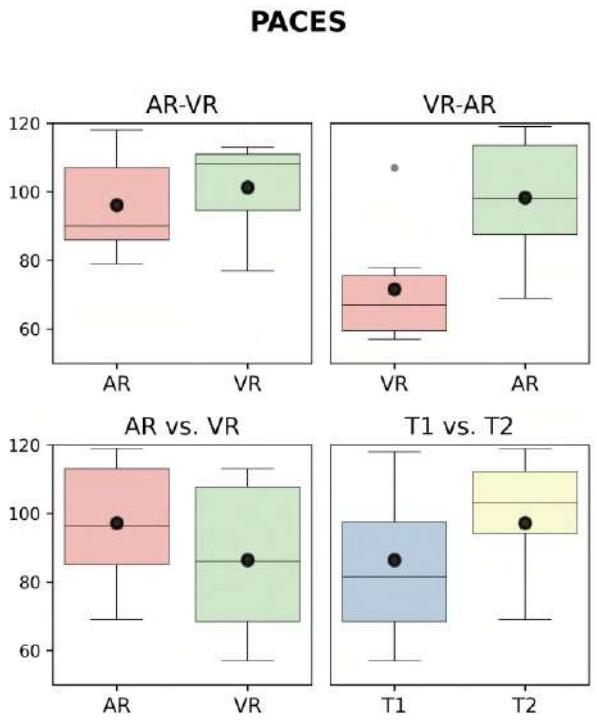

Fig. 3: Boxplots of score in PACES in the four comparisons. The first and second boxplots represent the AR-VR and VR-AR groups, respectively. The third boxplot shows data from AR and VR, regardless of task order. The fourth boxplot compares the first and second tasks. The red, green, blue, and yellow boxes represent AR, VR, first task, and second task, respectively. The black circle in the middle indicates the mean value.

IV. Conclusions and Future Work

This paper evaluated differences in walking assisted by a smart walker (SW) in augmented reality (AR) and virtual reality (VR) environments. Fourteen volunteers, with no prior experience with AR, VR, or the robotic device, were divided into two groups: AR-VR and VR-AR. Both groups performed a task of collecting virtual items while walking with the UFES WalkerXR in both AR and VR environments.

The results showed a slight increase of 6.2% more items collected in the AR environment, although no significant difference was found when analyzing this variable. In terms of enjoyment, volunteers reported greater enjoyment using AR, with a difference that was statistically significant, as measured by PACES questionnaire scores (mean 99.14 out of 126 for AR and mean 93.85 out of 126 for VR). These findings are supported by the responses to the open-ended question, where 10 out of 14 volunteers expressed a preference for AR, citing increased confidence and a sense of safety due to the ability to see the real world.

The main contribution of this paper lies in its exploration of how AR and VR environments affect the walking experience when using a SW. The study demonstrates that while

TABLE II: Descriptive statistics for PACES questionnaire in both AR and VR environments, including the mean, minimum (min), and maximum (max) values, and the p-value from the paired t-test in the four comparisons.

PACES					
		Mean	**Min**	**Max**	**p-value (t-test)**
AR-VR	AR	97.57	84	118	0.76
	VR	96.57	77	109	
VR-AR	VR	91.14	69	107	**0.005**
	AR	100.71	74	119	
AR vs. VR	AR	99.14	74	119	**0.03**
	VR	93.85	69	109	
T1 vs. T2	T1	94.71	74	118	0.17
	T2	98.28	69	119	

both AR and VR offer enjoyable experiences, AR may offer greater enjoyment and confidence. The integration of virtual elements into the real world appears to enhance participants' sense of safety and control during assisted walking. These findings provide promising evidence of AR's applicability in rehabilitation contexts, encouraging future studies to explore its potential benefits for individuals with mobility impairments.

Despite these insights, a limitation of the study is that all participants were a small sample size of young healthy adults, while the UFES WalkerXR is intended for individuals with cognitive and gait impairments, typically older adults. Future research will address this limitation by testing the device with the appropriate target population in real rehabilitation scenarios.

Therefore, these findings will inform future investigations, with plans to evaluate the UFES WalkerXR among volunteers with cognitive and gait impairments. Additionally, further research could explore the long-term benefits of AR and VR technologies in enhancing functional outcomes, quality of life, and motivation in rehabilitation settings.

Enhancing Seated Lower Limb Training: Evaluating an Exergame-Integrated Stepper for Weight-Shift and Muscle Activation

Beycan EMRE *Student Member ICORR*, Ofori SEYRAM, L.W.R. JOSHUA, Ashwin Narayan *Associate Member IEE*, Haoyong YU *Senior Member, IEEE*

***Abstract*— Incorporating technology into exercise-based treatments is a prominent and promising strategy in rehabilitation. This study compares the biomechanics of the seated ankle dorsi-plantar flexion (ADPF) exercises performed without a stepper (WoS) to seated stepping-in-place exercises performed with an exergame-integrated stepper (WS). Does an exergame-integrated stepper device enhance seated lower limb training by providing the weight-shift and muscle activation compared to conventional ankle dorsi-plantar flexion exercises without a stepper? Ten healthy participants completed exercises at 0° and 45° tilted sitting conditions. Weight-shift, and electromyographic (EMG) activity of gait muscles were measured bilaterally during exercises. In the WS condition, weight-shift significantly increased by 72% during 0° sitting and increased by 22% during 45° sitting conditions ($p < 0.05$). EMG activation significantly decreased for all muscles in the WS condition ($p < 0.05$) except in the Rectus Femoris activation (Left RF: $p = 0.646$, Right RF: $p = 0.445$). This initial study combines bilateral training with the exergame-integrated stepper device, demonstrating its potential to provide weight-shift and muscle training for the lower limb. Seated stepping exercises can be implemented on current rehabilitation protocols and developed device can be an alternative to conventional ADPF exercise in stroke rehabilitation.**

I. Introduction

Stroke causes motor impairment, particularly affecting the lower limb, which hinders the mobility and functional independence of individuals [1]. Loss of weight-shifting ability [2] and muscle weakness [3] result in prolonged sitting, either in a standard chair or wheelchair during the early stages of rehabilitation. Seated exercises such as ankle dorsi-plantar flexion (ADPF) are safe and frequently utilized in conventional rehabilitation for early-stage stroke patients due to their accessibility and low risk of falls [4]. However, the ADPF exercise, applied unilaterally, represents a limited approach to addressing comprehensive lower limb rehabilitation. Integrating exergaming technologies with seated stepping exercises that target bilateral lower limb exercises into rehabilitation interventions holds promise for enhanced treatment.

Seated exercises play a pivotal role in stroke rehabilitation [5], particularly for older and/or severely affected patients [6]. During the initial stages of recovery, 41% of post-stroke patients relied on wheelchairs, highlighting the considerable demand for seated rehabilitation interventions [7]. A randomized controlled trial, which implemented seated stepping as an exercise, demonstrated significant improvement in gait performance among stroke patients [8]. Although seated stepping is a safe and promising exercise, its biomechanical effects, such as weight-shift and muscle activation, need further study to support its implementation in seated rehabilitation.

Rehabilitation techniques, including unilateral and bilateral methods, are essential for addressing post-stroke lower limb impairments [9]. Bilateral training demonstrated superior effectiveness compared to unilateral alone in the lower limb [10]. Training on the inactive side proved equally vital in improving stability and walking ability. Moreover, bilateral coordination is crucial for various activities of daily living (ADL), including walking, running, and jumping [11]. Engaging in bilateral exercises activates both the unimpaired and impaired hemispheres, promoting neuroplasticity in the brain [12].

Active patient involvement is essential during the early stages of intensive stroke rehabilitation [13]. Muscle weakness, induces muscle fatigue, thereby constraining the patient's participation in treatment [3] and diminishing the repetitions in exercises [14]. A parallel relationship was observed between fatigue and activation of muscle, indicating that reduced muscle activation could facilitate intensive therapy [15]. Therefore, we aim to compare ADPF and stepping exercises based on muscle activation, as this aspect still needs to be more adequately understood.

Weight-shift, the ability to distribute body weight efficiently and effectively, is fundamental to maintaining balance and postural stability during various ADLs [16]. However, post-stroke individuals commonly exhibit deficits in weight-shift capacity, which can further compromise their balance and mobility [17]. Weight-shift training approaches, including both static and dynamic exercises, have occurred as potential strategies to enhance postural control [18], weight-bearing symmetry [19], balance [20], and functional mobility [21] in individuals

recovering from stroke. The existing literature lacks comprehensive investigations of alternative methods for seated weight-shift training.

Clinical trials have demonstrated the safety and efficacy of ADPF and stepping exercises in stroke and elderly individuals. However, a comprehensive analysis and comparison of their biomechanical properties currently need to be included in the academic literature. Our study evaluated and compared the biomechanics of ADPF and stepping exercises based on weight-shift and muscle activity under sitting at 0°and 45° tilted conditions. We hypothesized that an exergame-integrated stepper during seated stepping exercise would offer lower muscle activation and facilitate wider weight-shift in the lower limb compared to ADPF exercise.

II. Materials and Methods

A. Development of the Exergame-Integrated Stepper

The stepper device utilized in this investigation (see Fig. 1) has been adapted from the commercially available MS100 stepper (Decathlon, Singapore). Two sandals are attached to footplates that move reciprocally through a mechanical connection. This device facilitates stepping training, engaging the left and right lower limbs. For improved portability, the electronic components have been positioned at the front. The device's left joint has been adjusted with a stabilizer to integrate a magnetic rotary encoder for measuring movement angles. The data from the sensor were read using a custom-made STM32F446 microcontroller and transmitted to the PC over a serial port.

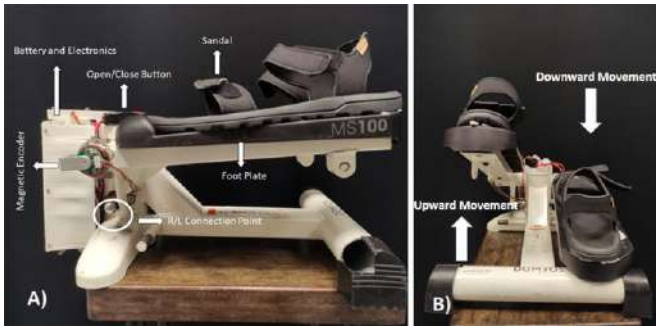

Figure 1. Stepper Components (A) and Movements of the Stepper (B)

The 3D farmer exergame was created utilizing Unity-3D and integrated with the device to provide feedback. The main objective of the exergame is to guide participants in performing bilateral stepping exercises by synchronizing their movements with on-screen targets. During each cycle, participants must time their stepping movements to 'catch' virtual animals appearing alternately on the leftmost and rightmost sides of the screen, each lasting for 2 seconds. The angular data acquired from the magnetic encoder served as the basis for controlling the avatar. Specifically, the angle data were mapped to control the left (Figure 2A) and right (Figure 2B) movements of the avatar. The game's design ensures that players must utilize the entire motion of the device to successfully catch the appearing animals, as shown in Figure 2.

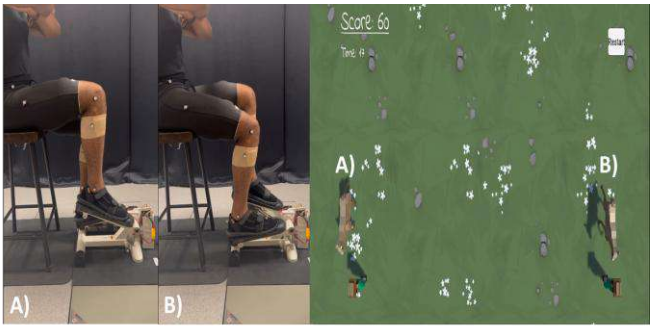

Figure 2. Exergame and stepping exercise interaction seated position. A) Avatar moves left when left foot goes down, B) Avatar moves right when right foot goes down.

B. Participants

Ten healthy volunteers (5F, 5M, mean ± SD, age: 24.8 ± 2.8 years, height: 167.5 ± 8.7 cm, weight: 70.2 ± 16.8 kg, BMI: 24.5 ± 3.9 kg/m2) were enlisted to confirm the viability and effectiveness of the bilateral stepping exercise for rehabilitation. Inclusion criteria were (a) aged 21-40, (b) no disability or chronic lower limb disease, (c) completion of the PAR-Q questionnaire that shows no restrictions or contraindications for physical activity [22], and (d) refrained from engaging in intense physical activity before the study. The recruitment of subjects, information sheet, permission form, data form, and experimental questionnaire received approval from the National University of Singapore Institutional Review Board (NUS-IRB-2022-9) on November 24, 2022.

C. Data Collection

During the experiment, two types of data were gathered. First, the vertical component of the ground reaction force (GRF) from both the left and right sides represents the vertically applied force (Fz). Second, electromyographic activity (EMG) depicts muscle status through electrical signals in the lower limb.

The GRF data were captured using two adjacent AMTI force plates (Advanced Mechanical Technology Inc., MA, USA) embedded parallel in the floor. In the WoS condition, each foot was placed directly on an individual force plate, allowing direct measurement of the vertical GRF applied by each side. In the WS condition, the stepper device was positioned on top of both force plates, meaning that force applied by one foot to the stepper could be partially transmitted to the opposite side. This setup was taken into account during the analysis of weight-shift measurements.

Maximum voluntary contraction (MVC) and EMG activation of lower limb muscles: Rectus Femoris (RF), Tibialis Anterior (TA), Biceps Femoris (BF), Gastrocnemius Medialis (GM), and Soleus was recorded using ten Trigno™ Sensor (SC-F03) wireless EMG sensors (Delsys, USA) bilaterally. The skilled

physical therapist placed EMG sensors to ensure correct positioning based on the SENIAM guide [23].

D. Experimental Protocol

The selected exercises for this study were bilateral ADPF (Fig. 3A, 3C) and stepping performed by an exergame-integrated stepper (Fig. 3B, 3D). Participants performed exercises seated at two different tilt angles (0° and 45°). To ensure a consistent initial knee angle across participants, seat height was adjusted based on individual leg lengths. This helped maintain a standardized starting posture despite differences in lower limb dimensions. Participants completed the exercises seated with their feet positioned on either the force plates or the stepper. To minimize compensatory upper body movements, they were instructed to keep their arms crossed over their chest during trials. Figure 3 images are posed to illustrate the experimental setup.

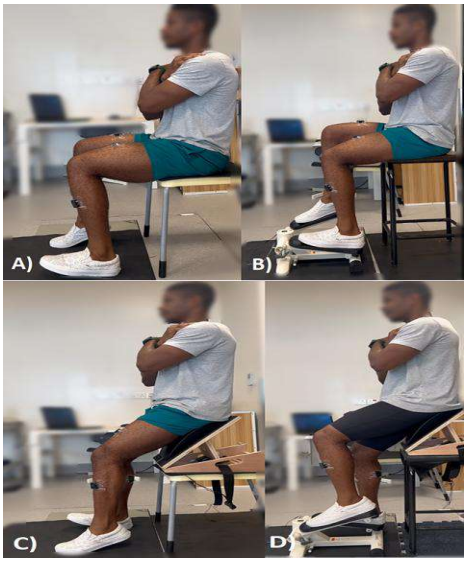

Figure 3. Exercise with stepper and without sitting at 0° ((A), ((B)) and 45° ((C), ((D)) tilted positions.

The first trial involved a bilateral ADPF exercise called without stepper (WoS). Participants performed bilateral ADPF exercises at 30 beats per minute (bpm). They were instructed to achieve maximum dorsiflexion and plantarflexion during each repetition while synchronizing their movements with the metronome beat. The exercise comprised two sets of 10 repetitions. Overall, each trial lasted 30 seconds, including 5 seconds waiting at the start, 20 seconds doing exercise, and 5 seconds waiting at the end.

In the subsequent second trial, participants adhered to the same sets and repetitions as in the first trial, but with an exergame-integrated stepper device. In the exergame, participants were requested to catch animals that appeared on both sides of the screen alternatingly at two-second intervals using the stepping exercise. The two-second interval of the exergame matched the 30 beats per minute (bpm) to ensure comparability with WoS exercise.

E. Data Analysis

The collected Fz data were filtered with a third-order low-pass Butterworth filter at 100 Hz. The filtered Fz data of each subject were normalized based on their total body weight. Afterward, MATLAB (R2023a) was utilized to apply a Butterworth (low-pass sixth order) filter with a cutoff frequency of 1 Hz to extract the envelope of the normalized force data. This process was iterated for each subject's force data, then averaging the first and second sets.

Weight-shift analysis was performed by calculating the differences between the peak Fz values of the right and left sides, as shown in Fig. 4 (A). For each of the ten repetitions, the peak Fz value of the right side during its downward phase was labeled as R1, and the lowest Fz value of the left side during its upward phase was denoted as L1. We employed a modified version of Sato and Heise's method to calculate weight-shift, tailoring it to our specific experimental conditions and objectives [24]:

$$WS = \frac{1}{N}\sum_{k=1}^{N}|(R_k - L_k)|$$

where WS is the average weight shift, R_k and L_k represent the peak vertical GRF values for the right and left sides in each repetition, and N is the total number of repetitions per trial. By subtracting the corresponding Fz values and averaging them across the repetitions, an overall measure of weight shift bilaterally during the stepping exercise was obtained. Then, weight-shift analysis was conducted by first computing the peak weight shift values for each trial separately and then averaging these discrete values across the two sets. This approach ensured that variations in timing did not artificially influence the results.

The raw MVC and EMG data underwent band-pass filtering with Butterworth (second order, 10-450 Hz) [25]. Subsequently, the filtered EMG data were normalized based on their corresponding peak MVC values. A low-pass Butterworth filter (fourth-order, 3 Hz) was then employed to generate the envelope. Then, the first and second sets were averaged.

Statistical analysis was conducted using MATLAB (R2023a). The Shapiro-Wilk test was utilized to assess normal distribution of the data, revealing a lack of normal distribution. Wilcoxon signed-rank test was employed to compare the mean values using the α-level of 0.05.

III. Results

The study involved ten (5M, 5F) healthy participants engaging in ADPF and stepping exercises. The ADPF referred to as the 'Without stepper' condition, was compared with the stepping exercise performed with an exergame-integrated stepper device. The analysis focused on weight shift and muscle activation under both 0° and 45° tilt conditions in the lower limb.

A. Weight-shift

Figure 4B illustrates a bar graph representing the average weight-shift without and with stepper conditions under 0° and 45° tilt. Our results demonstrate a significant increase of 72% at 0° tilt and an increase of 22% at 45° tilt in the WS compared to WoS condition ($p < 0.05$). This substantial shift was apparent in the transition from 0° to 45° tilted sitting positions, exhibiting a significant increase of 188% ($p < 0.01$) in the WoS and a significant increase of 93% ($p < 0.01$) in the WS conditions.

B. Muscle Activity

Figure 5 displays electromyographic (EMG) recordings of lower limb muscles, specifically RF, TA, BF, GM, and Soleus, under both 0° and 45° tilt conditions.

All muscles engaged in bilateral exercises exhibited decreased muscle activation in the WS compared to WoS conditions. The reduction in muscle activation for all muscles was statistically significant ($p < 0.05$), except for rectus femoris (Left RF: $p = 0.646$, Right RF: $p = 0.445$) at 0° and 45° tilt positions. The results demonstrate a direct influence of the exergame-integrated stepper in reducing muscle activity, especially on the main ADPF muscles, TA, GM, and Soleus. Detailed results and p-values for each muscle are shown in Table 1.

Table 1. With-without stepping EMG differences and p-values of lower limb muscles. Percentage differences indicate changes in EMG amplitude normalized by maximum voluntary contraction (MVC).

Muscles	0° Seated % Difference (p-value)	45° Tilted % Difference (p-value)
Left RF	7% (p = 0.646)	%4% (p = 0.646)
Right RF	13% (p = 0.445)	4% (p = 0.445)
Left TA	75% (p<0.01) **	71% (p<0.01) **
Right TA	80% (p<0.01) **	78% (p<0.01) **
Left BF	17% (p = 0.05) *	26% (p = 0.05) *
Right BF	22% (p = 0.05) *	40% (p = 0.05) *
Left GM	48% (p<0.01) **	48% (p<0.01) **
Right GM	58% (p<0.01) **	50% (p<0.01) **
Left Soleus	%56 (p<0.01) **	%32 (p<0.01) **
Right Soleus	%65 (p<0.01) **	%26 (p<0.01) **

'*' denotes ($p < 0.05$), while '**' denotes statistical significance ($p < 0.01$).

IV. Discussion

We assessed the biomechanics of ADPF and stepping, performed with a developed exergame-integrated stepper device, exercises, and compared weight-shift and muscle activity variables.

Rhythmic bilateral training of the lower limb has emerged as a promising approach to stroke rehabilitation [26]. Studies have shown the benefits of synchronizing exercises with visual and auditory cues, such as metronome beats and exergames [27, 28]. Moreover, the majority of ADLs necessitate the bilateral use of the lower extremities, Jeon and Hwang (2018) [10] demonstrated the superiority of the bilateral approach over unilateral methods in post-stroke lower limb rehabilitation. Our results show that a developed exergame-integrated stepper can provide rhythmic and bilateral lower-limb stepping exercises. Thus, exergame-integrated stepper training can be a promising approach to address deficits in motor coordination, enhancing functional mobility, and ADL training for stroke survivors.

After a stroke, individuals commonly encounter challenges in bearing weight on their affected limb [29-31]. Mizrahi et al. indicate that a significant majority (79% to 87%) of stroke survivors bear less weight on their affected limbs during static and dynamic activities [32]. Furthermore, Goldie et. all, reported that healthy individuals exhibit a mediolateral weight-bearing ability of 95%, whereas stroke patients demonstrate 65% [33]. In our study, we observed that the weight-shift was greater in the condition involving the stepper compared to the condition WoS, indicating that the integration of the stepper device promotes a greater weight-shift. Cheng, et. all, have proposed that the uneven distribution of body weight during rising from a chair may contribute to falls in stroke survivors [34]. Aruin et. all, showed that creating a height difference between the right and left sides facilitates weight shift in the lower limb [19]. Our results were parallel with this and suggest that bilateral ADPF exercise induces weight shift, however, the developed exergame-integrated stepper, which has a 10 cm height difference between the right and left sides, provides more weight shift.

Muscle weakness is commonly observed during acute-stage post-neurological diseases, leading to neuromuscular fatigue, limiting patient attendance, and exercise repetitions [3, 35]. Ducrocq and Blain, observed a connection between escalating neuromuscular fatigue and heightened exercise intensity, as evidenced by EMG amplitude during exercise [15]. In parallel with this, reducing muscle activation plays an important role in facilitating intensive treatment in rehabilitation [36]. Our findings indicated that the stepper device could provide lower EMG activation than the WoS condition. Specifically, during the stepping exercise with the exergame-integrated stepper, significantly lower EMG activation

was observed in the TA, GM, and Soleus muscles except RF, which was lower but not significant. The stepper's capability to synchronize the movement of both sides, enabling bilateral assistance, may primarily contribute to the observed reduction in muscle activation. Thus, this synchronization mechanism of the stepper can alleviate the challenge of exercising against gravity, resulting in lower EMG activation.

There are several limitations to this study. Firstly, the sample size was small, consisting of only ten healthy participants, which could potentially restrict the generalizability of the findings. Secondly, due to the limited time frame, each condition involved completing 2 sets of 10 repetitions, which may restrict the depth of analysis and the ability to capture the nuanced effects of the measurement. Nevertheless, our results can be transferred to stroke rehabilitation, as seated stepping exercises can be utilized at 0° seated for early-stage rehabilitation and at 45° seated for stroke patients who are capable of sitting in a tilted position. Future studies should evaluate seated stepping's impact on functional outcomes in stroke patients or the elderly over extended exercise durations.

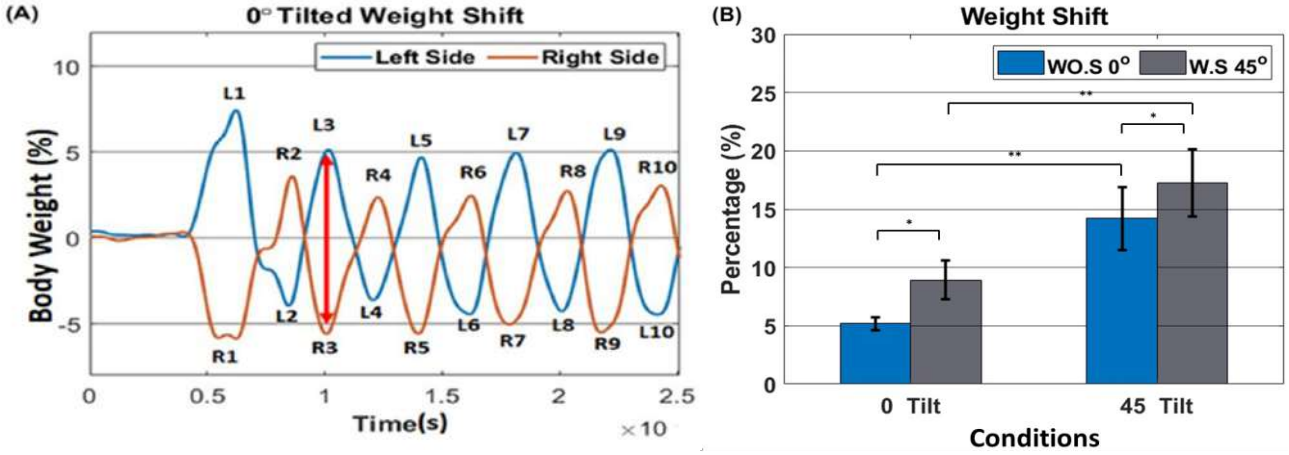

Figure 4. Sample of subject 7's weight-shift data on 0° Tilted Stepper condition (A), Average weight-shift of all subjects under conditions; 0° and 45° Tilted. (B). '*' denotes ($p < 0.05$), while '**' denotes statistical significance ($p < 0.01$).

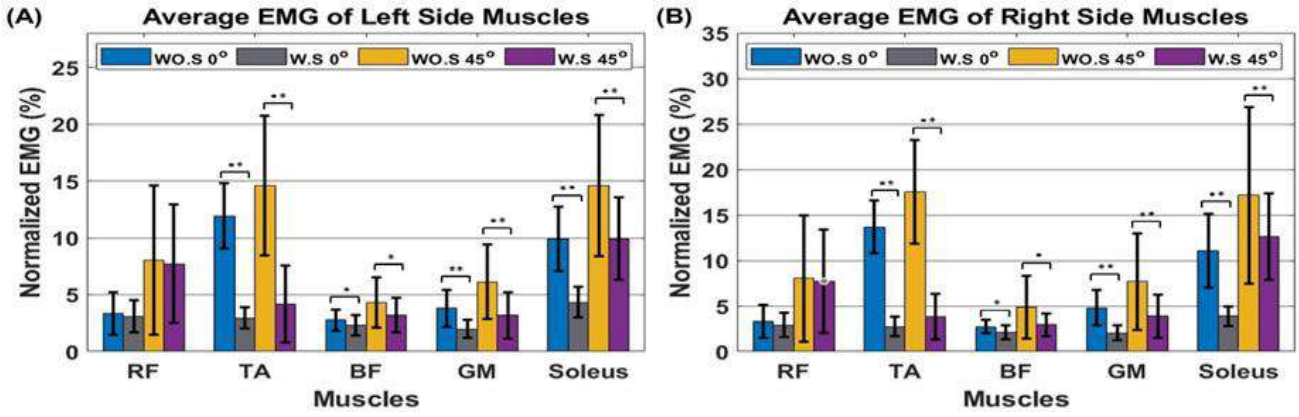

Figure 5. Average EMG graphs for the right (R) and left (L) sides under two conditions (WO. S: without stepper, W.S: with stepper) at 0° and 45° tilts. '*' denotes ($p < 0.05$), while '**' denotes statistical significance ($p < 0.01$).

V. Conclusion

This study is the first to explore the biomechanics of seated ankle dorsi-plantar flexion (ADPF) and exergame-integrated stepping exercises based on weight shift and muscle activation in the lower limb. Our study clearly contributes to rehabilitation literature by highlighting the potential advantages of incorporating bilateral seated stepping exercises, demonstrating their positive impact on lower limb weight shift and muscle training. We recommend implementing stepping exercises in future clinical trials to thoroughly investigate their impact on functional outcomes, including walking speed, balance, and activities of daily living (ADL) capacities.

VI. Acknowledgments

This work was partially supported by a Promotion of Doctoral Studies scholarship from the Singapore International Graduate Awards (SINGA). The study sponsor had no involvement in the study design, data collection, analysis, interpretation, manuscript writing, or the decision to submit the manuscript for publication. Effect of Robotic Assistance on the Synergistic Organization of Reaching Movements

Indya Ceroni[1,2], Florencia Garro [1] and Marianna Semprini[1]

***Abstract*— Wearable robotic devices for rehabilitation have gained particular interest as they can improve the intensity and repeatability of rehabilitative treatments, leading to better rehabilitation outcomes. However, objective characterization of the effects of robotic interventions is still missing. Here we leverage on muscle synergies theory to provide a quantitative assessment of the effects of an upper limb exoskeleton on the organization of reaching movements in healthy individuals. For this, we computed muscle synergies from 20 subjects performing a standardized reaching task. We found that the robotic assistance does not disrupt the physiological structure of reaching movement but modulates it: a higher number of motor modules are necessary to explain the structure of reaching when using the exoskeleton. We derived an objective analysis of the implications of the more complex and fragmented movement strategy, which can potentially inform the design and testing of robotic prototypes, with the ultimate aim of improving technology-supported rehabilitation interventions.**

I. INTRODUCTION

Motor impairments induced by neurological disorders have a severe impact on the independence and quality of life of affected subjects [1]. In this context, numerous technological solutions have been introduced, including robot-assisted rehabilitation systems designed to aid recovery [2]. These devices operate either by driving an end effector or by being wearable, allowing movement within them [3]. However, despite advancements in mechatronic design and control, these devices can influence how motor actions are performed, making it crucial to monitor differences with unassisted movements. To accurately evaluate how assistive devices influence motor control, we need objective and reliable measurements of motor performance, along with standardized tasks enabling comparisons of motor output across different contexts [4].

Muscle synergies are defined as coordinated patterns of muscle activation, which the central nervous system uses to simplify motor control [5]. They have been employed to investigate the neural basis of motor control [6] and quantify the effect of neurological diseases on motor production [7].

Here, muscle synergies are used to assess whether and how the assistance provided by the Float upper limb exoskeleton [8] affects the modular organization of physiological reaching movement. This investigation is done by exploiting a standardized benchmarking platform, named *NeBULA* (i.e., Neuromechanical Biomarkers for Upper Limb Assessment), specifically designed to evaluate and compare the effects of different robotic technologies for upper limb rehabilitation [9]. NeBULA implements a standardized reaching task framework to extract neuromechanical biomarkers derived from electromyography (EMG) and electroencephalography (EEG), allowing a reliable and repeatable quantification of the effects of different types of robotic assistance on motor control during functional tasks [9].

This study aims to: (i) characterize the synergistic organization of reaching in unassisted and in exoskeleton-assisted movements; (ii) investigate modulation of level of assistance on synergy recruitment. From these findings, we will derive implications for further iterations of exoskeleton design.

II. MATERIALS AND METHODS

A. Participants

20 healthy right-handed subjects were enrolled in the study (10 male, 10 female, age 31.6+/-6.2 years old). Subjects with any chronic inflammatory diseases, orthopedic conditions or neuro-muscular disorders were excluded from the study. All participants signed an informed consent and the experimental procedures were approved by the local ethical committee (CER Liguria: 784/2022 - DB id 12044).

B. The Float upper limb exoskeleton

Float has been developed at the Rehab Technologies Lab of IIT to support the rehabilitation of the shoulder complex in orthopaedic and neurological subjects [8]. It consists of five rotational joints, with each degree of freedom representing a movement of the shoulder complex. Float features a model-based feed-forward compensation of friction at each joint. This 'transparency mode' also provides active assistance at the level of joint 4, which helps the user to flex the shoulder and perform upward vertical motion of the arm. The assistance can be set at two different levels: low and high. The gains for these assistance levels are fixed and were calibrated empirically based on the average weight of a human arm as described in [8].

This work was supported by the Italian Ministry of Research, under the complementary actions to the NRRP "Fit4MedRob - Fit for Medical Robotics" Grant (PNC0000007). It is also funded by the European Union - NextGenerationEU and by the Ministry of University and Research (MUR), National Recovery and Resilience Plan (NRRP), Mission 4, Component 2, Investment 1.5, project "RAISE - Robotics and AI for Socio-economic Empowerment" (ECS00000035) and by the Istituto Nazionale Assicurazione Infortuni sul Lavoro (INAIL) (Project grant number PR19-RR-P2 - ROBO-GYM).

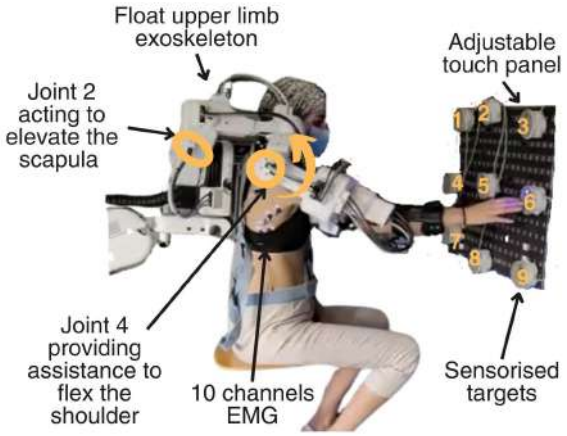

Fig. 1. Setup of the experiment, featuring the Float upper limb exoskeleton providing two different levels of assistance for shoulder flexion and an ad-hoc adjustable touch panel endowed with nine sensorized targets. 10 channels of surface EMG are synchronized with the touch panel.

C. Experimental design

The experimental procedure followed the standardized framework NeBULA [9]. During the experiment, participants were seated in an adjustable chair in front of a touch panel with nine targets arranged to allow full arm extension (Fig. 1). The targets were positioned to adapt to the user's anthropometric measures. Each target has a light indicator that cued the participant to reach that specific target. The time instant in which the participant reached the target was recorded thanks to the capacitive layer.

The experimental task involved 10 repetitions of reaching towards each of the 9 targets in a pseudorandomized order (Fig. 2 A). Each participant repeated the task three times: without wearing Float (free condition), wearing Float providing low assistance (low condition), and wearing Float providing high assistance (high condition). The order of assistance levels was randomized across participants.

Surface EMG signals were recorded from 10 muscle groups of the right upper limb: 1) biceps brachii (long head), 2) anterior deltoid, 3) middle deltoid, 4) posterior deltoid, 5) triceps brachii (long head), 6) upper trapezius, 7) medial trapezius, 8) lower trapezius, 9) pectoralis major, and 10) brachioradialis. EMG was acquired at 1 KHz, using the Cometa Waveplus System, synchronized with the panel.

D. EMG preprocessing

EMG was first segmented in the reaching phase. For each epoch, we applied a band-pass filter between 20 and 350 Hz (4th order Butterworth with zero-phase distortion) and rectified. Then, we applied an ad-hoc median filter, and values over 600 μV were substituted with the median in a 50-sample sliding window. In addition, we applied a 4th order Butterworth low-pass filter at 5 Hz with zero-phase distortion to obtain the envelope of the signal. We normalized the EMG envelopes taking the maximum value achieved for each muscle in the complete dataset [10], [11]. Since the task was self-paced, we time-scaled all epochs to the same duration of 500 samples (0.5 s) [12].

E. Synergies extraction

First, we concatenated the EMG data from all muscles. Then, we used the non-negative matrix factorization algorithm (NNMF) [13] to factorize the concatenated EMG matrix into N vectors of 10 constant weights w_i and N time-varying coefficients $c_i(t)$

$$EMG(t) = \sum_{i=1}^{N} c_i(t) w_i \tag{1}$$

Each spatial synergy w_i is a set of 10 weights describing how muscles synergistically couple to each other to produce movements. The coefficients of activation $c_i(t)$ describe how much each synergy is active during movement.

To investigate how the exoskeleton modulates reaching movements, we extracted muscle synergies for each subject using two different datasets. First, we applied NNMF in the free condition to identify the muscle synergies that characterize the physiological reaching movement performed without any external assistance ("free dataset synergies"). Then, we considered all conditions together to characterize the modularity of the entire experimental paradigm ("whole dataset synergies"). During every synergy extraction procedure, we implemented NNMF with alternating least squares and repeated it 100 times starting from new random values to avoid local minima [11].

To select the appropriate number (N) of free and whole dataset synergies for each subject, we repeated the NNMF extracting a number of synergies ranging from 1 to the number of EMG channels. For each factorization, we computed the percentage of variance of the original EMG data that was reconstructed by the extracted synergies, as $R^2 = 1 - SSE/SST$, where SSE is the sum of squared residuals and SST is the sum of the squared differences with the mean EMG vector [10].

For each subject, we selected the smallest number of synergies for which the variance accounted for (R^2 or VAF) was equal to or greater than 0.9 (i.e., 90% of data variability is explained by the combination of extracted muscle synergies and coefficients of activation).

We then averaged the obtained number of synergies across subjects to compute an average number of free (N_{free}) and whole dataset synergies (N_{whole}). Finally, NNMF was applied for each subject, imposing the extraction of N_{free} free dataset synergies from the free condition and N_{whole} whole dataset synergies from the entire experiment.

F. Synergies averaging

To represent the modularity shared by the 20 participants, we averaged spatial synergies across subjects. A preliminary clustering procedure was needed as not all subjects shared the same synergies, and also the shared synergies could be extracted in different order across different subjects due to the random initialization of the NNMF algorithm. The

clustering procedure implemented was inspired by [12] and was built on the identification of the synergies shared among at least half of the participants. Synergies were grouped using a measure of similarity based on the cosine of the angle between the vectors representing the spatial synergies, as in [10]. Such similarity measures range from 1 (identical synergies) to 0. Briefly, we divided free and whole dataset synergies into 10 clusters based on the most expressed EMG channel in each synergy. We explicitly excluded synergies of the same subject in the same cluster. Then, we selected clusters containing at least 10 synergies. We averaged the selected clusters to obtain a set of "reference synergies".
We then regrouped single subjects' synergies based on their cosine similarity with the reference synergies, excluding single subjects' synergies with less than 0.5 similarity with one of the reference synergies.
Synergies were finally averaged to obtain a set of averaged free and whole dataset synergies. The first represented the modularity of the physiological anterior reaching movement, and the second the modularity of the entire experimental protocol, characterizing the effect of robotic assistance.

G. Computation of activation coefficients

Activation coefficients c_i describe how each of the averaged free and whole dataset synergies is enrolled during each repetition of reaching of the entire experiment. We computed the activation coefficients of the averaged free and whole dataset synergies at the subject level for movements performed in all the conditions (free, low, and high). For this, we calculated the Moore-Penrose pseudoinverse [14] of the averaged synergies and computed the dot product of the pseudoinverse with the matrix of concatenated EMG of each subject, as in [12]. We averaged across repetitions to obtain the activation coefficients for each subject, which ranged from 0 to 1 and were distributed over 500 temporal samples.

III. Results

A. Characterization of spatial muscle synergies

During the first computation of free and whole dataset synergies, we respectively extracted an average of 4 free dataset synergies (3.75 ± 0.97) and 5 whole dataset synergies (4.5 ± 0.83) per subject, with an average VAF of 0.93.

The free and whole dataset synergies extracted from each subject were grouped based on the most expressed muscle within each synergy (Fig. 3). For free dataset synergies, 3 clusters contained more than 10 synergies and thus were selected to compute the reference synergies, while for whole dataset synergies we selected 6 (Sec. II-F).

The free dataset synergies of single subjects (80 in total) were then grouped in 3 clusters, based on their similarity with the three reference synergies (Fig. 3). During this procedure, 2 synergies out of 80 (2.5 %) were excluded as their cosine similarity with the reference synergies was below 0.5. Similarly, the whole dataset of synergies of single subjects (100 in total) was grouped in 6 clusters based on their similarity with the 6 reference synergies, and 13 synergies (13 %) were excluded.

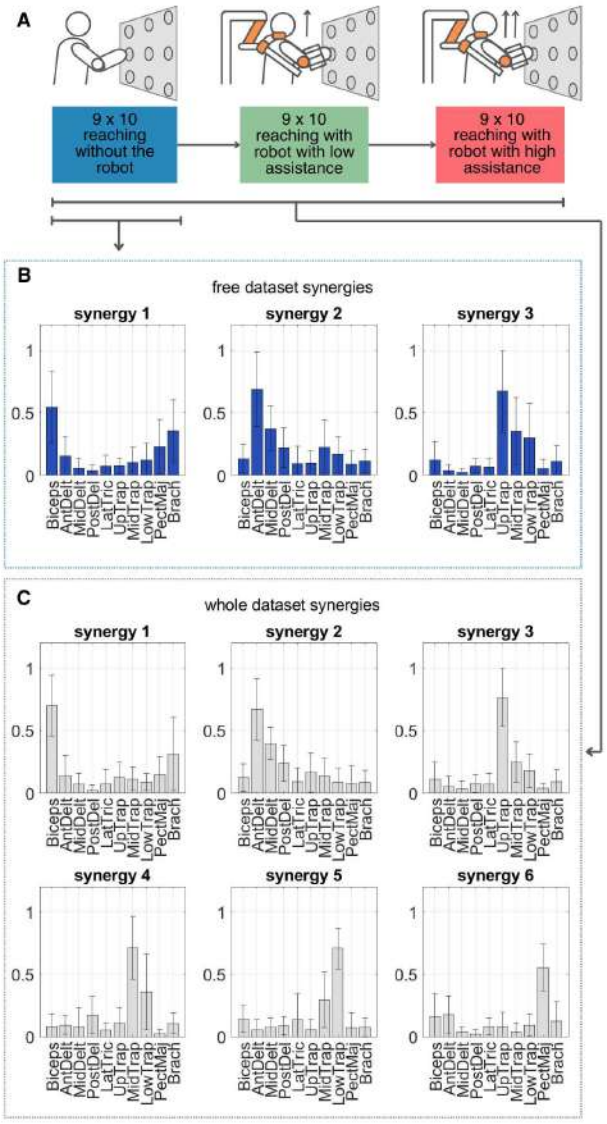

Fig. 2. A) Experimental paradigm involving 10 repetitions of reaching movement towards each of the 9 targets in a pseudorandomized order. The task is repeated without the robot and with the robot with low and high assistance. B) Free dataset synergies obtained considering only repetitions executed without the robot. C) Whole dataset synergies obtained considering all reaching movements of the entire experimental paradigm.

Free and whole dataset synergies were averaged within each group to obtain 3 free and 6 whole dataset synergies representative of the modularity shared by the 20 healthy subjects that participated in the study. The three averaged free dataset synergies (Fig. 2 B) are extremely similar to the first three whole dataset synergies (Fig. 2 C). The values of cosine similarity between the two sets of synergies are shown in Fig. 4, which exhibits high similarity between synergy 1 of free (s1_free) and whole (s1_whole) dataset (0.975) as well as between synergy 2 of free (s2_free) and whole (s2_whole) dataset (0.9861) and synergy 3 of free (s3_free) and whole (s3_whole) dataset synergies (0.9751). For synergies 4 of the whole dataset (s4_whole) high similarity values are obtained

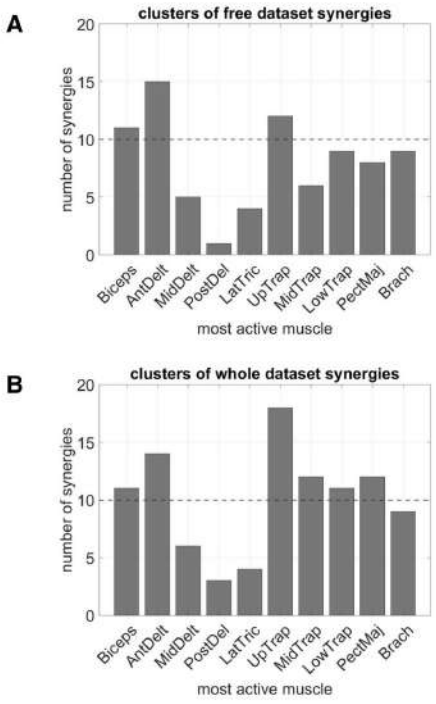

Fig. 3. Clusters of synergies based on the most active EMG channel inside the synergy. A) Clusters of free dataset synergies. B) Clusters of whole dataset synergies.

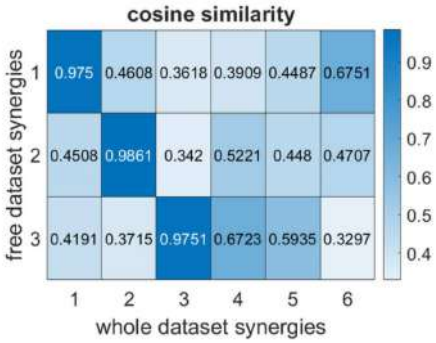

Fig. 4. Cosine similarity between the averaged free and whole dataset synergies. Cosine similarity is computed as the dot product of the synergies vectors divided by the product of their magnitude.

with synergies s3_free (0.6723) as well as for synergy 5 of the whole dataset (s5_whole, 0.5935). Synergy 6 of whole dataset (s6_whole) had highest similarity with s1_free (0.6751).

For both s1_free and s1_whole the two most expressed muscles are biceps and brachioradialis. These two muscles work synergistically to produce the flexion of the elbow; thus, we can consider these synergies as representative of elbow flexion. In s1_free also the pectoralis shows some activation, while in s1_whole the weight of the pectoralis is much lower. This can be due to the fact that for the whole dataset, the pectoralis is mostly expressed in s6_whole, which indeed shows good similarity (0.6751) with s1_free. s2_free and s2_whole mainly express the anterior and middle deltoids that are responsible for shoulder flexion and shoulder abduction, respectively. s3_free and s3_whole express a significant activation of the trapezius muscle with the predominance of the upper trapezius, which elevates the scapula to ensure a full range of motion for arm elevation. The less significant contribution of middle and lower trapezius in s3_whole with respect to s3_free can be the results of the presence of two additional synergies: s4_whole and s5_whole. s4_whole mainly expresses the middle trapezius that retracts the scapula, while s5_whole shows greater contribution of lower trapezius, which medially rotates the scapula.

B. Characterization of activation coefficients

Coefficients of activation for each averaged free and whole dataset synergy are depicted in Fig. 5 for two representative movements, i.e., towards target 1 and towards target 5.
We divided the time span of 500 samples into 3 equal segments, and we computed the integral of the activation coefficients over each segment. Wilcoxon signed rank test was performed on the estimated integrals to test for any statistical difference between the activation coefficients of each synergy in the free, low, and high assistance conditions. The results were corrected for multiple comparisons following the Bonferroni criterion. Horizontal blue/gray brackets above the temporal coefficients in Fig. 5 indicate the presence of a statistically significant difference across conditions in that specific time interval.
The activation coefficient of s3_free in the initial phase of movement towards target 1 is statistically higher during the high condition with respect to the free condition (Fig. 5 A). The same was found for movements towards target 2. A similar statistical difference between free and high condition was found for s3_free in the final phase of movement towards target 9.
In the last phase of movement towards target 5, the activation coefficient of s3_whole is significantly higher when wearing Float with high assistance with respect to the free movement (Fig. 5 B).
Table I reports the statistically significant differences found for the free vs. high condition, while no differences were found neither for the free vs. low condition nor for the low vs. high condition.

TABLE I
COMPARISON OF ACTIVATION COEFFICIENTS

Synergy	Target	Phase of movement	Conditions	p-value
s3_free	1	initial	free vs high	0.00039
s3_free	2	initial	free vs high	0.00052
s3_free	9	final	free vs high	0.00045
s3_whole	5	final	free vs high	0.00039

IV. DISCUSSION

With this analysis, we obtained two sets of spatial synergies that represent the common modularity among all subjects. We found that: (i) the synergistic structure of reaching is preserved during exoskeleton-assisted movement;

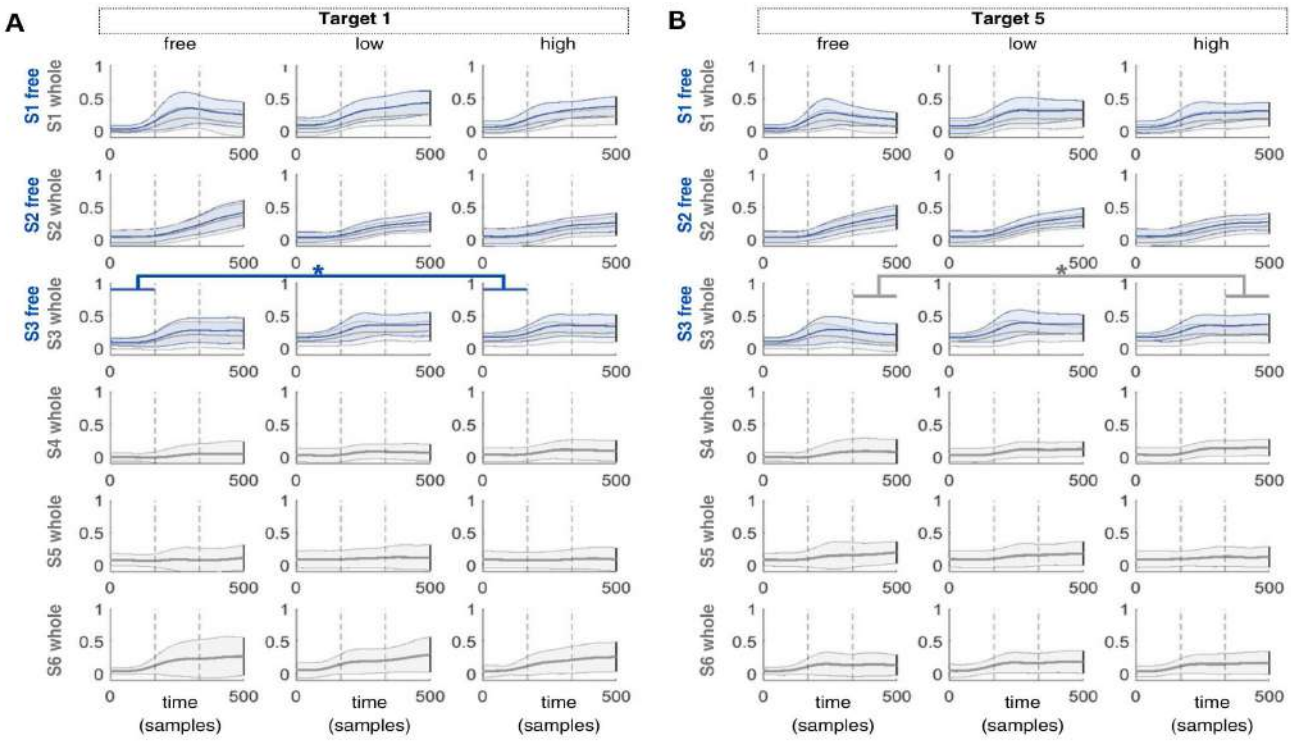

Fig. 5. Activation coefficients for movements towards target 1 (A) and target 5 (B). The solid lines represent the mean and the shaded areas the standard deviation over subjects. In blue are reported the coefficients of the free dataset synergies and in gray the ones of whole dataset synergies. Horizontal blue/gray brackets over the temporal coefficients indicate a statistical difference between the coefficients of free and of the whole dataset synergies for that time interval.

(ii) the use of the exoskeleton enforces increased activation of the upper trapezius.

A. Synergistic structure of reaching

The 3 free dataset synergies (Fig. 2 B) are coherent with previous literature investigating frontal reaching [15]. s1_free mainly expresses biceps and brachioradialis and enforces elbow flexion; s2_free mainly expresses the deltoids with a prevalence of the anterior deltoid and enforces shoulder flexion and abduction, while s3_free mainly expresses the trapezius muscle with a prevalence of upper trapezius, stabilizing and rotating the scapula upwards. The high similarity between these synergies and the first three synergies of the whole dataset suggests that the fundamental synergistic structure of reaching is preserved when movement is assisted by Float.

Moreover, 3 additional synergies emerge in the whole dataset (s4_whole, s5_whole, s6_whole, Fig. 2 C), which express mainly the middle trapezius, lower trapezius, and pectoralis. These muscle groups are present with a significant activation also in the free dataset synergies (Fig. 2 B): middle and lower trapezius are active in s3_free and pectoralis in s1_free. This suggests that a simplified yet efficient actuation of the shoulder and elbow joints is obtained in the free condition, while the control of joint movements appears fragmented into the activation of single muscles or couples of muscles when including the movement with the robotic assistance.

B. Modulation of synergy recruitment

We found significantly higher activation coefficients of high vs free conditions for s3_free and s3_whole (Table I). This occurred in the initial phase of movement towards targets 1 and 2 and in the final phase of movement towards target 9 for s3_free as well as in the final phase of movement towards target 5 in s3_whole. Both s3_free and s3_whole represent trapezius activation, making the increased activity of this muscle during assisted movement appear counterintuitive. However this could be attributed to the presence of the corset that constitutes the interface between Float and the user, as it forces the user to maintain a posture more rigid and straighter with respect to the natural sitting position. Moreover, we observed that in the initial phase of movement, s3_free presents a significantly higher tonic activity in high with respect to the free condition, probably generated to counterbalance the exoskeleton's weight (Fig. 5 A). We thus hypothesize that a high assistance during shoulder flexion increases the weight perceived by the user on the shoulder complex. To reduce this effect, joint 2 of Float (Fig. 1) should cooperate with the upper trapezius muscle in supporting scapula elevation.

Future work foresees examination on the effect of assistance on the phasic and tonic component of muscle activity [10].

C. Implications for exoskeleton design

Our data suggest that joint 2 acts in resistance to the action of upper trapezius, in particular in the initial phase

of movement. This could be due to the model-based friction compensation of the exoskeleton. This model compensates friction by providing a low-frequency sinusoidal voltage to the motors if the velocity is null. Otherwise, for non-null velocities, it models friction torque as a function of angular velocity. Such model, although sub-optimal, has proven to be effective when movements are performed slowly and continuously as it occurs during rehabilitation sessions. In our case study, the limitations of this model-based friction compensation were more evident, since we tested self-paced functional movements in healthy subjects. Especially in movements towards higher targets (i.e., 1 and 2) performed with high assistance, the friction compensation resulted ineffective. This lead to a greater tonic activation of the trapezius muscle (in particular the upper portion) to elevate the scapula and counterbalance the inertia perceived.

Currently, Float provides assistance exclusively on joint 4 (Fig. 1, Sec. II-B), which actuates purely shoulder flexion. This assistance reduces the synergies' activation for shoulder flexion (Fig. 5 A-B). We thus propose that implementing a feed forward assistance at joint 2 could be an effective strategy to reduce the described tonic activation of upper trapezius.

Moreover, Float reduces the activation coefficients of synergy 2 of free/whole dataset without altering the synergy pattern, similar to what happens when applying arm weight support [16]. This is highly promising as interventions with arm weight support have demonstrated to improve the reaching function both in healthy subjects and in stroke patients [17] [18]. Reducing the activation of anterior and middle deltoid could be beneficial for stroke patients, as it may counteract the abnormal coupling between shoulder abductors and elbow flexors that often affects stroke survivors [19]. Future works will extend this analysis to post-stroke subjects, to verify this hypothesis and whether model-based compensation of friction could affect already altered patterns of motor production.

V. Conclusion

This work exploits the NeBULA framework to compute standardized metrics, allowing objective characterization of movement's performance. We applied muscle synergy analysis to quantitatively describe the effects of the assistance of Float on the structural organization of reaching movements and found that synergistic organization of reaching is mainly preserved during assisted movements. Moreover, this study characterized the potential benefits and limitations of Float for shoulder rehabilitation interventions, by studying its impact on the patterns of muscle activity of healthy individuals. These findings have direct implications on Float control strategies and therapeutic interventions, aiming at enhancing its design to maximize its beneficial impact.

ACKNOWLEDGMENT

We special thank members of Rehab Technologies Lab for continuous support during the project. We also thank L. De Michieli, M. Laffranchi and A. Turolla for useful discussion.

Concurrent Learning Augmented DNN-based and Admittance Control of a Hybrid Exoskeleton

Sujata Basyal*, Kislaya Mishra*, Jonathan Ting*, Brendon Allen*

***Abstract*—People suffering from neurological conditions (NCs) can benefit from motorized functional electrical stimulation (FES)-based rehabilitation equipment, called hybrid exoskeletons. These hybrid exoskeletons incorporate muscle-motor interaction that requires both the control of human muscles (i.e., FES) and robot motors to obtain a desirable performance. Two types of controllers (deep neural networks (DNN)-based and Admittance-based) were developed in this paper for a hybrid exoskeleton to control both human muscles and the exoskeleton's motors. The uncertain dynamics of the hybrid exoskeleton are approximated by DNN to enable efficient FES control. The approximated DNN weights and biases were implemented in a control law where they were updated in multiple timescales. Specifically, the inner-layer DNN weights were updated iteratively offline while the outer-layer weights were updated online in real-time. The update law for the output-layer DNN weights was augmented with a concurrent learning (CL) inspired term to improve the learning performance of the DNN and, consequently, the overall system performance. The admittance-based motor controller uses torque feedback and desired torque contribution from the participant to modify the motor's desired trajectory without forcing the participant to follow along predetermined trajectories and to promote the overall safety of the system. A Lyapunov-based stability analysis was completed for both control systems to ensure overall system performance.**

I. Introduction

In America, neurological conditions (NCs) such as cerebral palsy, spinal cord injury, neuromuscular disorders, and Parkinson's disease, affect millions of people and account for billions of annual medical expenses each year [1]–[5] which negatively affects the quality of life of the individuals. The majority of patients with NCs have restricted muscular movement, which may contribute to further secondary health issues like diabetes, obesity, etc [6]–[10]. To address the variety of health issues brought by muscle inactivity, different rehabilitation exercises have been introduced that increase muscle mobility and ultimately improve an individual's health condition. Unfortunately, individuals with NCs might not have the strength or motor control necessary for rehabilitative exercises using traditional machines, which makes it challenging to reach the exercise intensities necessary to reap the advantages of training.

In order to compensate for the limitations of traditional rehabilitation tools and techniques, functional electrical stimulation (FES) was introduced for rehabilitation training. FES aids the individual in attaining the adequate threshold for exercise intensity, improving neuromuscular conditions. FES sends electrical pulses to the neuromuscular complex, which induces artificial, involuntary contractions in particular muscles, resulting in the functional movement of a body part [11], [12]. However, FES-based control involves a combination of continuous and discrete dynamics which consequently results in a jump discontinuity in the dynamics. Careful control of FES-based systems is necessary to facilitate the intended neuromuscular restoration. Hybrid exoskeletons that integrate FES control with rehabilitation machines have proven to improve musculoskeletal and cardiorespiratory fitness as well as other neurological, physiological, and psychological measures [13].

The majority of prior control strategies for hybrid exoskeletons focus on tracking desired position or force trajectories (cf. [14]–[16]). However, these trajectory-based control schemes are unable to provide customized control for each person because they are designed to follow the same basic trajectory and torque objective. The admittance control approach developed by [17] is a suitable addition since it strikes a balance between force and position control [18]–[24]. Implementing admittance control to the control structure enables the indirect tracking of desired torques, thereby augmenting the human-robot interaction experience. Admittance-based control is more concerned with a system's dynamic performance than its explicit position and torque tracking. It offers a clever approach for robots to engage with humans in a safe manner by resolving conflicts in motion between the humans and robots. The admittance parameter can be modified [25], [26] based on individual need for support or to oppose torque required during rehabilitation exercise [27]. Although admittance control is considered to be safer than a general force tracking controller, improper selection of a control parameter might result in the instability of the overall system. Therefore, a stability analysis of the developed controller is required to guarantee a stable response of the system.

The primary objective of this paper is to develop a safe and stable control law for a hybrid exoskeleton that is used in rehabilitation. Therefore in this paper, a DNN- and admittance-based control framework for a hybrid exoskeleton is developed. Specifically, DNNs were used to approximate the complex dynamics of a hybrid exoskeleton and were inte-

grated into the FES controller. Admittance is integrated into the motor controller of the hybrid exoskeleton to indirectly track a desired torque trajectory. An advantage of DNN-based FES control is that it is an adaptive control approach and can be adjusted according to user dynamics. High FES inputs can be uncomfortable and result in a rapid onset of fatigue, which could impede rehabilitation. In this work, the inner-layer weight and biases of the DNNs are updated offline; whereas, the output-layer weights are updated online using a Lyapunov-based adaptive update law. In an effort to improve the DNN performance, this work builds upon the authors' preliminary works in [28], [29] to augment the real-time output-layer DNN update law with concurrent learning (CL) inspired terms for the first time in a hybrid exoskeleton (i.e, dynamic model with two inputs). CL is a data-based approach that uses both current and past data concurrently to enable the output-layer DNN weights to converge to a small neighborhood around their ideal values. This work represents the first to develop a closed-loop admittance and DNN-based control scheme, the first to develop a DNN-based controller for a multi-joint hybrid exoskeleton, and the first to augment the DNN with CL for a hybrid exoskeleton system. The FES system presented unique challenges due to its switched nature that were solved in this work. Lyapunov-based stability and passivity analyses were performed to ensure semi-global uniformly ultimately bounded position tracking of FES controller and passivity of the admittance controllers in addition to global tracking of the admittance errors. Finally, a preliminary simulation was done to evaluate the performance of the proposed control approach.

II. Dynamics

The switched, nonlinear dynamic model for an FES-based n-joint rehabilitation robotic system can be modeled as[1]

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + G(q) + P(q,\dot{q}) + F\dot{q} + d(t) = \underbrace{B_F(q,\dot{q},t)u_f(t)}_{\tau_{FES}(q,\dot{q},t)} + \underbrace{B_{mor}u_{mor}(t)}_{\tau_{motor}(t)}, \tag{1}$$

where $q : \mathbb{R}_{\geq 0} \to \mathcal{Q}^n$ denotes measurable joint angles, $Q^n \subseteq R^n$ denotes the set of all possible joint angles for the rehabilitation robot, and $\dot{q} : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ and $\ddot{q} : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ denote the measurable joint angular velocities and unmeasurable joint angular accelerations, respectively. The dynamic functions $M : \mathcal{Q}^n \to \mathbb{R}^{n\times n}$, $C : \mathcal{Q}^n \times \mathbb{R}^n \to \mathbb{R}^{n\times n}$, $G : \mathcal{Q}^n \to \mathbb{R}^n$, $P : \mathcal{Q}^n \times \mathbb{R}^n \to \mathbb{R}^n$, $F \in \mathbb{R}^{n\times n}$, and $d : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ denote the inertia matrix, centripetal-Coriolis matrix, gravitational effects, viscoelastic tissue effects, viscous coefficient matrix, and unknown disturbances, respectively. The torques applied to each joint by the exoskeleton's electric motors are denoted by $\tau_{motor} : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ and are defined as $\tau_{motor} = B_{mor}u_{mor}(t)$, where $B_{mor} \in \mathbb{R}^{n\times n}$ denotes the known current to torque scaling factor for the motor and $u_{mor} : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ denotes the motor input. The torque generated from FES is defined as $\tau_{FES} = B_F(q,\dot{q},t)u_f(t)$, where $u_f : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ denotes the FES control input and $B_F : \mathcal{Q}^n \times \mathbb{R}^n \times \mathbb{R}_{\geq 0} \to \mathbb{R}^{n\times n}$ denotes the diagonal and unknown lumped FES control effectiveness matrix and is defined as

$$B_{F,i}(q,\dot{q},t) \triangleq \sum_{m\in\mathcal{M}_i} B_m(q_i,\dot{q}_i,t)\,k_m\sigma_m(u_{f,i}(t)), \forall i \in \mathcal{N} \tag{2}$$

where, $\mathcal{N} \triangleq \{1, 2, \ldots, n\}$, $B_{F,i}$ denotes the i^{th} diagonal element of B_F (i.e., $B_{F,i}$ is the lumped FES effectiveness about the i^{th} joint of the exoskeleton), q_i and $\dot{q}_i$ are the i^{th} joint's angular position and velocity, respectively, $\mathcal{M}_i$ is the set of muscles that produce forces about the i^{th} joint and is defined as $\mathcal{M}_i \triangleq \{Ag_i, An_i\}$, Ag_i and An_i denote the agonist and antagonist muscle groups acting about the i^{th} joint, and u_i is the FES input associated with the i^{th} joint. Furthermore, for each muscle $m \in \mathcal{M}_i$ and $\forall i \in \mathcal{N}$, $k_m \in \mathbb{R}_{>0}$ denotes a selectable constant, $B_m : \mathcal{Q}\times\mathbb{R}\times\mathbb{R}_{\geq 0} \to \mathbb{R}$ denotes the muscle's unknown stimulation-to-torque scaling factor, and $\sigma_m : \mathbb{R} \to \{0, 1, -1\}$ denotes a piecewise constant FES switching signal. The stimulation input into the m^{th} muscle is denoted by $u_m : \mathbb{R}_{\geq 0} \to \mathbb{R}$ and is defined as $u_m(t) \triangleq k_m\sigma_m(u_{f,i}(t))u_{f,i}(t)$. The FES switching signal $\sigma_m, \forall m \in \mathcal{M}$, must be designed in such a way that B_F defined in (2) remains invertible to facilitate the subsequent analysis. The switching signal σ_m can be defined $\forall m \in \mathcal{M}_i$ and $\forall i \in \mathcal{N}$ as

$$\sigma_{Ag_i}(u_{f,i}) \triangleq \begin{cases} 1, & u_{f,i} \geq 0 \\ 0, & u_{f,i} < 0 \end{cases}$$
$$\sigma_{An_i}(u_{f,i}) \triangleq \begin{cases} -1, & u_{f,i} < 0 \\ 0, & u_{f,i} \geq 0 \end{cases}. \tag{3}$$

The switching signal in (3) allows for an agonist-antagonist muscle pair to be effectively treated as a single actuator with a lumped FES control effectiveness $B_{F,i}$ and FES input $u_{f,i}$, where positive $u_{f,i}$ is applied across an electrode on the agonist muscle and negative $u_{f,i}$ is applied across an electrode on the antagonist muscle. It should be noted that the stimulation input into a muscle must be positive. This factor motivated the use of a -1 in the antagonist switching signal in (3). Furthermore, it should be noted that $B_m > 0$ for agonist muscles and $B_m < 0$ for antagonist muscles. Consequently, the design of (3) ensures that $B_{F,i}$ is continuous and that $B_{F,i} > 0$ always holds, and thus B_f^{-1} always exists. The dynamics in (1) have the following common properties:

Property 1. The inertial matrix M can be upper and lower bounded as $c_m \leq \|M(q)\| \leq c_M$, where $c_m, c_M \in \mathbb{R}_{>0}$ are known constants and $\|\cdot\|$ is the standard Euclidean norm.

Property 2. The centripetal-Coriolis matrix satisfies $C(q,x)v = C(q,v)x, \quad \forall x, v \in \mathbb{R}^n$ and can be upper bounded such that $\|C(q,\dot{q})\| \leq c_C\|\dot{q}\|$, where $c_C \in \mathbb{R}_{>0}$ is a known constant.

[1]For the notational brevity, all explicit dependence on time, t, within the terms $q(t)$, $\dot{q}(t)$, and $\ddot{q}(t)$ is suppressed.

Property 3. The gravitational constant, viscoelastic tissue effects, viscous coefficient, and unknown disturbances can be upper bounded as $\|G(q)\| \leq c_G$, $\|P(q,\dot{q})\| \leq c_{P1} + c_{P2}\|\dot{q}\|$, $\|F\| \leq c_F$, and $\|d(t)\| \leq c_D, \forall t \geq t_0$, where c_G, c_{P1}, c_{P2}, c_F, and $c_D \in \mathbb{R}_{>0}$ are the known constants and $t_0 \in \mathbb{R}_{\geq 0}$ is the initial time.

Property 4. The system follows the skew-symmetric property such that the centripetal-Coriolis effects and the time derivative of the inertial effects satisfy $x^T\left(\frac{1}{2}\dot{M}(q) - C(q,\dot{q})\right)x = 0,\ \forall x \in \mathbb{R}^n$.

Property 5. The torque generated by FES, $B_F(q,\dot{q},t)\,u_f(t)$, can be linearly parameterized as

$$B_F(q,\dot{q},t)\,u_f(t) = Y(q,\dot{q},t,u_f(t))\,\theta, \tag{4}$$

where $Y(q,\dot{q},t,u_f(t)) \in \mathbb{R}^{n\times g}$ is a measurable regression matrix, $g \in \mathbb{N}$ is the number of unknown parameters in the unknown lumped FES control effectiveness matrix, and $\theta \in \mathbb{R}^g$ is a constant vector with unknown terms. The i^{th} component of the unknown vector θ, θ_i, can be bounded as $\underline{\theta}_i \leq \theta_i \leq \overline{\theta}_i$ where $\underline{\theta}_i$ and $\overline{\theta}_i \in \mathbb{R}_{>0}$ are lower and upper bounds of θ_i for all i, respectively. Since B_F is unknown, an approximation is necessary to facilitate the control development which can be done by an estimation of the FES torque, denoted as $\hat{\tau}_{FES}$, and defined as $\hat{\tau}_{FES} \triangleq \hat{B}_F u_f$, where $\hat{B}_F(q,\dot{q},t) : \mathcal{Q}^n \times \mathbb{R}^n \times \mathbb{R}_{\geq 0} \to \mathbb{R}^{n\times n}$ is an estimate of $B_F(q,\dot{q},t)$. Note that the estimate of the FES torque can expressed as

$$\hat{B}_F(q,\dot{q},t)\,u_f(t) = Y(q,\dot{q},t,u_f(t))\,\hat{\theta}, \tag{5}$$

where $\hat{\theta} \in \mathbb{R}^q$ is an estimate of θ.

Property 6. The difference between the unknown vector θ and its estimate $\hat{\theta}$ can be quantified as a parameter estimation error $\tilde{\theta} \in \mathbb{R}^g$, which is defined as $\tilde{\theta} \triangleq \theta - \hat{\theta}$.

III. Controller Development

In the subsequent sections, an admittance control system is developed for the system's motors to ensure safety and a DNN-based FES control system is developed to track a desired trajectory within FES regions. The admittance controller is developed to be passive with respect to the FES torque and is designed to help the individual indirectly track a desired torque. The DNN-based controller is augmented with a Lyapunov-based CL update law which guarantees convergence of the output-layer DNN weights towards a neighborhood of their ideal values.

A. Admittance Controller

The admittance-based motor controller uses force feedback to modify the motors desired trajectory, allowing the exoskeleton to safely interact with the participant without forcing them to adhere to predefined trajectories. Admittance control is commonly used for tracking torque indirectly by employing an interaction torque error, denoted as $e_\tau : \mathbb{R}^n \times \mathbb{R}_{\geq 0} \to \mathbb{R}^n$, which is defined as $e_\tau \triangleq \tau - \tau_d$, where $\tau, \tau_d : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ denote the actual and desired interaction torques between the exoskeleton and the participant. As is typically the case, the interaction torque is assumed to be measurable and bounded (i.e., $\tau \in \mathcal{L}_\infty$). A feature of admittance control is that it will enable the motors to assist or resist the participant as is required. The trajectory for the admittance control law can be obtained by implementing an admittance filter defined as[2]

$$e_\tau \triangleq M_d\ddot{q}_a + B_d\dot{q}_a + K_d q_a, \tag{6}$$

where $q_a,\ \dot{q}_a,\ \ddot{q}_a : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ denote the admitted trajectory, and $M_d, B_d, K_d \in \mathbb{R}^{n\times n}$ represent the desired inertia, damping, and stiffness, respectively, selected to ensure that $q_a,\ \dot{q}_a,\ \ddot{q}_a \in \mathcal{L}_\infty$ (i.e., the transfer function of the filter is passive [30, Lemma 6.4]). The tracking performance of the admittance controller can be quantified using an admittance error system defined as

$$\xi(t) \triangleq q_a(t) + q_d(t) - q(t), \tag{7}$$

where $q_d : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ denotes the desired angular joint positions. The desired angular position, its derivative, and its double derivative are designed to be bounded such that $q_d,\ \dot{q}_d,$ and $\ddot{q}_d \in L_\infty$. The auxiliary admittance error denoted as $\Psi : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ can be defined as

$$\Psi(t) \triangleq \dot{\xi}(t) + \beta\xi(t), \tag{8}$$

where $\beta \in \mathbb{R}_{>0}$ is a known constant. Notice that if the participant is generating the desired torque that the admitted trajectory generated from (6) will be approximately zero, which will cause the admittance controller to drive the exoskeleton towards q_d. The open-loop error dynamics for the admittance-based system can be obtained by taking the time derivative of (8), multiplying it by M, and substituting in (1), (7), and (8), and is represented as

$$M\dot{\Psi} = -C\Psi - B_F u_f - B_{mor}u_{mor} + \chi_1, \tag{9}$$

where χ_1 represents an auxiliary signal that is defined as $\chi_1 \triangleq M\ddot{q}_a + M\beta\dot{\xi} + M\ddot{q}_d + C(\dot{q}_a + \dot{q}_d + \beta\xi) + G + P + F\dot{q} + d$ and can be upper bounded using Properties 1-3 such that $\|\chi_1\| \leq c_t + c_u\|\phi\| + c_v\|\phi\|^2$, where $c_t,\ c_u,$ and $c_v \in \mathbb{R}_{\geq 0}$ are known constants, and the error vector $\phi \in R^{5n}$ is defined as $\phi \triangleq \left[\xi^T,\ \Psi^T,\ q_a^T,\ \dot{q}_a^T,\ \ddot{q}_a^T\right]^T$. Based on the admittance open-loop error system in (9), an admittance controller is developed as

$$u_{mor} \triangleq B_{mor}^{-1}\left(k_1\Psi + (k_2 + k_3\|\phi\| + k_4\|\phi\|^2)\,\mathrm{sgn}(\Psi) + \xi\right), \tag{10}$$

where $k_1,\ k_2,\ k_3,$ and k_4 are user-selected constants and sgn$(\cdot)$ denotes the signum function. Substituting the controller in (10) into the open-loop error dynamics in (9) yields the closed-loop error dynamics as

$$\begin{aligned} M\dot{\Psi} = \ & -C\Psi - B_F u_f - k_1\Psi - \xi + \chi_1 \\ & - \left(k_2 + k_3\|\phi\| + k_4\|\phi\|^2\right)\mathrm{sgn}(\Psi). \end{aligned} \tag{11}$$

[2]For notational brevity, all functional dependencies are hereafter suppressed unless required for clarity of exposition.

B. DNN-based FES Controller

The tracking objective for the FES controller can be quantified using an angular position error denoted as $e : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ and is defined as

$$e \triangleq q_d - q. \tag{12}$$

The auxiliary position error for the dynamics (1) is denoted as $r : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ and can be defined as

$$r \triangleq \dot{e} + \alpha e, \tag{13}$$

where $\alpha \in \mathbb{R}_{>0}$ is a user-selectable constant. Using the position error in (12) and the auxiliary error in (13), the composite error vector $z : \mathbb{R}_{\geq 0} \to \mathbb{R}^{2n}$ is defined as $z \triangleq \left[r^T,\ e^T\right]^T$. Taking the time derivative of (13), multiplying it by M, and substituting in (1) and (12) yields the open-loop error system as

$$\begin{aligned} M\dot{r} &= M\ddot{q}_d + C\dot{q} + G + P + F\dot{q} + \chi_2 \\ &\quad -B_F u_f - B_{mor} u_{mor}, \end{aligned} \tag{14}$$

where the auxiliary term χ_2 is equal to $\chi_2 \triangleq M\alpha\dot{e} + d$. Using Properties 1 and 3, the auxiliary term can be upper bounded as $\|\chi_2\| \leq c_a + c_b \|z\|$, where c_a and c_b are known constants.

Property 7. Using the definition of z, Property 2, and the error definitions in (12) and (13), $C(q, \dot{q})$ can be upper bounded as $C \leq (c_d + c_e \|z\|)$, where c_d and c_e are known constants.

1) DNN Approximation: The uncertain dynamics in (1) are approximated using a DNN that is augmented with CL-inspired terms. To facilitate the CL development, the dynamics being approximated by a DNN are represented by a function, denoted as $f_1(x_1) : \mathbb{R}^{3n} \to \mathbb{R}^n$, and defined as

$$f_1(x_1) \triangleq M\ddot{q} + C\dot{q} + G + P + F\dot{q}, \tag{15}$$

where $x_1 \triangleq \left[q^T,\ \dot{q}^T,\ \ddot{q}^T\right]$. Substituting (15) into the dynamic model in (1) yields

$$f_1(x_1) + d = B_F u_f + B_{mor} u_{mor}. \tag{16}$$

However, $\ddot{q}$ is unknown in real-time and thus cannot be implemented in the control system. Consequently, the function f_1 can be rewritten as $f_2(x_2) : \mathbb{R}^{3n} \to \mathbb{R}^n$, which is defined as

$$f_2(x_2) \triangleq M\ddot{q}_d + C\dot{q} + G + P + F\dot{q}, \tag{17}$$

where $x_2 \triangleq \left[q^T,\ \dot{q}^T,\ \ddot{q}_d^T\right]$. Functions in (15) and (17) have similar form, however angular the acceleration $\ddot{q}$ in (15) has been replaced by desired acceleration $\ddot{q}_d$ in (17). A DNN will be developed to approximate f_2, called DNN2, and will be included in the FES control system since x_2 is known. However, the update laws for the DNN will include CL terms, which motivates the use of a DNN to approximate f_1, called DNN1 (otherwise bounds for $\ddot{q}$ would need to be determined a priori). Since the CL terms use previously recorded data, $\ddot{q}$ can be numerically determined and filtered prior to use in the CL framework. A multiple timescale approach is used to update both DNNs. Specifically, a gradient descent algorithm is used to retrain the inner-layers of the DNNs offline using data collected concurrent to real-time execution and the retrained DNNs can then be updated in batch updates. Furthermore, a Lyapunov-based adaptive law is used to update the output-layer DNN weights in real-time. Another challenge is that DNNs can only estimate functions that lie on a compact set, which requires x_1 and x_2 to be bounded. Let $\Omega \subset \mathbb{R}^{3n}$ be a simply connected compact set, then if $x_1, x_2 \in \Omega$, the functions (15) and (17) can be represented using the universal function of approximation theorem of neural networks.

For the function $f_1(x_1)$, there exists a DNN (named DNN1) with ideal biases, weights, and activation functions as per the universal function approximation theorem for neural networks such that it can be represented as

$$f_1(x_1) = W^T \varrho(\Phi_1(x_1)) + \epsilon_1(x_1), \tag{18}$$

where $W : \mathbb{R}_{\geq 0} \to \mathbb{R}^{u \times n}$ represents the ideal DNN output-layer weight matrix, $\varrho : \mathbb{R}^p \to \mathbb{R}^u$ represents the unknown vector of activation functions, $\Phi_1 : \mathbb{R}^n \to \mathbb{R}^p$ represents the unknown inner-layer weights and activation functions for DNN1, and $\epsilon_1 : \mathbb{R}^n \to \mathbb{R}^n$ represents the unknown reconstruction errors. The unknown inner-layers of DNN1 with unknown weights and activation functions can be represented as $\Phi_1 = V_{L_1}^T \phi_{L_1}(V_{L_1-1}^T \phi_{L_1-1}(V_{L_1-2}^T \phi_{L_1-2}(\ldots V_1^T \phi_1(x_1))$, where V_j represents the weights of the j^{th} inner-layer $\forall j \in [1, L_1]$, ϕ_j represents activation functions for the j^{th} inner-layer $\forall j \in [1, L_1]$, and $L_1 \in \mathbb{N}$ represents DNN1's number of inner-layers. The function $f_1(x_1)$'s DNN estimation can be denoted as $\hat{f}_{1,k} : \Omega \to \mathbb{R}^n$ and can be expressed as

$$\hat{f}_{1,k} = \widehat{W}^T \hat{\varrho}_{1,k}(\Phi_{1,k}(x_1)), \tag{19}$$

where $\widehat{W} : \mathbb{R}_{\geq 0} \to \mathbb{R}^{u \times n}$ represents the estimate of the output-layer weight matrix for DNN1, $\hat{\varrho}_{1,k} : \mathbb{R}^p \to \mathbb{R}^u$ represents the k^{th} estimate of the activation functions for DNN1's output-layer, and $\hat{\Phi}_{1,k} : \mathbb{R}^n \to \mathbb{R}^p$ represents the k^{th} estimate of the inner-layers of DNN1, and $k \in \mathbb{N}$ indexes the training iteration for DNN1.

Similarly, for the function $f_2(x_2)$, there exists a DNN (named DNN2) with ideal biases, weights, and activation functions as per the universal function approximation theorem for neural networks such that it can be expressed as

$$f_2(x_2) = W^T \varrho(\Phi_2(x_2)) + \epsilon_2(x_2), \tag{20}$$

where the terms in DNN2 are defined similarly to those in DNN1. The function $f_2(x_2)$'s DNN estimate can be denoted as $\hat{f}_{2,i} : \Omega \to \mathbb{R}^n$, and can be expressed as

$$\hat{f}_{2,i} = \widehat{W}^T \hat{\varrho}_{2,i}(\Phi_{2,i}(x_2)), \tag{21}$$

where $i \in \mathbb{N}$ indexes the training iteration for DNN2, $\hat{\varrho}_{2,i} : \mathbb{R}^p \to \mathbb{R}^u$ represents the i^{th} estimate of the activation functions for DNN2's output-layer, and $\hat{\Phi}_{1,i} : \mathbb{R}^n \to \mathbb{R}^p$ represents the i^{th} estimate of the inner-layers of DNN2. The

difference between the output-layer weight matrix and its estimate can be quantified by the weight estimation error $\widetilde{W}(t) : \mathbb{R}_{\geq 0} \to \mathbb{R}^{u \times n}$, which is defined as

$$\widetilde{W}(t) = W - \widehat{W}(t). \tag{22}$$

Property 8. The ideal output-layer DNN weights, W, the activation functions, ϱ, the function estimation errors of DNN1, ϵ_1, and DNN2, ϵ_2, and the estimate of the ideal activation functions for DNN1, $\hat{\varrho}_{1,k}$, and DNN2, $\hat{\varrho}_{2,i}$, can be upper bounded by $\overline{W}$, $\overline{\varrho}$, $\overline{\epsilon}_1$, $\overline{\epsilon}_2$, $\overline{\hat{\varrho}}_1$, $\overline{\hat{\varrho}}_2 \in \mathbb{R}_{>0}$, respectively, such that $\|W\| \leq \overline{W}$, $\|\varrho\| \leq \overline{\varrho}$, $\sup_{x_1(t)\in\Omega} \|\epsilon_1(x_1)\| \leq \overline{\epsilon}_1$, $\sup_{x_2(t)\in\Omega} \|\epsilon_2(x_2)\| \leq \overline{\epsilon}_2$, $\|\hat{\varrho}_{1,k}\| \leq \overline{\hat{\varrho}}_1, \forall k \in \mathbb{N}$, and $\|\hat{\varrho}_{2,i}\| \leq \overline{\hat{\varrho}}_2, \forall i \in \mathbb{N}$.[3] Additionally, the estimate of DNN1 is selected such that $\sup_{x_1(t)\in\Omega} \|\varrho(\cdot) - \hat{\varrho}_{1,k}(\cdot)\| \leq \overline{\tilde{\varrho}}, \forall k \in \mathbb{N}$, where $\overline{\tilde{\varrho}} : \mathbb{R}_{\geq 0}$ denotes a known constant.

2) Control Development: Substituting (17) into the open-loop error law in (14), adding and subtracting $Y\hat{\theta}$, and using Properties 5 and 6 yields

$$M\dot{r} = \chi_2 + f_2(x_2) - Y\widetilde{\theta} - B_{mor}u_{mor} - \hat{B}_F u_f. \tag{23}$$

A modified open-loop error system is developed by substituting (20) into (23), which can be expressed as

$$\begin{aligned} M\dot{r} = \; & \chi_2 + W^T\varrho(\Phi_2(x_2)) + \epsilon_2(x_2) - Y\widetilde{\theta} \\ & - B_{mor}u_{mor} - \hat{B}_F u_f. \end{aligned} \tag{24}$$

Based on (24), the controller for the FES input can be developed as

$$\begin{aligned} u_f \triangleq \; & \hat{B}_F^{-1}\sigma_s(q)\Big(k_5 r + e + \hat{f}_{2,i} + \\ & \left(k_6 + k_7\|z\| + k_8\|z\|^2 + k_u\|u_{mor}\|\right)\operatorname{sgn}(r)\Big), \end{aligned} \tag{25}$$

where k_5, k_6, k_7, k_8, and $k_u \in \mathbb{R}_{\geq 0}$ are user-defined constants and $\sigma_s(q)$ is a switching signal, defined as

$$\sigma_s(q) \triangleq \begin{cases} 1, & q \in \mathcal{Q}_{FES} \\ 0, & \text{otherwise} \end{cases}, \tag{26}$$

where $\mathcal{Q}_{FES} \subseteq \mathcal{Q}$ is a set of joint angles where the lumped FES control effectiveness is above a user-selected threshold (i.e., joint angles that correspond to effective FES-based torque production). Substituting (25) and (21) into (24) yields the closed-loop error system as

$$\begin{aligned} M\dot{r} = \; & \chi_2 + W^T\varrho(\Phi_2(x_2)) + \epsilon_2(x_2) - Y\tilde{\theta} \\ & - \sigma_s k_5 r - \sigma_s e - \sigma_s\widehat{W}^T\hat{\varrho}_{2,i}\left(\hat{\Phi}_{2,i}(x_2)\right) \\ & - \sigma_s\Big(k_6 + k_7\|z\| + k_8\|z\|^2 \\ & + k_u\|u_{mor}\|\Big)\operatorname{sgn}(r) - B_{mor}u_{mor}. \end{aligned} \tag{27}$$

Based on the subsequent stability analysis, the adaptive laws to estimate the unknown vector, θ, and the output-layer weight matrix, W, are denoted as $\dot{\hat{\theta}} \in \mathbb{R}^g$ and $\dot{\widehat{W}}(t) : \mathbb{R}_{\geq 0} \to \mathbb{R}^{u\times n}$ and are designed as[4]

$$\dot{\hat{\theta}} = -\text{proj}\left(\Gamma_2 Y^T(q, \dot{q}, t, u_f(t))\, r(t)\right), \tag{28}$$

$$\begin{aligned} \dot{\widehat{W}} = \; & \text{proj}\left(\Gamma_1\hat{\varrho}_{2,i}\left(\hat{\Phi}_{2,i}(x_2)\right) r^T\right. \\ & + k_{cl}\Gamma_1 \sum_{j=1}^{h} \hat{\varrho}_{1,k}\left(\hat{\Phi}_{1,k}(x_{1,j})\right) \\ & \left.\left(\tau_{total,j} - \widehat{W}^T\hat{\varrho}_{1,k}\left(\hat{\Phi}_{1,k}(x_{1,j})\right)\right)^T\right), \end{aligned} \tag{29}$$

where $\Gamma_1 \in \mathbb{R}^{u\times u}$ and $\Gamma_2 \in \mathbb{R}^{g\times g}$ are positive definite user-defined gains for the output-layer weights and the unknown constant parameter vector, respectively, proj$(\cdot)$ is the smooth projection function used in [31] and it is used to ensure that the unknown parameter estimates in $\hat{\theta}$ and the output-layer weight estimates in $\hat{W}$ stay within user-defined bounds, $k_{cl} \in \mathbb{R}_{\geq 0}$ is a user-selected control gain, $\tau_{total,j} \in \mathbb{R}^n$ is the total applied torque defined as $\tau_{total,j} \triangleq \hat{\tau}_{FES,j} + \tau_{motor,j}$, $\{x_{1,j}, \tau_{total,j}\}_{j=1}^{h}$ denotes the recorded history stack of previous states and total torque for the times corresponding to $t_j \leq t, \forall j$, and $h \in \mathbb{N}$ denotes the history stack size.

Property 9. Using Property 8 and the update laws presented in (29) the weight estimation error $\widetilde{W}$ defined in (22) can be upper bounded, by a known constant $\overline{\widetilde{W}} \in \mathbb{R}_{>0}$, such that $\left\|\text{vec}\left(\widetilde{W}\right)\right\| \leq \overline{\widetilde{W}}$. Furthermore, using Properties 5 and the update law in (28), the parameter estimation error $\widetilde{\theta}$ defined in Property 6 can be upper bounded as $\left\|\widetilde{\theta}\right\| \leq \overline{\widetilde{\theta}}$, where $\overline{\widetilde{\theta}} \in \mathbb{R}_{>0}$.

Assumption 1. There is sufficient excitation of the system over a finite duration of time such that $\lambda_{\min}(A_{el}) > \lambda_{ss} > 0, \forall t \geq T$, where $\lambda_{ss} \in \mathbb{R}_{>0}$ is a user-defined constant, $\lambda_{\min}$ is the minimum eigenvalue of $(\cdot)$, $T \in \mathbb{R}_{\geq 0}$ is finite time, and

$$A_{el} = \sum_{j=1}^{h} \hat{\varrho}_{1,k}\left(\hat{\Phi}_{1,k}(x_{1,j})\right)\hat{\varrho}_{1,k}\left(\hat{\Phi}_{1,k}(x_{1,j})\right)^T. \tag{30}$$

Data collected from previous experiments can be used to pre-train the estimation of the DNNs in (19) and (21). The initial estimates of inner-layers of the DNNs, $\hat{\Phi}_{1,1}(\cdot)$ and $\hat{\Phi}_{2,1}(\cdot)$, and the output-layer weights of both DNNs, $\widehat{W}$, can be determined by the pre-training of DNN1 and DNN2. The inner-layer weights of the DNNs are updated iteratively using traditional DNN training methods while the output-layer weight are updated in real-time using an update law comprised of CL terms. The states and inputs are collected in real-time and are used to train the inner-layer weights of the DNNs offline. Likewise, the states and input data

[3] DNN activation functions for both DNNs, $\hat{\varrho}_{1,k}\left(\hat{\Phi}_{1,k}(x_1)\right)$ and $\hat{\varrho}_{2,i}(\Phi_{2,i}(x_2))$, can be represented as $\hat{\varrho}_{1,k}$ as $\hat{\varrho}_{2,i}$, respectively, for notational brevity.

[4] The update law for the output-layer weights of the DNNs consists of two parts; an adaptation part, based on more traditional Lyapunov-based methods, and an innovative CL part. It should be noted that the adaptation part of the law comprises DNN2 terms and the CL part comprises DNN1 terms. Having two DNNs facilitates the numerical analysis, especially the analysis of the CL developments.

are collected in real-time and stored in the history stack for the CL law. Once the inner-layers of DNN1 and DNN2 are trained with sufficient data, these inner-layers are updated to develop the next iteration of the inner-layer DNN estimates, $\hat{\Phi}_{1,k+1}(\cdot)$ and $\hat{\Phi}_{2,i+1}(\cdot)$.

IV. Stability Analysis

To facilitate the following analysis, switching times are represented as $\left\{t_n^i\right\}, i \in \{s, e\}, n \in \{0, 1, 2, ...\}$, which represent the instants in time when σ_s becomes one ($i = s$) or zero ($i = e$). For the subsequent analysis, a positive definite storage function denoted as $V_1 : \mathbb{R}^{2n} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ is defined as

$$V_1 \triangleq \frac{1}{2}\Psi^T M \Psi + \frac{1}{2}\xi^T \xi, \tag{31}$$

where $\varsigma \in \mathbb{R}^{2n}$ is the concatenated error vector defined as $\varsigma \triangleq \left[\Psi^T,\ \xi^T\right]^T$. The storage function in (31) can be bounded using Property 1 such that $\rho_1 \|\varsigma\|^2 \leq V_1 \leq \rho_2 \|\varsigma\|^2$, where $\rho_1,\ \rho_2 \in \mathbb{R}_{\geq 0}$ are known constants and are defined as $\rho_1 \triangleq \min\left(\frac{1}{2}c_m, \frac{1}{2}\right)$ and $\rho_2 \triangleq \max\left(\frac{1}{2}c_M, \frac{1}{2}\right)$. For the stability analysis of a position tracking DNN-based controller, a common Lyapunov function candidate is denoted as $V_2 : \mathbb{R}^{n(2+u)+g} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ and is defined as

$$\begin{aligned} V_2(y,t) \triangleq\ & \tfrac{1}{2} r^T M r + \tfrac{1}{2} e^T e + \tfrac{1}{2}\text{trace}\left(\widetilde{W}^T \Gamma_1^{-1} \widetilde{W}\right) \\ & + \tfrac{1}{2}\widetilde{\theta}^T \Gamma_2^{-1} \widetilde{\theta}, \end{aligned} \tag{32}$$

where $y \in \mathbb{R}^{n(2+u)+g}$ is the concatenated state vector defined as $y \triangleq \left[r^T,\ e^T,\ \text{vec}\left(\widetilde{W}\right)^T,\ \widetilde{\theta}^T\right]^T$ and $\text{vec}(\cdot)$ is the vectorization of $(\cdot)$. The Lyapunov function candidate in (32) can be bounded using Properties 1 and 9 such that

$$\begin{aligned} \eta_1 \|z\|^2 &\leq V_2 \leq \eta_2 \|z\|^2 + w_1, \\ \eta_3 \|x\|^2 &\leq V_2 \leq \eta_4 \|x\|^2 + w_2, \\ \beta_1 \|y\|^2 &\leq V_2 \leq \beta_2 \|y\|^2, \end{aligned} \tag{33}$$

where $\eta_1 \triangleq \frac{1}{2}\min(c_m, 1)$, $\eta_2 \triangleq \frac{1}{2}\max(c_M, 1)$, $\eta_3 \triangleq \frac{1}{2}\min\left(\eta_1, \lambda_{\min}\left(\Gamma_1^{-1}\right)\right)$, $\eta_4 \triangleq \frac{1}{2}\max\left(\eta_2, \lambda_{\max}\left(\Gamma_1^{-1}\right)\right)$, $\beta_1 \triangleq \frac{1}{2}\min\left(\eta_3, \lambda_{\min}\left\{\Gamma_2^{-1}\right\}\right)$, $\beta_2 \triangleq \frac{1}{2}\max\left(\eta_4, \lambda_{\max}\left\{\Gamma_2^{-1}\right\}\right)$, $x \triangleq \left[r^T,\ e^T,\ \text{vec}\left(\widetilde{W}\right)^T\right]^T$, $w_1 \triangleq \frac{1}{2}\lambda_{\max}\left(\Gamma_1^{-1}\right)\overline{\widetilde{W}}^2 + \frac{1}{2}\lambda_{\max}\left(\Gamma_2^{-1}\right)\overline{\widetilde{\theta}}^2$, and $w_2 \triangleq \frac{1}{2}\lambda_{\max}\left(\Gamma_2^{-1}\right)\overline{\widetilde{\theta}}^2$.

Theorem 1. *For the admittance error dynamic model in (6) and the closed-loop admittance error law in (11), the admittance-based control input in (10) is passive from input $\|\tau_{FES}\|$ to output $\|\Psi\|$ provided that the gain conditions in (34) are satisfied.*

$$k_2 \geq c_t,\ k_3 \geq c_u,\ k_4 \geq c_v\ . \tag{34}$$

Additionally, when FES is not applied to the system (i.e. $\|\tau_{FES}\| = 0$), the admittance controller yields global exponential tracking such that

$$\|\varsigma(t)\| \leq \sqrt{\frac{\rho_2}{\rho_1}}\|\varsigma(t_0)\| \, exp\left(-\frac{\delta}{2\rho_2}(t - t_0)\right), \tag{35}$$

where $\delta \triangleq min(k_1, \beta), \forall t \in [t_0, \infty)$.

Proof: Let $\varsigma(t)$ be a Filippov solution for $t \in [t_0, \infty)$ to the differential inclusion $\dot{\varsigma} \in K[h_1](\varsigma)$, where $h_1 : \mathbb{R}^{2n} \to \mathbb{R}^{2n}$ is defined as $h_1 \triangleq \left[\dot{\xi}^T, \dot{\Psi}^T\right]^T$ and $K[\cdot]$ is the differential inclusion operator defined in [32]. Due to the discontinuity occurring in the admittance-based controller in (10), the derivative of V_1 exists almost everywhere (a.e.) for almost all $t \in [t_0, \infty)$ such that $\dot{V}_1(\varsigma) \overset{a.e.}{\in} \dot{\widetilde{V}}_1(\varsigma)$, where $\dot{\widetilde{V}}_1$ is the generalized derivative of (31). Taking the generalized derivative of (31), using the calculus of $K[\cdot]$ from [32] and Property 4, substituting in the closed-loop error dynamics in (11) and the auxiliary error in (8), and canceling common terms yields

$$\begin{aligned} \dot{\widetilde{V}}_1 \subseteq\ & -k_1 \Psi^T \Psi - \beta \xi^T \xi + \Psi^T \chi_1 - \Psi^T K[B_F u_f] \\ & - \left(k_2 + k_3\|\phi\| + k_4\|\phi\|^2\right)\Psi^T K[\text{sgn}(\Psi)]. \end{aligned} \tag{36}$$

Notice that the design of the switching signals in (3) ensure that B_F is always continuous. Consequently, $K[B_F u_f] = B_F u_f = \tau_{FES}$ when $q \in \mathcal{Q}_{FES}$ (i.e., when $\sigma_s = 1$) and $K[B_F u_f] = 0$ when $q \notin \mathcal{Q}_{FES}$. Considering the case when $q \in \mathcal{Q}_{FES}$ (i.e., $t \in [t_n^s, t_n^e), \forall n$), noting that $-\Psi^T K[\text{sgn}(\Psi)] \leq -\|\Psi\|$, using the upper bound of χ_1 from under (9) and the gain conditions in (34) yields an upper bound for (36) as

$$\dot{V}_1 \overset{\text{a.e.}}{\leq} -k_1\|\Psi\|^2 - \beta\|\xi\|^2 + \|\Psi\|\|\tau_{FES}\|, \tag{37}$$

$\forall t \in \left[t_n^e, t_{n+1}^s\right), \forall n$. As per definition 6.3 in [30], the exoskeleton system dynamics are strictly passive with $\|\tau_{FES}\|$ as the input, $\|\Psi\|$ as the output, and V_1 as the storage function. Considering times when $q \notin \mathcal{Q}_{FES}$ (i.e., $t \in \left[t_n^e, t_{n+1}^s\right), \forall n$) results in no FES forces being present (i.e., $\|\tau_{FES}\| = 0$). Consequently, the derivative in (37) can be further bounded by using the V_1 bound defined after (31) and the definitions of ς and δ as

$$\dot{V}_1 \overset{\text{a.e.}}{\leq} -\frac{\delta}{\rho_2}V_1,\ \forall t \in \left[t_n^e, t_{n+1}^s\right), \forall n. \tag{38}$$

Therefore, the storage function V_1, as per the zero-state observability condition defined in [30, Definition 6.5], can be considered as a positive definite (PD) Lyapunov function and results in global exponential admittance trajectory tracking when $\tau_{FES} = 0$. The result in (35) considers a scenario where FES is never applied (i.e., $\tau_{FES} = 0, \forall t$) and is obtained by solving (38) and using the bounds under (31). Recall that it was previously assumed that the participant's interaction torque is bounded, which requires that the FES-induced forces are likewise bounded. This is a reasonable assumption since human strength is finite and since all implemented FES systems saturate the FES input (often in an ad-hoc manner) to ensure participant comfort and safety.

Consequently, the passivity result in (37) and the result in (38) imply that $V_1 \in \mathcal{L}_\infty$, which implies that $\varsigma \in \mathcal{L}_\infty$ and thus that $\Psi\,, \xi \in \mathcal{L}_\infty$. Furthermore, recall that (6) is designed such that $q_a,\ \dot{q}_a,\ \ddot{q}_a \in \mathcal{L}_\infty$. Therefore, it can be proven that the motor controller in (10) is bounded. ■

Theorem 2. *For the closed-loop error law in (27) and for $q \in \mathcal{Q}_{FES}$, the DNN-based control input in (25) yields a bounded result prior to sufficient learning in the sense that*

$$\|y(t)\| \leq max\left(\sqrt{\frac{\beta_2}{\beta_1}}\|y(t_0)\|, \sqrt{\frac{v_1}{\delta_1\beta_1}}\right), \tag{39}$$

$\forall t \in [t_0, T) \cap [t_n^s, t_n^e)$, *where* $\delta_1 \triangleq \frac{min(\alpha, k_5)}{\eta_2}$ *and* $v_1 \triangleq \frac{min(\alpha, k_5)}{\eta_2} w_1 + C_1\widetilde{\overline{W}}$, *and semi-global exponential convergence toward an ultimate bound after learning has been completed in the sense that*

$$\begin{aligned}\|y(t)\|^2 \quad \leq \quad & \tfrac{\beta_2}{\beta_1}\|y(t_n^s)\|^2 \exp\left(-\delta_2(t-t_n^s)\right) \\ & + \tfrac{v_2}{\delta_2\beta_1}\left[1-\exp\left(-\delta_2(t-t_n^s)\right)\right],\end{aligned} \tag{40}$$

$\forall t \in [T, \infty) \cap [t_n^s, t_n^e)$, *where* $\delta_2 \triangleq \frac{min\left(k_z, \frac{1}{2}k_{cl}\lambda_{ss}\right)}{\eta_4}$ *and* $v_2 \triangleq \frac{min\left(k_z, \frac{1}{2}k_{cl}\lambda_{ss}\right)}{\eta_4} w_2 + \frac{C_1^2}{2k_{cl}\lambda_{ss}}$, *provided that the subsequent gain conditions are satisfied:*

$$\begin{aligned} k_6 &\geq c_a + \overline{W}\left(\overline{\varrho} + \overline{\hat{\varrho}}_2\right) + \overline{\epsilon}_2 \\ k_7 &\geq c_b + c_d,\ k_8 \geq c_e,\ k_u \geq c_{b_m}. \end{aligned} \tag{41}$$

Proof: Taking a generalized derivative of (32) using a procedure similar to Theorem 1, substituting in the closed-loop error dynamics in (27), the adaptive laws in (28) and (29), the auxiliary error law in (13), and the estimation errors in (22) and Property 6, using Property 4 and the properties of the trace and vectorization operators, considering the case when FES forces are present (i.e., $[t_n^s, t_n^e), \forall n$ such that $K[\sigma_s] = 1$) and an arbitrary $k \in \mathbb{N}$ and $i \in \mathbb{N}$ such that terms with subscript i and k are continuous, using the gain conditions in (41), the fact that $\|r\| \leq \|z\|$ and $-r^T K[\text{sgn}(r)] \leq -\|r\|$, adding and subtracting terms, noting that $\|B_{mor}\| \leq c_{b_m}$, and using Properties 7 and 8, and the upper bound of χ_2 yields

$$\begin{aligned}\dot{V}_2 \overset{\text{a.e.}}{\leq} \quad & -\alpha\|e\|^2 - k_5\|r\|^2 \\ & -\text{trace}\left(k_{cl}\widetilde{W}^T \sum_{j=1}^{h} K\left[\hat{\varrho}_{1,k}\left(\hat{\Phi}_{1,k}(x_{1,j})\right)\right] \times \right. \\ & \left.\left(\tau_{total,j} - \widehat{W}^T K\left[\hat{\varrho}_{1,k}\left(\hat{\Phi}_{1,k}(x_{1,j})\right)\right]\right)^T\right).\end{aligned} \tag{42}$$

Now using (16), (18), (22), (30), and Properties 3 and 8 yield

$$\begin{aligned}\dot{V}_2 \overset{\text{a.e.}}{\leq} \quad & -k_z\|z\|^2 - \text{trace}\left(k_{cl}\widetilde{W}^T A_{el}\widetilde{W}\right) \\ & + \left\|\text{vec}\left(\widetilde{W}\right)\right\| C_1,\end{aligned} \tag{43}$$

where $k_z \triangleq \min(\alpha, k_5)$ and $C_1 \in \mathbb{R}_{\geq 0}$ is a known constant. The inequality in (43) holds true for all $t \in [t_n^s, t_n^e), \forall n$ because it holds true for any arbitrary i or k. If sufficient excitation has not been reached, A_{el} will be positive semidefinite, as stated in Assumption 1; whereas A_{el} will be PD after learning has been completed. Using Property 9 and Assumption 1 for both the cases prior (i.e., $t \in [t_0, T)$) and after sufficient learning (i.e., $t \in [T, \infty)$, in addition to completing the squares yields

$$\begin{aligned}\dot{V}_2 &\overset{\text{a.e.}}{\leq} -k_z\|z\|^2 + C_1\widetilde{\overline{W}}, \forall t \in [t_0, T) \cap [t_n^s, t_n^e) \\ \dot{V}_2 &\overset{\text{a.e.}}{\leq} -k_x\|x\|^2 + \tfrac{C_1^2}{2k_{cl}\lambda_{ss}}, \forall t \in [T, \infty) \cap [t_n^s, t_n^e),\end{aligned} \tag{44}$$

where $k_x \triangleq \min\left(k_z, \frac{1}{2}k_{cl}\lambda_{ss}\right)$. Using (33) with (44) yields the results in (39) and (40). From (39) and (40) and the results in Theorem 1, the DNN-based FES controller in (25) is bounded. ■

V. Simulation

A preliminary simulation using the Euler-Lagrange dynamics in (1) was performed for a knee extension exercise (note that the system model is omitted due to space constraints). Both of the DNNs (i.e., DNN1 and DNN2) used in the control law had five layers and a similar architecture. The output-layer had a linear activation function while the other four layers had a tangent sigmoid function as their activation functions. The number of neurons in the input-layer, and the first, second, and third hidden-layers were 15, 10, 7, and 7, respectively. To collect the data for pre-training the DNN, a simulation of the actual dynamics was performed using the desired trajectory and its derivative as the input. The input and output data from the simulation were collected and used to pre-train the DNN. After pre-training, the DNN- and admittance-based controllers were implemented for the Euler-Lagrange dynamics. The re-trainings of the DNN were performed while running the simulation. The input and output data obtained during the simulation were used to retrain the DNN. The simulation ran for 150s at in which two re-trainings were done and error graphs were developed to analyze the performance of developed controllers.

VI. Results

The tracking of the developed controllers is depicted in Figure 1. The first solid vertical line Figure 1 indicates that the DNN re-training had been started for the first time and the second solid vertical line indicates the time when the second re-training started. The dashed vertical lines indicate the times when the newly trained weights and biases were implemented. Row 1 of Figure 1 shows the difference between the desired angle and the actual angle, and Row 2 of Figure 1 depicts the auxiliary position error. It can be seen that the angular position error is gradually improving with time and with each retraining, demonstrating the effectiveness of the proposed controllers.

VII. Conclusion

Hybrid exoskeletons require the control of both humans and robots for optimal rehabilitation. In this project, two controllers were proposed to obtain proper rehabilitation for

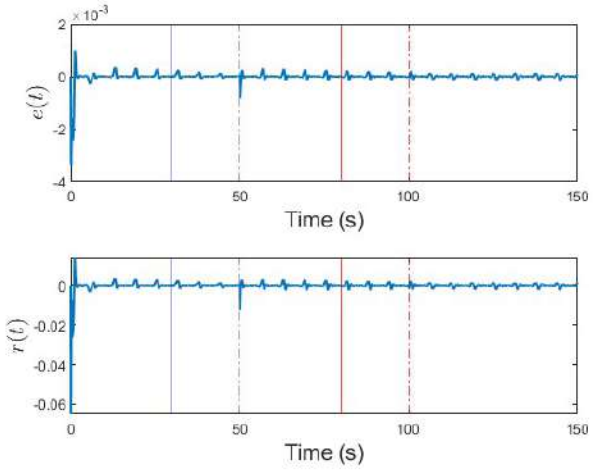

Figure 1. The tracking error and auxiliary error for the knee extension dynamics are depicted. The solid lines indicate the times when the DNN re-training started and dashed lines indicate when the retrained weights and biases were implemented.

individuals with NCs. The FES controller utilized DNN-based control approaches to track a desired trajectory. Furthermore, the DNN update law for the output-layer weights was augmented with CL to improve the DNN learning performance. Conversely, admittance was implemented to the robot controller to enhance robot-human interaction and augment rehabilitation. A rigorous Lyapunov-like stability analysis was performed for both of the controllers to ensure stability. Finally, the simulation result demonstrates the potential of the proposed control framework.

Dynamic Adaptation of Robotic Ankle-Foot Prostheses to Compliant Terrain: Reacting to Surface Stiffness Changes in Real-Time

Charikleia Angelidou, Benjamin Chen and Panagiotis Artemiadis*, *IEEE Senior Member*

***Abstract*— Real-time adaptability to varying terrain stiffness is a critical factor in enhancing the functionality of robotic ankle-foot prostheses. This paper introduces a novel reactive control framework that classifies surface stiffness and adjusts the prosthesis' behavior in real-time on compliant terrain, utilizing kinematic data from the prosthesis. The framework is tested with three able-bodied participants who completed treadmill walking trials on simulated rigid and compliant surfaces, replicating typical real-life scenarios. The proposed framework employs a Support Vector Machine (SVM) classifier that leverages data such as ankle angle, ankle moment, and Inertial Measurement Unit (IMU) measurements from a powered prosthesis to differentiate between terrains of different stiffness. Results show a classification accuracy of up to 88%, while the classification process is streamlined for rapid decision-making, enabling surface adaptation within milliseconds of initial foot-ground contact. This approach represents a significant step toward creating responsive, user-centric assistive technologies for individuals with lower-limb amputation.**

I. Introduction

Navigating dynamic terrains, including compliant surfaces and non-level ground, remains a significant challenge for individuals relying on robotic lower-limb prostheses [1,2]. Specifically for individuals with lower-limb amputation (LLA), transitions between surfaces of varying stiffness, such as transitioning from a paved sidewalk to grass or sand, can destabilize gait and compromise user safety [3]. While modern prostheses excel in replicating steady-state walking patterns on rigid terrain [4] and enable safe transitions between different locomotion modes [5, 6], their limited ability to adapt dynamically to surface changes highlights a critical need for improved control frameworks that integrate both environmental sensing and human feedback.

A growing body of research highlights the importance of considering human-robot interaction as a holistic system, where both human and robotic feedback play a critical role in optimizing performance. In this context, effective physical human-robot interaction requires bidirectional communication, encompassing not only the robotic system's ability to adapt to environmental cues but also its capacity to interpret and respond to signals from the human user [7]. Specifically in the context of compliant terrains, recent works have delved deeper into the latter, closely studying the mechanisms of human locomotion over surfaces of varying stiffness and utilizing biomechanical inputs from the human user to predict the upcoming surface stiffness [8, 9].

These works specifically elaborate on a high-level control framework for lower-limb prosthesis, which based on the predicted surface compliance, adjusts the prosthetic limb's behavior before foot contact with the ground, making real-time modifications to match the terrain. The prosthetic limb then moves according to these adjustments and interacts with the environment, a mechanism illustrated in Fig. 1. Feedback from interacting with the compliant environment shows potential for developing reactive control frameworks that refine prosthesis control in real-time, especially during unexpected terrain stiffness changes that could result from sensory occlusion (i.e. not visually perceiving an upcoming compliance change) or distracted walking (i.e. reduced anticipation). Although leveraging the generated prosthesis feedback can enhance both prosthetic functionality and user experience, it remains unexploited in the field of powered prostheses and their adaptation to compliant terrains.

As a preliminary effort to address this gap and improve mobility for individuals with LLA, this paper presents a novel reactive control framework designed to respond to surface stiffness changes in real time, utilizing direct feedback from the user's wearable device or powered prostheses. The goal of this research is to develop a compensatory control mechanism that will identify surface stiffness promptly after the initial contact of the prosthesis with the new surface to improve overall stability and robustness of the prosthesis. By classifying terrain characteristics within a few milliseconds after initial contact with the ground, the goal is to facilitate rapid prosthesis adjustments, mimicking the natural reflexive responses of the human nervous system. The overarching objective of this work is to provide a personalized and intuitive experience for individuals with LLA, ultimately improving the quality of life for users relying on assistive and prosthetic devices.

II. Methods

The proposed control framework was designed, developed, and tested using experiments with able-bodied participants wearing a robotic ankle-foot prosthesis using a bypass adapter. The methodology encompassed data acquisition, data preprocessing, and segmentation, supervised machine learning model training, as well as real-time simulation testing. The following sections present each of the distinct study components in more detail.

The green dashed line represents the anticipatory module of the proposed framework [8, 9]. The red dashed line represents the compensatory module discussed in detail in this work.

A. Experiment Protocol

1) Ruggedized Odyssey Ankle Prosthesis: For this study, the powered Ruggedized Odyssey Ankle (ROA) prosthesis (SpringActive, Inc) was used (see Fig. 2) [10, 11]. The ankle features a 250 W brushless DC motor connected in series with a 377 kN/m elastic spring, which transitions to a rigid carbon fiber foot. This design allows the spring to store and release elastic energy during the gait cycle, while the motor supplements any additional energy required. A motor encoder tracks the motor position, and an ankle encoder monitors the ankle angle. Additionally, an inertial measurement unit (IMU) is integrated within the casing above the ankle joint. The spring-generated ankle moment is estimated using a lookup table, developed by SpringActive, Inc., based on the motor position and ankle angle.

By default, the ROA prosthesis is controlled using a continuous phase-variable controller called the tibia controller (TC) [12]. The TC utilizes tibia kinematics to produce a reference motor trajectory that replicates the ankle angle patterns typically observed in the gait of healthy individuals without gait impairments. The TC has successfully been tested with individuals with transtibial (TT) LLA in walking and running activities on rigid terrain [12, 13]. However, the TC performance on bilaterally compliant terrain remains inferior to a recently proposed admittance controller (AC) [14], tailored for compliant surface walking.

2) Variable Stiffness Treadmill 2: The walking assessment of the recruited participants was performed using a specialized robotic platform developed by our lab, known as the Variable Stiffness Treadmill 2 (VST 2) [15] (see Fig. 2). The VST 2 can independently adjust the stiffness of both belts to simulate walking on compliant terrain. This experimental platform allows for the simulation of everyday walking conditions by recreating compliant surfaces and mimicking real-world stiffness scenarios in the lab.

3) Participant Data: Three healthy participants (two females, one male; age: 22 $\pm$ 1.73 years; height: 1.66 $\pm$ 0.03 m; weight: 58.98 $\pm$ 2.27 kg) completed walking trials on the VST 2 [15] wearing the ROA prosthesis. The prosthesis was attached via a carbon fiber bypass adapter on the left leg of the participants, preserving knee movement, while an adjustable shoe-lift (Evenup Corp., Buford, GA) was used on the right leg to compensate for height differences.

Fig. 2: Front and side view of a subject standing on the VST 2, while wearing the powered ankle-foot prosthesis Ruggedized Odyssey Ankle (ROA) attached to an ankle bypass adapter.

The study involved two sessions for training and data collection, respectively. During the training session, participants acclimated to the treadmill's stiffness levels without the prosthesis. They were then asked to identify a comfortable walking speed while using the prosthesis under rigid stiffness conditions. The independently selected comfortable walking speed was 0.65 m/s for all three study participants, which also reflects the preferred treadmill speeds previously reported by individuals with gait impairments (e.g., individuals with LLA or stroke survivors) [16]. Subsequently, participants performed short trials at that speed across rigid and compliant terrains, using the default controller (TC) of the ROA.

4) Data Acquisition: During the data collection session, participants completed walking trials at their self-selected comfortable speed. The first trial included walking for 200 gait cycles on a rigid surface using the TC. Subsequent trials included walking on bilaterally compliant terrain with stiffness levels mimicking rubber-on-foam (63 kN/m) and foam pads (25 kN/m), using the TC. Five-minute rest periods

between trials were imposed to minimize participant fatigue. All participants provided written consent, and the presented experimental protocol was approved by the University of Delaware Institutional Review Board (IRB ID#: 1520622-8).

A motion capture system equipped with 8 cameras was used to collect kinematic data at 100 Hz (Vicon Motion Systems Ltd.). Additionally, the vertical Ground Reaction Force (GRF) response and the center of pressure (CoP) under each leg of the subjects was recorded at 65 Hz using a force sensor mat (Medical Sensor 3140TM, Tekscan, Inc., South Boston, MA) placed underneath both belts of the treadmill. Data from the prosthesis, such as ankle angle and moment, were recorded at a rate of 100 Hz.

B. Data Analysis

Based on previous works, it is safe to assume that the TC is the optimal controller for walking over rigid surfaces [12], while the AC performs better for walking tasks on compliant terrain [14]. This work aims to address the switch between the two controllers during transitions from rigid to compliant surfaces, aiding the rapid, real-time adaptation of the ROA to the new terrain. Considering that a natural human reflexive response takes place after a sensory stimulus (i.e. contact of the foot with a surface of different compliance), there is a reaction delay in the resulting compensatory response (i.e. adapting ankle stiffness to the new terrain). This reaction delay can be analogously compared to the time required to classify terrain stiffness upon contact with the ground and switch from a rigid ground controller (TC) to a compliant terrain controller (AC). During this time delay, the prosthesis controller remains set to its default setting for rigid surface walking. For this reason, this work will only focus on using trial data recorded using the default (TC) controller of the ROA. Additionally, it should be noted that since the focus of this study is concentrated on utilizing direct feedback from the ROA, the motion capture and force data will not be further analyzed within the scope of this work. From hereon, all data analysis will refer solely to the kinematic data captured by the ROA. Finally, analysis will be centered around classifying between the rigid (1000 kN/m) and the most compliant (25 kN/m) surface cases.

Data collected from the prosthesis included 22 quantifiable variables related to the prosthetic kinematics, including but not limited to ankle angle, ankle moment, IMU measurements, and gait parameters, such as gait progression and stride length among others. Kinematic data were sampled at 100Hz. Utilizing the prosthesis parameters, the ankle angular velocities were also derived as the time derivatives of the ankle angles. All kinematic data was then filtered via a 2nd order, low-pass Butterworth filter with a cut-off frequency of 5 Hz. Following the visual inspection of all prosthesis variables and comparing the average gait cycle data across the stiffness conditions of interest (1000 kN/m and 25 kN/m), we identified significant differences in the average values of several variables during the stance phase of gait. Statistical significance was calculated using an independent 2-sample t-test at the 95% confidence level and the selected variables included the ankle angle, ankle moment, IMU gyroscopic data (x-axis), and ankle angle velocity. Distinguishing between surface types during the first half of the gait cycle (i.e., the stance phase) was particularly critical, as surface identification in the latter half has minimal impact on user stability. This highlights the importance of focusing on early gait phases for effective terrain classification and stability enhancement.

Data were subsequently segmented into individual gait cycles and labeled according to terrain stiffness. These labeled data were then split into training (70%) and testing (30%) sets, with the training set used to develop machine learning classifiers capable of differentiating between rigid and compliant terrains and the testing set for real-time evaluation of the classification framework.

C. Classification Framework

1) Windowing Segmentation: A windowing segmentation analysis with non-overlapping windows was employed to preprocess the data for use as inputs to our classifier. Segmenting data into windows is a well-established practice in time-series analysis, as it enables the extraction of localized patterns and trends within specific intervals of the data [17]. Non-overlapping windows simplify computation by avoiding redundancy and ensuring that each segment contributes unique information to the model. This approach is particularly advantageous in gait analysis, where biomechanical variables such as ankle angle or moment evolve systematically over the gait cycle. By isolating discrete segments of the data, the classifier can more effectively learn distinct signals associated with different surface stiffness levels. Additionally, the segmentation process aligns with the natural periodicity of human locomotion, ensuring that inputs represent physiologically meaningful intervals.

For this reason, we utilized a windowing segmentation of 5 and 10 samples per window - corresponding to a window duration of 50 ms and 100 ms, respectively- to compare the effect of the window length in our classification strategy. The segmentation started at the beginning of the gait cycle – defined at heel-strike – and extended up to sample 60 ($\approx 50\%$ of the gait cycle), resulting in a total of 12 or 6 windows, respectively, for the 50 and 100 ms windows. The windowing process was capped at 50% of the gait cycle, which corresponds to the late stance phase of gait, as decisions made after this point offer limited practical value for identifying transitions to compliant surfaces.

2) Support Vector Machine (SVM) Classifier: Our goal is to classify gait cycles into two class labels according to whether the transition happens on a (1) rigid or (2) compliant surface. We therefore analyzed the efficiency of different classification methods in identifying and classifying walking patterns related to compensatory reactions during early transitions between surfaces of variable stiffness.

Using MATLAB's Classification Learner, we evaluated various classifier types, including k-Nearest Neighbors (kNN), Linear Discriminant Analysis (LDA), Neural Networks (NN), and Support Vector Machines (SVM). While

the results across kNN, Neural Networks, and SVM were similar, SVM generally outperformed the other models in terms of both accuracy and computational efficiency. For our SVM model, we utilized MATLAB's $fitcsvm$ function to train the SVM models on the provided dataset for each segmented window. To further enhance performance, we ran hyperparameter optimization for each window to determine the best parameters tailored to the specific characteristics of the data within that window.

3) Final Classification Decision: In this preliminary study, a total of 6 (or 12) decisions were made during the SVM classification phase, corresponding to the 100 ms (or 50 ms) segmented windows within the gait cycle. To derive a reliable classification outcome, a consensus-based approach was employed to consolidate these individual predictions into a single, final decision.

Specifically, the classifier confirmed its prediction if at least four (out of 6) or seven (out of 12) consecutive windows agreed on the outcome, prioritizing consistency in predictions over a simple majority vote. This method was chosen to leverage the temporal coherence of gait data, ensuring that decisions are based on stable trends rather than isolated predictions.

If consecutive agreement was not feasible, the final decision defaulted to the prediction of the last segmented window. This assumption rests on the premise that the later in the gait cycle a prediction is made, the more informative the classification inputs are likely to be.

4) Real-Time Testing and Framework Evaluation: A real-time simulation framework was designed to emulate the process of continuous data streaming from the ROA. The experimental data, gathered in the previously described controlled trials, were used offline to train the different classifiers. The partitioned test set data were then processed as if they were being streamed live from the prosthesis, simulating the conditions of real-time operation without the need to conduct new walking trials.

Specifically, data were simulated to arrive at a frequency of 100 Hz, replicating the actual sampling rate of the prosthesis sensors. The gait progression variable, a key output of the ROA, was used to detect heel-strike events, which served as markers to initiate the windowing segmentation outlined in earlier sections of this paper. To maintain robustness, a sliding buffer aggregated incoming data in chunks corresponding to the size of each window that was defined as 5 or 10 samples, equivalently 50 or 100 ms, per window. The segmented data windows were then filtered using a 2nd order, low-pass Butterworth filter (cut-off frequency of 5 Hz) to prepare them for classification, following the same processing pipelines as the training set data. Each window was passed sequentially to its respective trained classifier for real-time prediction. The distinct classifiers each provided a classification output that was then used to derive a conclusion about the stiffness of the terrain. A consensus-based decision-making process was used, in which a decision was finalized after achieving consistency across several consecutive outputs. This approach was aimed at mitigating the impact of transient noise or errors in individual predictions.

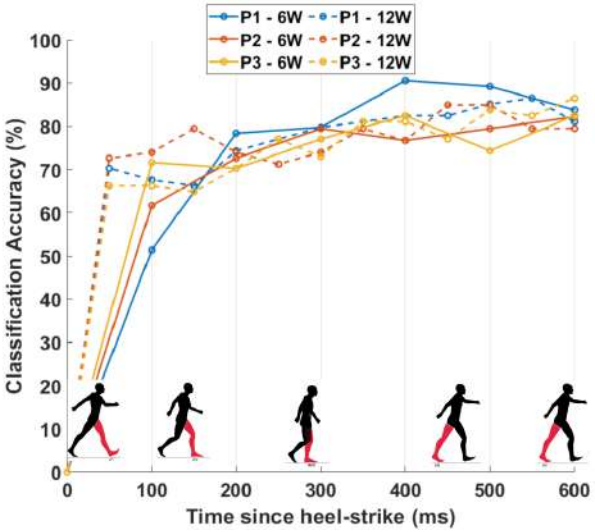

Fig. 3: Accuracy metric across participants (P1, P2, P3) using SVM window-classifiers within 600 ms of heel-strike. The solid lines represent the accuracy progression for the case of the 100 ms windows, corresponding to a segmentation of 6 Windows (6W). The dashed lines represent the accuracy progression for the case of the 50 ms windows, corresponding to a segmentation of 12 Windows (12W).

The performance of the framework was assessed by comparing predicted classifications with ground truth labels and the results were visualized using confusion charts. The framework was evaluated on a series of metrics based on the structure of a binary classification confusion matrix [18]. The metrics that were chosen to evaluate our model are briefly presented below.

- Accuracy: Proportion of true results (both Rigid and Compliant) in the data.
- Precision: A metric representing how many observations predicted as Compliant were in fact Compliant.
- Recall: A metric representing how many observations out of all Compliant observations have been classified as Compliant.
- F1-score: Harmonic mean between precision and recall. It ranges between 0 and 1, with 1 indicating perfect precision and recall.

Finally, the framework was evaluated not only on its accuracy, but also on how quickly decisions could be made following the detection of a heel-strike event, ensuring that the system's response time met the requirements for real-time prosthesis control. This simulation approach allowed for rigorous testing of the classifiers under conditions that closely mimic real-world prosthesis operation.

III. Results

A. Performance Comparison using 50 ms versus 100 ms Windows

In our comparison of the SVM classifier's performance with 50 ms and 100 ms window sizes, we found that a finer segmentation (50 ms) did not yield significant improvements

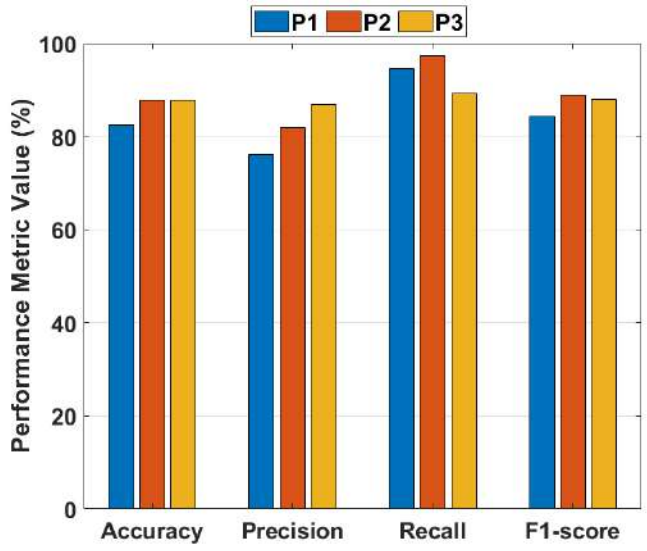

Fig. 4: Performance evaluation metrics across participants (P1, P2, P3) using SVM window-classifiers. The classification results depict the final decision metrics for the case of the 600 ms classification (decision taken at late stance phase) using a consensus-based decision process.

in classification metrics when compared to the 100 ms windows (see Fig. 3).

This can be attributed to the bandwidth limitations of the prosthesis, which constrain its ability to detect or respond to rapid changes within a 50 ms window. As a result, the signals extracted over shorter windows may not exhibit significant variability, leading to comparable classification outcomes between the 50 ms and 100 ms windows. Interestingly, classification accuracy was also observed to spike between 150 ms and 400 ms, highlighting the classifier's ability to make prompt and reliable decisions during the early and mid-stance phases of gait. This performance suggests that the 100 ms window allows enough time for the system to effectively adjust prosthesis parameters during these critical phases of walking.

B. SVM Classifier Performance

The performance of the proposed SVM-based binary classification framework demonstrates its ability to reliably distinguish between rigid and compliant surfaces with high accuracy and responsiveness within a short period of time after heel contact of the prosthesis with the ground. The detailed performance metrics for each participant are summarized in Fig. 4 for the full 600 ms. Across all participants, the SVM classifier consistently achieved high accuracy (82.4%–87.8%) along with strong precision, recall, and F1 scores. These results indicate that the classifier not only predicted surface compliance correctly in most cases but also maintained a balanced performance across true positives and false negatives, ensuring reliability in its decision-making. The high recall values should be noted, as they reflect the classifier's capacity to minimize misclassifications while ensuring accurate predictions of rigid and compliant surfaces.

Interestingly, looking at the precision scores of all participants, analysis of misclassified instances reveals a bias toward predicting rigid surfaces as compliant rather than the reverse. This behavior is advantageous in practical applications, as it prioritizes safety by ensuring that the prosthesis errs on the side of caution. Misclassifying a compliant surface as rigid could result in insufficient adjustments, potentially leading to instability or falls. In contrast, treating a rigid surface as compliant poses a lower risk, as the prosthesis would still be able to provide the required support to walk on a rigid terrain, ensuring a sub-optimal, yet stable gait [14].

By reliably distinguishing between rigid and compliant surfaces and prioritizing safety in its classification biases, the framework offers a reactive approach to terrain adaptation.

C. Classification Timing and Implications for Real-Time Prosthetic Control

The consensus-based approach demonstrated the ability to provide reliable predictions for the majority of gait cycles by the time we reached window 4, eliminating the need to wait through all 6 windows. This early decision-making process highlights the potential of leveraging such techniques to enhance the robustness of the final prediction. As shown in Fig. 5, which illustrates the number of correctly classified gait cycles versus misclassifications across all participants, the majority of gait cycles were accurately predicted by the time window 4 (W4) was reached (i.e., when 4 consecutive identical predictions occurred). Misclassifications were minimal, especially for participants P1 and P2. For participant P3, predictions were more evenly distributed across windows 4 (W4), 5 (W5), and 6 (W6), with a comparable number of misclassifications occurring in W4 and W6. These findings demonstrate the promising potential of using data from the early stance phase of gait for accurate terrain classification, thus underscoring the ability of our system to make reliable decisions early in the gait cycle. However, the consensus-based approach introduces some practical limitations, as alternative methods — such as probabilistic models or confidence-weighted voting — could potentially provide more robust and nuanced final decisions. Future work will explore these possibilities to improve the reliability, adaptability, and speed of the classification process.

IV. Discussion

The proposed reactive control framework demonstrates promise in adapting robotic prostheses to varying terrain conditions. However, some limitations need to be addressed. Specifically, this study was conducted at a fixed walking speed, so future work will investigate how the framework performs across different speeds to improve its adaptability. While the classification response time closely aligns with the average human reaction times reported previously in the literature [19], further optimization is needed to enhance real-time performance. Adaptive control strategies could refine reaction times, making prosthetic adjustments even more seamless. Additionally, the current approach differentiates only between rigid and one level of compliant surfaces.

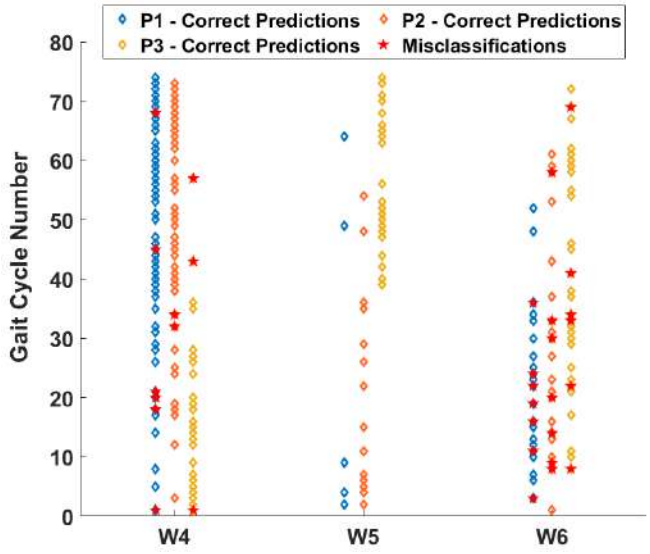

Fig. 5: Final classification prediction across participants (P1, P2, P3) per tested gait cycle following a consensus-based decision process for the case of the 600 ms classification. W4, W5, and W6 correspond to the segmented windows 4,5, and 6.

Expanding classification to intermediate stiffness levels will improve real-world applicability, while integration into a closed-loop prosthetic system and validation through testing on individuals with TT LLA remain crucial next steps. These efforts will refine the framework, making it more robust for everyday prosthetic use.

V. Conclusion

This paper introduces the first reactive controller framework using SVM-based classification to adaptively adjust robotic prosthesis ankle stiffness in response to surface compliance changes. The proposed framework incorporates kinematic data from a robotic ankle-foot prosthesis, enabling real-time classification of surface stiffness upon 400 ms after initial foot-ground contact. The SVM-based classifier demonstrated reliable performance in distinguishing between rigid and compliant surfaces, achieving an accuracy of up to 88%. This ability to classify surface compliance in real-time utilizing direct feedback from the prosthesis allows for adaptive control strategies that dynamically tune the prosthesis's parameters during locomotion. The integration of this reactive control mechanism into a high-level prosthetic system could enable reactive adjustments, enhancing both the stability and adaptability of prosthetics and wearables during transitions from rigid to compliant surfaces.

The results of this study are particularly significant as they underline the feasibility of using machine learning-driven classification to inform real-time control in lower-limb prosthetics. This approach paves the way for advanced prosthetic and wearable devices that consider human-robot interaction as a holistic system, where both human and robotic feedback play a critical role in optimizing performance.

VI. Acknowledgments

We sincerely thank Dr. Chrysostomos Karakasis for generously providing the experimental data used in this study.

Stimulation in Training Data to Improve Proportional Motor Control in a Dexterous Sensorimotor Task

Caroline H. Casumpang, Nathan Griffin, and Mark Brinton, *Member, IEEE*

***Abstract*—While electrocutaneous stimulation provides a low-cost approach to sensory feedback, it produces signal artifact which corrupts sEMG and can create errors in sEMG motor control. Eight volunteers with intact limbs controlled a 5-degree-of-freedom virtual hand using surface electromyography. The hand was trained by mimicking flexion and extension of each degree-of-freedom five times, holding each position for three seconds. Participants received sensory feedback in the form of electrocutaneous stimulation: 100 microsecond pulses at 100 Hz with amplitude linearly proportional to the force experienced by the index finger while pressing a virtual block. We compared ability to discriminate between block compliance when using training data with and without stimulation artifact. Though not statistically significant, randomly occurring stimulation during training improved ability to discriminate more compliant objects from 76 to 82% and 72 to 85% correct for two proportional control algorithms—a modified Kalman filter and a convolutional neural network. This approach requires no extra computational resources while providing improved motor control for bidirectional prostheses.**

I. Introduction

Between 30-50% of upper-limb amputees do not regularly use their prosthesis, in part because the prosthesis does not provide a sense of touch [1], [2]. Electrocutaneous stimulation is a low-cost approach to sensory feedback that has a slim form factor that could be easily integrated with clinically available prostheses. Different than transcutaneous electrical stimulation (which targets underlying nerve bundles to induce referred sensations in the distal limb), electrocutaneous stimulation aims to activate the underlying mechanoreceptors in the skin. This requires a small active electrode (about 1 cm2, or smaller), placed close to one or more larger return electrodes, to create a localized region of high current density near the active electrode. The localized, tactile sensations generated provide similar sensitivity to changes in stimulus intensity as those produced with intraneural stimulation [3]. Constant current stimulation is preferred to ensure changes in impedance at the electrode skin interface (which can vary widely from tens to hundreds of kilo-ohms with skin dryness, sweating, or other environmental conditions) have little impact on the cutaneous current density [4]. Stimulation paradigms often mimic invasive neurostimulation with cathodic-first, biphasic, constant-current pulses delivered at frequencies of 0 to over 150 Hz [3], [5] (even up to 2kHz [6]). Current amplitude is often in the range of a few milliamps, but depends on both the electrode size and the pulse-width (which can range between tens of μs to about 1 millisecond) [3], [7], [8]. The biggest difference in stimulation parameters for electrocutaneous stimulation is the need for high-voltage (often over a hundred volts) to drive pulses of current through the high-impedance electrode-skin interface [7]. As with other types of invasive and noninvasive neurostimulation, these high-voltage, pulses of current generate artifacts that can corrupt the recorded surface electromyography (sEMG) used to decode arm movements [9], [10]. These artifacts can be particularly disruptive for proportional control algorithms—a class of movement decoders which predict arm positions in real-time and provide the user with the fine motor control necessary to perform delicate sensory tasks [11], [12].

Only a few studies have explored removing stimulation artifacts in sEMG controlled upper-limb prostheses, and most of these were focused on classification algorithms. Early work demonstrated that separating the recording and stimulating electrodes several centimeters apart enabled interference-free traditional myoelectric control; however, separation of stimulation and recording electrodes is not always possible, particularly for individuals with short residual limbs [13]. More recently in participants with upper-limb amputations, various signal blanking procedures improved classification of arm position during electrocutaneous stimulation to the performance level of classifiers using data without any artifact [9]. They also demonstrated that blanking worked for pulse widths up to 400 μs and frequencies of 150 Hz. While blanking may be useful with classification algorithms, they are more likely to interfere with real-time proportional control algorithms that constantly rely on up-to-date data to predict new arm positions at regular intervals (e.g., 30 Hz) [12]. More advanced algorithms have relied on template subtraction (e.g., mathematically subtracting artifacts identified during stimulation from newly collected, artifact-corrupted data) and algorithms that predict the artifact waveform and subtract it from recorded EMG in real-time using an adaptive least-mean-squares algorithm. This study used invasive nerve stimulation in two transhumeral amputees (i.e., implanted nerve cuff electrode)—noninvasive stimulation would likely produce different outcomes [14].

We expanded on these studies with upper-limb, myoelectric prostheses, by exploring the effect of stimulation artifacts in training data for two proportional control algorithms: a modified Kalman filter (KF) [12] and a convolutional neural network (CNN) [11]. We explore whether the addition of electrocutaneous stimulation in the training data improves ability to distinguish between two-

levels of force applied to the index finger of a virtual hand during a sensorimotor block-push task.

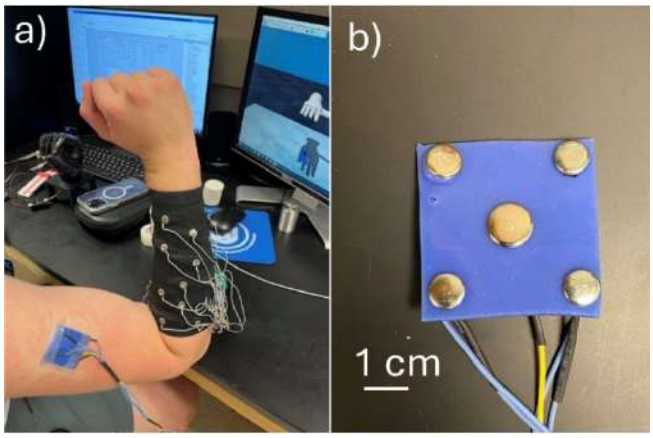

Figure 1. (a) The surface electromyography (sEMG) sleeve was placed on the participant forearm for signal recording and the electrocutaneous (EC) stim pad was placed on the lateral upper-arm. (b) The stim pad had a 1-cm diameter active electrode with 0.75-cm return electrodes at each corner of a 9-cm2 quincunx pattern.

II. Methods

A. Participants

Eight participants (5 male, 3 female) with intact limbs were recruited for the study (ages 18-45). All participants provided informed consent prior to the experiment. All procedures were approved by the Elizabethtown College Institutional Review Board.

B. Experiment Preparation

For sEMG collection, a 32-electrode sleeve was placed on the forearm (Fig. 1a), lining up the signal-recording ground and reference electrodes along the ulna. The electrodes and associated wires were securely wrapped to the forearm, reducing the likelihood of movement artifacts and ensuring stable contact throughout the experiment. Participants were instructed to rest their elbow on the table and to maintain a similar position throughout the experiment.

Participants dampened their skin using a wet paper towel on their upper arm to enhance the skin conductivity prior to taping the stimulation pad (Fig. 1b) on the lateral side of the upper arm, about 1/3 of the way between the shoulder and elbow (Fig. 1a). We found the minimum amplitude threshold of detection using the method of descending limits—reducing the amplitude until they could not feel the stimulation anymore.

Prior to the main experiment, participants underwent a practice session to familiarize themselves with how to train the arm by mimicking predefined hand movements. The training guided participants through 5 degrees-of-freedom (DOFs), including thumb flexion/extension, thumb adduction/abduction, index finger flexion/extension, middle finger flexion/extension, and wrist flexion/extension. Each DOF was repeated for five trials, with each position held for 3 seconds before returning to the natural resting position. Coaching was provided to ensure participants understood the movement patterns and when to flex and relax their muscles.

C. Motor Decoders and Control

To decode motor intent, we employed a KF and a CNNF [11]. During training participants mimicked movements of a 5-DOF virtual arm (MuJoCo, DeepMind) [15], [16]. sEMG signals were sampled at 2 kHz, filtered (15 to 375Hz bandpass; 60/120/180Hz notch), digitized and recorded using the Explorer Quest and front-end amplifiers (Ripple Neuromed; Salt Lake City, Utah). These recording parameters were chosen to capture the full range of muscle activity while minimizing noise and interference from other biological signals.

A total of 496 mean-absolute-value (MAV) features were extracted from the sEMG data using a 300-ms buffer and all possible differential pairs of the 32-electrode array. Of these features, the 48 most relevant were selected using Gram-Schmidt forward selection [17], [18] for use in the KF model based on correlation with the intended movements. This feature selection process ensured that only the most informative signals were used, improving the efficiency and accuracy of the decoding algorithm. The KF and CNN algorithms allowed for precise and adaptive decoding of motor intent based on the participants' sEMG data. After training, all DOFs were fixed in position except the index finger, which had a latching filter applied to further smooth movements [17]. By fixing the thumb, middle, ring and little fingers in position, unwanted movements during index control were ignored—allowing researchers to more easily visualize each block-push and preventing the middle finger from inadvertently moving the block from its rest position (occasional possibility for first time myoelectric users like our participants). Because we were focused primarily on object discrimination and participants were blind to all movements of the virtual hand, this simplification allowed them to focus on moving the index finger and interpreting the sensory response. By training on 5 DOFs, even though they were not used in the experimental setup, we ensured that algorithm training and data collected describe the more general scenario of 5-DOF control. Custom Matlab® software with a user interface was developed to manage the training process and decode movements in real time.

D. Electrocutaneous Stimulation

Stimulation was provided by an Arduino-based custom high-voltage constant current stimulator [7]. For the block-push experiment, participants completed the 5-DOF training (10 trials per DOF) twice: once with stimulation (S) and once without stimulation (NS). Half of the participants trained first with stimulation, and the other half with no stimulation first. Stimulation consisted of 100-µs biphasic, cathodic-first, pulses delivered at 100-Hz to the upper arm through a 0.8-cm² electrode. Pulse frequency at 100-Hz was selected because higher frequencies feel more natural and more like pressure than stimulation at lower frequencies which feels like tapping rather than continuous touch [19][20]. The selection of pulse-width is not as important; however, using a short pulse width (e.g., 100 µs) allows a wider range of pulse-amplitude before the sensations become intense or uncomfortable. During experimentation, stimulation amplitude varied with the applied force. During motor control training, bursts of 100-Hz, 100-µs pulses occurred randomly with each DOF movement

and with one of three randomly selected durations (3.8, 1.9, or 0.95 sec) and amplitudes (2, 4, or 6 mA).

E. Block-Push Experiment

During the main experiment, participants interacted with the virtual environment by pressing blocks and receiving sensory feedback (Fig. 2). After pushing a block, participants were prompted to provide their perception of the block's hardness—whether they pushed against a "soft" or "hard" block. The 2x1.7x1.7-cm block could slide along a frictionless virtual table, recoiling back to its initial location after release (i.e., stiffness set to 100 N/m and the damping set to 500 N-sec/m; the mass of the block was 50kg). The stimulation for sensory feedback was proportional to the normal force experienced by the virtual fingertip touch sensor (normalized to the range 0-1 for sensory encoding). For the "hard" block, the force was scaled by 1.5, and for a "soft" block, by 0.75 prior to encoding the stimulation amplitude (because the object shape was not compressible, we opted to scale the force directly rather than adjust the block stiffness and/or damping). Scale factors were set based on pilot data so that performance without stimulation in training data would be near 75% correct in the box-push task (e.g., half-way between chance, 50%, and perfection, 100%). Stimulation amplitudes ranged linearly between the minimum amplitude threshold of detection to 3-mA above the threshold.

To avoid order effect in the collected data, participants completed the block-push experiment 4 times, in a pseudorandom order: KF trained on data with stimulation, KF trained on data without stimulation, CNN trained on data with stimulation, CNN trained on data without stimulation. For each training condition, 32 blocks were presented (of which 16-17 were "soft", and 15-16 were "hard"). Participants were blind to the virtual environment and focused solely on the sensory feedback provided. The collected data was analyzed to determine the participants' ability to distinguish between different levels of stimulation and block hardness.

F. Data Analysis

The percentage of correctly identified "soft" and "hard" blocks were calculated for each participant. Tests for normality indicated that the data were non-parametric (Kolmogorov-Smirnov; $p < 0.01$). The resulting non-parametric tests for an effect due to stimulation in the training data indicated a non-significant result (Friedman's test: $p = 0.13$; $df = 1$; $\chi 2 = 2.26$). However, this may be a result of the limited power of non-parametric tests with very small sample sizes ($n = 8$).

III. Results

The percent correctly judged "soft" and "hard" were calculated for each participant and are presented in Fig. 3. With stimulation included in the training data, both the KF and the CNN led to more correctly identified "soft" blocks: 75.9% to 81.8% and 71.8% to 84.9%, respectively. Although the increases were not significant, performance trends toward improvement with stimulation artifact in the training data in all cases. Identifying the "hard" blocks appears to be more difficult under all scenarios. For the CNN there seemed to be

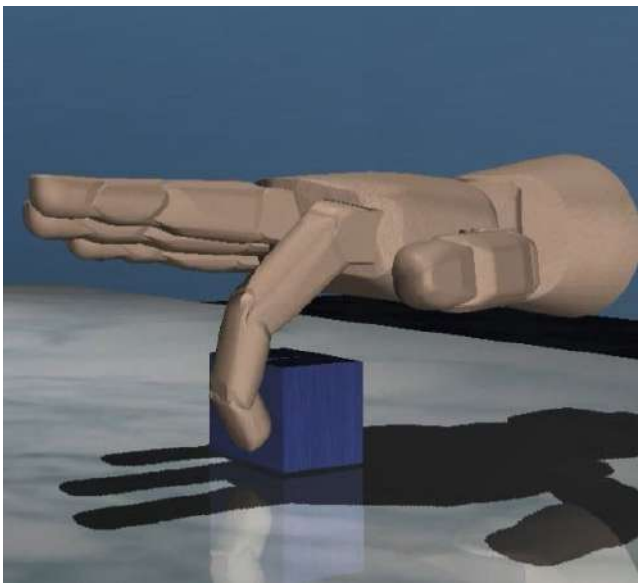

Figure 2. Participants controlled an arm in the virtual (MuJoco software). During the experiment, the user pushed a block while feeling electrocutaneous stimulation proportional to the force experienced by the virtual finger. Based on the sensory feedback, the user identified the blocks' hardness (i.e., "hard" or "soft").

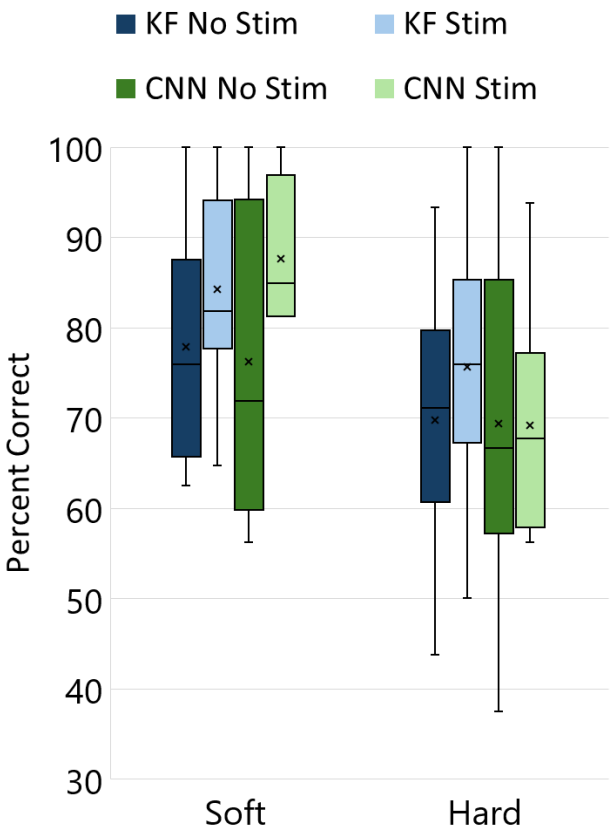

Figure 3. The percentage of trials that participants correctly identified as either "soft" or "hard" for the Kalman filter (KF) and the convolutional neural network (CNN), with and without stimulation in the training data. The box represents the interquartile range (IQR; 25th and 75th percentiles) and the line inside the box represents the median (x = mean).

little benefit from stimulation in the training data when identifying "hard" blocks. There is large variability in most conditions, where some participants performed perfectly and others much worse.

IV. Discussion and Conclusions

Our data suggests that training with stimulation may improve discrimination of "soft"-blocks from the "hard". It appears that both proportional control algorithms could reduce the effect of stimulation artifact on hand control in sensorimotor tasks—though the results need to be confirmed with larger sample sizes and stimulation electrodes located closely to the sEMG recording sites.

This is the first exploration of sEMG artifact removal during proportional motor control, as well as the first to explore how the artifacts in training data affect algorithm performance in sensorimotor tasks. We have shown previously that for these two decoding algorithms, decoder performance depends on the training data and training paradigms used [11]. Here, we also observed that both algorithms seemed to exhibit improved motor control when trained on data that included stimulation artifact in the sEMG. Because many sensorimotor tasks require proportional control to adapt in real-time to sensory feedback, it is paramount to develop methods that ignore or are unaffected by stimulation artifact.

Improvement in object detection likely occurs from improved motor control. Occasionally, we observed that algorithms trained without artifact would jump, either flexing or extending, on contact with the object and at the onset of stimulation. This uncontrolled behavior would immediately disrupt the typical movement of the block, the force applied to the index finger, and the resulting sensory feedback. Because participants were blind to the movement of the index finger, inconsistent feedback signals would easily lead to confusion and a guess at whether the block was soft or hard to push.

The benefits of this approach, in comparison to others who implemented specific algorithms to filter artifact [14], is that it requires no extra computation during real-time predictions. It may also work for various algorithms with high- (CNN) and low- (KF) computational demands; and perhaps even more so for our low-computationally demanding algorithm, making it an attractive approach for deployment in clinical systems. Our approach differs from the signal blanking during stimulation method [9] because it avoids removal of potentially useful data near or during stimulation. Dexterous proportional control relies on continuous sEMG inputs so that blanking data could substantially degrade control during the types of object manipulation where dexterous control is most useful. Furthermore, because natural feeling feedback occurs with higher frequency stimulation, this effect could be exacerbated with stimulation designed for natural feeling sensory percepts [20]; however future work should confirm these hypotheses.

The limitations of this approach include that the algorithms train on the artifacts available during training alone, which are likely to present differently throughout the day as the user moves and moisture accumulates at electrodes' interfaces (a common problem for any myoelectric system with or without sensory feedback). Second, while we did not observe a movement delay, increased variation in the sEMG features could produce movement delay for the KF which relies on the variance of its feature distributions to decide how much weight to place on a new prediction. Third, stimulation artifacts may be larger and more difficult to address in individuals with limb amputation where the recording and stimulating electrodes are more closely located. Out of convenience in experimental setup, we placed stimulation electrodes several centimeters away from recording electrodes. It is likely that relocating stimulation closer to recording electrodes could increase the benefit of including artifact in the training data because artifact could be larger and more likely to interfere with motor control. In any event, in a clinical setting, recording and stimulating electrodes are likely to be placed near each other in a prosthetic socket, so future studies should explore this configuration and its effects on motor control.

***Abstract*—Hand spasticity and hypertonia are common in individuals who have sustained an upper motor neuron (UMN) injuries due to stroke and traumatic brain injury. While rehabilitation robots and hand exoskeleton-based therapy treatments have shown great promise of improving motor function, the frequency of use and the nature of the repetitive therapeutic tasks can limit the promotion of neuroplasticity. The use of an assistive hand exoskeleton, meant to help the user perform activities of daily living (ADL), leverages the principals of neuroplasticity regarding increased frequency of use and increased specificity in doing functional tasks, to further improve neuroplasticity. Therefore, the use of an assistive hand exoskeleton may have neurorehabilitative benefits. The HOPE Hand — hand orthosis with powered finger extension — was designed to provide active finger flexion and extension of the fingers in the presence of increased muscle tone to assist individuals to perform ADLs. User testing was conducted with 3 control subjects and 2 subjects with hand spasticity and hypertonia due to a traumatic brain injury (TBI) and a stroke, respectively. This user test evaluated the user's ability to perform a functional task with the hand exoskeleton as well as their brain's engagement in the task using functional near-infrared spectroscopy (fNIRS) towards understanding neurorehabilitation benefits of assistive exoskeleton use. Results show the impaired subjects performed the functional water bottle task in significantly less time with the exoskeleton than without it. The fNIRS data showed that their motor cortex and speech centers of the brain were activating despite sustaining damage. By combining performance metrics and neuroimaging, we can further evaluate the HOPE Hand and other assistive exoskeletons to study their potential for promoting neurorehabilitation.**

***Index Terms*—Assistive device, hand exoskeleton, wearable robotics, hemiparesis, hand spasticity, neurorehabilitation**

I. Introduction

Stroke and traumatic brain injury (TBI) can result in upper motor neuron injuries, leaving 55-75% of survivors with hemiparesis and subsequent upper limb motor impairment, including hand impairment [1]. Hand impairment can physically manifest as both positive and negative symptoms in the upper limb. Negative symptoms like weakness and loss of dexterity manifest as a flaccid hand. Positive symptoms like spasticity—a velocity dependent increase in muscle tone—and hypertonia—an increased resting muscle tone—result in the individual exhibiting a closed fist posture. In addition to increased finger flexion, this flexor synergy pattern also includes reflexive wrist flexion, elbow flexion, and internal rotation of the shoulder [2]. Individuals with this condition can have some to no volitional ability to extend their fingers, wrist, or elbow. Stimuli such as physical tasks or cognitive tasks may trigger the reflexive synergy, increasing the muscle tone of the hand, and leading to stronger flexion forces.

Robotic motor rehabilitation has been shown to improve rehabilitation outcomes, comparable to or beyond conventional therapy [3]. Upper limb and hand exoskeletons are used to engage the impaired limb in movement routines, promoting neuroplasticity and use of the limb [4]. Some have employed rehabilitation games with robotic exoskeletons [5]. While these devices show great promise for motor rehabilitation, there are some inherent limitations. Rehabilitative hand exoskeletons, such as those previously mentioned, are typically used for short sessions a few times a week, limiting the user to the clinical environment and repetitive motor activities, as opposed to engaging in activities of daily living (ADLs).

In regards to daily life, these individuals have learned to compensate by performing single-handed and bimanual tasks with their able hand. Excluding the impaired hand and limb

from ADLs can lead to learned non-use; the brain reallocates resources, leading to poor functional improvement or rehabilitation of the limb. This a principal of neuroplasticity, "use it or lose it" [6]. Non-robotic therapy methods have shown that maximizing the use of the impaired limb can prevent or reverse learned non-use [7]. Assistive devices like hand exoskeletons can also be used to re-engage the impaired hand enabling individuals to complete ADLs, especially bimanual tasks [8]. According to additional principals of neuroplasticity, the more frequent, specific, and salient the use of the impaired limb is, the better the neurorehabilitative outcomes [6]. As an individual uses an assistive hand exoskeleton to perform necessary tasks for daily independent living with increased frequency and purpose, we can hypothesize that they will experience increased neurorehabilitative outcomes. Neuroimaging can be used to measure this brain engagement during exoskeleton use. Portable neuroimaging techniques such as functional near-infrared spectroscopy allow for the brain data to be collected in a real-world environment to monitor the brain's engagement with assistive technology [9].

Assistive exoskeleton user studies allow us to evaluate user performance with the device and monitor the brain's response to the technology with neuroimaging. Spasticity has precluded some individuals from participating in user studies. One large user study was conducted with an upper limb exoskeleton and 60% of the candidates were excluded from the study because they had moderate to severe spasticity [10]. We want to study exoskeleton use for people with hand spasticity.

The goal of our user study is to evaluate individuals' ability to perform a functional task with an exoskeleton designed to accommodate spasticity and to record their the neurological response during use. Neuroimaging data can provide insights into brain activation and engagement in tasks, with implications for neurorehabilitation. To conduct this study, an exoskeleton capable of extending the fingers of individuals with spasticity was needed. The exoskeleton must apply adequate torque at the finger joints, not obstruct the palmar surface of the hand, and minimize weight where possible.

Of the existing hand exoskeletons designed to accommodate spasticity, some only allow for passive finger extension, such as the saeboFlex glove by Saebo (Saebo, North Carolina, USA). This device works well for individuals who have decent motor control of hand flexion. However, the passive finger extension is applying constant forces, without an active way to release those forces. Gasser et al. presented an upper limb exoskeleton that can accomplish hand opening and closing (the power grasp) in the presence of muscle tone and spasticity [11]. The fingers are designed to move together which limits the amount of functional grasps that can be performance by the device. Individuated finger motion can be beneficial in power grasps because it allows for conformal grasping, meaning the fingers can flex to the contours of the object for a more stable grasp. Gasser et al. conducted user testing with their exoskeleton using a water bottle opening and closing task. This task requires the use of both hands, is a functional task, and can be timed to assess performance as speed [11]. This functional task was incorporated into the user study presented in this work. Yurkewich et al. presented the HERO Grip Glove which provides individuated finger extension, however their testing was limited to subjects with mild to moderate spasticity with Modified Ashworth Scale (MAS) scores ≤ 2 [12].

In this paper we present the Hand Orthosis with Powered Extension (the HOPE Hand), designed for individuals with hand spasticity and hypertonia, to assist them in completing ADLs. We present the design requirements, mechanical design, actuation design, and simulated, or "Wizard-of-Oz", voice control. In addition to providing assistance, the daily use of hand exoskeletons may also have neurorehabilitative benefits. To evaluate the performance and neural engagement with the hand exoskeleton, a user study was conducted with three control subjects and two subjects with hand impairment due to TBI and stroke, respectively. Time for task completion was used as a performance metric, and functional near-infrared spectroscopy was used to measure changes in brain activation towards demonstrating brain engagement during exoskeleton use.

II. Hand Exoskeleton Design

A. Design Requirements

The HOPE Hand was designed with the following requirements:

- Apply greater than 0.5 Nm of torque at the interphalangeal joints and 0.75 Nm of torque at the metacarpophalangeal (MCP) joint to extend the fingers [13]
- Provide individuated finger flexion to allow the user's hand to conform to the object being grasped
- Avoid components on the palmer surface of the hand which would interfere with grasping
- Allow for portable use with greater than two hours of battery life
- Minimize weight
- Employ a user interface that is compatible with individuals with spasticity due to upper motor neuron injuries

B. Design and Construction

The HOPE Hand consists of a semi-rigid hand orthosis worn on the dorsal surface of the hand, and an actuation unit to provide the pushing and pulling forces which is worn on the upper arm (Figure 2).

1) Hand Orthosis: Each finger was designed based on the kinematic concepts shown in Figure 1. Cable guides attached to the dorsal surface of the hand create an offset d to the joint centers of the MCP and proximal interphalangeal (PIP) joints, reducing the cable tension needed to oppose the resisting torque at each of these joints. The distal interphalangeal (DIP) joint was splinted in a straight position as coordination of the PIP and DIP in the presence of spasticity is difficult with non-rigid mechanisms. The exoskeleton provides two degrees of motion for the thumb. A channel across the back of the hand guides a cable to the thumb's metacarpal where it is fixed. Rotation and abduction of the thumb into opposition is accomplished by manually pushing the cable across the

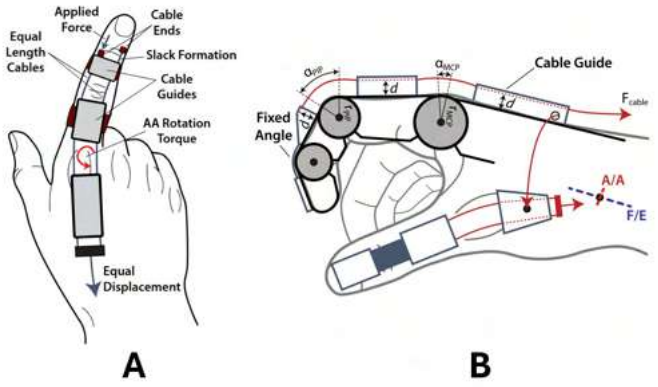

Fig. 1. A) Self regulating abduction/adduction rotation using two cables for finger extension. Due to a constant path length for both cables and an equal displacement imposed by the actuation unit, slack forms between the cable guide on the inside radius and the terminal cable guide. This causes an imbalance in tension between the two cables which creates a moment that seeks to re-center the abduction/adduction axis of the MCP joint [14] B) Flexion/Extension (FE) of the fingers and the thumb provided by pushing and pulling cables running along their dorsal surface. Abduction/adduction/opposition (AA) of the thumb's carpalmetacarpal joint was provided by manually pushing and pulling a cable across the dorsal surface of the hand terminating at the first metacarpal [15].

hand as in the kinematic drawing in Figure 1 B, and in the Figure 2. To maintain thumb opposition, a screw is used to lock the cable position. Flexion/extension of the thumb's MCP can be achieved actively by pushing or pulling a second cable running along the dorsal surface, in a similar direction to the FE force for the fingers. The exoskeleton is 3D printed from a photopolymer material (Durable Resin, Formlabs) and weighs 240g with Bowden cables, not including actuation unit [15].

2) Actuation Unit: Force is applied to the finger extension/flexion cables using DC motor driven linear actuators. Based on the peak torque measured in [13], a desired 1 second response from full flexion to full extension, and an assumed quintic joint velocity profile, a peak power of 3-5W delivered to each finger was determined necessary to extend the joints against chronic spasticity. A ballscrew with 90% efficiency (MTF-0601, THK) was used to generate the cable pull through a 60-70% efficient Bowden cable (Figure 3). Based on these parameters, a 3W continuous power (DCX14L EB SL 6V, Maxon, inc.) brushed DC motor was chosen under the provision that over-driving by 2-3 times the continuous power rating is permissible for several seconds as per manufacturer guidelines. Four of these motor and ballscrew actuators were integrated into a remote actuation unit mounted to the upper arm as seen in Figure 4. A SAM3X8E ARM Microcontroller (ATMEL, USA), on the remote actuation unit, can connect to a host controller via wired USB or XBee wireless communication (S2C DigiMesh Mesh 2.4, Digi International). The microcontroller runs position control loops for each of the linear actuators with the orthosis's compliance regulating the force applied to the user. The actuation unit weighs 768g with battery capacity of 12.2Wh [15].

3) Summary of Significant Characteristics: The HOPE Hand weighs approximately 1 kg including the actuation unit and the hand orthosis. It can provide individuated finger motion with up to 0.75 Nm of torque at the finger joints for finger extension. It can perform active finger flexion to accomplish conformable power grasps with an unobstructed palmar hand surface. Finger flexion is accomplished using a combination of the cable stiffness pushing the fingers into flexion, the relieving of extension forces, and the user's spasticity to close the hand.

III. Experimental Assessment

A. Subjects

This study was approved by the Worcester Polytechnic Institute's institutional review board (HHS 00007374). Three control subjects (2 male, 1 female; 22 ± 0.5 y.o.) and two impaired subjects (1 male, 32 y.o.; 1 female, 28 y.o.) were recruited for this study. The control subjects were recruited from the population of graduate students at Worcester Polytechnic Institute (Massachusetts, USA). Control subjects had no neurological or muscular injuries or conditions, were right handed, and were native English speakers. The impaired subjects were recruited from the patient population at Pine Bush Physical Therapy (New York, USA) through recommendation by their physical therapist. Inclusion criteria for impaired subjects was as follows: (a) individual has a neurological condition affecting the motor system, (b) individual displays spasticity in their hand with MAS $\geq$ 2 (c) individual exhibits mild to moderate Broca's aphasia (d) individual is deemed to be a candidate for an upper limb assistive device by the collaborating physical therapist. All subjects were able to provide informed consent.

Both impaired subjects had hand impairment due to an upper motor neuron injury: one had a stroke, and the other had a TBI. Both impaired subjects exhibited mild to moderate Broca's aphasia. Impaired subjects completed the disabilities of arm, shoulder, and hand (DASH) questionnaire to quantify their level of upper limb disability. Our collaborating physical therapist evaluated the subjects' level of hand spasticity using the Modified Ashworth Scale on the finger flexor muscle group; both impaired subjects had a MAS = 3, no volitional ability to extend their fingers, and some ability to volitionally flex their fingers. Subject information is shown in Table I.

B. User Interface and Control

When designing a user interface, it is important to consider not only the symptoms of hand impairment but also the comorbidities often associated with hemiparesis, such as speech aphasia. 80% of individuals with Broca's aphasia also have hemiplegia, and these conditions "do not just coexist, they interact" . This comorbidity presents an opportunity to implement a user interface that engages multiple areas of the damaged brain, as motor and speech rehabilitation have synergistic positive effects [16]. Therefore, voice control is a promising user interface for the HOPE hand as it could lead to improvements in both speech and motor rehabilitation.

All subjects wearing the HOPE Hand used verbal commands of "open" and "close," to control the opening and

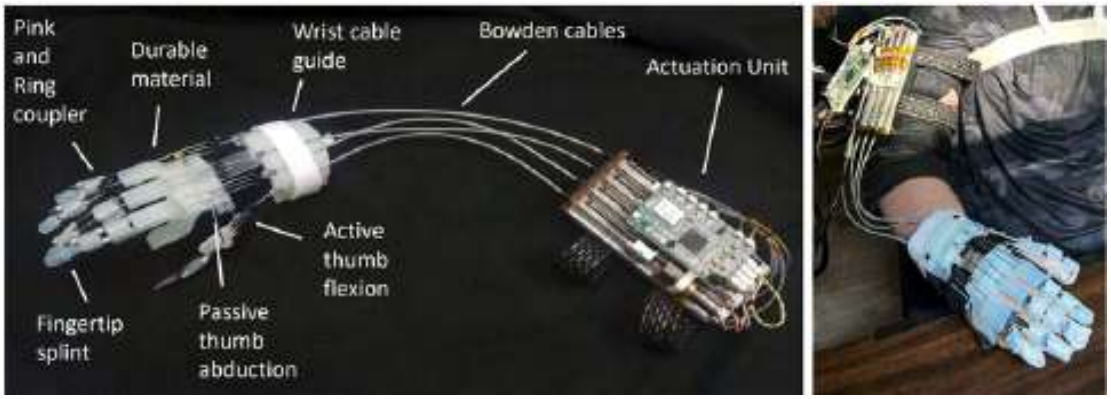

Fig. 2. *On the left:*Annotated image of the Hand Orthosis with Powered Extension (HOPE) Hand. *On the right:* Impaired subject wearing the HOPE Hand.

TABLE I
SUBJECT DEMOGRAPHICS

Subject	Age(Yrs)	Height (cm)	Weight (kg)	Gender	Mod. Ash.	DASH	Condition	Years since Injury
1	28	165	58.5	F	3	57	TBI	9
2	32	178	127	M	3	44	Stroke	3
Controls (3)	22 ± 0.5	176 ± 9	75.6 ± 2.8	4F/4M	-	-	-	-

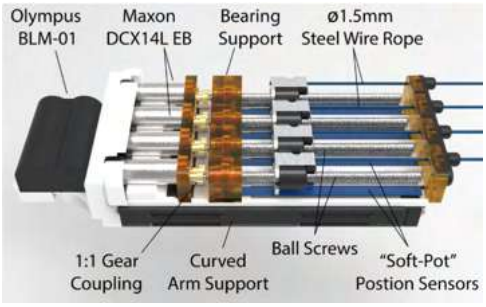

Fig. 4. Annotated render of the actuation unit [14].

closing of the exoskeleton, respectively, through a "Wizard-of-Oz" interface. This means that the users perceived the voice control as autonomous while, a researcher manually interoperated the open and close input using a graphical user interface (GUI) in response to their interpretation of subjects' verbal commands. Individuals with Broca's aphasia, including the two impaired subjects recruited for this study, have discontinuous, non-fluent speech. This makes it challenging for speech recognition algorithms and devices to interpret their speech [17], even when their speech is interpretable by other humans (as was the case for the two impaired subjects in this study). In order to simulate a "perfectly accurate" speech recognition algorithm for a hand exoskeleton user interface, this "Wizard-of-Oz" approach was implemented in HOPE Hand testing. This idealized user interface removed potential confounding factors of frustration resulting from any command recognition errors. In future versions of the HOPE Hand, a robust automated voice control algorithm will be implemented so the device can be used independently.

Upon the HOPE hand receiving an "open" command from the GUI, the DC motors turn the ballscrew, moving the coupler further from the exoskeleton, pulling the cable to extend the finger, while monitoring the position of the finger using the position sensors connected to the coupler. When the set point is reached the exoskeleton remains stationary. Similarly, receiving a "close" command from the GUI moves the coupler closer to the exoskeleton, pushing the cables and flexing the fingers until the desired set point is reached. The extension and flexion set points are entered into the GUI during the exoskeleton fitting stage, to ensure the subject's finger length and the stroke length of the cable movement will be sufficiently matched.

C. Neuroimaging

A NIRScout functional near-infrared spectroscopy (fNIRS) Neuroimaging System (NIRx, Orlando, Florida, USA) was used to measure changes in the concentration of oxygenated hemoglobin (HbO) and de-oxygenated hemoglobin (HbR) in the brain as a proxy for brain activation during all tasks. Measuring blood oxygenation level dependent (BOLD) signal changes in the brain allows us to explore the neurological

effects of exoskeleton use by looking at which areas of the cortex are activating during which tasks. The hemodynamic response function describes how the changes in brain activation result in changes of measured BOLD signal; this response is typically delayed 2-5 seconds following a stimulus.

A montage consisting of eight sources (red dots) and eight detectors (yellow dots) using the 10-20 system was created to capture activation in the motor cortex and Broca's area of the brain (Figure 8 top). During active hand motor tasks, it is expected that the medial motor cortex will be activated. During the water bottle task with the verbal "open" and "close" commands the lateral motor cortex and Broca's area will be activated. Passive hand movement tasks may or may not show activation in the motor cortex. The regions mentioned can be seen in Figure 8. The homunculus shows the location on the motor cortex in which the hands and mouth are controlled.

D. Experimental Protocol

Subjects were seated at a table throughout the study session. Research assistants put the fNIRS cap on the subject's head to ensure proper placement. Subjects performed two motor tasks prior to putting the exoskeleton on to collect brain data and performance metrics on tasks with no exoskeleton assistance. The HOPE Hand was then put on the subject, starting with a soft commercial splinting elbow brace (TISMOD, China) to immobilize the elbow joint approximately 135-100°to prevent reflexive elbow flexion, keeping the forearm and hand in a usable workspace to manipulate objects on the table from a seated position. A soft wrist brace was used to immobilize the user's wrist in a neutral position. The actuation unit was strapped to the upper arm, and the hand orthosis was attached to the dorsal surface of the hand using a velcro palm strap. The length of the exoskeletal fingers were adjusted on the HOPE Hand to account for subjects' various finger lengths, and the rigid finger segments were attached the subjects' fingers using medical tape. Subjects were given a short demonstration of the task and were allowed one practice trial. Subjects then performed the motor tasks with exoskeleton assistance. The tasks are listed below in the order in which they were completed by all subjects.

Fig. 5. Experimental set-up: subject shown with HOPE Hand on his right arm and hand. Subject shown performing the task of grasping a water bottle with the exoskeleton.

To collect the neuroimaging data in a block paradigm, each task was broken into Active blocks [A], during which the subject was doing a task for a set or variable amount of time, and Rest blocks [R] during which the subject was asked to stare at a fixation cross. As to not rush the subjects, some active blocks were initiated by the researchers and concluded when the subject completed the task, represented by time "X," which is how long it took the subject to complete each active block, respectively [XA]. Each Rest block (R) was 60 seconds represented as [60R].

- **Hand Open and Close - No Assist.** Subject was instructed to move their right hand opened and closed through the range of motion repeatedly during active blocks. Task paradigm was the following [60R - 30A - 60R - 30A - 60R].
- **Water Bottle Task - No Assist.** Subjects were instructed to grasp a water bottle with their impaired/right hand, unscrew the cap with their able/left hand, screw it back on, and remove the hand from the water bottle. Impaired subjects were given guidance from the physical therapist on the best approach for getting their impaired hand around the water bottle. The time it took to complete each water bottle open and close was recorded as a performance metric [11]. Task paradigm was the following [60R - XA - 60R].
- **Hand Open and Close - Exo Assist.** Subject was instructed to relax their hand (be passive) as the hand exoskeleton moves the right hand through the range of motion repeatedly. This task represents a potential rehabilitation routine, moving the user's hand through the range of motion to maintain flexibility and prevent contractures. Task paradigm was the following [60R - XA - 60R - XA - 60R].
- **Water Bottle Task - Exo Assist.** Subjects were instructed to used voice commands "open" and "close" to use the hand exoskeleton to grasp a water bottle with their impaired/right hand, unscrew the cap with their able/left hand, screw it back on, and remove the hand (with the exo) from the water bottle. Impaired subjects were given guidance from the physical therapist on the best approach for getting their impaired hand around the water bottle. The time it took to complete each water bottle open and close was recorded as a performance metric [11]. Task paradigm was the following [60R - XA - 60R].

1) Data Analysis: A performance metric was collected during the water bottle tasks, both with and without the use of the HOPE Hand. Control subjects were asked to open and close the water bottle five times without the HOPE Hand and five times with the HOPE Hand. The water bottle task consisted of a sequence of subtasks: grasping the bottle, unscrewing the cap, screwing it back on, and removing their hand. This was considered one trial. The time it took to complete each trial was recorded to the nearest second. The individuals with TBI and stroke were only asked to complete the water bottle task without the HOPE Hand three times because their hand spasticity made the task challenging. These individuals completed the water bottle task with the HOPE

hand six times each, as it was a unique opportunity for them to use the exoskeleton. The water bottle task was recorded during TBI and stroke subject sessions to extract the completion time for each subtask.

In addition to this functional performance time-completion measurement, brain activation data was collected using fNIRS. This data was first pre-processed using nirsLab (NIRx, Florida, USA). Pre-processing steps included removing spike artifacts due to motion, checking the signal quality (channels with a coefficient of variation below 20% were used in further analysis), and band pass filtering with a high pass frequency cutoff of 0.17Hz, and a low pass frequency cutoff of 0.005Hz. Then a Generalized Linear Model (GLM) was used to calculate the activation of each channel during active blocks convolved with the hemodynamic response function. Statistical parametric mapping was used to spatially display statistically significant activation ($p < 0.05$) as changes in HbR across the measured brain region.

IV. Results

A. Task Performance

The time it took the subjects to complete each water bottle trial is shown in Figure 6; trials with no exoskeleton assistance are shown on the left, and trials with exoskeleton assistance on the right. The median time it took control subjects to complete water bottle trials with no exoskeleton assistance was $10seconds$, and the range was from $8seconds$ to $14seconds$. For the TBI and stroke subjects, trials ranged from $61seconds$ to $94seconds$, approximately 6-9 times higher than the control subjects. Figure 7 shows the average time it took for the TBI and stroke subjects to complete each subtask, which demonstrates that the increased time is largely due to the challenge of getting their hand around the water bottle.

In comparison, the time it took for control subjects to complete the water bottle trials with the exoskeleton was higher than without, with a median of $30seconds$ and a range from $25seconds$ to $34seconds$. The time it took for the TBI and stroke subjects to complete the trials decreased to $34seconds$ to $46seconds$, which overlaps with the upper range of the control trials. There is also a decrease in variability between the time metric of the TBI trials with no exo assistance ($54 - 94seconds$) and with exo assistance ($34 - 46seconds$). Figure 7 shows the same subtask breakdown for both impaired subjects using the exoskeleton to complete the tasks, and the grasping subtask decreased by approximately $49.7seconds$ for the TBI subject and approximately $12.1seconds$ for the stroke subject. The stroke subject also showed an $11.8second$ decrease in the unscrewing the cap and an $8.3seconds$ decrease in screwing-on the cap.

B. Neuroimaging Results

The SPM results can be seen in Figure 10, with the columns representing the tasks, and the rows representing the subjects. The colored locations on each head represent significant brain activation measured as changes in de-oxygenated hemoglobin during the task.

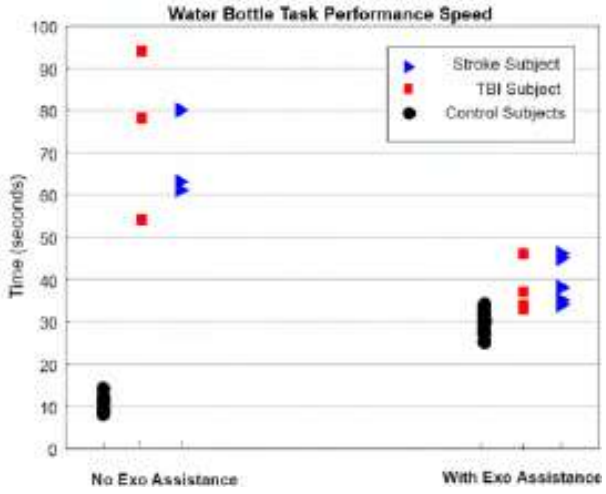

Fig. 6. 15 trials from 3 control subjects (5 each) shown as black circles for trials with no exo assistance, and with exo assistance, respectively. Individual trials from TBI and Stroke subjects shown as a red square and blue triangle, respectively.

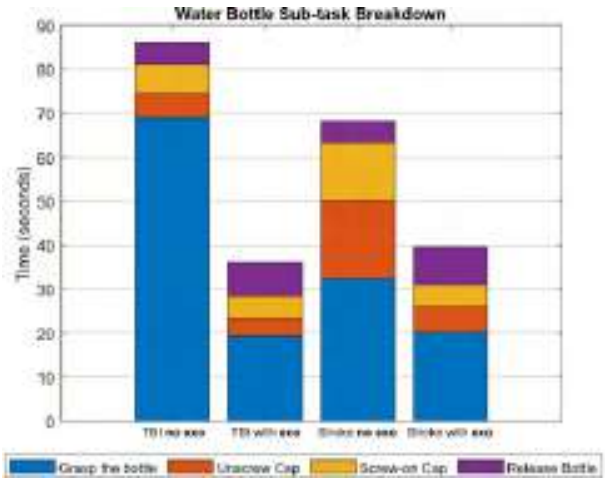

Fig. 7. Average breakdown for TBI subject without exo (n=2) and with exo assistance(n=6), and stroke subject without exo (n=3) and with exo assistance (n=5)

More activation can be seen in the medial motor cortex (cortex for hand motor control) in the tasks with no assistance, especially the water bottle task because it requires the use of both hands. When participants are actively participating in a task, there is more activation, as opposed to the exoskeleton assisted tasks in which the users are instructed to remain passive. For the water bottle with exoskeleton assistance task, there is activation in the lateral motor cortex (cortex for mouth motor control and Broca's region) which reflects the subject using verbal commands to open and close the exoskeleton.

Both the TBI and stroke subjects sustained their brain injuries on the left side of their brain, resulting in hemiparesis of the right side of their body. It is encouraging to see brain activation in the left side hand motor cortex for both impaired subjects (D.i., D.ii., D.iii., E.i., E.ii., E.iv.) because it shows

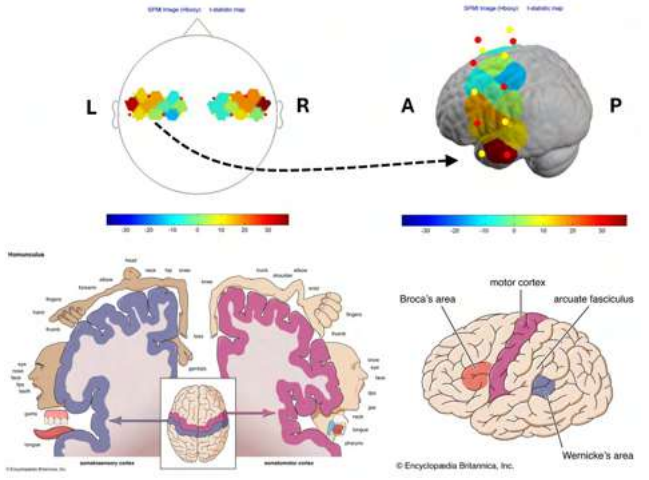

Fig. 8. The fNIRS montage shown in the top two images was designed to capture brain activation in the motor cortex, and the broca's area of the brain [18]. The homunculus and the image of the brain in the bottom right contextualize the locations of the brain to their functional purpose [19]. We expect to see activation in the Broca's area during the use of voice commands, and we expect to see activation in the medial left motor cortex, which control the right hand.

there may have been engagement with the damaged areas of the brain. There is also activation in the speech areas of the brain (D.iv.,E.iv.) during the water bottle with exoskeleton assisted tasks, which is also encouraging as they both have Broca's aphasia.

Fig. 9. Stroke subject performing the water bottle task without exoskeleton assistance. Subject's impaired hand (right hand) is shown tightly around the top of the water bottle, partially obstructing the cap.

V. Discussion

The HOPE Hand exoskeleton can successfully open and close the hand in the presence of increased muscle tone (MAS $\geq$2). It can assist the user in accomplishing functional bimanual tasks such as opening a water bottle. The "Wizard-of-Oz" voice control demonstrated that an accurate, robust, voice recognition algorithm and control would be a feasible user interface for individuals who have speech aphasia in addition to hand spasticity, and it also elicited brain activation in the speech production centers of the brain which could have rehabilitative benefits.

The results of the water bottle task show that the use of the HOPE Hand decreases the time it takes to complete the task for

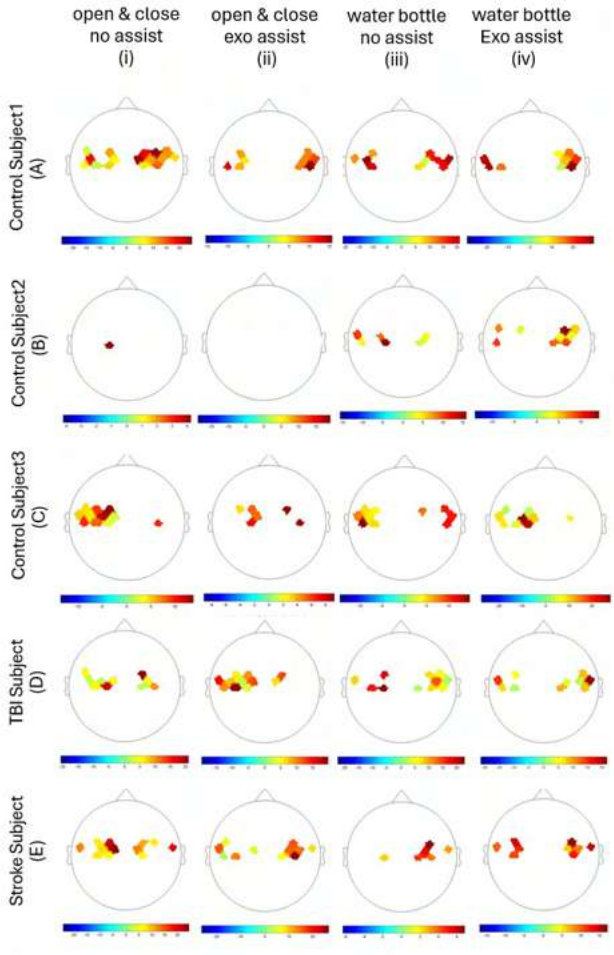

Fig. 10. Statistical Parametric Mapping (SPM) results for two impaired subjects and 3 control subjects. The colored bar along the bottom of each head figure is the intensity of the hemodynamic response. Only channels with significant activation ($p<0.05$) are shown.

impaired subjects, being the most helpful for the grasping and unscrewing subtasks. The decrease in variability also suggests the consistency provided by the exoskeleton. While the able-handed individuals are able to perform the task faster on their own than using the exoskeleton, the impaired subjects are able to achieve close to the same performance with the exoskeleton as the controls with the exoskeleton. The TBI subject was relatively consistent in the unscrew cap, screw-on cap, and remove hand subtasks in both no exo and with exo trials, while the stroke subject took longer to unscrew the cap and screw-on the cap. This was due to the physical limitation of getting his hand low enough on the bottle to have clear space around the cap making it challenging for his able hand to then unscrew and screw-on the cap (shown in Figure 9). With the exoskeleton, his hand was able to open wider, allowing him to position his hand lower on the bottle and giving him space to access the cap.

The SPM results from the impaired subjects show that the damaged areas of the brain may still be active during motor

and speech tasks. This interpretation assumes that the montage provides adequate coverage and that activation would occur in the expected areas according to a standard brain atlas. While this assumption may be inaccurate due to functional reorganization of the brain, anatomical references and assumptions must be made with the limited spatial coverage.

More brain engagement seen with tasks when the subject is actively moving their own hand. This means that a hand exoskeleton user may see more of a rehabilitative benefit by trying to use their hand even in exoskeleton assisted tasks. Because actively engaging their impaired hand often leads to increase muscle tone, it is increasingly important that hand exoskeletons are designed to resist their muscle forces. The combination of the neuroimaging data and the performance data illuminate important questions at the intersection of assistance and rehabilitation.

While fNIRS is commonly used to study brain activation, there is speculation on whether a single subject's fNIRS data can be interpreted individually, although the field is trying to move in this direction. For example, Control Subject 2 showed no significant activation in the Hand Open & Close - Exo Assist Task (Figure 10). Assumptions are made that the optodes are placed in the desired anatomical locations to collect brain activation from specific cortical areas, but heads can be a variety of shapes and sizes that make the cap fit differently for each person. Controlling these variables for able-bodied subjects is challenging, and these assumptions are more tenuous when working with injured brains. Brain activity does guarantee that learning or adaptive neuroplasticity occurred, especially over one session, however changes in brain engagement over time could indicate learning, which is a topic of interest for future work. Despite the challenges, fNIRS is a promising neuroimaging technique for capturing brain activation in real-world settings, and the results shown in this study have implications for future hand exoskeleton development, control, and rehabilitation techniques.

Small sample size is another limitation of this study as it prevents statistical significance calculations on the group level. In future work, we will conduct a longitudinal study with a larger number of impaired subjects, in which they use the voice-controlled exoskeleton daily at home to assist with ADLs. Their rehabilitative progress would be monitored over time using intermittent neuroimaging and clinical evaluations.

VI. Conclusion

The HOPE Hand was presented as an assistive hand exoskeleton design for individuals with spasticity and Broca's aphasia following a brain injury. A user study was conducted on 3 control subjects and 2 subjects with hand impairment and Broca's aphasia due to UMN injuries. We evaluated the ability of the exoskeleton to assist the user in functional tasks, and measured subjects' brain response to exoskeleton use. Using a combination of performance metrics and neuroimaging we can gain insights into how assistive exoskeletons may be used to increase neuroplasticity through increased purposeful hand engagement.

Design of a Breakaway Utensil Attachment for Enhanced Safety in Robot-Assisted Feeding

Hau Wen Chang[1], J-Anne Yow[1,2], Lek Syn Lim[1] Wei Tech Ang[1,2]

***Abstract*—Robot-assisted feeding systems enhance the independence of individuals with motor impairments and alleviate caregiver burden. While existing systems predominantly rely on software-based safety features to mitigate risks during unforeseen collisions, this study explores the use of a mechanical fail-safe to improve safety. We designed a breakaway utensil attachment that decouples forces exerted by the robot on the user when excessive forces occur. Finite element analysis (FEA) simulations were performed to predict failure points under various loading conditions, followed by experimental validation using 3D-printed attachments with variations in slot depth and wall loops. To facilitate testing, a drop test rig was developed and validated. Our results demonstrated a consistent failure point at the slot of the attachment, with a slot depth of 1 mm and three wall loops achieving failure at the target force of 65 N. Additionally, the parameters can be tailored to customize the breakaway force based on user-specific factors, such as comfort and pain tolerance. CAD files and utensil assembly instructions can be found here: https://tinyurl.com/rfa-utensil-attachment**

***Index Terms*—Robot-Assisted Feeding, Assistive Robotics, Mechanical Fail-Safe**

I. Introduction

Robot-assisted feeding systems offer a promising solution for improving the quality of life of those requiring feeding assistance and alleviating the burden on caregivers. Despite significant advancements in developing robust, intelligent, and personalized robot-assisted feeding systems [1], [2], a notable gap exists in designing mechanical fail-safes to ensure user safety. One of the critical safety concerns is the excessive force that can be applied during feeding due to the close physical human-robot interaction required for the task, which poses risks such as discomfort, injury, or damage to the user's oral cavity.

To address this, designing robot systems that limit the force applied during interaction is paramount. Current research systems often focus on sophisticated control algorithms and sensor feedback mechanisms to reduce force [3], [4]; however, mechanical fail-safes provide an additional layer of protection, particularly in unforeseen scenarios where software-controlled mechanisms may not respond. A mechanical solution offers a passive, reliable response to excessive force without relying on the system's active feedback loops.

This work presents a breakaway utensil attachment designed for robot-assisted feeding. The mechanism ensures that when the robotic arm applies excessive force on the user, the spoon automatically detaches, effectively preventing further force transmission to the user. By incorporating this passive fail-safe, we aim to enhance user safety and provide a safeguard against potential harm in unpredictable scenarios.

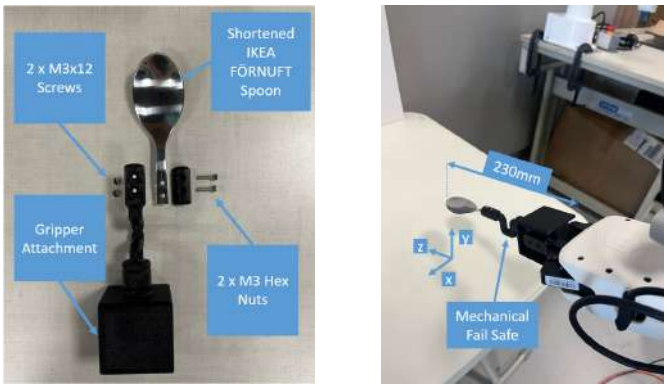
II. Related Work

A. Utensil Attachments for Robot-Assisted Feeding

Grasping a utensil directly using a two-finger gripper, commonly found on robot manipulators, is challenging. To address this, utensil attachments are typically employed to enable secure grasping by connecting utensils, such as spoons or forks, to structures that are easier for the robot to handle [1]–[5]. Additionally, force-torque (FT) sensors are often integrated into these attachments to provide haptic feedback, enabling more precise control during feeding tasks.

Recently, more innovative utensil designs have been proposed that do not take the form of a traditional spoon or fork – Kiri-spoon [6] uses a soft kirigami structure, allowing it to encapsulate and release food easily during bite acquisition. Separately, Gordon *et. al.* [2] presented their robot-assisted feeding system, which features a utensil attachment with a mechanically engineered weak point. This weak point is designed to break when excessive force is applied, eliminating any physical interaction between the robot and the user. However, the design specifics of this mechanism are not detailed, and there remains limited research exploring the integration of mechanical fail-safes in robot-assisted feeding systems.

B. Safety in Assistive Robotics



Safety in human-robot interaction is paramount, especially in assistive robotics, where physical human-robot interaction is common, and robots operate in close proximity to vulnerable users. Existing research on safety can be categorized into three main categories – control methods, motion planning, and behavior prediction. Approaches relying on control methods typically use force-torque sensors, impedance control, or compliance-based control to detect and mitigate excessive forces during interaction [3], [4]. Motion planning approaches aim to preemptively avoid collisions by generating safe trajectories based on real-time sensing and constraints [7]. However, contact is unavoidable in physically assistive tasks such as feeding. For behavior prediction, the focus is on

predicting human intent and motion [8], [9], enabling the robot to adapt its actions proactively to prevent potentially unsafe interactions.

While these methods effectively reduce safety risks, they primarily rely on software-based solutions and AI-driven models, which can be limited by sensor inaccuracies, computational latency, and unanticipated failure modes. Furthermore, these approaches often depend on complex system integrations [10] that may not respond adequately in every scenario. In contrast, our work introduces a safety feature based on mechanical principles, providing an additional safety layer in assistive robotic systems.

III. Approach

A. Design Considerations and Constraints

We designed a utensil attachment for the IKEA Förnuft spoon, ensuring compatibility with any robot manipulator with a two-finger gripper. To secure the spoon, its handle was shortened and attached to the utensil holder using two M3 screws and nuts, as shown in Fig. 1a. The utensil and attachment's total length was limited to a maximum of 230mm to maintain the robot's range of motion during feeding and prevent interference with its movements of the surrounding environment (Fig. 1b).

In assistive feeding, excessive force can occur in two scenarios: (1) sudden impact collisions and (2) slow compressive forces. Sudden impact collisions, such as an unintended rapid movement of the arm striking the user, pose a greater hazard as they can deliver high, localized forces in a very short time frame, increasing the risk of injury. Thus, this work focuses on addressing sudden impact collisions. The mechanical fail-safe was optimized to break at an impact force of $F_{\text{impact}} = 65N$, based on the maximum permissible force that collaborative robots can safely exert on a human face, as defined by ISO 15066 [11], which details safety requirements for collaborative robots.

Additionally, the utensil attachment must be robust enough to withstand forces encountered during normal feeding operations, such as acquiring food and transferring it to the user's mouth. To determine the minimum force threshold, we recorded force-torque data while scooping uncooked black beans, representing a high-force food scenario. To account for variability in food textures, we applied a safety factor of 2.5, resulting in a minimum force threshold of $F = 25N$. This balance between breakaway safety and functional durability is critical to the attachment's performance in real-world use.

B. Breakaway Mechanism Design

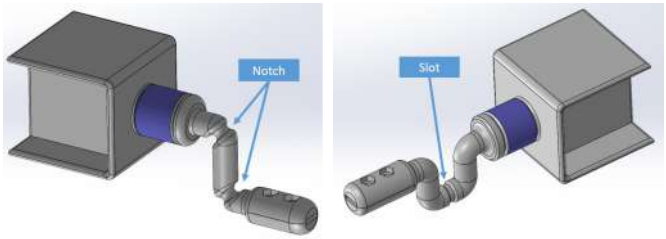
Standard breakaway mechanisms like shear pins, slip clutches, and magnetic couplings were initially considered but introduced bulk, complexity, and higher costs. Instead, we integrated the failure point directly into the 3D-printed shaft, eliminating additional components while maintaining a compact design. We achieved controlled failure by leveraging force moments and reducing the cross-sectional diameter, amplifying stress within the part. Localized stress concentration features, such as notches and slots, were introduced to create predictable failure points, ensuring a consistent breakaway force while maintaining a compact and lightweight design.

The reduced diameter d in these regions increases both torsional stress τ and bending stress σ, as described by:

$$\tau = \frac{16T}{\pi d^3}, \sigma = \frac{32M}{\pi d^3} \tag{1}$$

where T is the applied torque, M is the bending moment, and d is the diameter of the shaft. These stresses combine to produce higher equivalent (Von-Mises) stresses σ_e, which predict failure under complex loading conditions. Von-Mises stress is calculated as:

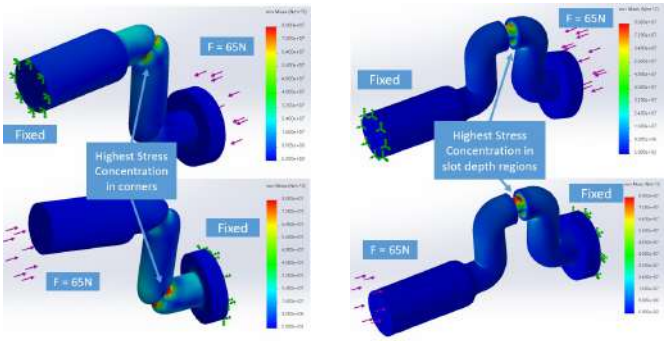
$$\sigma_e = \sqrt{\sigma_x^2 + \sigma_y^2 + \sigma_x^2\sigma_y^2 - 3\tau_{xy}^2} \tag{2}$$



where σ_x and σ_y are the normal stresses in the x and y directions, and τ_{xy} is the shear stress in the x-y plane. Von-Mises stress is used in Section III-C to analyze how the stress is distributed under different loading conditions (Fig. 3).

Guided by these principles, two breakaway mechanism designs were developed: (1) an L-shaped design with notches at the corners and (2) a U-shaped design with a slot in the horizontal section (Fig. 2). These features ensure failure occurs predictably at the intended points under applied forces.

C. Finite Element Analysis (FEA)



Finite Element Analysis (FEA) was conducted using SolidWorks to evaluate the stress distribution and predict the failure points for each design under a compressive force of $F_{\text{compressive}} = 65N$, corresponding to the ISO 15066 [11] threshold. Regions with high-stress concentrations were identified as likely failure points under accidental impacts.

To simulate real-world conditions, FEA was performed with different ends of the part fixed, accounting for variations in how the utensil attachment might interact with the robot's end-effector or contact the user. This provided a comprehensive

evaluation of stress behavior. We focused on front-facing impacts, as they are the most common during feeding, with the robot and spoon approaching the user from the front.

As the parts were designed for 3D printing, anisotropic strength properties resulting from the layer-by-layer construction process introduced challenges in accurately simulating their performance [12], [13]. Factors such as print orientation, infill pattern, and wall thickness influence strength, making it difficult for FEA to provide exact predictions [14]. Therefore, the FEA results were treated as qualitative guides for identifying potential failure points rather than definitive performance metrics.

FEA results on the L-shaped design revealed that stress concentrations were highest at the corners of the bend (Fig. 3a). However, the specific failure location varied based on which end of the part was fixed. This made predicting the exact failure location challenging, complicating systematic testing and parameter adjustments.

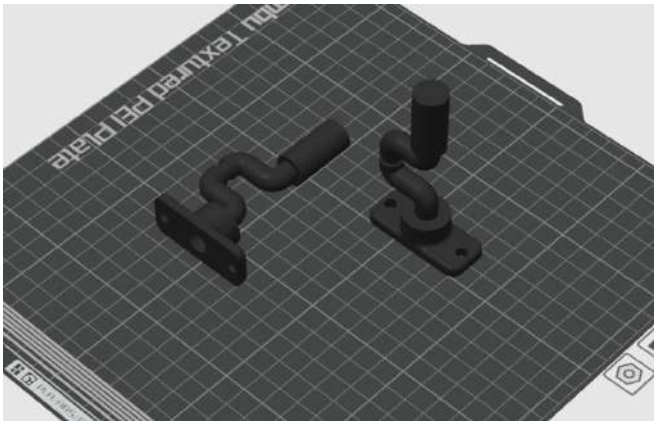
In contrast, the U-shaped design demonstrated consistent stress concentrations at the slot, resulting in a single predictable failure point (Fig. 3b). Given its predictability, the U-shaped design was ultimately selected. The slot depth d was identified as a key variable for systematically evaluating breakage forces.

D. Fabrication via 3D printing

To facilitate rapid prototyping and iterative testing, the utensil attachments were 3D printed. Beyond varying the slot depth d, 3D printing parameters such as wall thickness w and print orientation (Fig. 4a) were adjusted to control the strength and performance of each part. A 15%-density grid pattern was used as the infill for all printed parts. All parts were printed using the Bambu Lab X1C 3D printer (China) and the eSun PLA+ 1.75mm filament (China) to ensure uniformity across iterations and eliminate variability from printer inconsistencies.

Print orientation was critical due to the anisotropic strength of 3D-printed parts. Initially, parts were oriented with layer lines perpendicular to the intended breaking line to maximize strength [15], [16]. However, this configuration resulted in inconsistent and unclean breaks (Fig. 4b), making it more challenging to predict the failure behavior.

To address this, the layer lines were aligned parallel to the breaking line (Fig. 4c). This orientation leveraged the inherent layer-to-layer weakness of 3D printing, ensuring predictable failure at the desired location. The mechanical failure point resulting from a collision produces a clean break with smooth edges, minimizing the risk of injury to the patient. Wall thickness w was also varied to fine-tune the breakaway force, with thicker walls increasing strength and thinner walls reducing the force.



IV. Experiments

A. Experimental Setup and Design

A drop test rig was developed to evaluate the impact strength of the utensil attachments (Fig. 5). The rig included a 20kg single-point load cell with an intrinsic resolution of 1/3000 of its full-scale range (SIWAREX WL260 SP-S SA, Siemens, Germany) to measure the impact forces. Data acquisition (DAQ) was facilitated using a 24-bit amplifier (DAT 1400, Pavone Systems, Italy), which amplified and conditioned the signals from the load cell. The system was calibrated using the Optimation software (Pavone Systems, Italy) with a scaling factor of 1V = 20N for voltage-to-force conversion. The amplifier's display resolution was set to $\pm 0.01N$.

A motion capture system (Qualisys AB, Sweden) was employed to record the load cell readings and the kinematics of each drop, including position, velocity, and acceleration. Retro-reflective optical markers were placed on the basket of the test rig for precise motion tracking. The Qualisys Track Manager (QTM) v2019 was used as an integrated software interface for seamless and easy-to-use data recording, which we used to synchronize the cameras with the load cell. The trajectories of the markers and the load cell readings were captured synchronously at 200Hz and 2000Hz, respectively.

To ensure consistent alignment during testing, a 500mm linear guide rail with two linear guide blocks stabilized the weight basket. Grease was applied to the rail interface to reduce friction and ensure smooth motion. The weight basket was designed to hold varying masses, and the test parts were attached to it for drop testing.

(a)

(b)

(c)

Fig. 4: 3D printing orientations – (a) Visualization of two 3D printing orientations in the Bambu slicer: the left corresponds to (b), and the right corresponds to (c). (b) Print orientation with layer lines perpendicular to the breaking line for strength, resulting in an unclean break (c) Print orientation with layer lines parallel to the breaking line, producing a clean break

The drop height was controlled using a 3D-printed slot and a brass rod mechanism. The slot, mounted on the central aluminum profile, held the brass rod in place until manually released. This setup ensured consistent and reliable impact force readings at each height.

The rig's framework was constructed using 40 x 40mm aluminum profiles and secured with L-brackets to minimize structural damping during collisions. Additionally, two 10kg weights were placed on the rig to enhance stability and further reduce damping effects.

B. Validation of Test Rig

Before conducting our experiments, we conducted some validation checks. Static validation was performed by loading calibrated weights onto the load cell and verifying that the readings matched the known weights. The measured readings were consistent with the known weights, confirming the static accuracy of the load cell.

The actual impact force F_{actual} was determined using the peak voltage V_{peak} from the voltage-time graph recorded by the load cell. With a scaling factor of 1V/20N, the impact force was calculated as:

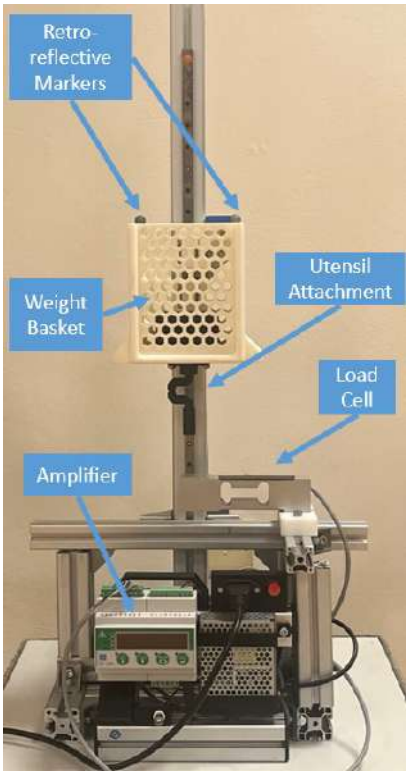


Fig. 5: Drop test rig

$$F_{\text{impact}} = (\frac{20N}{V})V_{\text{peak}} \tag{3}$$

The theoretical impact force $F_{theoretical}$ was calculated based on the principle of energy conservation, assuming no energy losses during impact. The kinetic energy of the weight basket and utensil attachment before impact KE was equated to the work done WD on the load cell:

$$KE = \frac{1}{2}mv^2, WD = Fd_{\text{stop}}, KE = WD$$

From these equations, the impact force was derived as:

$$F_{theoretical} = \frac{mv^2}{2d_{\text{stop}}} \tag{4}$$

where m is the total mass of the weight basket and attachment, v is max velocity before impact, and d_{stop} is the stopping distance, approximated as the difference between the resting position p_{rest} and the lowest position p_{lowest}, i.e. $d_{\text{stop}} = p_{\text{rest}} - p_{\text{lowest}}$. The lowest position is determined by identifying the lowest point on the displacement vs. time graph, while the resting position is obtained from the initial state when the weight basket rests on the load cell.

The sample values used in the validation are summarized in Table I. As expected, the theoretical impact force was greater than the experimental value due to the assumption of no energy losses in the theoretical calculation. In real-life experiments,

TABLE I: Sample Values for Impact Force Validation

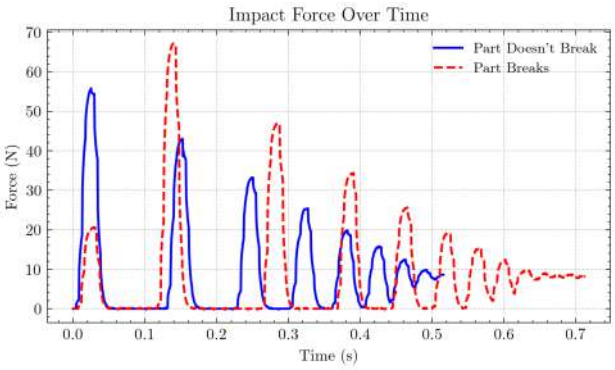
Variable	Value
Mass, m	0.735 kg
Resting Position, p_{rest}	690.489 mm
Lowest Position, p_{lowest}	687.429 mm
Max Velocity, v	860.634 mm/s
Theoretical Impact Force, $F_{\text{theoretical}}$	89.0 N
Peak Voltage, V_{peak}	3.78 V
Actual Impact Force, F_{actual}	75.6 N
Percentage Error, e	17.7%

energy losses occur due to factors such as sound generation and damping in the rig structure. The difference between the theoretical and actual impact forces of $13.4N$ corresponds to an error of 17.7%, which is within the acceptable range, validating the rig for further testing.

C. Experiment Procedure

In our experiments, we evaluated the strength of the utensil attachment by varying two parameters: the slot depth d and the number of wall loops w used during 3D printing. To determine the minimum force required to break the attachment, we conducted drop tests by varying the height at which the weight basket and attachment were released onto the load cell. If the attachment did not break, we recorded the peak forces and incrementally increased the drop height by $1.0cm$ until the attachment broke.

Once the approximate range of heights where the part transitioned between breaking and not breaking, we refined our testing by reducing the height increments to $0.2cm$. Height increments were limited to $0.2cm$ during this stage, as smaller increments of $0.1cm$ were impractical to achieve consistently. For instance, if the part broke at $h = 5.0cm$ but did not break at $h = 4.0cm$, we tested intermediate heights such as $h = 4.8cm$ and $h = 4.6cm$. Starting from the highest height within the identified range, we conducted three trials at each height to ensure consistency and reliability of the results.



If the part consistently broke at a specific height, we decreased the height incrementally and repeated the trials until the parts stopped breaking. The impact force was the primary peak force in the force-time graph for parts that did not break (Fig. 6a). However, for parts that broke, the impact force could not be derived from the graph due to the smaller first peak, as energy is dissipated through the breaking process rather than being fully transferred to the load cell (Fig. **??**). Thus, the breaking height was the highest height where the part did not consistently break across trials. For example, if the part consistently broke at $h = 4.6cm$ but started not breaking at $h = 4.4cm$, we considered $h = 4.4cm$ as the breaking height as shown in Table II.

Once the breaking height was determined, we calculated the average peak force recorded during the trials at that height, where some or all parts did not break, to estimate the breaking force. This approach provided a conservative estimate of the breaking force, reflecting the force just below the threshold of consistent failure. Hence, the actual impact force required to break the attachment is slightly higher than the average impact force recorded.

TABLE II: Peak Impact Forces for $d = 1.0mm$ and $w = 3$

Height (cm)	t_1 (N)	t_2 (N)	t_3 (N)	Average (N)
4.2	62.8	63.4	63.4	63.2
4.4	N/A	65.0	N/A	65.0
4.6	N/A	N/A	N/A	N/A

Fig. 6: Force-time graph for a part that does not break (blue solid line) and a part that breaks (red dashed line). The impact force is determined from the primary peak in the blue solid line, representing the maximum impact force experienced by the part. In contrast, for the red dashed line, the impact force cannot be derived due to the smaller first peak, which occurs as the part breaks upon impact.

Fig. 7: Consistent failure point at the slot of the breakaway mechanism

V. Results

The results from the experiments are summarized in Table III. Based on the data, we observe that the impact force

TABLE III: Effect of Slot Depth d and Wall Loop w on Impact Force

Slot Depth d (mm)	Wall Loops w	Average Peak Force F_{avg} (N)
1.0	6	75.6
1.0	3	65.0
2.0	6	53.1
2.0	3	45.0

required to break the attachment increases with the slot depth d and decreases with the number of wall loops w.

The configuration that produces an impact force closest to the maximum permissible force $F_{\text{max}} = 65N$ is achieved when the attachment has a slot depth of $d = 1mm$ and is printed with $w = 3$ wall loops, which yielded an average impact force of $F_{\text{impact}} = 65.0N$. This configuration is selected as the optimal design for the breakaway mechanism.

In scenarios where the maximum permissible force needs to be reduced – for example, to accommodate lower pain thresholds or to prioritize enhanced safety – the parameters can be refined to achieve the desired reduction. For instance, if a maximum permissible force of $F_{\text{max}} = 50N$ is desired, the configuration with $d = 2.0mm$ and $w = 6$ wall loops, which produces an average impact force of $F_{impact} = 53.1N$, could be adjusted by reducing the number of wall loops to lower the breaking force further.

These results demonstrate the utility of systematically varying slot depth and wall loop parameters to design a breakaway mechanism that can be tailored to meet specific force requirements. Furthermore, our experiments revealed that our design resulted in a consistent failure point, which is at the slot of the utensil attachment (Fig. 7).

VI. Conclusion and Future Work

In conclusion, we designed a utensil attachment with a mechanical fail-safe that breaks around the maximum permissible force exerted on a human face by robots $F_{\text{max}} = 65N$. To ensure the part breaks at a consistent breaking point, the parts were printed with the layer lines parallel to the intended breaking line, allowing for controlled and predictable failure behavior. To evaluate the performance of the mechanism, we developed a drop test rig, simulating collisions between the robot arm and the user and conducted systematic experimental testing. Through our experiments, we established how design parameters such as slot depth d and wall loops w affect the impact force required to break the attachment.

While the results offer valuable insights into designing effective mechanical fail-safes, the study has some limitations. For instance, the testing procedure did not account for impacts at angles, which could affect the breaking behavior. The experiments were also conducted in a controlled setting using a drop test rig, which does not fully replicate real-world interactions between the utensil and user.

Future work should address these limitations by testing angled impacts and testing with the actual robotic arm and utensil to evaluate performance under real-world conditions. Additionally, other design and 3D printing parameters, such as infill density and infill pattern, could also be investigated to optimize the attachment further. Furthermore, determining the maximum permissible force based on user-specific factors, such as pain tolerance and comfort levels [17], could further enhance the safety and customization of these attachments.

Learning Speed-Adaptive Walking Agent Using Imitation Learning With Physics-Informed Simulation

Yi-Hung Chiu*[1], Ung Hee Lee*[2], Changseob Song[1], Manaen Hu[1], and Inseung Kang[1] *Member, IEEE*

***Abstract*— Virtual models of human gait, or digital twins, offer a promising solution for studying mobility without the need for labor-intensive data collection. However, challenges such as the sim-to-real gap and limited adaptability to diverse walking conditions persist. To address these, we developed and validated a framework to create a skeletal humanoid agent capable of adapting to varying walking speeds while maintaining biomechanically realistic motions. The framework combines a synthetic data generator, which produces biomechanically plausible gait kinematics from open-source biomechanics data, and a training system that uses adversarial imitation learning to train the agent's walking policy. We conducted comprehensive analyses comparing the agent's kinematics, synthetic data, and the original biomechanics dataset. The agent achieved a root mean square error of 5.24±0.09 degrees at varying speeds compared to ground-truth kinematics data, demonstrating its adaptability. This work represents a significant step toward developing a digital twin of human locomotion, with potential applications in biomechanics research, exoskeleton design, and rehabilitation.**

***Index Terms*— Speed-Adaptive Walking Agent, Imitation Learning, Physics-Informed Simulation, Human Locomotion**

I. Introduction

Human mobility is a fundamental aspect of daily life, as it allows essential activities, promotes health through physical exercise, and contributes to psychological well-being [1], [2]. However, millions of people in the United States alone face mobility challenges due to conditions such as loss of limbs, paraplegia, and obesity, which decrease quality of life by affecting daily tasks, limiting exercise, and often leading to mental health issues such as depression and anxiety [3], [4]. Restoring gait functionality is crucial to improving the quality of life of people with mobility impairments, necessitating a deep understanding of gait mechanics. Although traditional methods such as motion capture systems and force plates have been used for gait analysis [2], [5], these approaches are costly, time-consuming, and labor intensive, highlighting the need for more efficient and accessible alternatives to support rehabilitation and improve mobility outcomes.

Digital twins, a virtual representation of physical systems, have emerged as a powerful tool in biomechanics and rehabilitation [6], [7]. These computational models simulate human gait biomechanics in controlled environments, eliminating the need to collect human motion data while providing valuable information on joint coordination, muscle activities, and gait balance [8], [9]. In addition, these models are particularly beneficial when developing wearable assistive devices or novel rehabilitation techniques [10]–[13]. Digital twins can model how these devices interact with the human body, offering a safe alternative to testing new control strategies directly on human subjects in physical settings. However, a significant challenge remains in ensuring that these digital twins accurately represent the real human body and its interactions with the environment, which is commonly referred as a sim-to-real gap [14], [15]. The fidelity of these models is vital for translating simulation results into practical applications, and ongoing research aims to bridge the gap between virtual simulations and real-world performance.

Significant efforts have been made within the biomechanics community to develop realistic simulation environments for human movement analysis. Among these, OpenSim [6], an open-source platform, is renowned for its comprehensive musculoskeletal models, enabling researchers to study joint dynamics and muscle forces. Despite its strong community support, OpenSim's relatively steep learning curve, high computational demands, and limited integration with machine learning (ML) frameworks present challenges for researchers looking to leverage data-driven approaches. Similarly, AnyBody [16], a proprietary system, offers detailed musculoskeletal modeling with robust industrial applications in ergonomics and orthopedics. However, its high cost and restricted accessibility hinder widespread adoption. Recent advancements, such as MyoSuite [17], have begun bridging these gaps by offering open-source musculoskeletal environments built on the multi-contact physics engine MuJoCo [18]. MyoSuite combines anatomical fidelity with seamless integration into widely used machine learning frameworks, making it well-suited for tasks such as musculoskeletal motor control using reinforcement learning; however, it is relatively underdeveloped compared to more established tools. These tools collectively demonstrate a spectrum of capabilities, catering to various research needs and priorities.

Accurately recreating human movements in virtual models is vital for analyzing gait biomechanics, as realistic simulation environments alone are insufficient. Replaying motion capture data alone is insufficient because it does not account for variations in human morphology (e.g., differences in height), tasks, and activities [19]. In addition, locomotive strategies often vary between individuals. To address these challenges, researchers have developed control policies for

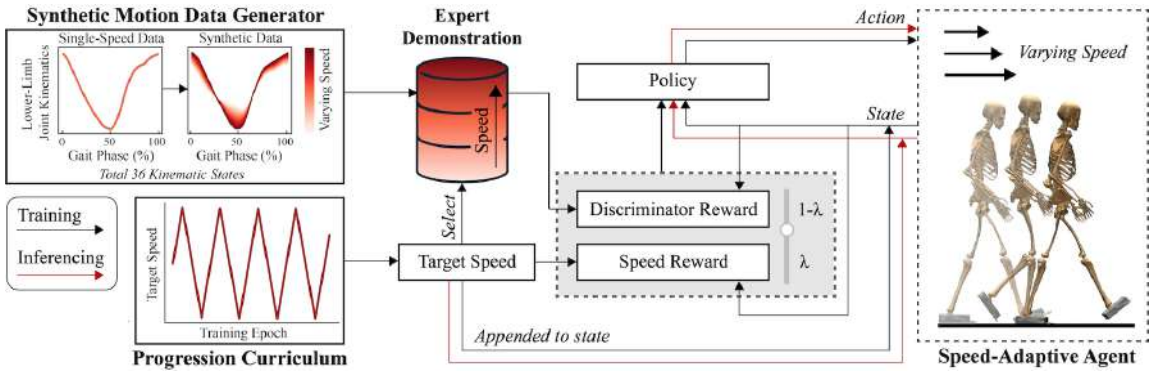

Fig. 1. Overview of our framework for training a speed-adaptive walking agent. The framework includes two main components: generating expert demonstrations and policy optimization. Expert demonstrations from motion data are used to train a discriminator that distinguishes expert- from policy-generated actions at different speeds. The reward function combines the discriminator's output with a speed reward (difference between the agent's target and actual center of mass speed). These rewards optimize the walking policy using trust region policy optimization. The target speed is part of the agent's observation space, with a progressive curriculum exposing the agent to a range of speeds during training. Evaluation tests the agent's ability to achieve the desired speed under varying conditions.

virtual skeletal humanoids to mimic human gait biomechanics. Techniques such as imitation learning and reinforcement learning have been employed to simulate human locomotion in virtual environments [20], [21]. However, these methods focus on training agents to replicate kinematic profiles for a single locomotor task or a single target speed [22], [23]. Such approaches lack generalizability for different tasks, speeds, and subjects, significantly limiting their applicability. This constraint undermines the utility of virtual models, restricting their use to narrow, task-specific scenarios rather than to the diverse applications that they are intended to support. Although there are ongoing efforts to train a single policy that can generalize across different speeds within specific activities, these studies typically employ agents with limited DOF compared to musculoskeletal models, reducing their potential for real-world interpretability [20], [21], [24].

In this work, we trained and validated a skeletal humanoid agent using imitation learning, capable of generalizing across various walking speeds using a high-fidelity physics engine. The key contributions of our study are as follows: (1) we developed a robust pipeline for generating synthetic lower-limb motion data derived from real-world lower-extremity gait biomechanics dataset, (2) using this synthetic dataset, we trained an agent with adversarial imitation learning that is capable of a natural and stable locomotion, (3) we performed an ablation study incorporating curriculum learning and an additional speed-based reward term to evaluate the agent's generalizability across speeds, and (4) we conducted comprehensive statistical analyses to compare the synthetic motion data-based agent's resulting kinematics and the original gait biomechanics dataset. Our work represents a significant step toward developing a digital twin that replicates human lower-limb gait biomechanics, with potential applications in biomechanical research, the design of wearable assistive devices, and rehabilitation. Our implementation of the proposed pipeline is publicly available at: `https://metamobility.cmu.edu/speed-adaptive-agent/`.

II. Methods

This study aims to develop a virtual locomotion agent capable of adapting to varying walking speeds while exhibiting gait profiles that closely resemble those of its biological counterpart. We designed a framework to train a speed-adaptive agent using imitation learning to replicate expert demonstrations derived from an open-source biomechanics dataset [25] (Fig. 1). This section outlines the simulation environment and skeletal model utilized, the training pipeline using our synthetic data generator, the learning algorithm via curriculum strategies, and the statistical analyses to compare the agent's performance against a baseline benchmark.

A. Environment and Task

We used LocoMuJoCo [26] as the simulation environment to train a walking skeletal agent. The simulation is designed to enable researchers to train and evaluate ML-based agents for locomotion tasks in realistic environments. LocoMuJoCo was selected because it offers high-DOF skeletal models that resemble human biomechanics, seamless ML integration, and realistic multi-contact dynamics via MuJoCo physics simulator [18].

Among the skeletal humanoid models available in LocoMuJoCo, we selected the one tailored to our study's focus on locomotion. LocoMuJoCo provides muscle and skeletal models and has four different categories of age groups. Specifically, we utilized an adult-sized skeletal model in which joint torques are directly actuated, bypassing the complexity of muscle contraction and the higher DOF present in muscle-actuated models. This model preserves the relevant joints (i.e., action and observation spaces) for walking while simplifying or omitting other components of the body (e.g., upper limb). The model, adapted from [27], represents an adult human with a total body mass of 86.62 kg. The upper body was fixed, and the foot structure is represented as a rigid box, omitting the subtalar and metatarsophalangeal joints. The observation space comprises 36 dimensions, which capture the angles and angular velocities of the lumbar,

hip, knee, and ankle joints, as well as the vertical position and velocity of the pelvis. The action space includes 13 dimensions, controlling the torques applied to the lumbar, hip, knee, and ankle joints. These abstractions maintain essential locomotion dynamics while improving computational efficiency.

LocoMuJoCo offers two locomotion tasks: walking and running. For the scope of our study, we selected the walking task. Additionally, the environment provide datasets for each task, and we utilized the dataset consists of a single subject walking for 15 minutes at a speed of 1.25 m/s, post-processed from a motion capture system [26].

B. Synthetic Motion Data Generator

We developed a synthetic motion data generator to approximate biomechanics across a diverse range of walking speeds. Humans adapt their walking patterns to environmental conditions (e.g., terrain context) and intentions (e.g., walking faster) by adjusting stride length, gait, and balance. Capturing these variations is crucial to creating a digital twin capable of producing human-like locomotion in everyday scenarios. However, most existing datasets only capture discrete conditions within a task (e.g., specific speeds or slope inclines), primarily due to the limitations of generating such conditions in lab settings with human subjects [28]–[30]. While collecting multi-speed motion capture data is feasible, it requires significant time and resources. To address these challenges, we designed the generator to produce synthetic yet biomechanically natural data, enabling the creation of realistic gait trajectories for training a virtual agent.

The synthetic motion data generator leverages an open-source lower-limb biomechanics dataset [25] that provides treadmill walking data from 22 subjects, covering speeds from 0.5 m/s to 1.85 m/s in 0.05 m/s increments. The dataset includes detailed lower-limb joint (i.e., hip, knee, and ankle) kinematics and kinetics, offering a comprehensive biomechanical representation of human gait. Using this dataset, we aggregated and averaged gait profiles across subjects within a gait cycle (heel strike to heel strike of the right leg) at each speed. We created synthetic gait kinematics by fitting a linear model to the open-source biomechanics dataset averaged across subjects. By applying the linear model to the LocoMuJoCo's single-speed walking dataset, we generated artificial data that vary across speeds. The use of synthetic kinematics instead of the open-source dataset ensured adherence to the model's physical morphology while maintaining realistic biomechanical correlations across varying speeds. Specifically, we first uniformly distributed 21 points within a gait cycle from the open-source biomechanics dataset, and then a linear model was fitted to each point as a function of walking speed. The number of points was determined to effectively capture the kinematic changes across different speeds while avoiding overfitting to the open-source dataset. Synthetic velocity data were derived by differentiating the synthetic position data.

The quality of the synthetic data was evaluated by comparing the gait profiles of the synthetic dataset to the open-source biomechanics dataset. The root mean square error (RMSE) and the coefficient of determination (R^2) were calculated for the hip, knee, and ankle joint kinematics, which were averaged over all gait cycles, providing a quantitative evaluation of the generated joint trajectories.

C. Training Speed-Adaptive Imitation learning Agent

We employed Variational Adversarial Imitation Learning (VAIL) to train the agent's control policy under varying speeds [24]. VAIL uses a Generative Adversarial Network structure—where the generator (policy π) competes with the discriminator D—with an encoder mapping outputs to a latent space to regularize training.

To facilitate the training of a speed-adaptive imitation learning agent, we incorporated the target speed into the observation space as a proxy of the human intent of desired walking speed, allowing the agent to dynamically adapt to varying speed commands. The agent processed the skeletal model's kinematics as inputs and returned joint torques as actions. The reward function was defined as follows

$$r = (1-\lambda)(-\log(1-\frac{1}{1+\exp(-D(\mathbf{z}))})) + \lambda r_{speed} \quad (1)$$

$$\mathbf{z} \sim E(\mathbf{z}|s,a) \quad (2)$$

where $D(\mathbf{z})$ is the discriminator output that measures the closeness of state and action pair of the agent to the expert demonstration, $\mathbf{z}$ is the encoding sampled from the latent space representation by the encoder given state s and action a, and r_{speed} is the speed reward which captures the difference between the target and simulated velocity. Specifically, speed reward was defined as the exponential of the negative error squared of the target speed and the current speed of the agent's center of mass (COM) velocity in the Sagittal plane. These two rewards were adjusted during training with a weighting ratio λ. This formulation allowed the agent to match its gait profiles with the expert demonstration (i.e., synthetic motion data) while simultaneously tracking the target speed. Trust Region Policy Optimization [31] was used to optimize the policy with reward as the objective. We trained the agent for 4000 epochs with 5000 environment steps per epoch. The policy was updated every 1000 steps and the discriminator was updated every 3000 steps.

1) Curriculum learning: Curriculum learning specifies the order of training data, which can improve the robustness and generalization of the model. In this study, we tested two curriculum approaches to train a walking agent: a random curriculum, where target speeds were randomly selected at the start of every epoch, and a progressive curriculum, where the target speed gradually cycled back and forth across the range of speeds. The range of target speeds were capped at the speeds available in the dataset, from 0.65 m/s to 1.85 m/s.

2) Balancing reward contributions: We also studied the balance between two reward streams: (1) speed rewards that represent how well the agent maintains the specified target speed and (2) discriminator rewards, which reflect how closely the agent matches the biomechanics in the dataset.

We tested the reward ratios of discriminator reward to speed reward, ranging from 0 to 1 in increments of 0.1 to determine the optimal balance for achieving the best performance.

3) Baseline agent: To evaluate our speed-adaptive agent training pipeline, from synthetic data generation to training with imitation learning, we configured a baseline agent. This baseline agent had limited access to multi-speed data from our synthetic generator, but was otherwise trained under identical conditions to the agent utilizing the full training pipeline with the optimal setting. Although the baseline agent had access to different speed information during the training process, this was only through the speed-based reward and the target speed state.

D. Model Evaluation and Analysis

To evaluate a fully trained agent against ground-truth kinematic data and its generalizability across different speeds, we conducted five simulation experiments. In each trial, the agent was evaluated over three episodes at each target speed, ranging from 0.65 to 1.85 m/s in 0.1 m/s increments. Each episode lasted for a maximum of 1000 time steps or until the agent fell, whichever occurred first. During these evaluations, we collected time series data of joint kinematics for analysis. The collected data were segmented into individual gait cycles by identifying the local minimum peaks at the hip joint in the Sagittal plane. To ensure reliable gait segmentation, we discarded gait cycle data that had a stride duration less than 60 time steps (0.6 seconds).

We evaluated the agent's performance by calculating the RMSE of the averaged differences in the hip, knee, and ankle joint angles between the synthetic dataset and the generated gait profiles of the trained agent across all speed conditions. We used R^2 to assess how closely the agent's predicted joint angle profiles matched the dataset. Additionally, we measured the agent's COM velocity and compared that to the target speed we prescribed during evaluation. The optimal configuration of the curriculum strategies and reward ratios was identified by the aggregated R^2 values, comparing synthetic data to the agent's kinematic output, across joint angles and speeds. We prioritized R^2 because RMSE values, expressed in different units (degrees and m/s), complicated cross-experiment comparisons.

To compare the agent's performance between the baseline and optimal settings, we performed statistical analyses using a paired sample t-test, with a significance level of 0.05. We also compared the agents' ability to track dynamic target speeds. During this test, we calculated the average measured speed over 10 episodes of 50-second inference with a time-varying sinusoidal target speed (i.e., chirp signal), where the frequency linearly increased from 0.01 Hz to 0.05 Hz.

III. Results

A. Synthetic Motion Data Generator

The kinematic gait profiles (i.e., joint angles) generated by the linear model demonstrated consistent variations and shapes across speeds for each lower-limb joints: hip, knee, and ankle (Fig. 2). Across all lower-limb joints, the synthetic data resulted in an RMSE of 8.10±0.16°and an R^2 of 0.59 compared to the biomechanical ground truth.

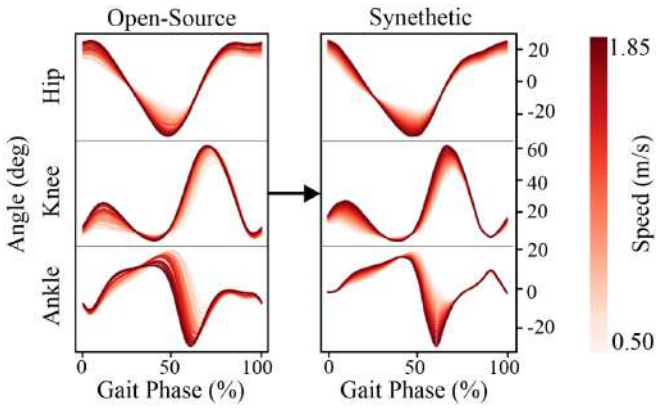

Fig. 2. Comparison of joint kinematics between open-source biomechanics and synthetic data across varying speeds. A linear model was fitted to joint kinematics from an open-source gait biomechanics dataset. This model was then used to generate synthetic kinematic profiles during training.

B. Effect of Curriculum Learning

We evaluated the differences in the joint angles between the synthetic data and the trained agent at various speeds using two curriculum strategies. In addition, we analyzed the differences between the target and the simulated COM speeds achieved by the agent under these conditions. The progressive curriculum strategy resulted in a 41.48±3.06% reduction in RMSE and a 47.77±4.37% increase in R^2 for joint angles compared to the random strategy (Fig. 3). Similarly, the progressive curriculum strategy achieved a 35.11±16.46% lower RMSE and a 5.67±2.31% higher R^2 for speed tracking compared to the random strategy.

C. Effect of Reward Contributions

We evaluated the joint angle differences between the synthetic dataset and the trained agent at various speeds under different ratios of two reward components: discriminator and speed (Table I). In addition, we evaluated the discrepancies between the target and the simulated COM speeds of the agent under these conditions. These differences were quantified using RMSE and R^2. Speed reward ratios of

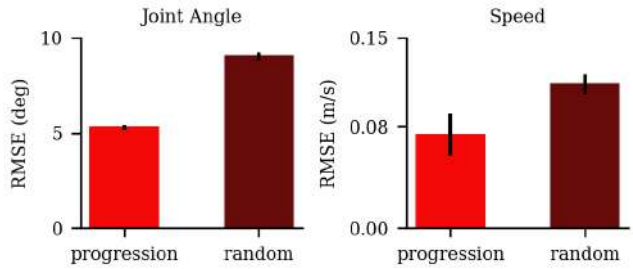

Fig. 3. Effect of curriculum learning on the walking agent's performance during training. The red plot represents the case for changing the target speed in a progressive way and the brown plot stands for a random case at every training epoch. Error bars indicate ±1 standard deviation.

0.4 and above 0.5 were excluded from our analysis due to the absence of viable samples after filtering gait cycles with values below 0.6 seconds, which exhibited unnatural gait patterns (Fig. 4). Among the included ratios, a speed reward ratio of 0.1 resulted in the lowest RMSE and the highest R^2 for joint angle differences, while the 0.5 ratio achieved the lowest RMSE and highest R^2 for speed comparisons.

TABLE I

EFFECT OF WEIGHTING OF THE REWARD CONTRIBUTIONS.

Reward Ratio		Target vs. Measured Speed		Ground Truth vs. Measured Joint Angle	
Discriminator	Speed	RMSE (m/s)	R^2	RMSE (°)	R^2
1	0	0.51±0.02	-0.85±0.14	5.42±0.16	0.80±0.01
0.9	0.1	0.19±0.01	0.73±0.02	**3.86±0.07**	**0.90±0.01**
0.8	0.2	0.13±0.01	0.88±0.01	4.97±0.06	0.85±0.01
0.7	0.3	0.08±0.02	0.95±0.02	5.38±0.15	0.81±0.01
0.6	0.4	0.07±0.01	0.96±0.01	-	-
0.5	0.5	**0.06±0.01**	**0.98±0.01**	5.24±0.08	0.83±0.01

Effect of varying speed and discriminator reward ratios during training. Results with bold fonts indicate the best walking performance for each evaluation criteria (i.e., target speed and kinematic profile).

D. Optimal Agent Settings

Based on the aggregated R^2 values across speed and joint angle comparison, the best-performing agent utilized a speed reward ratio of 0.5, a discriminator ratio of 0.5, and a progressive curriculum strategy. The agent with optimal settings significantly outperformed the baseline benchmark in both speed and joint angle metrics (p <0.05). Specifically, the optimal agent achieved an RMSE of 0.06±0.01 m/s and 5.24±0.09°, and an R^2 of 0.98±0.01 and 0.83±0.01 for speed and joint angles, respectively. In contrast, the baseline agent resulted in an RMSE of 0.24±0.01 m/s and 6.49±0.12°, and an R^2 of 0.59±0.01 and 0.70±0.02 for speed and joint angles, respectively. Lastly, the optimal agent outperformed the baseline in tracking dynamically changing speeds, accurately matching targets across all frequency ranges. In contrast, the baseline struggled to follow the target speeds, only approximating the rough trend (Fig. 5).

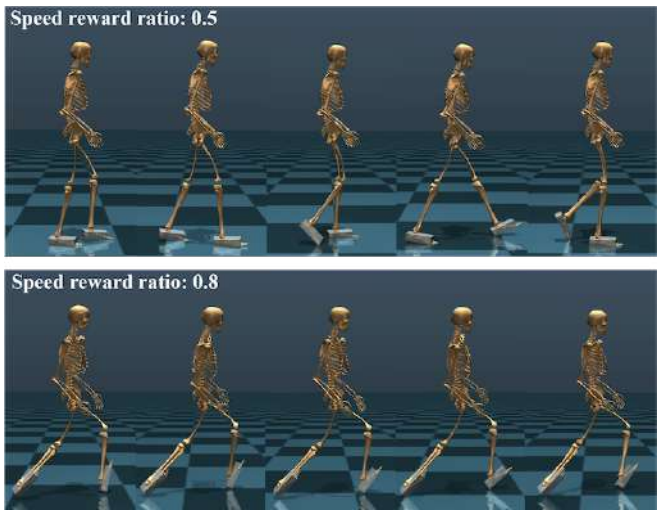

Fig. 4. Representative walking agent with optimal (top) and suboptimal (bottom) settings. Suboptimal agent (e.g., higher ratio of speed reward) exhibited abnormal gait patterns, such as irregular limb coordination, exaggerated dorsiflexion, and asymmetric range of motion.

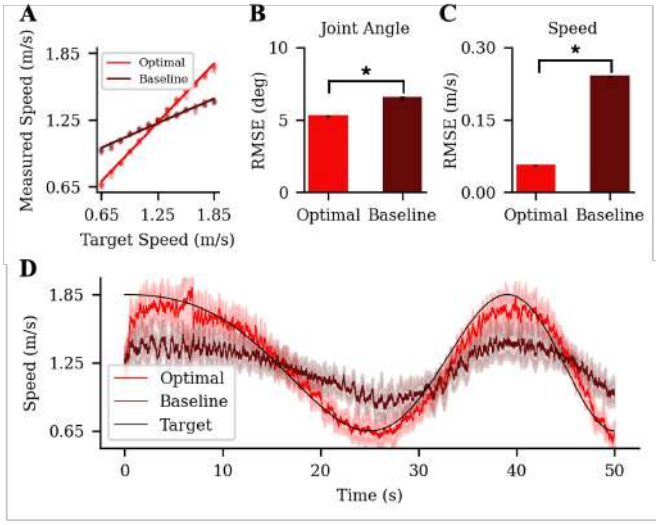

Fig. 5. Walking agent performance with optimal and baseline settings. (A) Target speed tracking performance across varying conditions. Tracking error for (B) joint angles and (C) COM speed relative to ground-truth data. (D) Walking agent's adaptability to dynamically changing walking speeds. Error bars and shaded regions indicate ±1 standard deviation, and asterisks indicate statistical significance ($p < 0.05$).

IV. DISCUSSION AND CONCLUSION

In this work, we presented a pipeline for optimizing a speed-adaptive walking agent using synthetic motion data and adversarial imitation learning, where our optimal agent achieved a stable, biomechanically plausible locomotion. The agent with optimal settings outperformed the baseline, highlighting the effectiveness of our pipeline. This included the synthetic data generator, underscoring the importance of speed-dependent data for producing biologically plausible gait while achieving target speeds. Furthermore, an evaluation of curriculum learning strategies showed that progressive speed transitions significantly outperformed random shuffling. We attribute this to frequent and abrupt changes in the target speed under the random strategy, which likely disrupted the agent's ability to establish a stable walking pattern. In contrast, the progressive curriculum facilitated a smoother transition between speeds, allowing enough time for the agent to develop stable walking dynamics without falling. Compared to prior methods on imitating human walking in simulation [32]–[34], our results not only achieved comparable kinematic profiles but also biomechanically plausible joint moments and powers (Fig. 6). These additional metrics provide deeper biomechanical insights, extending the analysis beyond kinematic comparison, and enhancing the framework's applicability to the real-world use case.

Despite these contributions, our framework has several limitations. First, the synthetic data generator uses a lin-

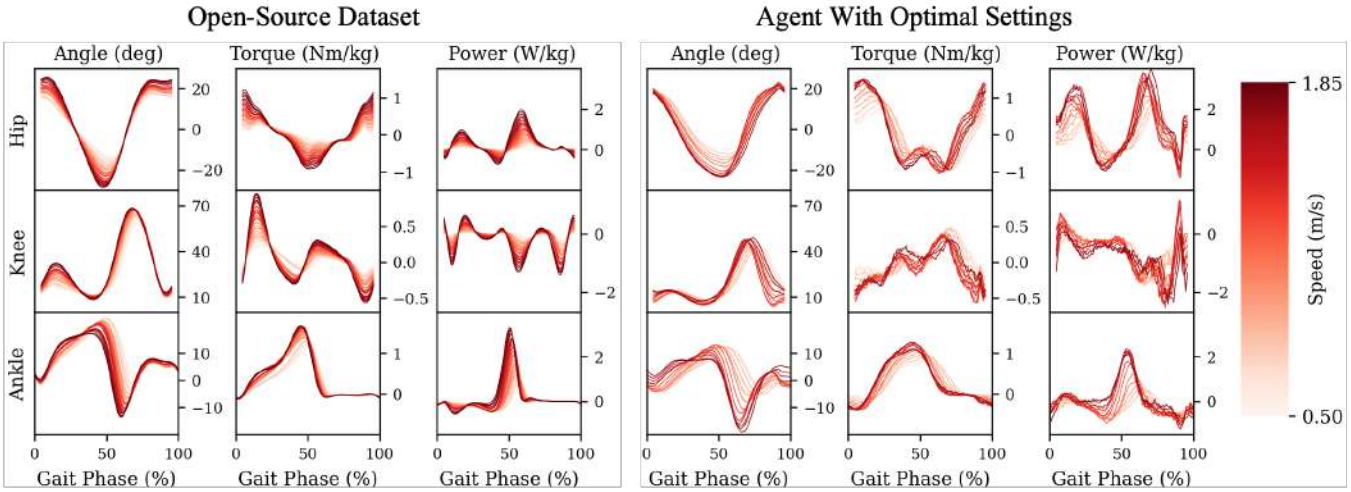

Fig. 6. Gait biomechanics comparison between the open-source dataset (left) and our optimal walking agent (right) across varying speeds. Each curve from the open-source dataset represents the average gait across all subjects in the dataset, while each curve from the optimal walking agent represents the average gait across 50 episodes of evaluation. Torque and power values were normalized by body mass.

ear model to capture gait trends, which may oversimplify the nonlinear behaviors seen at certain speeds (e.g., slow walking) and contribute to deviations from actual human biomechanics (Fig. 2), ultimately affecting the trained agent's gait profile (Fig. 6). Moreover, the linear model was fitted to the average data of 22 subjects, which filtered out individual variations in human gait dynamics. As a result, synthetic data may not adequately reflect the unique biomechanics of real individuals.

We investigated the use two reward components, the discriminator and the speed reward, to enable the agent to achieve a desired speed while exhibiting natural walking patterns. However, redundancy may have existed in our reward formulation, as the COM speed was already encoded in the discriminator, which evaluated kinematics against expert data at each speed. We hypothesized that an explicit speed reward would improve accuracy and our results supported this, with the RMSE decreasing as the speed reward ratio increased (Table I). However, beyond a 0.5 ratio, the agent produced unrealistic gait profiles, as shown by the RMSE trend and visual inspections (Fig. 4). This limitation is mainly due to the speed reward enforcing constant COM speed across gait cycles, which conflicts with the natural cyclic variations of human gait.

Although our optimal agent showed reduced kinematic deviations from the ground truth compared to the baseline agent, notable discrepancies were observed when compared to real human biomechanics (Fig. 6). For example, the agent's hip torque profile showed an additional extension peak around 50% of the gait cycle. Additionally, the agent's knee joint torque and power profiles deviated from those of biological counterparts. These discrepancies were mainly due to the gap in expert demonstrations using our synthetic data, which only provided joint kinematics but not corresponding kinetics. Lastly, a simplified box foot model, which reduces the complexity of contact dynamics, likely contributed to the additional sim-to-real gap. These limitations show that biomechanically plausible kinematics do not always translate into accurate interactions or contact physics, ultimately leading to differences in joint kinetics.

In future work, our aim is to develop a more representative human gait reward function to facilitate training schemes that produce a walking agent that is biomechanically plausible both kinematically and kinetically. Specifically, we plan to design rewards that assess the complete kinematic profile across the entire gait cycle, rather than evaluating it at individual time steps. This approach will address the previously discussed limitations of redundancy in the speed reward by dynamically assigning appropriate COM target speeds throughout the gait cycle. This enhanced reward function will incorporate lower-limb biomechanical metrics such as stride length, cadence, and stability, further improving the agent's ability to replicate human-like gait patterns. Additionally, we will explore the integration of our improved reward functions with adaptive curriculum strategies—such as Gaussian scheduling and self-paced learning—to ensure consistent intermediate reward signals within each gait cycle and further enhance training stability and performance.

There are several exciting directions from our work. First, we plan to extend our model to capture a broader spectrum of gait patterns across diverse demographics—including older adults and individuals with disabilities—by leveraging generative techniques (e.g., diffusion models [35], generative adversarial networks [36]) to create physically plausible gait trajectories from limited data. We also aim to integrate unsupervised clustering methods (e.g., Deep Embedded Clustering [37]) to identify latent subgroup characteristics, enabling the conditioning of our generative process on these features to produce tailored gait profiles that more accurately reflect natural variations in human locomotion. Second, we plan to extend the agent's task beyond level-ground walking to more complex locomotor activities such as sit-to-stand and

stair descent. Lastly, we are envisioning to utilize the walking agent for tuning control policies of wearable robots, such as exoskeletons. By incorporating real-world exoskeleton hardware into the simulation environment, we can rapidly iterate and test various control strategies without the need for human subject testing. Minimizing the sim-to-real gap will enable direct transfer of control parameters to physical systems or fine-tuning policies with minimal real-world training data. This approach is particularly advantageous for robotic prostheses, where robust control strategies are critical to ensure user safety and prevent potentially harmful failures.

***Abstract*—This study explores the potential of using wrist-worn inertial sensors to automate the labeling of ARAT (Action Research Arm Test) items. While the ARAT is commonly used to assess upper limb motor function, its limitations include subjectivity and time consumption of clinical staff. By using IMU (Inertial Measurement Unit) sensors and MiniROCKET as a time series classification technique, this investigation aims to classify ARAT items based on sensor recordings. We test common preprocessing strategies to efficiently leverage included information in the data. Afterward, we use the best preprocessing to improve the classification. The dataset includes recordings of 45 participants performing various ARAT items. Results show that MiniROCKET offers a fast and reliable approach for classifying ARAT domains, although challenges remain in distinguishing between individual resembling items. Future work may involve improving classification through more advanced machine-learning models and data enhancements.**

***Index Terms*—ARAT, machine learning, ROCKET, IMU, time series classification, auto-labeling**

I. Introduction

Over 100 million people worldwide are living with the consequences of a stroke [1], a condition that frequently results in long-term motor impairments. Of stroke survivors, 85% present with initial upper limb impairments [2] and 60% of survivors report motor disabilities that persist even after rehabilitation [3]. Upper limb impairments span different domains and can include muscle weakness, changes in muscle tone, impaired motor control, and laxity of joints [4]. Importantly, these upper limb impairments lead to reductions in motor function, which consequently have a negative impact on quality of life. Clinically, standard assessments exist to evaluate both impairment and function. These are important both to track rehabilitation progress, as also to evaluate intervention efficacy and optimize therapy content. The Action Research Arm Test (ARAT) is a popular standard clinical assessment for motor function that evaluates the capacity to perform functional movements. The test consists of 19 movements (items) of different complexities for each arm (e.g. Fig. 1), which are sequentially performed and split into 4 subcategories (grasp, grip, pinch, gross). Each item is rated by an assessor on a scale of 0-3, based on the success, speed, and closeness to physiological motion. Scores are typically summed into subcategories to create a global score. The ARAT demonstrates good clinical properties with high interrater reliability, repeatability, and construct validity [5]. There is an ongoing discussion in the field as to what extent motor impairment may be approximated from the ARAT [6].

Given that the ARAT is well established in clinical routine and shows promise to measure both impairment and function,

there have been many approaches to investigate and better understand movement kinematics or at least statistical features of motion during the different movement items [7]–[9]. Instrumentation of the ARAT can give more details on the underlying kinematics, but at the same time, opens an opportunity for automation of the testing procedure. Automation is a necessary step for both clinical decision support and self-assessment, and a pre-requisite for any extension of ARAT measurements to the home. All of these topics are central pillars if rehabilitation as a field is to expand from a point-of-care to a continuum-of-care approach.

While motion capture systems and video recordings are well-suited to recognize human movements [10], these systems are expensive and can only be used in restricted environments. In contrast, wearable sensors such as inertial measurement units (IMUs) have no infrastructural requirements, are low-cost, and easy to use. These characteristics enable the use of IMUs at scale in a broad range of situations [11], including rehabilitation. Recent studies have demonstrated that IMU recordings are suitable for capturing essential characteristics of human movement across various tasks and activities [11]–[14]. Specifically, for upper limb movement assessments, IMU-based systems coupled with suitable analytics have been shown to deliver reliable and accurate results for many relevant movement metrics [4].

In terms of automation, previous work of our group has shown the ability to use wearable sensors to predict global ARAT assessor scores, achieving close to 80% accuracy over all domains [15]. In the next step, we investigate whether wearable sensor data can be used to automatically identify each of the 19 individual ARAT items from wearable sensor signals, specifically triaxial acceleration and gyroscope data in various different neurological populations. When working reliably, this automatic scoring proposal could be used as a clinical decision support system. For this purpose, we employ MiniROCKET [16], a method that can efficiently be executed in real-time on wearable devices, ensuring feasibility for practical applications.

This objective gives rise to two research questions:

RQ 1: With which mean accuracy are we able to automatically identify individual items of the ARAT?
RQ 2: To which extent does the impairment level affect the accuracy of the classification?

II. Method

A. Study design

We present a retrospective analysis (EKNZ 2024-00196) of instrumented ARAT data that was collected as part of the clinical routine at the cereneo - Center for Neurology and Rehabilitation from 1.1.2020 - 30.06.2024. All patients gave written informed general consent, which allowed their data to be used for retrospective analysis (EKNZ 2017-00730).

B. Data

The ARAT belongs to part of the core clinical assessment battery of this participating clinic and was routinely performed by trained and experienced physiotherapists on in-patients, often at multiple time points. In this analysis, we included only patients with a present upper limb impairment, represented by Fugl-Meyer scores between 12-59. In total, this led to a dataset containing 2,725 correctly performed and labeled ARAT items. Additionally, items not contributing to ARAT scores due to early starts or supervision uncertainties were relabeled as *junk*, adding 647 time sequences. However, this exceeded the number of each other label. To prevent the model from overfitting the junk data, we randomly removed junk sequences such that the number of junk labels was the same as that of the ARAT item with the most recordings. Of all the included individuals, 35 were men with a median age of 65 and 10 women with a median age of 70 years. The median height of all participants was 175 cm and the median weight was 55.2 kg. Five wearable sensors (Movella Dot) were mounted on each patient (Sensor location: left and right wrist, left and right middle of the upper arm, middle of the sternum), however, for all analyses presented here, only the two wrist sensors were used. These sensors were by far the best accepted and show the greatest promise for generalization to a home use case. The sensors recorded the following signals at a rate of 60 Hz: Triaxial acceleration [$\frac{m}{s^2}$], triaxial rotational acceleration [$\frac{deg}{s}$], and magnetic field strength [Gs]. Magnetometer data was discarded, as deemed too unreliable due to a measurement location close to a clinical MRI. Orientations were calculated as quaternions on board the device using the VQF (Versatile Quaternion-based Filter) magnetometer-free estimation [17]. Table II shows all further preprocessing steps that were tested.

Fig. 1. Patient performing ARAT item, Cube 10cm

C. Analytics

To distinguish and correctly classify the labels of each time sequence, the ROCKET [18] approach was used, as it is lightweight and well-suited to time series classification tasks. Specifically, we chose the MiniROCKET [16] adaptation as it is highly efficient, robust, and delivers comparable performance across diverse datasets [18]. Table I highlights the differences from the original ROCKET method. MiniROCKET has demonstrated the ability to effectively capture patterns in Human Activity Recognition time series data [16], [19]. As shown in Fig. 2, the method first applies 1-D convolutional kernels and extracts feature values with pooling operations.

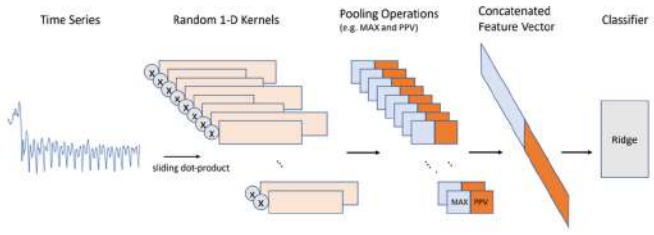

Fig. 2. RandOm Convolutional KErnel Transform (ROCKET) approach [20].

TABLE I
SETUP DIFFERENCES ROCKET AND MINIROCKET [16].

	ROCKET	MiniROCKET
length	$\{7, 9, 11\}$	9
weights	$\mathcal{N}(0, 1)$	{-1, 2}
bias	$\mathcal{U}$(-1, 1)	from convolution output
dilation	random	fixed (rel. to input length)
padding	random	fixed
features	PPV + max	PPV
number of features	20,000	10,000

The resulting feature vector is subsequently used as input for a classifier.

Table I shows the differences in the setup for ROCKET [18] and MiniROCKET [16]. The table illustrates that ROCKET kernels have random lengths from the set $\{7, 9, 11\}$. Each kernel is initialized with weights $\sim \mathcal{N}(0, 1)$, bias terms $\sim \mathcal{U}(-1, 1)$, random dilations, and random paddings. For each applied kernel, the proportion of predicted positives (PPV) and the maximum value are calculated. These result in a default total of 20,000 features [16].

With MiniROCKET [16], the randomness from ROCKET [18] is partially removed by using kernels with a fixed length of 9. Furthermore, weights are chosen from the set $\{-1, 2\}$. The authors show that kernels should be as small as possible to maximize computational efficiency. $2^9 = 512$ possible kernels can be chosen for a kernel length of 9 and two possible weights. In [16], an optimum of 84 is proposed to balance accuracy and computational cost. For a time series *X*, kernel W_d, and bias *b*, the PPV is given by Equation 1 [16].

$$PPV(X * W_d - b) = \frac{1}{N} \sum [(X * W_d - b) > 0] \quad (1)$$

For a kernel W_d, dilation spreads the kernel over the input by applying it to every dth element, where *d* is the dilation factor. In MiniROCKET, dilations are assigned from a fixed set based on the ratio of the input length and kernel length [16]. The bias values *b* are selected from the [0.25, 0.5, 0.75] quantiles of the convolution output for a given kernel *W* and dilation *d* on a randomly chosen training example. While this selection is random, the bias values themselves are derived from a fully deterministic convolution process, making MiniROCKET minimally random. Here, *N* refers to the number of elements in the transformed time series for one sample. The only randomness in MiniROCKET is the selection of training examples for sampling bias values.

TABLE II
THE TESTED DATA PREPROCESSING STEPS.

Preprocessing	**Values**
padding	Mean-padding; Zero-padding
Butterworth-filter frequencies	10Hz; 20Hz; No
freed acceleration	Yes; No
freed angular velocity	Yes; No
gaussian noise for acceleration	μ: 0 and σ: [0.1, 1]; no
gaussian noise for angular velocity	μ: 0 and σ: [1, 5]; no

The advantage of PPV is that this feature summarizes key statistical properties of the time series, which often contain sufficient discriminatory information for classification tasks. In addition, while more features can provide more information, they can also introduce noise and overfitting to the model. Only using PPV reduces the risk of overfitting, especially on small datasets, as it acts as a regularizer by focusing on a single, robust feature. In the end, MiniROCKET achieves almost the same accuracy as Rocket using a mostly deterministic and much faster procedure [16]. For these reasons, MiniROCKET was used for our further analysis [16].

III. EXPERIMENTS

For the experiments, the open-source library sktime [21] offers a built-in multivariate MiniROCKET implementation that was used for the classification tasks in this investigation.

A. Validation

We used a K-Fold Cross-validation (KFCV) with ten folds for all the experiments. This means we split the data into ten non-overlapping subsets (folds). Afterward, ten different models are trained on nine of the ten folds. For each model, the remaining tenth fold is subsequently used for validation. Here, the validation fold changes for each model until all folds are used exactly once for validation. Standard KFCV is not ideal for time series data where temporal ordering matters between multiple sequences. However, in this research, the data set consists of independent time sequences. Therefore, we can split the data into folds, including complete item executions. Before splitting the data into the folds, the time sequences were shuffled individually with a random seed of 42 to retain reproducibility.

B. Data Preprocessing

In the first experiment, we took all 19 ARAT items and junk as individual classes. To determine which data preprocessing method works best, we tested all the combinations from Table II on the data for the right and left wrists separately. Afterward, we chose the setup with the best mean accuracy for further investigation. During this process, we also observed the differences in the final accuracy. The model trained and tested on data from both wrists demonstrated the lowest accuracy. To provide an initial benchmark for potential performance on one wrist, we selected the wrist with the less accurate results as the focus for further investigation in this study.

C. Input Features

Having defined preprocessing and source data, we investigated which sensor recordings capture meaningful features for the classification task, therefore improving the model's performance and which input streams can be neglected to reduce computational costs. For this, the following three different sets of input streams were compared.

- 3-axis acceleration + 3-axis angular velocity
- 4-axis quaternions
- 3-axis acceleration + 3-axis angular velocity + 4-axis quaternions

D. Domain-Level Classification

Each ARAT item belongs to a specific movement domain, *Grasp, Grip, Gross,* and *Pinch*. Therefore, with the best-performing setup for all individual items, we also investigated the classification possibilities of the different ARAT domains. This classification assessment helps evaluate whether patterns from individual items can be generalized across the domains, offering a more comprehensive understanding of the model's capabilities.

E. Sequence Length Impact

Finally, due to the large variation in data segment lengths, we investigated to what extent especially long sequences from the distribution tail impact the performance of the classification. For this, we trained one model on only 75% of the shortest sequences.

IV. Results

The accuracies presented in this section refer to the average results of all ten models from the cross-validation. Due to the simplicity of MiniROCKET, calculating all embeddings and training a single model takes, on average, under 170 seconds on an Intel Core i5, 8th generation CPU, and 16GB RAM.

A. Data Preprocessing

The grid search for the best preprocessing resulted in the setups with the five best accuracies illustrated in Table III. The best result from Table III includes a mean padding and an applied Gaussian noise with a mean of 0 and a standard deviation of 0.5 for the acceleration and 3 for angular velocity. Furthermore, the data was not freed from gravity, and no low-pass filter was applied. The preprocessing steps with the best result were applied before all other experiments.

We proceeded with the experiments with the data from the left wrist since the models trained and validated on this data split achieved, with around 5% difference, less accurate results than models related to the right wrist data.

B. Input Features

The investigation of different input streams shows that including all available recording streams is beneficial. Using only acceleration and angular velocity as input features, the models were able to correctly classify about 42.7% of the classes. In comparison, when working only with the calculated quaternions, the performance dropped to around

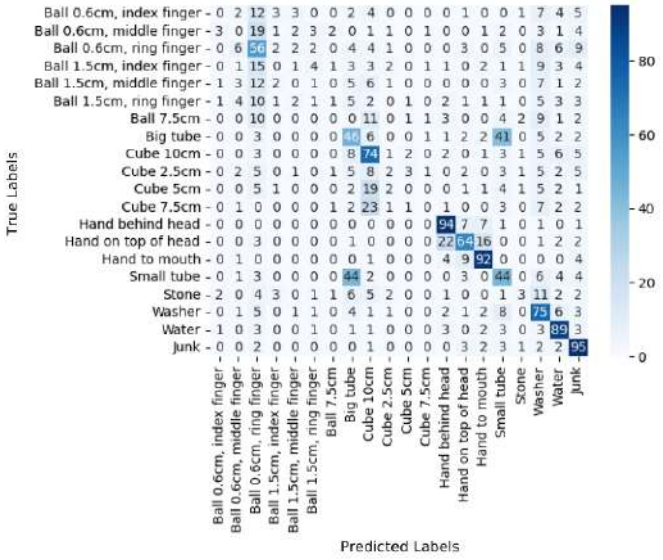

Fig. 3. Confusion matrix of the aggregated validation results for the all-item classification, using the complete left wrist

Fig. 4. Confusion matrix of the aggregated validation results for the item-domain classification, using the complete left wrist data.

34.3% accuracy. However, combining both sets of features improved the classification accuracy to 47.2%. Fig. 3 shows the confusion matrix for the best-performing model with all ten input features for the left wrist.

C. Domain-Level Classification

Even though these results do not seem promising for applied labeling of each item, Fig. 3 shows that most misclassifications belong to similar items. This leads to the result that for the classification of the domains, the same approach as for all 20 labels results in 82.3% accuracy and the confusion matrix illustrated by Fig. 4.

D. Sequence Length Impact

Discarding the 25% longest sequences, as the final step of this experiment, led to two main insights. The first main result

TABLE III
THE FIVE BEST DATA PREPROCESSING SETUPS AND THEIR MEAN ACCURACY RESULTS AVERAGED FOR BOTH ARMS. THE DATA WAS REDUCED TO 75% OF THE SHORTEST SEQUENCES TO REDUCE TIME CONSUMPTION.

Std. noise acceleration	Std. noise ang. vel.	Padding	Filter frequency acceleration ang. vel.	Freed sensors	Mean accuracy
0.5	3	Mean	0 / 0	False	64.5%
0	0	Zero	0 / 0	False	64.2%
0.5	1	Mean	0 / 0	False	63.6%
0.1	1	Zero	0 / 10	False	63.1%
0.1	3	Mean	20 / 20	False	62.9%

concerns the effects of data sequence length. Removing the longest time sequences reduced the number of time sequences that achieved the ARAT item scores zero or one from 16% to only 3%. For the 937 left-over sequences, the count of each ARAT item was reduced by similar amounts. Removing the longest sequences reduced the maximal sequence length to 318 ± 73 time steps. Consequently, all paddings were reduced to around 10% of the original length, reducing the run time by around 90%. Removing the longest time sequences and therewith the most strongly impaired movements, the classification facilitates significantly. We observe an increase in performance to around 61% accuracy for the classification of all ARAT items and to 93.9% for the domain classification.

V. DISCUSSION

The experiments of this investigation have demonstrated the possibilities of automatic ARAT item labeling using lightweight approaches.

A. Validation

In general, the KCFV approach allows us to use a large number of data for training. In addition, it provides a more stable and reliable estimation of the model's performance compared to a single train-test split by averaging the results of several train-test combinations. However, using an item-specific split leads to movement sequences of the same person being included in training and validation. While this can improve performance compared to the classification of a totally novel subject, it also favors models that overfit the training subjects.

B. Experimental Results

The first notable part of the preprocessing is that neither zero-padding nor mean-padding greatly impacts the resulting accuracy. This is because time series classification models like MiniROCKET primarily focus on patterns within observed data. MiniROCKET's kernel-based feature extraction is robust to padding due to its invariance to constant offsets and reliance on PPVs, which are robust to zero padding. Secondly, filtering high frequencies from the data and freeing acceleration or angular velocity recordings from gravity result in lower accuracies. One underlying reason for this may be that the frequency filter and the freed inputs reduces the information from essential features. The last observation concerning preprocessing is the possible model improvement through additional noise. Noise can be characterized by its statistical moments and the range of values it spans. It should relate to the data's range and statistical moments. Noise should not distort nor overwhelm the original data recordings, ensuring that the underlying patterns remain intact for accurate analysis. However, noise can result in a more generalizable model when applied correctly. This is because noise can introduce variability into the training data, preventing the model from overfitting the training samples [22].

With regard to the decision to use the left wrist data. The lower performance for left wrist data, compared to right wrist data, reflects its more diverse score distribution. This diversity represents a more balanced dataset and reduces the overfitting risks, supporting its use in this study. As scores were item- and side specific, there was no requirement to define an affected and unaffected side.

The experiments with different input streams demonstrate that while IMU readings and quaternions individually provide valuable activity recognition features, each has its limitations. However, when combined, the model's performance improves. We can assume that the input features complement each other. For future research, we would recommend integrating both inputs to enhance performance.

With regard to research question one (**RQ 1**), the final results indicate that while the current approach effectively disambiguates ARAT domains, fine-grained classification of individual items within a single domain remains limited. Addressing these challenges will require incorporating additional sensors, features, or enhancing feature extraction techniques in future work.

Fig. 4 demonstrates that the ARAT domains can be effectively distinguished with the current dataset using a lightweight and straightforward approach. The most frequently confused classes by the model are *Grasp* and *Pinch*. This is likely due to challenges in differentiating between certain *cube* items within the *Grasp* domain and *ball* items within the *Pinch* domain using only a wrist mounted IMU which encodes no information on the finger motion.

In terms of clinical utility, the current classification accuracy can only be considered as a proof of concept. The use of a minimal wearable sensor set reduces set up time and complexity, two very relevant aspects for clinical and home use. The addition of more wearable sensors will reduce feasibility. However, sensor fusion between video systems and wearable sensors may provide a straightforward solution to balancing data-greediness with practicality.

Regarding the second research question (**RQ 2**), the last experiment highlights the retaining large variance in the length of item sequences (ie. item duration) significantly

complicates the classification task. Long item sequences were mainly caused by inaccurate use of the start/stop function, which resulted in some sequences being 10x longer than the ARAT cutoff times. Slow executions are also frequently linked to greater impairment, hence our decision to remove the slowest 25% disproportionately affected scores 0 and 1, of which the relative proportion dropped drastically. This makes it very challenging to disentangle the confounding effects of decreased execution velocity and reduced movement quality. Adding well-understood hand-crafted metrics such as smoothness and trunk compensation metrics to the model may support do disentangle velocity effects through improved inference. None-the-less, reducing temporal variation of item length significantly boosted prediction accuracy for the current approach. This also would be a further incentive for examining ARAT item time cut-offs at an item-specific level, as opposed to the current "one-time-fits-all" approach.

C. Limitations and Future Work

In future work, we would aim to better disentangle execution velocity and compensation from movement quality. Furthermore, we would endeavor to develop multi-stage classification models to better handle class 0 & 1 scores, or add patient-specific priors that generalize across tasks. Finally, we would add additional sensing modalities to the data collection to be able to incorporate finger motion into our classification. This will allow us to improve the fine-grained item classification within single domains. From a model perspective, we would consider more data hungry approaches such as transformers which we would pre-train on public datasets or with synthetic data.

VI. Conclusion

We developed an auto-labeling model for individual ARAT items using two IMUs on the wrists. With its fast runtime and simplicity, MiniROCKET functions as a practical proof of concept to automatically classify ARAT items in neurological patients. The findings demonstrate that meaningful features can be effectively extracted from wrist-worn sensors. Despite the item classification still needing improvement, MiniROCKET allows for reliable differentiation between task domains. Finally, the analysis demonstrates that longer and more variable item sequences, typically associated with greater impairment levels, significantly decrease classification accuracy.

VII. Acknowledgments

Mechatronic Design of a 2-DoF Wearable Robot for Wrist Stiffness Assessment

Giorgia Giovannetti[1], Alessia Noccaro[1], Nevio Luigi Tagliamonte[2], and Domenico Formica[1,3]

***Abstract*—Parkinson's Disease (PD) is a neurodegenerative disorder characterized by a variety of motor symptoms including joint rigidity, typically assessed through semi-quantitative clinical scales, which are subjective and low-reliable. To address the limitations of current methods, we introduce in this paper the PDMeter2, a portable, wearable device for objective, quantitative assessment of wrist rigidity along two coupled Degrees of Freedom (DoFs): Flexion-Extension (FE) and Radio-Ulnar Deviation (RUD). The system includes two actuators to deliver controlled and repeatable perturbations to the wrist, and simultaneously measures provided torques and joint motions necessary for estimating the stiffness, which is closely related to clinical rigidity. Its lightweight aluminum structure and 3D-printed interfaces prioritize wearability and comfort, facilitating assessments in non-clinical environments without clinicians' supervision. In this work we present the mechatronic design of the PDMeter2 and its functional characterization in terms of restrictions to the wrist Range Of Motion (ROM). Results suggest that wrist ROM is primarily reduced along the FE DoF; however, the available ROM remains suitable for effective stiffness assessment and ADLs performance. The PDMeter2 represents a significant step toward more accessible, objective, and cost-effective diagnostic and treatment management tools for Parkinson's Disease.**

***Index Terms*—Wearable Robot, Wrist Exoskeleton, 2-DoF Wrist Stiffness.**

I. Introduction

Parkinson's Disease (PD) is a chronic neurodegenerative disorder associated with significant health issues and high mortality rates [1]. Approximately 6.1 million people are diagnosed annually, with incidence rates ranging from 5 to $>$35 new cases per 100,000 individuals per year [2], [3]. PD is characterized by the progressive degeneration of dopamine-producing neurons and the formation of α-synuclein protein aggregates, particularly in the substantia nigra of the basal ganglia [1], [4]. This degeneration causes over-inhibition of efferent neural pathways, resulting in motor and non-motor symptoms. The cardinal motor symptoms include *bradykinesia* (slowness of movement), *joint rigidity* (increased resistance to passive joint motion), and *resting tremor* (involuntary and periodic body part oscillation) [1], [3], [4]. Nonmotor symptoms involve sleep behaviour disorder, depression, constipation, fatigue, hyposmia, anxiety, excessive daytime somnolence, and, in later stages, autonomic dysfunction, dementia and psychosis [1]–[3].

Although non-motor symptoms are equally prevalent and significantly affect the long-term course of PD, clinical diagnosis is only possible when motor symptoms manifest. Motor and non-motor symptoms are clinically evaluated using the semi-quantitative Unified Parkinson's Disease Rating Scale (UPDRS) [5]. However, while the clinical diagnosis for patients with fully developed motor features may seem straightforward, misdiagnosis is highly common [1]–[3]. In the early stages, error rates in the diagnosis can reach 24% even in specialised centres and can be affected by the clinician expertise [2], [6], [7]. This highlights the subjective and time-consuming nature of the semi-quantitative assessment based on the use of UPDRS and underscores the need for an objective and quantitative method for PD diagnosis [2], [6], [7].

Moreover, PD symptoms are currently managed with dopamine-targeting treatments such as L-DOPA, dopamine agonists, continuous L-DOPA infusion, or deep brain stimulation. These treatments cause varying dopamine levels, leading to significant symptom fluctuations, that are not easily detected in a single clinical evaluation. Therefore, continuous daily monitoring of motor parameters could be beneficial for treatment management [1]–[3].

To address these challenges, our research group previously developed a portable and wearable mechatronic device, known as the PDMeter [8]–[10], aimed to:

- Perform objective and quantitative evaluation of wrist rigidity along Flexion-Extension (FE), thus assisting PD diagnosis;
- Enable rigidity measurements during Activities of Daily Living (ADLs), to enhance understanding of the disease and associated motor control abnormalities;
- Enable multiple daily measurements, allowing continuous symptom monitoring and treatment optimization;
- Facilitate assessments in non-clinical environments, thereby reducing costs and required personnel time.

The focus on wrist rigidity arises from its prominence in UPDRS assessments [5], driven by the wrist's susceptibility to abnormal muscle tone and spasticity in neuromuscular disorders, as well as the central role of rigidity as a cardinal motor symptom of PD. The physical quantity that best fits with the clinical definition of rigidity is the stiffness, i.e., the static part of the joint torque-angle relationship. Hence, measuring wrist stiffness requires to gently perturb the joint while recording the delivered torques and related angular displacements [8], [9].

The main limitation of the PDMeter is its capability to measure wrist rigidity only along 1 Degree of Freedom (DoF), i.e. FE. However, natural wrist rotations occur in combination of 2 DoFs, i.e., Flexo-Extension and Radio-Ulnar Deviation (RUD), which are coupled through interaction forces deriving from stiffness [11]–[13]. A few studies have measured 2-DoF wrist stiffness and they have used bulky, general-purpose robotic systems [11], [14], [15]. These robots are typically limited to structured lab environments and lack portability. In contrast, manual systems are more compact and portable, and are designed for the assessment in a broader range of environments. However, they are non-actuated and rely on a human operator to produce mechanical perturbations, thus limiting the ability to provide consistent and objective measurements [9].

In this work, we present an evolution of the PDmeter design to include a second active DoF (i.e., RUD), with the aim of proposing a portable and wearable device for reliable 2-DoF wrist stiffness estimation in unstructured environments. Overcoming the limitations of the previous system, this new device, hereafter called PDMeter2, integrates two actuators to provide controlled and repeatable wrist perturbations along FE and RUD, with delivered torques estimated from motor currents and joint motion tracked via encoders. This paper presents the mechanical and electronic design of the device, as well as its functional characterization in terms of limitation to the wrist ROM.

II. Materials and Methods

A. Mechanical Design

Fig. 1 illustrates the mechanical structure and the kinematic sketch of the device. It consists of two kinematic chains, each one designed to actuate one human DoF and leave free the other one. The chain actuating the FE DoF is hereafter referred to as the *FE chain*, whereas the one actuating the RUD DoF is hereafter referred to as the *RUD chain*.

Each chain includes five revolute joints: *i)* one proximal active joint (blue in Fig. 1), which has an axis parallel to the one of the human DoF to be actuated; *ii)* three intermediate passive joints (purple in Fig. 1), which have their axes perpendicular to the one of the active joint, to allow the free movement around the other human DoF; *iii)* a distal passive joint (green in Fig. 1), whose axis is parallel to the one of the active joint. The two kinematic chains are secured to the hand through their distal links (link 6A and link 6B) and to the forearm through their proximal links (link 2 and link 10), connected to the active joints. They are functionally connected in parallel to the human (forearm-wrist-hand) chain to eventually create a closed-loop 2-DoF chain.

As shown in Fig. 2, each chain can be analyzed in two orthogonal planes: $PS-FE$ and $PS-RUD$, where PS refers to Prono-Supination. The RUD chain in the $PS-RUD$ plane is equivalent to the FE chain in the $PS-FE$ plane. With reference to Fig. 2, this planar mechanism is composed of three purple rotary joints (3R chain) and one grey human joint.

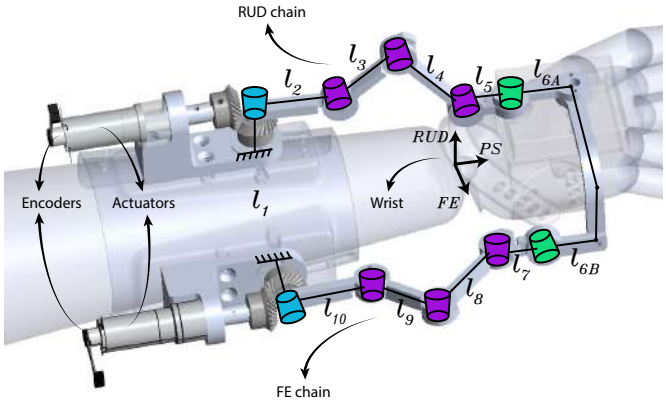

Fig. 1: Overview of the mechanical structure of the device. The frame (FE, RUD, PS) shows the rotation axes of the wrist DoFs. The kinematic sketch is superimposed: for each chain, the axes of the proximal active (blue) joint and of the distal passive (green) joint are parallel to the axis of the human DoF to be actuated (FE/RUD) whereas the axes of the intermediate passive (purple) joints are perpendicular to it, i.e., parallel to the DoF actuated by the other chain (RUD/FE). l_i are the links composing the kinematic structure, being l_1 the forearm and l_{6A} and l_{6B} secured to the hand.

The 3R chain can be represented as an equivalent prismatic joint in the corresponding orthogonal plane.

The RUD chain in the $PS-FE$ plane is equivalent to the FE chain in the $PS-RUD$ plane. With reference to Fig. 2, this planar mechanism is composed of two rotary joints (one active, in blue, and one passive, in green) and one purple prismatic joint (equivalent to the 3R chain in the corresponding orthogonal plane).

The number of DoFs F for each planar mechanism can be computed according to the Chebychev–Grübler–Kutzbach criterion [16]:

$$F = \lambda(l - j - 1) + \sum_{i=1}^{j} f_i, \tag{1}$$

where $\lambda = 3$ is the mobility parameter in the 2-dimensional space, l is the number of links, j is the number of joints and f_i is the number of DoFs of the $i-$th joint.

For each of the four planar chains of Fig. 2, $l = 4$, $j = 4$ and $f_i = 1$, leading to $F = 1$.

The actuation system was selected to optimize torque, speed and power requirements together with efficiency, weight, size, and cost. Previous studies on estimating wrist stiffness in healthy individuals conducted by our research group showed that the torque required for a passive wrist was less than 0.7 Nm [17]. Given that the rigidity typically observed in patients with PD would increase the torque needed to achieve the same motion, we designed the actuation system to have a nominal torque of 1 Nm in each actuated DoF [8]. To avoid triggering motor reflexes, the device must be operated in a smooth and slow manner. Previous studies in our group have implemented movement trajectories with an average velocity of 0.14 rad/s

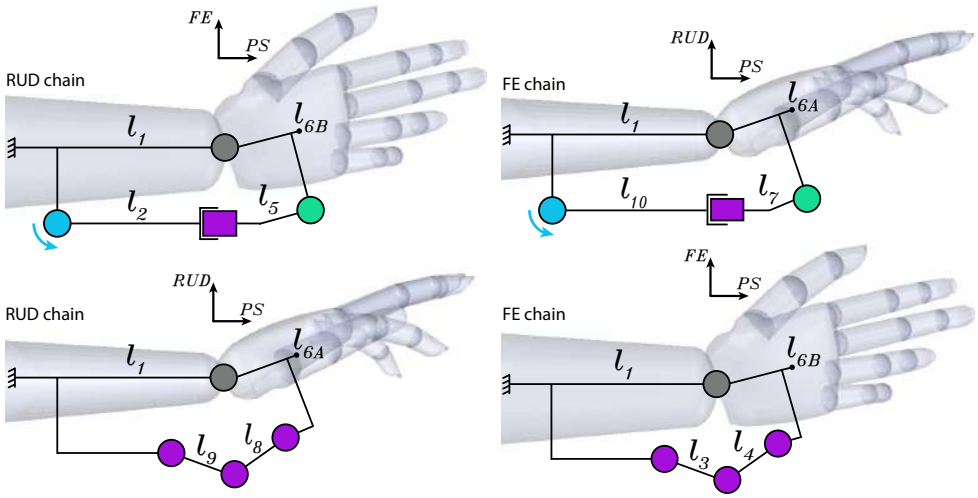

Fig. 2: Kinemtic sketches of the two chains: left) RUD chain, providing 1 actuated DoF (RUD) in the $PS-FE$ plane and 1 passive DoF (FE) in the $PS-RUD$ plane; right) FE chain, providing 1 actuated DoF (FE) in the $PS-RUD$ plane and 1 passive DoF (RUD) in the $PS-FE$ plane. Light blue arrows indicate actuated joints. Purple chains composed of three rotary joints in one plane can be represented as an equivalent prismatic joint in the orthogonal plane. Each chain represented in each plane has 1 DoF.

($\sim$1.33 rpm) [17]. However, to enable the device to assist with daily tasks and follow natural wrist movements, back-driveability of the system is also essential. Consequently, the device should be capable of passively following the user's motion when controlled in *transparent mode* (i.e., when stiffness is not being measured), increasing the required actuation speed to approximately 38 rpm [8].

Based on these criteria, we selected a commercial actuation system manufactured by Maxon Motors Inc., consisting of:

- a DC brushed motor: model DCX19S @ 12V, with a nominal torque of 11.4 mNm;
- a 3-stage planetary gearhead: model GPX22A, with a reduction ratio of 62 and an efficiency of 0.74;
- an incremental differential encoder: model ENX10 EASY 512IMP, with a count per turn of 512, providing a resolution of approximately 0.0028 deg [8].

To minimize encumbrance, the motors were positioned longitudinally to the forearm and connected to the proximal joint with high-efficiency bevel gears (ground spiral miter gears SMSG1-25R/L from MISUMI). Additionally, to reduce weight and size, the shape of the rigid links composing the kinematic chains was optimized with respect to the PDMeter [8], allowing the use of a single ball bearing for each revolute joint instead of two. Furthermore, to prevent exceeding users' ROM, critical rigid links were designed to be secured to interchangeable mechanical stops.

The material of the links was Al 6082 T651, selected for its smaller density compared to steel while still providing adequate strength for our application. In contrast, joint shafts were made of BS 1407 silver steel to ensure higher strength.

Ergonomic forearm and hand physical interfaces, shown in Fig. 3, were designed and 3D printed in Thermoplastic Polyurethane (TPU), a flexible material that enhances comfort and wearability. Specifically, the forearm interface houses the motors and incorporates two external skate buckles for easy donning and doffing, enabling the patient to wear the device autonomously. The hand interface was designed with a modular closure system, that allows adjustment for different hand sizes. This interface secures the hand from the dorsal side, with straps that wrap around the ulnar side of the hand and lateral thumb areas. Different sizes of this interface can be easily attached and detached from the device using a sliding system, which features a Polylactic Acid (PLA) component secured to Link 6A. Both the forearm and hand interfaces are internally coated with a foam layer to maximize comfort against the skin.

B. Electronic Design

An STM32F446RE microcontroller from ST Microelectronics Inc. was used to manage actuation control and data acquisition. To control the actuators, the microcontroller sends commands to two low-level drivers (Escon Module 24/2 by Maxon Motors Inc.), which ultimately adjust the voltage and current levels required to drive the actuators via a PWM signal. The microcontroller is also responsible for measuring motor rotation through the incremental encoder, utilizing the embedded Quadrature Encoder Interface (QEI). Current provided to the two motors through the Escon modules is converted with a 16-bit Analog-to-Digital Converter (ADC, model MAX1167 by Maxim Integrated Inc.) and used to estimate the torque applied by the actuators. The ADC communicates with the microcontroller via the SPI protocol. Finally, collected data, including measured currents, motor rotations, and desired torques, are transmitted to an external laptop via UART. A

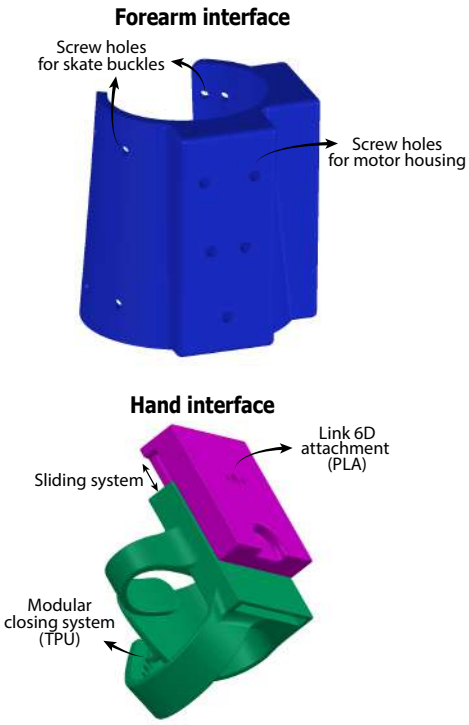

Fig. 3: Physical interfaces connecting the device to forearm and hand. The forearm interface is wrapped around through screwed skate buckles. The hand interface has a modular closure to adjust to different hand sizes and a sliding system to be easily attached and detached to the device. Drawings are not to scale.

scheme illustrating the architecture of the device electronics is shown in Fig. 4.

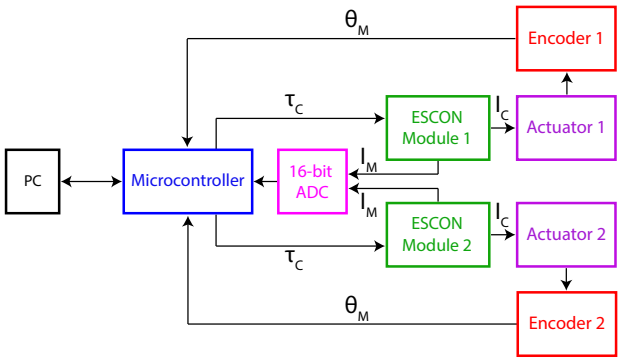

Fig. 4: Architecture of the PDMeter2 electronics. τ_C is the control torque, I_C is the control current, θ_M is the measured angle, I_M is the measured current.

We implemented a torque control based on a trapezoidal reference torque profile. This enables the two motors to operate individually for pure FE and RUD motions from a wrist neutral position to peripheral targets, or simultaneously to produce combined motions at 45 deg between the two. A GUI developed in the Qt environment allows users to select the desired ramp duration of the trapezoidal torque profile and the steady torque values, while the holding torque duration is fixed at 0.5 s.

C. Device Characterization

We characterized the device wearability and impact on natural wrist rotations in terms of maximum angular excursion of the wrist when performing FE and RUD motions with the exoskeleton, to identify any limitation to the movement due to its use.

1) Subjects: Four healthy volunteers (3 females; age range: 27-32) with no history of upper arm neuromuscular impairment were recruited. Written informed consent was obtained after participants were informed about the study's procedures. The experimental protocol was approved by Newcastle University's Ethics Committee (23-006-GIO) and conducted in line with the Declaration of Helsinki.

2) Experimental Setup & Protocol: Wrist motion data were acquired using an optical motion capture system (Motive OptiTrack, Natural Point Inc., Corvallis, OR, USA) with 5 infrared cameras and two rigid bodies positioned on the forearm and the hand, respectively. Fig. 5 shows the placement of the rigid bodies when performing wrist motions without (a) and with (b) the exoskeleton.

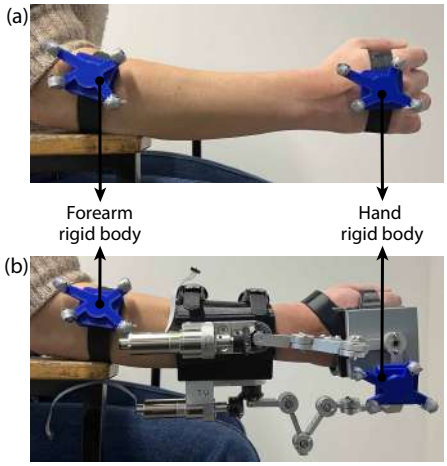

Fig. 5: Placement of the forearm and hand rigid bodies when performing wrist motions without (a) and with (b) the exoskeleton, during the functional characterization of the device. A set of 5 infrared cameras (not shown in the picture) were used to detect the rigid bodies motions.

Subjects sat on a chair with their right elbow resting on the chair's armrest and their forearm positioned horizontally, ensuring that the wrist could move freely and the device did not come into contact with the chair. Subjects were asked to move their wrist from a neutral position to eight peripheral targets representing pure FE, pure RUD, and combined motions at roughly 45 deg between them. The neutral position was defined according to the the International Society of Biomechanics recommendations [18], i.e., the long axis of the third metacarpal aligned with the long axis of the forearm.

Therefore, in each trial, participants were instructed to begin the movement by aligning middle finger knuckle to their forearm axis and to reach the maximum range of motion in each of the eight target directions. Three trials were performed while wearing the exoskeleton and three without it, with a rest of a few minutes in between, resulting in a total duration of the experiment of approximately 15 minutes.

3) Data Processing & Analysis: Data acquired from the cameras were resampled at a frequency of 100 Hz, low-pass filtered (5^{th} order Butterworth; cutoff frequency: 10 Hz) and cut to remove unnecessary information preceding and following the wrist motions.

Relative motions between the hand and the forearm rigid bodies were converted to wrist angles using a kinematic model of the human wrist [17]. Maximum angle values for flexion, extension, radial deviation, and ulnar deviation were extracted for each trial, as an indication of the ROM achievable along each direction. Extracted ROM data were then averaged per participant and finally analyzed with JASP software using a paired samples t-test, to identify any significant ROM differences with and without the device, after checking data normality with the Shapiro-Wilk test.

III. Results

After finalizing the design, the exoskeleton was manufactured in aluminum alloy (Fig. 6), with a total mass, including actuators and forearm/hand interfaces, of 1 kg.

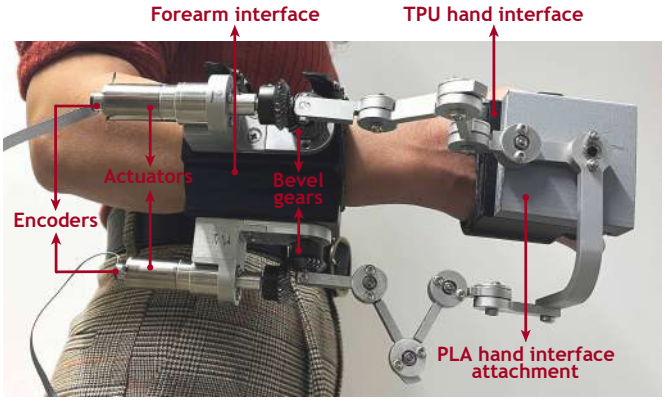

Fig. 6: Mechanical structure of the manufactured device.

Table I presents the mean ROM values achieved during extension, flexion, radial deviation, and ulnar deviation, both without and with the device, while Fig. 7 illustrates the results of the statistical analysis.

The results indicate that wearing the device impacts the achievable ROM to varying extents across the four directions of movement. Specifically, extension and flexion were the most affected. Extension exhibited a ROM reduction of approximately 56% (∼36 deg), while flexion showed a restriction of around 42% (∼34 deg). In contrast, radial deviation ROM showed no significant impact with or without the exoskeleton, while the ulnar deviation exhibited a percentage reduction of around 30% (∼14 deg), although no statistically significant differences were observed in this case.

MOTION	NO-EXO	EXO
EXTENSION	64 deg	28 deg
FLEXION	81 deg	47 deg
RADIAL D.	17 deg	21 deg
ULNAR D.	47 deg	33 deg

TABLE I: Mean ROM values achieved during extension, flexion, radial deviation, and ulnar deviation, without (NO-EXO) and with (EXO) the exoskeleton.

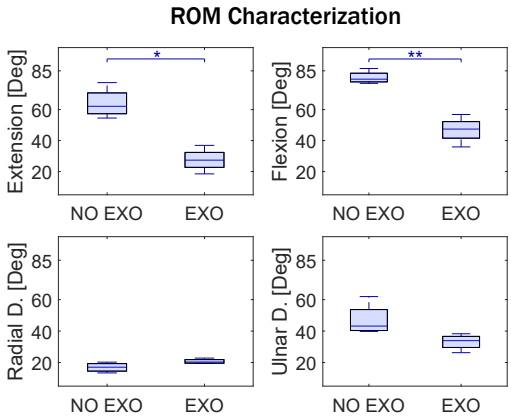

Fig. 7: Results of the statistical analysis conducted on the ROM values achieved during extension, flexion, radial deviation and ulnar deviation without (NO EXO) and with (EXO) the device. *: $p < 0.05$; **: $p < 0.005$.

IV. Conclusions

This work introduces the PDMeter2, a 2-DoF version of a wearable mechatronic device designed to measure wrist rigidity in PD patients along coupled FE and RUD. The device aims to support PD diagnosis by providing a quantitative and objective method to evaluate one of its cardinal symptoms. Such tool would facilitate reliable PD assessment even in the early stages, when current clinical methods still exhibit high error rates. Additionally, it enables treatment optimization through continuous symptom monitoring in non-clinical environments.

With respect to previous prototype [9], the system comprises two motors and two kinematic chains to deliver controlled and repetitive perturbations to the wrist along the FE and RUD DoFs, while simultaneously recording applied torques and joint motions to assess wrist rigidity. When not measuring stiffness, the device enables motion along the two DoFs, possibly allowing users to perform daily activities.

The device kinematic structure, made from aluminum alloy, is optimized to minimize weight and bulk. Additionally, 3D-printed body interfaces are designed to enhance both comfort and wearability.

We evaluated the restriction of wrist ROM caused by wearing the device compared to the natural ROM of the wrist during free movement. Results indicate that the most significant ROM limitations occur along the FE axis, where

the device allows a ROM of 28 deg and 47 deg in extension and flexion, respectively. While these values are significantly lower than the unrestricted ROM, they remain sufficient for stiffness assessment, which can be reliably conducted within a 20 deg motion range from the neutral position [11], [17], [19]. Moreover, ADLs such as personal hygiene and culinary tasks typically require approximately 35 deg of motion along FE and 25 deg along RUD [20], both of which are within the limits permitted by the PDMeter2.

The device affects ROM differently across the four movement directions, likely due to varying mechanical constraints during extending and bending of the kinematic chains. Additionally, the lack of a physical constraint on the neutral position may have introduced slight inter-trial variability, leading, for instance, to a radial deviation ROM with the device exceeding that without it, although the overall RUD ROM remains lower with the device. Future work will involve structural optimization to address ROM restrictions across the two DoFs and improvement of the experimental protocol.

Moreover, although not explicitly reported in the results, we noticed that the achievable ROM may slightly depend on the positioning of the forearm interface during the don procedure. This issue, likely due to the softness of the forearm's skin tissue, affects the level of extension of the kinematic chains and could be mitigated by optimizing the forearm interface design with an adjustable mechanism to customize fitting for each subject. However, ROM inter-subject variability remains minimal and does not affect stiffness assessment range, which always falls within the permitted limits.

To enhance wearability and simplify manufacturing, future work could explore replacing the aluminum kinematic links with 3D-printed plastic materials, which would reduce both weight and cost of the device. However, plastic presents certain drawbacks compared to aluminum, such as lower strength, reduced stiffness, and increased flexibility. As a result, the use of plastic materials would require a preliminary assessment of their suitability for motion transmission and reliability of the stiffness measurements due to the link deformation, as well as their resistance to fatigue loads and possible degradation. We anticipate that using plastic for the forearm and hand interfaces will not affect device performance. The forearm interface remains fixed, while the hand interface is rigidly attached to metal link 6A, minimizing any impact on motion transmission.

Initial testing of the device will involve healthy subjects to evaluate its reliability in assessing wrist rigidity. Following these tests, experimental trials will be conducted with PD patients to clinically validate the system's effectiveness.

After testing the device, future developments may include expanding the design to incorporate additional upper limb joints, e.g., the elbow, allowing for the simultaneous assessment of both joints in alignment with clinical UPDRS evaluations.

Simultaneous Perturbation of Knee and Ankle Joints During Stance Phase of Walking: Towards Biological Joint Impedance Estimation

Michele Paravano*, Mohamed Irfan Refai, Herman van der Kooij, Massimo Sartori

***Abstract*—Characterization of lower limb joint impedance during locomotion is crucial for advancing our understanding of walking biomechanics, while also guiding the development of assistive technologies and rehabilitation strategies. Identification of impedance parameters is dependent on perturbation strategies which elicit measurable responses at the joint of interest. However current perturbation methodologies applied during locomotion either work in the swing phase or employ exoskeleton based setups which can add complexity and weight to the leg. This study introduces and evaluates a perturbation methodology using a custom-designed pusher system to elicit multi-joint-level torque and angular responses during the stance phase of gait for different conditions. Controlled perturbations applied behind the tibia revealed measurable dynamic response at the knee and ankle joint, while preserving the gait cycle's overall pattern. Torque-angle and torque-velocity graphs reveal insights into energy and power changes between perturbed and unperturbed gait cycles. The method can be adapted to various walking speeds, perturbation intensities, and durations, providing the first step for future estimation of joint impedance during locomotion.**

***Index Terms*—Joint impedance, joint stiffness, stance perturbation, rehabilitation, system identification.**

I. Introduction

Joint impedance, a fundamental biomechanical property, governs how human joints respond to external forces and is continuously regulated by the nervous system to enable effective interaction with the environment. It encompasses stiffness, damping, and inertia, capturing the dynamic relationship between changes in joint kinematics and the resulting torques.

State-of-the-art techniques for estimating joint impedance primarily rely on perturbation-based methods. Early pioneering studies focused on perturbations under static, time-invariant conditions [1], [2], estimating joint impedance around a fixed operating point. This was followed by advancements in time-varying system identification techniques [3]–[5], and allowed usage of dynamometer setups to perturb individual joints during motion [6]–[8].

The need to estimate joint impedance during locomotion and everyday activities has driven the development of perturbation techniques targeting walking gait. For instance, platform-based setups have been designed to induce controlled ankle angle changes during stance, providing insights into the dynamic modulation of joint impedance based on perturbation timing and intensity [9]. Exoskeleton-based setups have also been explored, such as the work by Nazon and Rouse, who investigated knee impedance during gait using controlled perturbations to characterize dynamic joint properties [10]. An earlier contribution by Sinkjaer et al. pioneered an exoskeleton-like perturbation method for simultaneous knee and ankle perturbations during stance [11].

While platform-based perturbation setups are commonly used to study joint dynamics, they primarily focus on single-joint responses, often neglecting the interplay between multiple joints during gait. Exoskeleton-based perturbations can introduce additional weight and complexity, which may alter natural walking patterns [12]. In contrast, pusher-based perturbation techniques offer a lightweight and minimally intrusive alternative by applying controlled forces to the leg through an external rod.

Van der Kooij et al. demonstrated the effectiveness of the LOPER system in perturbing the leg during the swing phase, enabling simultaneous estimation of knee and hip joint impedance [13]. However, their approach was limited to swing-phase perturbations, leaving stance-phase unexplored.

During the stance phase of gait, ground reaction forces anchor the foot, making it harder to apply effective perturbations than during the swing phase. Enhanced muscle activation and co-contraction further stiffen the joints, which reflects the body's strategy for maintaining stability under load. This work explores whether a pusher-based system can overcome these challenges and induce meaningful multi-joint perturbations during stance without disrupting the gait pattern.

This study assesses an extension to the perturbation method in [13] targeting the lower limb kinematic chain during stance. Controlled perturbations applied behind the tibia propagate through the kinematic chain, inducing measurable torque and angular responses at both the knee and ankle joints.

The primary contribution of this work is the design and validation of an experimental-robotic setup for controlled stance-phase perturbations. Data from one subject illustrate differences in joint kinetics between perturbed and unperturbed conditions. The study presents work loop and power loop analyses and discusses the future steps for joint stiffness estimation. To the best of our knowledge this is the first study providing a stance-perturbation strategy using a pusher setup. This work can potentially advance our capabilities of measuring joint biomechanical quantities during gait in

multiple conditions and provides the base data acquisition process for lower limb joint impedance estimation.

II. METHODS

The lower limb perturbator (LOPER) design is extensively described in [13]. Here we present a brief overview. The experiments were conducted with the approval of the University of Twente Ethical Committee 241160, and participant provided written informed consent.

A. Experimental Setup

1) Hardware setup, as in Fig. 1:

- A split-belt instrumented treadmill Fig. 1 (**4.**) (Bertec FIT 5, USA) capable of independently measuring ground reaction forces (GRFs) and moments in three dimensions for each leg.
- A motion capture system Fig. 1 (**1.**) which records kinematic data for subsequent analysis to track limb motion (Qualisys AB, Sweden). The participant is equipped with 35 reflective markers placed on key anatomical landmarks used to scale the Gait2392 model of OpenSim.
- The participant's right leg is securely attached to a pusher rod via a brace strapped just below the knee. This location was selected for two primary reasons:
  - To maximize the moment arm for ankle perturbations.
  - To ensure proximity to the knee joint, allowing effective perturbations to be applied during the stance phase.

  A reflective marker is also placed on the pusher brace to track the location of the perturbation force with respect to the leg.
- The LOPER system Fig. 1 (**2.**) consists of a rod connected via a ball linkage to another link rigidly attached to a motor. This mechanical setup translates the motor's rotational torque into a linear push force applied to the participant's leg. Interaction forces between the pusher rod and the leg are measured using a load cell Fig. 1 (**3.**) (FUTEK FSH00086, USA) positioned between the motor's moment arm and the pusher rod. The load cell provides force measurements in three dimensions, enabling the implementation of real-time feedback control of interaction forces.
- For safety, the participant wears a ceiling-mounted harness designed to prevent falls in the event of tripping or loss of balance during the trials.

2) Software: All devices, including the treadmill, motion capture system, and pusher, are synchronized using a dedicated synchronization signal to ensure temporal alignment of all data streams. Motion capture data is acquired using the Qualisys system at a sampling frequency of 100 Hertz, while ground reaction forces and moments, are recorded at 2000 Hertz. Interaction forces from the pusher are sampled at 1000 Hertz and transmitted via the EtherCAT protocol, which is managed by TwinCAT on the main control PC. The control PC also runs a compiled Simulink model within TwinCAT, enabling real-time control of the pusher motor.

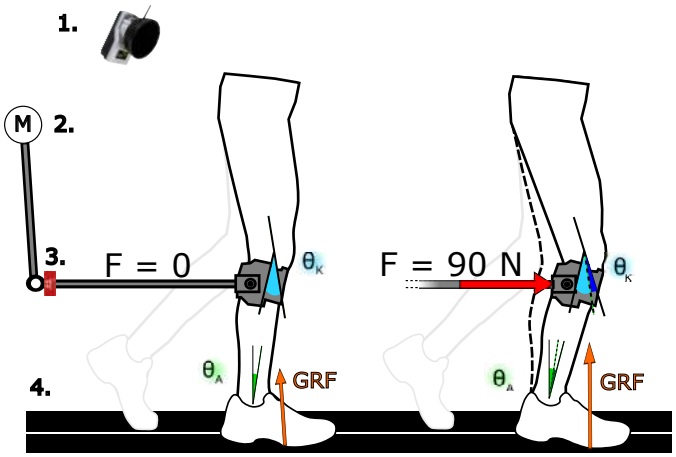

Fig. 1. Experimental setup for measuring joint impedance during locomotion, including a (1) motion capture system to track kinematics, (2) a LOPER pusher device to apply controlled perturbations, (3) a load cell to measure interaction forces, (4) and a split-belt treadmill for locomotion, with the left panel showing the unperturbed state (F=0) and the right panel depicting a 90 N perturbation force applied below the knee.

3) Control: The participant walks on the treadmill at a speed of $v = 0.8\,\text{m/s}$, which was determined to be a comfortable and normal gait speed by the participant. Before the start of the experiment the subject was given a test trial (5 min) to acclimate to the pusher interaction and the pushes. Heel strikes and toe-off timings are detected when the vertical ground reaction force exceeds 5% of the participant's body weight, as measured on the treadmill belt. A random perturbation is applied once within a range of 5 gait cycles to the participant's right leg, with a total of 20 perturbations delivered throughout the trial. Two separate trials are carried out, where perturbations are applied at the beginning of the stance phase and after 200 ms from heel strike. These instants correspond to $\approx 5\%$ (loading response) and $\approx 20\%$ of the gait cycle (mid-stance) respectively. The control strategy is divided into two modes:

- **Unperturbed gait**: Admittance control is implemented as described in [13] to minimize interaction forces between the pusher and the participant's leg, ensuring the system remains as transparent as possible. The control strategy aims to limit peak interaction forces to less than $20\,\text{N}$ and root mean square (RMS) forces to below $10\,\text{N}$. These thresholds are based on a study investigating the effects of adding inertia to the ankle, where $1.55\,\text{kg}$ resulted in changes in ankle and knee range of motion comparable to the natural variability across different subjects [14]. This mass was determined to be the upper limit for avoiding significant disruptions to natural gait. In contrast, a heavier mass of $3.5\,\text{kg}$ was shown to affect knee flexion and plantarflexion, which are more prominent during the swing phase rather than the stance phase. In addition, since the pusher in our setup is connected to

the shank rather than the ankle, these thresholds serve as conservative limits to ensure minimal gait disruption during perturbations.

- **Perturbed gait**: The pusher operates in admittance control mode until the perturbation instance. The perturbation signal is a square wave with duration $\Delta t_{\text{perturbation}} = 100\,\text{ms}$ and Intensity: $F = 90\,\text{N}$

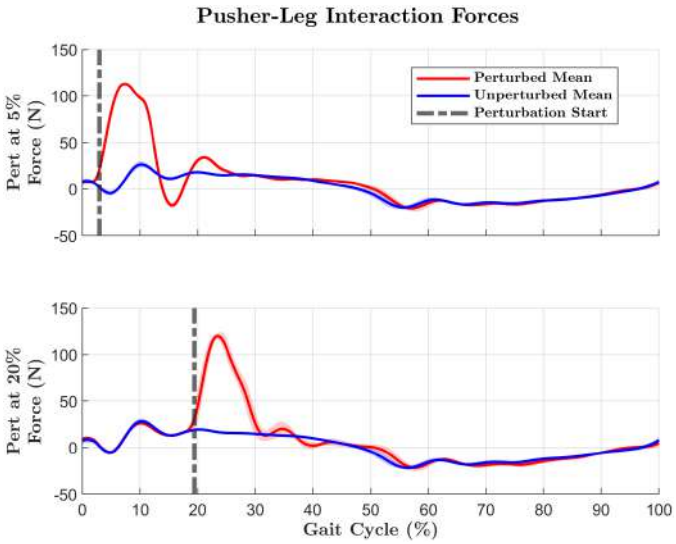

Fig. 2. Interaction forces between the leg and the pusher device during gait cycles. In blue, the interaction forces during unperturbed gait cycles, where the pusher's admittance controller aimed to minimize forces to achieve transparency. In red, the interaction forces during perturbed gait cycles. The top graph illustrates the average interaction forces when perturbations were applied during the loading response phase ($\approx 5\%$ of the gait cycle), while the bottom graph represents the interaction forces when perturbations occurred during the mid-stance phase ($\approx 20\%$). Shaded areas indicate the standard deviation (STD) around the mean for both perturbed and unperturbed trials. Pert stands for perturbation.

B. Data Processing

1) Pre-processing: Marker data is gap-filled using the Qualisys QTM software to address missing or incomplete data points, ensuring continuity in the recorded trajectories. The processed marker data is then exported into MATLAB format for further analysis. Both marker data and ground reaction forces (GRFs) are low-pass filtered using a 4th-order Butterworth filter to remove unwanted high-frequency noise while preserving the essential motion and force signals.

To ensure precise temporal alignment of all data streams, synchronization is performed using the previously mentioned synchronization signal. This step is necessary as the pusher data and the marker/GRF data streams do not share the same start time. Once synchronized, the pusher data is resampled at 2000 Hertz using a linear interpolation method to match the sampling frequency of the GRF data, allowing consistent analysis across all datasets.

2) Inverse Kinematics (IK) and Inverse Dynamics (ID): Marker trajectory data are processed using OpenSim, a biomechanical modeling software. OpenSim utilizes a scaled musculoskeletal model of the participant's skeleton to map marker positions to limb positions and joint angles (IK). During the IK process, the software minimizes the error between the experimentally observed marker positions and the corresponding virtual markers on the model by solving an optimization problem. This yields a time-series of joint angles that describe the participant's motion throughout the trial.

The joint angles derived from IK serve as inputs to the ID process, along with ground reaction forces (GRFs) and the interaction forces from the pusher. ID calculates joint torques by applying Newton-Euler equations of motion to the model.

3) Data Analysis: Inverse kinematics (IK) and inverse dynamics (ID) data were segmented into individual gait cycles based on heel-strike timing. To account for natural variations in gait cycle duration, all cycles were re-interpolated onto a fixed time vector for consistency. This standardization facilitates the visualization and comparison of gait cycles by ensuring they are of equal length. Additionally, gait cycles exceeding 1.5 seconds in duration were excluded from the analysis, as these were likely associated with treadmill acceleration or deceleration phases rather than steady-state walking. Finally, mean and standard deviation values were extracted from 60 unperturbed gait cycles and 20 perturbed gait cycles for each trial.

III. Results

A. Changes in Joint Angles and Torques Due to Perturbation

Fig. 2 illustrates the interaction forces between the pusher and the participant's right leg. During the unperturbed gait cycle (shown in blue), the interaction forces peaked at 28 N, with an RMS value of 13.7 N. Although the original perturbation signal is a square wave with an amplitude of 90 N, the interaction force exceeds this value, peaking at 117 N for perturbations occurring at 5% of the gait cycle and at 123 N for perturbations occurring at 20% of the gait cycle. Nonetheless this interaction force is consistent throughout multiple gait cycles, with little fluctuations around the mean value, which is crucial for ensuring reliable comparisons between cycles.

Fig. 3 presents the angular and torque responses at the ankle and knee joints during perturbed and unperturbed gait cycles for two different perturbation timings: at 5% and 20% of the gait cycle. Mean values are shown for both perturbed and unperturbed gait cycles. Perturbation can be seen to influence both joint kinematics and dynamics. Specifically:

- **Ankle Angle and Torque**: both trials (5% perturbation and 20% perturbation) present a higher range of dorsiflexion, both peaking at -0.25 rad but at different time instants. This corresponds to a significant increase in plantarflexion torque, where for both trials increases with a steeper slope than the unperturbed gait. The maximum difference in angle and torque between unperturbed and perturbed gait was 0.11 rad and 0.31 Nm/kg for the 5% trial and 0.09 rad and 0.36 Nm/kg for the 20% trial.
- **Knee Angle and Torque**: the perturbation introduces additional flexion in the knee joint, particularly around 15% and 30% of the gait cycle respectively. This increased

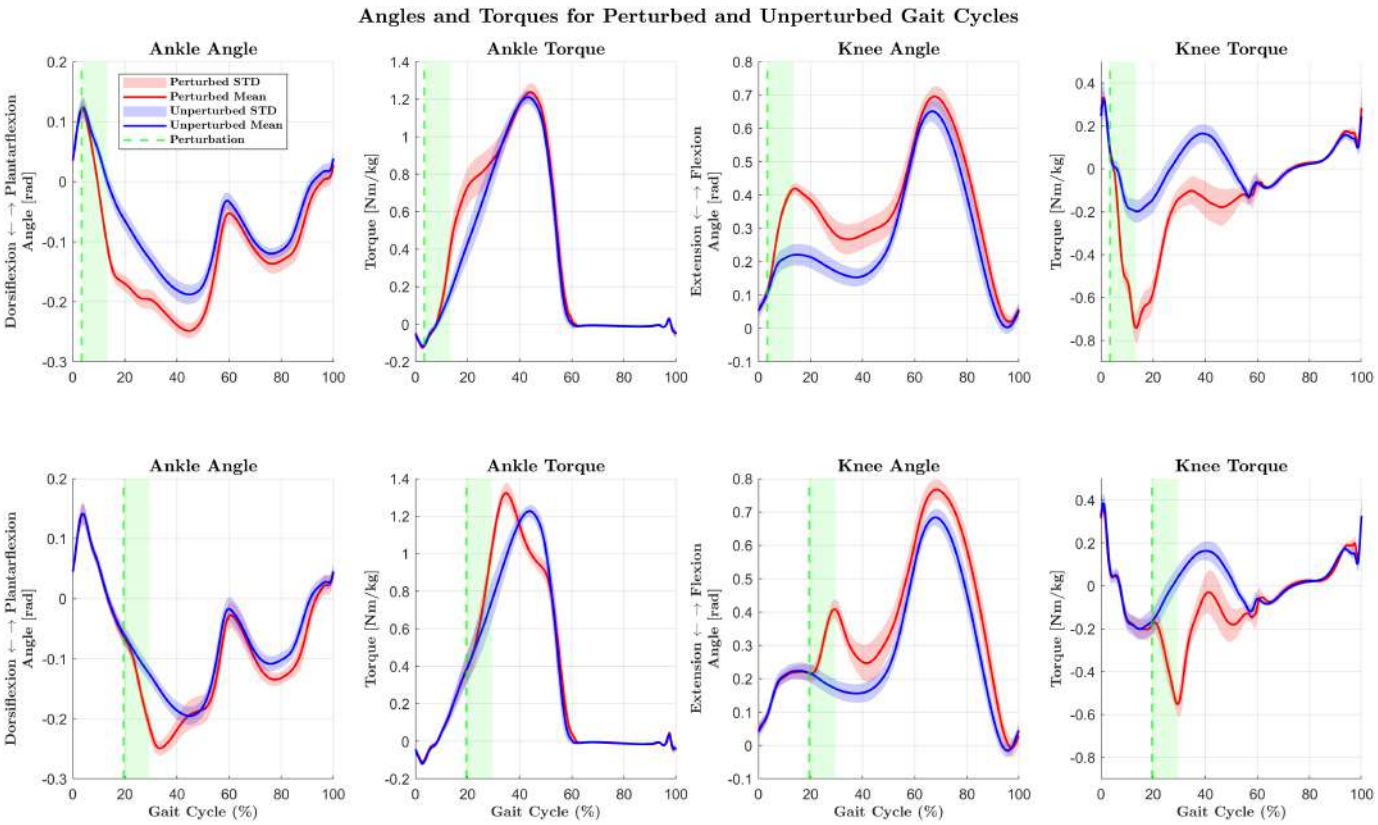

Fig. 3. Right leg joint angles and torques for perturbed and unperturbed gait cycles at the ankle and knee joints. The plots show mean values (solid lines) and standard deviations (shaded areas) for perturbed (red) and unperturbed (blue) conditions. The vertical dashed line indicate the onset of perturbation and the green shaded area represents the 100 ms duration of the perturbation. The top row illustrates ankle angle, ankle torque, knee angle, and knee torque when the perturbation onset is at $\approx 5\%$ of the gait cycle. The bottom row illustrates ankle angle, ankle torque, knee angle, and knee torque when the perturbation onset is at $\approx 20\%$ of the gait cycle. The x-axis represents the percentage of the gait cycle, while the y-axis indicates the respective joint angle (in radians) or torque (in Nm/kg).

knee flexion is accompanied by noticeable changes in the extension torque response, with peak timings matching the knee angle relative maximums. In addition, torque becomes increasingly more negative after the perturbation onset, contrary to the tendency of the unperturbed gait which is close to 0 or positive. The maximum difference in angle and torque between unperturbed and perturbed gait was 0.19 rad and 0.55 Nm/kg for the 5% trial and 0.23 rad and 1 Nm/Kg for the 20% trial.

B. Work and Power Loops

The work loops, as illustrated in Fig. 4, highlight the relationship between torque and angle (work loops) at the ankle and knee joints under perturbed and unperturbed conditions. Only the stance phase of the gait cycle is presented to avoid overcrowding the graphs. Additionally, the 100 ms duration corresponding to the perturbation is distinctly highlighted for better visualization and emphasis on the first affected segment of the curve.

- **Ankle Joint Work Loops:** The perturbed work loops exhibit a larger area compared to the unperturbed loops in the second quadrant for both trials. Perturbations occurring earlier in the gait cycle (5%) produce more pronounced deviations,with respect to the mid-stance (20%) perturbations.
- **Knee Joint Work Loops:** The knee perturbed work loops display a broader area under perturbed conditions in the 4th quadrant. Perturbation at 5% reach a higher peak torque at -0.78 Nm/kg.

The power loops, as illustrated in Fig. 5, highlight the relationship between torque and angular velocity (power loops) at the ankle and knee joints under perturbed and unperturbed conditions.

- **Ankle Joint Power Loops:** Earlier perturbation timing shows higher peak velocities (-3 rad/s). Both angle power loops present an increased activity in the 2nd quadrant with respect to unperturbed trials.
- **Knee Joint Power Loops:** The knee power loops demonstrate a similar trend, with enhanced activity in the 3rd and 4th quadrant. Angular velocity is higher after earlier perturbations, peaking at 5 rad/s, while only being 3.7 rad/s for mid-stance perturbation.

The analysis further highlights the ability of the perturbation method to elicit measurable responses that provide insight into joint behavior during dynamic tasks.

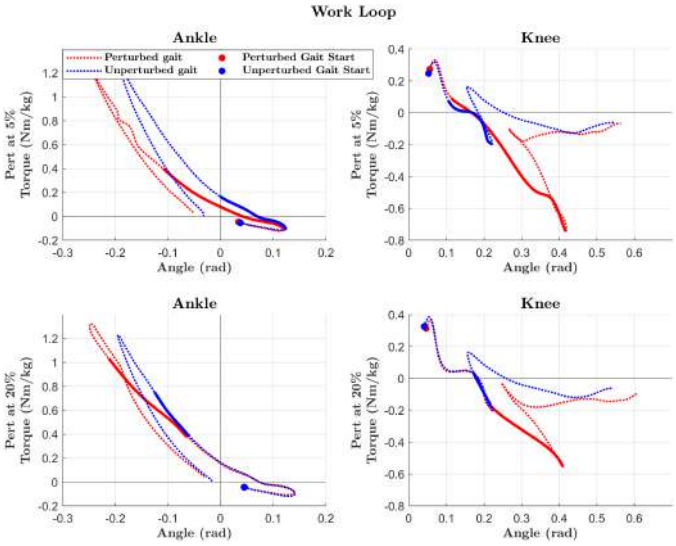

Fig. 4. Work loops of the stance phase for the ankle and knee joints under perturbed and unperturbed gait conditions. The red dashed lines represent the average of 20 perturbed gait cycles, while the blue dashed lines indicate the mean of 60 unperturbed gait cycles. Solid lines highlight the curve behavior during the perturbation. Solid dots mark the starting points for the perturbed (red) and unperturbed (blue) work loops. The top row shows the work loops for perturbations applied at $\approx 5\%$ of the gait cycle, with torque (Nm/kg) plotted against joint angle (rad). The bottom row illustrates the work loops for perturbations applied at $\approx 20\%$ of the gait cycle, highlighting timing-dependent variations in joint torque and angle behavior.

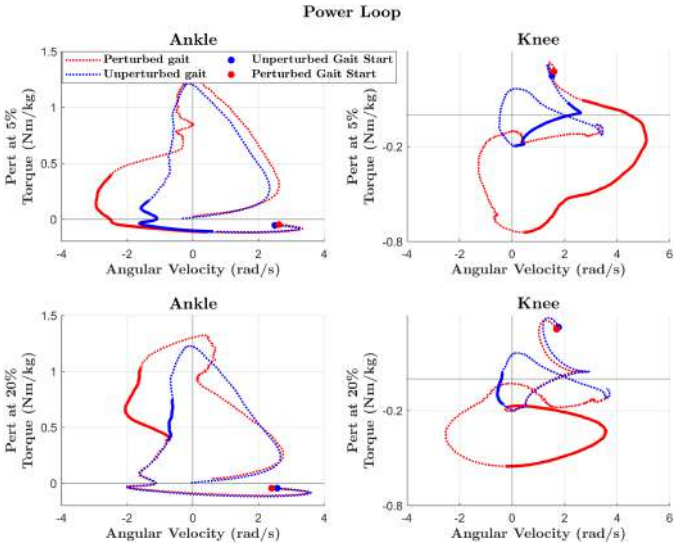

Fig. 5. Power loops of the stance phase for the ankle and knee joints under perturbed and unperturbed gait conditions. The red dashed lines represent the average of 20 perturbed gait cycles, while the blue dashed lines indicate the mean of 60 unperturbed gait cycles. Solid lines highlight the curve behavior during the perturbation. Solid dots mark the starting points for the perturbed (red) and unperturbed (blue) power loops. Thicker portions of the lines represent the variables during the perturbation duration (100 ms). The top row shows the power loops for perturbations applied at $\approx 5\%$ of the gait cycle, with torque (Nm/kg) plotted against angular velocity (rad/s). The bottom row illustrates the power loops for perturbations applied at $\approx 20\%$ of the gait cycle, emphasizing timing-dependent variations in joint torque and angular velocity behavior.

IV. Discussions

This study introduces and evaluates a perturbation method designed to elicit multi-joint-level torque and angular responses during the stance phase of the gait cycle. The proposed methodology effectively and consistently perturbs both the ankle and knee joints, as illustrated in Fig. 3, while preserving the gait cycle's overall pattern during unperturbed conditions. In addition, the pusher setup can offer a high versatility in terms of accessible perturbation conditions, being able to vary treadmill speed, perturbation timing and amplitude. The leg-pusher interaction forces demonstrate high repeatability in delivering consistent force-controlled perturbations. This consistency is important for ensuring the comparability of data across multiple trials.

The perturbation timing affects the amplitude and timing of angular and torque changes at the joints. Importantly, once the perturbation ends, the gait curves converge back to the original pattern, highlighting the leg's efficient recovery mechanism. A slight increase in the knee swing flexion angle was also observed for the perturbed gait, likely due to the compensatory behavior of the subject in response to the perturbation.

The work loops provide insights into the torque-angle behavior during the gait cycle. By examining the thick red lines, corresponding to perturbed conditions, a greater excursion in angle and torque over the same time period (100 ms) compared to unperturbed conditions (thick blue lines) can be observed.

The power loops further elucidate the joint behavior during perturbations. For the ankle, greater negative power is evident in the second quadrant during the perturbation, as the joint resists the imposed motion. This contrasts with the push-off phase in the first quadrant, where the ankle acts as an actuator producing positive power. Similarly, the knee exhibits negative power in the fourth quadrant, braking the fall of the leg and absorbing energy. Interestingly, after the perturbation subsides, the velocity switches sign, transitioning the power trajectory into the positive-power third quadrant. This indicates positive power production from the knee, which actively extends the leg after being forcefully flexed by the perturbation.

This study represents an initial step toward impedance estimation by developing a perturbation methodology specifically for the stance phase of gait. While previous methods employing a pusher system were limited to the swing phase, it was unclear whether a similar approach could be adapted for stance. Our findings confirm the feasibility of this adaptation, laying the groundwork for future studies on joint impedance parameter estimation during stance and expanding the potential for comprehensive gait analysis.

A. Limitations of the study

This study has certain limitations. Interaction forces during unperturbed gait cycles exceed the desired thresholds of 20 N peak and 10 N rms, indicating reduced pusher transparency during unperturbed gait.

The interpolation of gait cycles to a fixed length introduces minor distortions in the temporal characteristics of the data. However, given the treadmill's constant velocity and the

relatively small variation in gait cycle duration (14%), this adjustment was deemed acceptable for the purposes of visualization and comparison. Additionally, data were collected from a single participant, which limits the generalizability of the findings. To address this, future studies should incorporate a larger cohort to capture inter-individual variability in joint impedance responses.

Another limitation is the absence of electromyography (EMG) data, which would provide valuable insights into the neuromuscular contributions to joint dynamics during perturbations.

B. Future work

First, we will refine the admittance controller to improve transparency by reducing interaction forces during unperturbed gait. This will be done by retuning the controller's parameters. Additionally, we plan to implement feedforward control to further enhance system performance and responsiveness. Secondly, we will conduct a comparative analysis of the subject's joint angles during gait with and without the pusher to obtain a clearer assessment of its impact on natural movement. Thirdly we plan to investigate how joint kinetics correlate with perturbation duration and intensity. Most importantly, determining joint impedance from this data requires a system identification approach to relate changes in joint angle to corresponding changes in joint torque. Incorporating EMG data in future work could enhance our understanding of muscle activation patterns and the modulation of joint impedance. Furthermore, while this study focused on the ankle and knee joints, the methodology could be extended to include the hip, as perturbations are transmitted through the entire lower limb kinematic chain. This would allow for a more comprehensive analysis of lower limb dynamics. Further, these results can be used as a validation method to create model-based techniques as in [6], [15]–[17] for estimation of joint stiffness, which would not require perturbations.

V. Conclusions

In this study, we demonstrated the feasibility of eliciting joint-level angular and torque responses through a novel lower limb perturbation method applied during the stance phase of the gait cycle. Kinematic and dynamic data were collected from a single subject, providing a graphical comparison between perturbed and unperturbed gait cycles under two distinct perturbation timing conditions. The results confirmed the ability of the methodology to effectively perturb the lower limb. This approach shows good potential as a versatile testbed for evaluating various experimental conditions, walking speeds, and perturbation intensities. Furthermore, by enabling simultaneous perturbation of the ankle and knee, this methodology provides a useful tool for investigating joint impedance.

***Abstract*—Traditional medical diagnostics heavily rely on the subjective expertise of physicians during palpation procedures, where muscles or tissues are examined by manually applying pressure. This work presents a robotic solution using a KUKA iiwa 14 R820 to replicate this diagnostic technique, for addressing the physician shortage, enhancing physician training, and integrating robotic arms into diagnostics. We emulate the palpation process, measure and analyze the forces applied by the robot on a test bench, and compare the uncertainty with palpation forces applied by physicians and the palpometer. As pain perception during palpation can indicate potential underlying conditions, we further incorporate a pain equivalence measurement into our system using a hand grip force sensor, completing it by developing a graphical user interface for visualization and control. Our results indicate that, while errors within the robot dominate the accuracy of the force application, a well-chosen robot configuration achieves comparable force application errors at typical palpation forces of approximately 5 N, 10 N, and 20 N. The resulting maximum errors are 1.24 N, 0.67 N, and 0.565 N, respectively, which are smaller for both larger forces than the palpation uncertainties of trained physicians. Our findings demonstrate that robotic systems can effectively emulate and refine palpation techniques, providing a foundation for their broader adoption in healthcare.**

***Index Terms*—Medical diagnostics, robotic palpation, force sensing, temporomandibular disorders (TMD).**

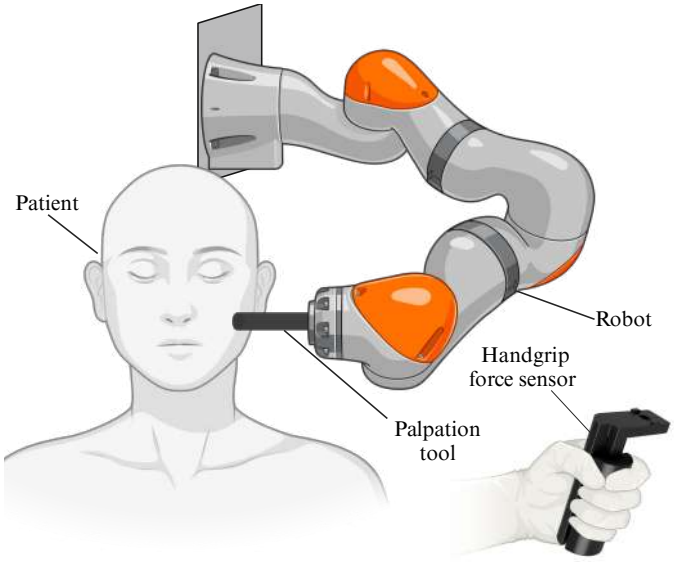

Fig. 1. Robotic palpation setup. The collaborative robot arm applies pressure to the region examined using a palpation tool, which is conventionally performed manually by a physician. The patient's handgrip force is measured as an objective pain equivalent. Figure created with BioRender.com.

I. Introduction

Palpation is a fundamental medical diagnostic technique where physicians use their hands to apply pressure to specific areas of a patient's body to detect abnormalities in texture, size, and consistency of underlying structures [1]. This hands-on method is crucial for assessing conditions that are not immediately visible through imaging or visual examination [2]. Palpation allows clinicians to detect abnormalities, assess organ sizes, evaluate tenderness, and determine the presence of fluid accumulations, among other diagnostic insights.

In dental medicine, palpation is particularly important as a primary diagnostic step for temporomandibular disorders (TMD), which encompass a range of conditions affecting the temporomandibular joint (TMJ), masticatory muscles, and associated structures [3], [4], [5], [6]. TMD includes various disorders such as muscle tenderness (myofascial pain syndrome), which involves pain and inflammation in the jaw muscles [7]; joint pain due to disc displacement, where the cushioning disc within the TMJ moves out of its normal alignment; and arthritis, which can cause degeneration of the joint tissues [8], [9]. These disorders are relatively common, affecting 3–19% of the population, with an estimated number of unreported cases reaching up to 40% due to underdiagnosis or misdiagnosis [10], [11], [12], [13].

The palpation process involves systematically searching the area for abnormalities by examining the area's texture, temperature, and elasticity, performing circular motions to locate the correct pressure position, and applying pressure within a specified force range while monitoring whether the patient feels pain. For the lower jaw, the applied pressure typically ranges from 3.92 N/cm^2 to 17.66 N/cm^2 [2], [14].

Consistent force application during palpation is crucial, as variations can affect pain perception. Efforts to measure and standardize the applied pressure, aimed at improving diagnostic accuracy, resulted in the development of the palpometer. This device allows the physician to recognize when the predetermined force threshold is reached, realized through a

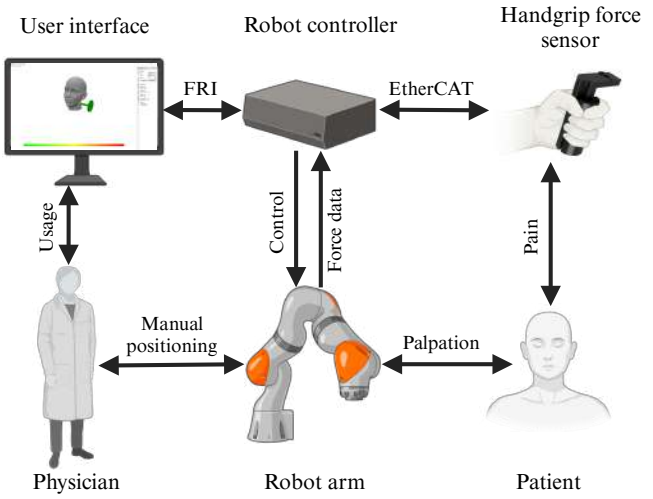

Fig. 2. Structure of the palpation system. The medical staff can control the program sequence with the help of a user interface. Palpation of the patient is carried out by the collaborative robotic arm, which can be manually positioned by the medical staff. At the same time, a handgrip force sensor is used to record the pain equivalent of the patient. Figure created with BioRender.com.

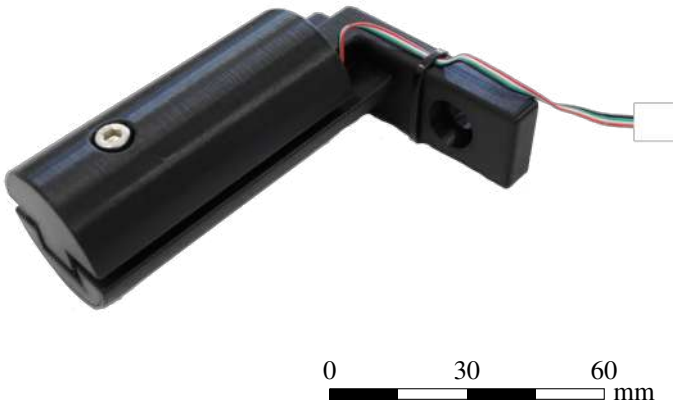

Fig. 3. Handgrip force sensor for measuring a pain equivalent during the palpation process. The current grip force, which is measured by an integrated load cell, is compared with the maximum grip force obtained during initial calibration. The ratio is taken as the measure for the pain.

tensioned spring and a tactile indicator at the device's rear end [1], [15].

Due to the complexity of palpation and the increasing physician shortage, robotic assistance presents a promising solution [16], [17], [18]. Recent research has demonstrated successful simulation and virtual performance of abdominal palpation using KUKA iiwa LBR robots, measuring forces with external sensors [19], [20]. However, practical implementation and efficacy assessment remain pending. Additionally, robotic systems have been explored for minimally invasive applications, such as texture discrimination using biomimetic prosthetic devices [21], and abdominal palpation with custom-designed robotic devices [22], [23].

In this work, we explore the potential of using a commercially available collaborative robot arm without external force sensing for dental palpation (Fig. 1) and discuss a complete palpation system comprising a user interface. We present a functional system that measures a patient's pain equivalent for diagnostic purposes in a model setup, and we then evaluate its force-application accuracy using a rigid test bench, comparing the results with those of trained physicians and the palpometer. By partially automating palpation, such systems can reduce physician workload, make training more uniform, and offer standardized diagnostics where experienced personnel may be limited.

II. Palpation System

The palpation system applies forces directly to the target area using a commercially available collaborative robotic arm (LBR iiwa 14 R820, KUKA AG, Germany) equipped with a palpation tool made of solid polylactic acid (PLA) with a probe area of 100 mm^2. The circular probe area of the palpation tool is identical to the palpometer, resulting in equivalent force application.

The robotic system consists of the robot arm and the robot controller. The robot controller runs the closed-loop controller for the robot arm and incorporates an integrated safety system. Being a collaborative robot, each joint contains torque sensors for real-time monitoring of external forces. If thresholds are exceeded, e.g., a sudden collision or a measured force higher than the desired palpation force, the robot stops. These safety features comply with relevant collaborative robot standards (e.g., ISO/TS 15066), which govern speed, force, and power limits for direct human-robot interaction. Medical staff can control the robot using a dedicated user interface on a computer, which communicates with the robot controller via the Fast Robot Interface (FRI), also providing visualization (Fig. 2).

During the palpation process, the robot operates in impedance mode, where the robotic controller simulates a spring-mass-damper system at the tool center point (TCP). The system consists of three translational springs for controlling position and three rotational springs for controlling orientation. The required force is set as an offset in the palpation direction, causing the robot to move with the specified offset force while maintaining position and orientation in other directions. Therefore, the stiffness of all springs is set to the maximum value (5000 N/m and 300 Nm/rad) except for the spring in the impact direction, which is deactivated, resulting in zero spring force. Gradual force application is critical to minimize discomfort [2]. Therefore, we ensure that the desired force is reached slowly by setting the rise time to 2 s, which prevents the robot arm from overshooting.

Measuring the handgrip force allows us to record patient pain during palpation, a method supported by literature for

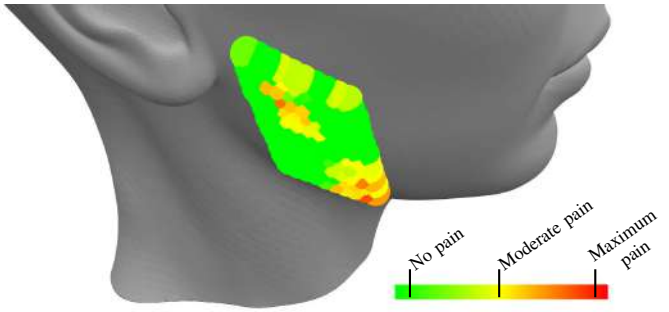

Fig. 4. A 3D head model is used to visualize the palpation results relative to the patient, with exemplary measurements performed on a styrofoam model. The individual palpated points are represented by a sphere in a 3D interface. The color of the sphere indicates the intensity of pain during the application of force. Perceived pain is quantified by the normalized handgrip force.

its linear relationship with perceived pain levels [24]. In this approach, no applied force represents a pain score of 0, increasing linearly to a score of 10 (NRS-11 scale), which corresponds to the patient's maximum handgrip force. The handgrip force sensor, comprising two hemispherical enclosing a load cell (CZL635-50Kg, CZL, China), is capable of measuring up to 600 N, accommodating the upper range of human handgrip force (Fig. 3) [25]. The output of the load cell is digitized by an EtherCAT module (EL3356-0010, Beckhoff Automation, Germany) and transmitted to the robot controller.

Medical staff can manually guide the robot in a handguiding mode to define the points or grids to be palpated and define the desired palpation force. For seamless integration into medical practice, the robotic system is designed to be user-friendly, eliminating the need for extensive training and experienced staff. Therefore, a simple user interface is created, allowing for definition of the target palpation force and grid sizes. Real-time display of the robot's position and the palpation results are provided, with each palpated point marked by a colored sphere, indicating the severity of the patient's pain (Fig. 4).

Accurate force application is crucial for effective palpation. The robot estimates the force at the TCP using torque sensors in its seven axes, which are processed through forward kinematics to calculate the forces acting on the TCP. However, the precision of this estimated force varies with the joint positions and drastically decreases in proximity to singularities.

III. Experiments

Using a 6-axis force sensor (K6D68, ME-Meßsysteme, Germany) and an evaluation unit (GSV-8DS, ME-Meßsysteme, Germany), the applied force is measured to evaluate the system's suitability for palpation. The sensor is positioned in different locations within the robot's workspace, and force is applied for 5 s (Fig. 5). During the experiment, the measured data from the force sensor and the robot arm's reported force values are recorded at a sampling frequency of 50 Hz.

The palpation tool attached to the robot's end-effector is aligned perpendicular to the force sensor to ensure accurate force transmission. Since human tissue is compliant and the force sensor is rigid, we estimate potential force overshoot

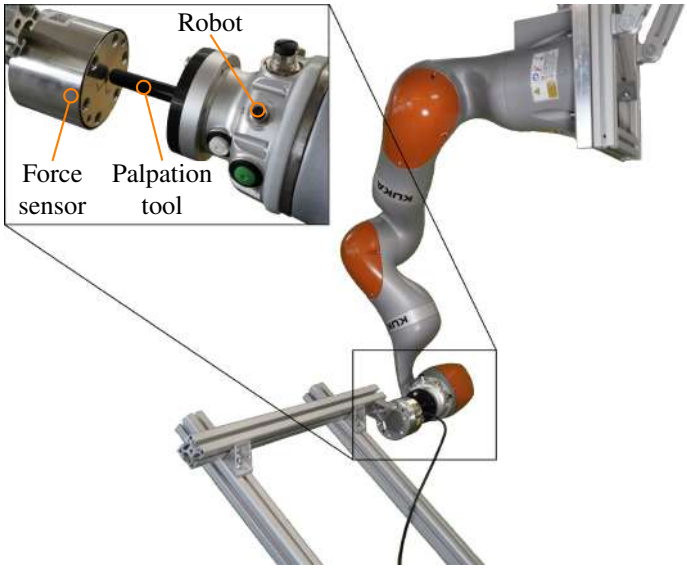

Fig. 5. Determining the uncertainty of our palpation system's force application involves mounting the robot horizontally and applying force to a rigidly mounted 6-axis force sensor using the palpation tool. The force sensor records the force in the direction of the robot's impact.

due to the robot's dynamics when interacting with a non-compliant surface. In order to overcome this overshoot, we filter out transient forces by discarding the initial 1 s of data and calculate the average of the remaining 4 s of sampled data for analysis.

Due to the robot's seven degrees of freedom, the robot controller allows movement within the nullspace, which means that the robot can adjust its joints while keeping the TCP fixed in position and orientation. To examine the influence of different joint configurations on the force output, we vary the dimensionless elbow parameter R in five increments across its permissible range in the robot's nullspace. We attempted to select these increments so that the elbow angle would change approximately linearly, but as the robot does not provide direct feedback on the exact value of R, slight deviations are possible. Nevertheless, these five nullspace configurations differ in the elbow region, which influences the robot's stiffness in the palpation direction and results in varying gravitational loads on the links. For each configuration, palpation is executed 400 times with a target force of 9.81 N and 100 times each with target forces of 4.9 N and 19.62 N. The target forces correspond to those used to verify the palpometer [15].

IV. Results and Discussion

It is essential to know whether the recorded applied palpation forces are normally distributed in order to compare it to other methods and to systematically determine sources of error, for which we use a Shapiro-Wilk test. Both the distribution over the entire measurement with different nullspace configurations (2000 measurements: $p = 2.3 \times 10^{-25}$) and each individual nullspace configuration (400 measurements: $p \leq 5 \times 10^{-16}$) are analyzed. The resulting p-values strongly reject the null

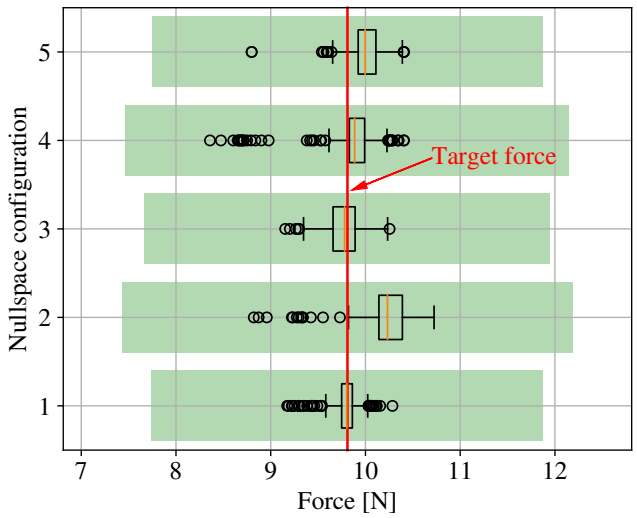

Fig. 6. Applied palpation forces (black) by the robot across five different nullspace configurations, each repeated 400 times, with a target force of 9.81 N (red). While the uncertainty differs across nullspace configurations, all measured forces lie within the uncertainty specified by the robot arm (green). These differences remain within the manufacturer-stated tolerance, indicating the system behaves as expected for a range of joint configurations.

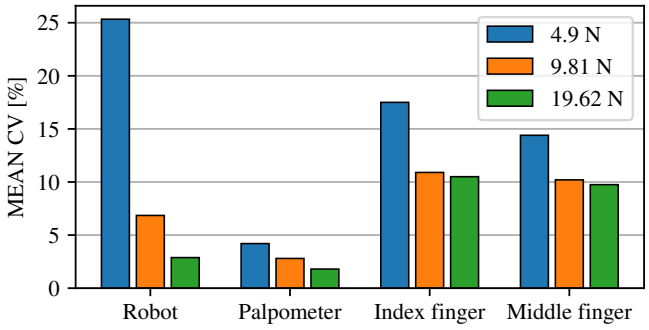

Fig. 7. Variability of palpation forces applied by the robotic arm compared to trained physicians using index and middle fingers as well as a palpometer [1], quantified by the mean coefficient of variation (CV). As the robot's force is non-normally distributed, the plot depicts the normalized maximum error for 95 % of the data. Notably, beyond a palpation force of 4.9 N, the robotic arm demonstrates lower uncertainty compared to trained physicians.

hypothesis of a normal distribution, indicating non-normality for all measurements.

The rejection of normality necessitates further investigation into the nature of the deviation. Therefore, the nullspace configurations are analyzed to identify whether they contribute to the observed deviations. Since the Shapiro-Wilk test strongly rejected normality, a non-parametric statistical approach was necessary. The Friedman test was chosen as it is a rank-based alternative to repeated measures ANOVA and is suitable for comparing multiple related groups when the normality assumption is violated.

The different nullspace configurations for the assembly position of the robot arm are evaluated to identify if the mean deviation differs across all nullspace configurations. The test yielded a statistic of 853 with a p-value of 2.4×10^{-183}, confirming a significant effect, which indicates that the nullspace configuration influences the error. This is also visually evident, as for some configurations (1 and 3) the applied median force to the target force is smaller than for others (Fig. 6). Since the robot's uncertainty varies with different nullspace configurations, it is reasonable to assume that it will also vary across different positions and orientations. The differing deviation from the target force suggests that the root cause lies within the robot arm itself, potentially due to imperfect alignment for gravity compensation or measurement uncertainties stemming from the individual torque sensors in the joints.

We compare the uncertainty of the applied palpation force over all nullspace configurations against the current state of the art to quantify the performance of our current palpation system. The deviations of trained physicians applying force with the index and middle finger [1] and those measured using the palpometer [1] are compared. Due to the non-normal distribution of the robot's values, the maximum error of 95 % of the measured data is evaluated. For mitigating the influence of outliers, we exclude the top and bottom 2.5 % of the data and normalize the maximum deviation to the target value (Fig. 7). In absolute values, the uncertainties are 1.24 N, 0.67 N, and 0.565 N for the palpation forces of 4.9 N, 9.81 N, and 19.62 N, respectively.

These uncertainties demonstrate a decreasing trend with increasing target force, which is consistent with the behavior observed for the palpometer [1]. At the lowest target force of 4.9 N, the uncertainty of our robotic system is much larger than that of the palpometer. This increased variability at lower force levels may be attributed to the limitations of the robot's torque sensors, which have reduced sensitivity and accuracy at lower torque values. At medium and high target forces (9.81 N and 19.62 N), our robotic system exhibits uncertainties that are lower than those observed when trained physicians use their fingers, but still slightly larger than those achieved with the palpometer. Thus, for forces around 10 N and 20 N, the system demonstrates sufficient precision that may be acceptable for clinical palpation ranges. However, direct comparison with prior literature must be interpreted cautiously, since the physician and palpometer data come from separate studies [1].

V. Conclusion and Outlook

In this work, we presented a test bench study of a robotic palpation system for the lower jaw, including a user interface and a handgrip sensor for measuring patient-reported pain equivalences. We found that the main source of uncertainty stems from the robot's indirect force measurement, relying on internal joint torque sensors prone to gravity-compensation errors and calibration drifts. These errors are inherent to the robot's method of force measurement, primarily attributed to two key factors: inadequate gravitational compensation and

measurement uncertainties associated with individual torque sensors. While our system achieved uncertainties smaller than those of trained physicians at higher forces ($\geq$9.81 N), it did not outperform the palpometer at the lowest tested level of 4.9 N.

An important future direction is to ensure that such a robotic palpation system complies with relevant medical regulations and standards. For future enhancements of robotic palpation systems, integrating external force sensors into the palpation tools will aim to improve measurement accuracy while addressing uncertainties related to tool positioning and nullspace interactions. Additionally, incorporating multimodal sensing capabilities, such as temperature and stiffness measurements, can enrich the diagnostic information obtained during palpation and can help to match the capabilities of physicians. This will enhance the diagnostic process for TMD, extend the application of robotic palpation to other medical fields, and potentially mitigate the impact of the physician shortage.

***Abstract*—Sonomyography is a technique that uses ultrasound imaging to measure muscle activity. Unlike traditional methods, sonomyography allows for real-time imaging of deeper muscles. Recent research has focused on developing wearable ultrasound devices to enable real-time muscle activity sensing, specifically for applications in proportional control systems. By tracking muscle movement intensity and dynamics, wearable sonomyography systems enable precise control in real-time applications, such as target tracking and robotic prosthetics, improving the functionality and user-friendliness of biomechatronic interfaces. In this paper, we explore the proportional control for target tracking using the sonomyography (SMG) signals, captured through a sensor array. We evaluated three feature extraction methods for comparison: peak location-based features, amplitude histogram features, and curve-fitting features. These features were used to train a regression model, which we evaluated for its effectiveness in controlling real-time gestures. The results demonstrate that the amplitude histogram feature set achieved the highest accuracy of 88.72$\pm$3.27 % when trained with an ensemble regression model during the target tracking proportional control task using the SMG signal.**

I. INTRODUCTION

Prosthetic devices are important for rehabilitation, as well as assistive technology and intuitive control to improve mobility and quality of life. They are essential for restoring movement and improving life for people with limb loss [1]. Recent advancements in prosthetics have focused on achieving intuitive and seamless control, allowing users to perform both daily activities and complex motor tasks using various control strategies. Traditional myoelectric prostheses utilize surface electromyography (sEMG) signals for non-invasive muscle activation detection from two measurement sites, which limit control to only a few movements to interpret user intent and translate it into precise movements [2]–[4]. To enhance control capabilities, multi-channel and high-density EMG (HD-EMG) systems have been developed. These systems enable more advanced control methods, including simultaneous, sequential, and proportional control of multiple movements, as well as gesture recognition through pattern recognition and machine learning using muscle force, estimation of the joint forces [5], [6] and joint kinematics [7]. However, issues like limited spatial resolution, poor signal-to-noise ratio, and signal instabilities lead to inaccurate real-time control of the biomechatronic devices [8], [9]. Therefore, other noninvasive methods are being explored to overcome the limitations of EMG.

In recent years, sonomyography (SMG) has become popular for detecting muscle deformation through ultrasound imaging. It provides a non-invasive method which is capable of resolving individual muscles spacially, including deep-seated muscles, and detecting dynamic activity within various functional compartments in real-time [10], [11]. Previous studies on sonomyography methods for gesture classification and joint force estimation have focused on changes in muscle structure observed in ultrasound images. This is achieved either by tracking specific landmarks within the images or by analyzing patterns over time from the ultrasound images. For example, Shi et al. demonstrated that tracking muscle thickness [12] and pennation angle [13] from ultrasound images can accurately estimate wrist angle. Some studies have focused on pixel intensity [14] from B-mode images to measure muscle activity. B-mode ultrasound devices are often bulky, making them less suitable for wearable applications. In contrast, several studies have shown that A-mode ultrasound signals can effectively detect various muscle activities, making them more appropriate for wearables. Wearable ultrasound systems that utilize single-element transducers provide a compact solution for wearable applications that use features such as waveform length [15] and mean absolute value [16], which are extracted from specific depth regions of the A-mode ultrasound signal. However, X. Yang et al. presented a wearable ultrasound-based interface for decoding simultaneous and proportional wrist/hand kinematics, demonstrating superior performance over surface electromyography and the potential for intuitive position-based control of future prosthetic devices [17]. They used time-domain features and frequency-domain features to compare different regression models and find out that the

This work was funded in part by the Anusandhan National Research Foundation (ANRF) through a Core Research Grant - CRG/2021/004967 (PI:BM) and by the Department of Biotechnology, Government of India-BT/PR50638/MED/32/951/2023 (PI:BM).

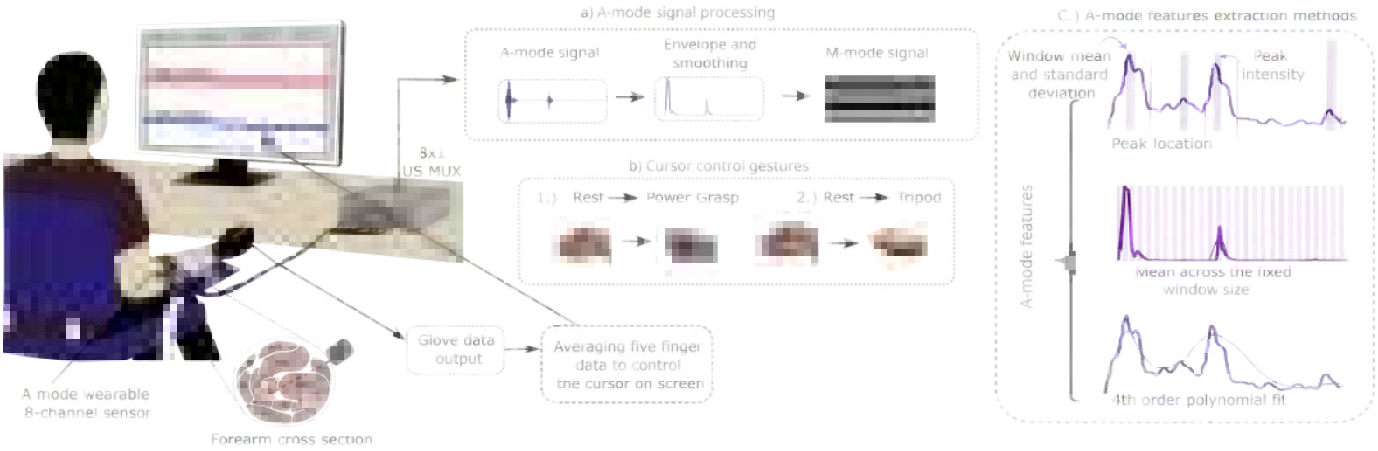

Fig. 1. Experimental setup for target tracking task during isokinetic movements and A-mode signal processing showing different feature extraction methods.

time histogram was outperforming. Similarly, another study used different feature sets to predict continuous isometric force levels using peak location features, mean, and standard deviation across those peaks [18] as features.

However, there has been no direct comparison of these feature sets for proportional control tasks. To address this gap, this paper evaluates three feature extraction methods peak location-based features, amplitude histogram features, and curve-fitting features by comparing their effectiveness in target tracking for proportional control. In the peak location-based approach, we identified significant peaks in the A mode signal and calculated the mean and standard deviation across these peaks to capture variability in muscle activity [18]. The amplitude histogram method analyzed the distribution of signal amplitudes by using an overlapping window size across the entire A mode signal. Finally, the curve-fitting approach modeled the SMG signal with a mathematical curve, using the coefficients from this model as features to train the proportional control model. These features were used to train various regression models, which we evaluated for their effectiveness during real-time movements.

II. Materials and Methods

A. Sensor Setup

In this study, an eight-channel wearable SMG sensor was used [19] which was made using lead zirconate titanate (PZT) transducers (SMD063T07R111, Steiner & Martins Inc., USA) and created using a piezoceramic disc with a diameter of 7 mm and thickness 0.7 mm. The resonant frequency of the transducer is 4.25 MHz, and the acoustic impedance is 33.7 MRayl. To improve the performance of the transducer and to dampen unwanted reverberations, an acoustic backing layer was created which consists of tungsten powder mixed with epoxy resin in a weight ratio of 4:1. Each transducer was connected to a matching circuit using a parallel L–C tank design (L = 5 µH, C = 511 pF). The fabricated transducer with a backing layer was tested using a pulse-echo method, as explained in [20] and [21]. They showed a bandwidth of about 470 ± 88 kHz and an axial resolution of 0.8 µm. Radial vibrations were greatly reduced, with improvements of over 100 dB after introducing the backing layer.

The eight sensors were placed in a custom 3D-printed case to hold the PZT elements and matching circuits. Each sensor was connected using 50 Ω RG-174 cables (model 8216 0101000, Belden Inc., USA), which were about 50 cm long. The transducers were then arranged within the enclosures and were sewn to the velcro band with an inter-transducer distance of 2 cm to form the wearable sonomyography transducer array. The sensors were attached to a fabric band, to fix them on the forearm.

B. Experimental Setup

In this study, we experimented to evaluate proportional control using A-mode data with various features. The primary aim was to compare different feature sets in controlling a cursor on a screen using hand gestures, specifically focusing on the power grasp and tripod grasp gestures. The experiment consisted of two phases: calibration and target tracking.

- *Calibration phase:* During the calibration phase, participants either rested or performed specific gestures for 10 s repeated three times to establish the signal range. The cursor movement corresponded to the average values from the fingers and this range was normalized between 0 (representing rest) and 1 (indicating full execution of the gesture). The signals recorded during both the resting and movement periods were saved as reference points.
- *Isokinetic target tracking phase:* In the target-tracking phase, participants controlled a cursor on the screen using their hand movements to follow a moving target, the cursor movement corresponded to the average of five finger values in real-time, which moved at a 10 %/s normalized velocity. The movements generated values normalized between ’0’ and ’1’, where 0 represented total relaxation of the hand and 1 indicated complete execution of the gesture. The cursor movement corresponded to the glove data values in real-time, which allowed participants to adjust their gestures to continuously track the target.

During the target tracking task, participants performed two types of hand movements: power grasp (PG) and tripod grasp (TG). These grasps were chosen because they are commonly used in everyday activities. The power grasp is used for holding large objects, while the tripod grasp is important for precise tasks like writing or picking up small items. Testing these movements helps evaluate how well different features from A-mode ultrasound data can control the cursor. Each movement was tested in five trials, with each trial including five target positions, repeated twice. This resulted in a total of 10 target positions, followed by 10 s rest intervals for power grasp as well as tripod experiment. The target positions were presented in a fixed order. The data collected from both hand gestures were used to compare the performance of various features extracted from the A-mode ultrasound data for proportional control.

C. Data Acquisition and Data Processing

Four healthy individuals (aged 29 $\pm$ 4 years) participated in the study. They were fully informed about the procedures and provided their consent to take part. All procedures were approved by the Institutional Ethics Committee at Indian Institute of Technology Delhi (Approval no. P021/050).

During the experiment, participants were asked to sit comfortably on a chair with their dominant arm resting on a handrest. A custom wearable sensor array for sonomyography was attached to their forearm approximately 4 cm from their olecranon process. The array was oriented such that four sensors imaged the flexors muscles while another four imaged the extensor muscle groups. The sensor array was connected to an eight-channel ultrasound pulser-receiver system (Lecoeur US-MUX, Lecoeur Electronique, France), which sent and received ultrasound signals using one transducer. The Lecoeur 8-channel US-MUX is designed for ultrasound acquisitions and measurements, featuring a transmitter that generates pulses with user-programmable voltage levels and widths, a receiver for signal amplification, and a digitizer with a 12-bit resolution capable of operating at frequencies at 80 MHz, which can function in either pulse-echo or pitch-and-catch mode, operates with a USB power supply and allows data acquisition using LabVIEW or MATLAB. The pulser was set to create a 90 V unipolar pulse that lasted 49.25 nanoseconds and repeated at a frequency of 15 kHz, allowing imaging up to 5 cm deep. We optimized the pulse width through acoustic testing to get the best possible signal strength [20]. The ultrasound echo signals were amplified using a time-gain compensation (TGC) amplifier, which increased the gain from 0 to 50 dB to help with tissue signal loss. The amplified signals were then digitized at a sampling rate of 80 MHz and sent to a computer (Intel Core i5-4790K, 16 GB RAM, 2 GB NVIDIA GeForce) via USB. A custom MATLAB application (Version 2022b, MathWorks Inc., Natick, MA, USA) processed these signals at a frame rate of 22 frames per second (fps) across all eight channels. A data glove (5DT Data Glove Ultra, Fifth Dimension Technologies, USA) was used for ground truth to measure the finger joint angles. Gesture tracking involved transitioning from rest to maximum motion and back.

The A-mode raw signals were recorded as 4000 points for a 5 cm depth. The data was manually verified for clear echoes from tissue changes during muscle movement. To analyze the raw data, the signal's envelope was extracted using the Hilbert transform with a window size of 25 points. All A-mode signals from the eight channels were combined into an array of 8×4000 for direct recording in MATLAB. Additionally, finger movement data from the data glove was recorded for all five fingers in both the resting and hand-closed positions. The average data for the five fingers was then normalized. Using this normalized average data, participants attempted to control a target-tracking cursor displayed on the computer screen, allowing for stable and accurate tracking of finger movements in real-time as they transitioned from open to closed in a continuous mode. After preprocessing the data, the next step was feature extraction, which involved deriving meaningful characteristics from the SMG signal for further analysis. In this study, three different feature extraction methods were applied to compare their effectiveness for proportional control.

- **Peak location-based features:** In the first approach, we identified the locations of significant peaks in the SMG signal and calculated the mean and standard deviation at these peak locations. These peaks help capture the variability of muscle activity during control tasks [18].
- **Amplitude histogram features:** The second approach focuses on creating an amplitude histogram from the SMG signal. This histogram is computed using both fixed window sizes and overlapping windows. Analyzing the distribution of signal amplitudes over time provides insights into muscle activation patterns during control tasks [17].
- **Curve Fitting Features:** The third approach is a polynomial-based curve-fitting technique to model the SMG signal. This method employs a mathematical equation that describes a set of data points using a 4th-order polynomial function. The coefficients obtained from this equation serve as features. These features create a continuous and smooth representation of the A-mode signal over time samples illustrating muscle activity [22].

The three feature sets were utilized to train various regression models, and their performance was compared through offline evaluations. The objective was to identify which feature extraction approach provides the most accurate and stable signal representation for proportional control tasks. To achieve this, the features were utilized to train different regression models using 5-fold cross-validation. In each fold, data from one trial was used for testing, while the data from the remaining four trials served as training data. Using training data models were trained and validation was performed on the test data, resulting in five-fold validation iterations. The average performance across the five folds for four subjects was then calculated. Four commonly used regression models were chosen for this analysis: Regression Tree Ensemble,

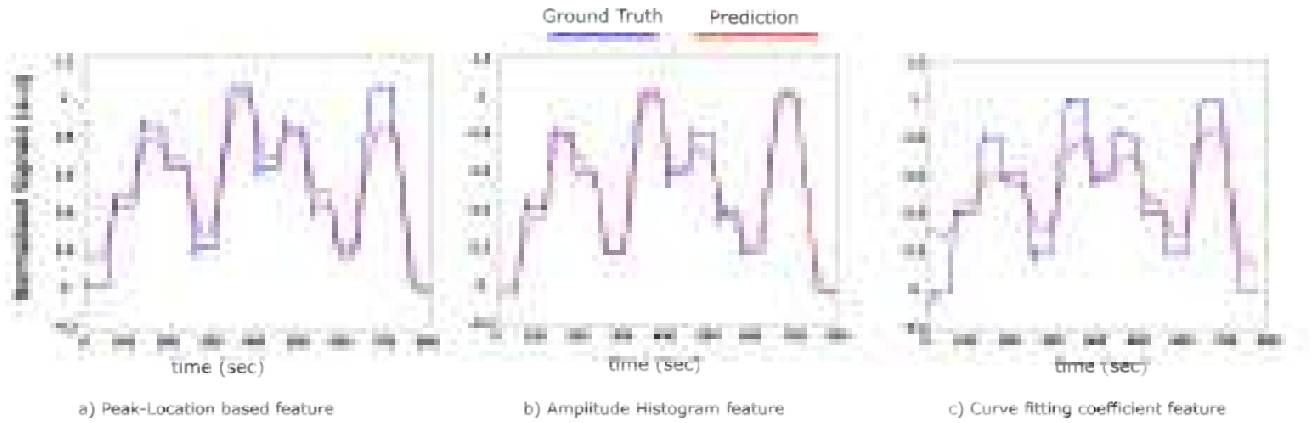

Fig. 2. Time series plot illustrating the measured and predicted outputs of the trained model for target tracking during proportional control for subject S1, using different feature extraction methods for power grasp and trained with ensemble tree regression.

Gaussian Process Regression, Support Vector Machine (SVM) Regression, and Linear Regression. For each model, the 5-fold cross-validation accuracy was computed as a measure of performance.

D. Statistical Testing

We performed a two-way Analysis of Variance (ANOVA) test using OriginPro (2020b, OriginLab Corporation, Northampton, Massachusetts, USA) with post-hoc Tukey comparison to assess the effect of feature type and regression model on the prediction performance.

III. Results and Discussion

The performance of various feature extraction methods and regression models were evaluated using 5-fold cross-validation to identify the most effective approach for the target tracking task during proportional control. Fig. 2 presents a time-series plot for the test trial, comparing the model prediction for ensemble regression model across three different feature extraction methods for a single fold and one representative subject. It demonstrates that amplitude histogram features exhibited the excellent tracking performance with an R^2 of 0.93 between the predicted and test data.

Since the models were trained separately for each grasp rather than distinguishing between them, the accuracy was first calculated for each grasp individually across different models. These values were then combined to obtain the final accuracy presented in Fig. 3. Fig. 3 displays a bar plot comparing all three feature extraction methods alongside all regression models across all subjects and grasp configurations. As a result, among all the regression models, the ensemble regression model achieved the highest mean accuracy of 88.72$\pm$3.27 % with amplitude histogram features. However, ensemble models underperformed with curve fitting features with the lowest accuracy of 68.5$\pm$7.08 %. This indicates that the ensemble regression model with amplitude histogram features offers superior predictive accuracy compared to the other models.

We conducted a two-way ANOVA test and found that the choice of features significantly affects predictive performance

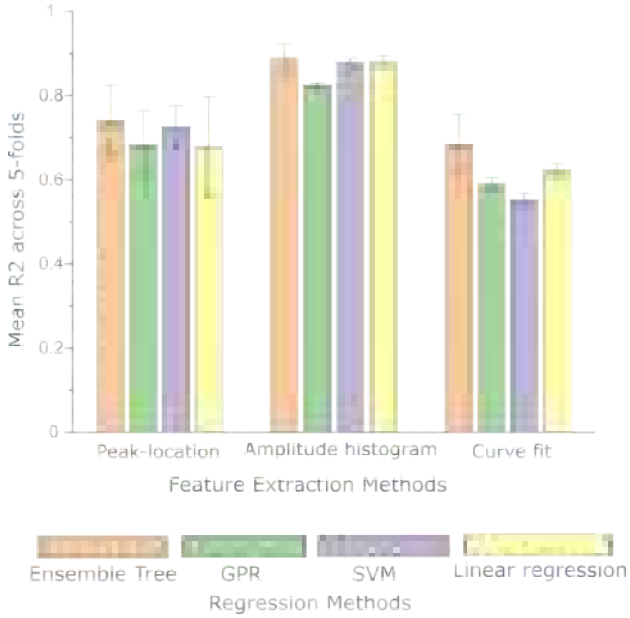

Fig. 3. Performance comparison of different feature extraction methods and regression models for target tracking task, showing the mean (R^2 value across 5-fold cross-validation, corresponding to each feature extraction method and different regression methods.

(F(2, 36) = 84.89, p $<$ 0.001). The type of regression model also has a significant influence on the accuracy (F(3, 36) = 3.54, p $<$ 0.024). However, we found no significant effect of the interaction of feature extraction methods and models (F(6, 36) = 1.42, p $<$ 0.232). Tukey's post-hoc comparisons also showed that the amplitude histogram method provides significantly better performance than the peak-location method (mean difference = 16.02, p $<$ 0.001) and the curve fitting method (mean difference = -25.47, p $<$ 0.001).

Conclusion and Limitations of the Approach

Wearable ultrasound-based human-machine interfaces have shown significant promise for the proportional control of modern biomechatronic devices. This study explored the role

of proper feature selection and the type of regression modeling methodology on the proportional control performance with three gestures. Our results demonstrate that the amplitude histogram method significantly outperforms both the peak-location and curve-fitting methods across all modeling techniques. The choice of regression model impacted the performance, with ensemble modeling outperforming other topologies. Our work only addresses isokinetic movements for a limited set of three gestures. A more comprehensive analysis involving proportional isometric and isotonic muscle contractions with an extended set of gestures will be explored in the future. Another limitation is that the study was done only on healthy subjects. Since the goal is to use this method for prosthesis control, future research will test individuals with trans-radial amputations to ensure the approach works well for them.

***Abstract*—Cognitive decline in older adults, even those without impairments, is well-established and becomes especially pronounced during dual-task situations. Advances in digital devices for cognitive assessment provide more precise evaluations compared to traditional oral or paper-based formats. However, most of these devices typically focus solely on cognitive performance without employing the Motor-Cognitive Dual-Task paradigm, which integrates cognitive tests with motor tasks. This study exploited such innovations by integrating digitalized cognitive tests with dynamic balance tasks, aiming to improve detection of age-related cognitive changes. Sixty-one participants completed Motor-Cognitive Dual-Task tests on a robotic platform under various balance conditions, both static and dynamic. The study validated the digital tests against their traditional counterparts and examined how age and balance conditions influenced cognitive performance. Results on cognitive performance showed how cognitive decline becomes more apparent with age, particularly in tasks requiring higher complexity. Both processing speed and working memory showed significant age-related reductions. Also, a deterioration in cognitive performance was shown in the most challenging balance scenarios, therefore revealing an effect of the balance task on cognitive performance. These findings suggest that combining dynamic balance tasks with cognitive assessments may effectively identify early cognitive changes.**

Keywords—motor-cognitive dual-task, cognitive performance, robotic-based assessment tests

I. Introduction

Cognitive decline is a common phenomenon observed in unimpaired older adults, often associated with age-related deficits that affect various cognitive functions, including memory, attention, processing speed, and executive function [1], [2]. As individuals age, structural and functional changes in the brain contribute to gradual reductions in cognitive abilities [3]. These changes can lead to challenges in daily functioning, impacting an individual's independence and quality of life [4]. Understanding the nature of age-related cognitive decline is essential for developing effective strategies to support aging populations and mitigate the impact of these deficits on physical and mental well-being.

Cognitive decline is commonly assessed using straightforward neuropsychological tests, typically administered in an oral or paper format. These tests are designed to be accessible and easy to administer, with outcomes measured through simple, quantifiable parameters such as the time taken to complete the test, the number of correct responses or the number of errors committed. Clinicians performing the tests directly record these parameters, providing immediate insight into cognitive performance. However, since clinicians manually compute these outcomes, they are subject to human error, which can introduce variability and limit the precision of these assessments. Traditional assessment tests also often rely on subjective interpretation, increasing the likelihood of variability between evaluators.

Over the past three decades, advancements in technology have led to the development of various devices and tablet-based applications for both the assessment and training of cognitive abilities [5], [6]. These digital tools offer various advantages, including automated data collection, standardized scoring, and the capacity to provide real-time, objective feedback [7]. By capturing a wider range of performance metrics, such as reaction times, error patterns, and response variability, these devices enable more accurate and comprehensive assessments of cognitive functions [8]. Although initially developed to target only cognitive functions, these devices can now be effectively integrated with motor assessment and training through Motor-Cognitive Dual-Task (MCDT) approaches. This integration is particularly valuable, as clinical research shows that older adults and individuals with neurological conditions frequently experience simultaneous cognitive and motor impairments [9].

The relationship between cognitive and motor functions is fundamentally bi-directional. Cognitive decline is often linked to motor impairments, manifesting as incoordination, balance instability, gait abnormalities, and an increased risk of falls [10]. This connection suggests that interventions addressing both cognitive and motor functions simultaneously may provide more effective support for both clinical populations and unimpaired older adults. Thus, in the last decade, there has been growing interest in the MCDT paradigm, an approach that involves performing a cognitive task simultaneously with a motor task. This increased focus on MCDTs due to its ability to reveal early cognitive impairments that may go unnoticed in single-task assessments. To this extent, a recent study highlighted how MCDT tests have shown promise as sensitive and objective tools for detecting early cognitive decline in patients with Parkinson's Disease [11]. The study's main finding was that MCDTs could identify subtle cognitive

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

deterioration even before the onset of motor symptoms, making them a valuable tool for early detection and timely management of cognitive decline.

While the MCDT paradigm has been extensively investigated when standing in static conditions, a significant research gap remains in understanding the effects of dual-task (DT) challenges on dynamic balance. Indeed, evaluating dynamic balance is crucial because it mirrors more accurately real-world scenarios, involves more complex motor and cognitive processes, and can better inform injury prevention, training and rehabilitation strategies. Apart from gait-related conditions, among the studies concerning dynamic balance, only one study has used platforms to focus exclusively on movements in a single direction, either anterior-posterior or mediolateral. However, this did not address dual-task abilities. [12]. Therefore, our study aims to address this gap by exploring MCDT assessments across various balance conditions, including both static and dynamic scenarios. For the first time, we digitized versions of several commonly used cognitive assessment tests, that have been integrated within hunova [13], a medical robotic device developed by Movendo Technology (Genoa, Italy). Thanks to the device's versatile platforms we were able to combine the digitalized cognitive assessment tests with different platform movements, not limited to a single direction. With this study, we first validated the cognitive metrics we computed within the device algorithms and then, we analyzed how the balance conditions influenced cognitive performance in different age groups. Specifically, we conducted a trial with 61 unimpaired subjects from three distinct age groups: young adults (YA), middle-aged adults (MA) and older adults (OA), who performed both the newly developed digital MCDT tests and their corresponding traditional versions. Indeed, this study had a threefold objective:

1. Evaluate the correlation between the evaluators obtained from the newly developed digital tests and those derived from their traditional counterparts.
2. Assess the influence of age on cognitive performance of the MCDTs conducted under a single specific balance condition.
3. Assess the impact of age and balance conditions on cognitive performance during MCDTs performed under various balance scenarios.

II. Materials and Methods

A. Set up and protocol

This study utilized hunova, a medical robotic device for sensory-motor rehabilitation and evaluation of lower limbs and trunk (Fig. 1). It features two electromechanical platforms, one positioned under the feet and another under the seat, integrated with an inertial sensor to be placed on the sternum to track trunk motion [13]. This device enables balance assessment in both static and dynamic conditions. In this study, we examined performance across these balance conditions, utilizing the platform under the feet. Indeed, we included the following three balance tasks:

- Static. The platform remained parallel to the horizontal plane without any movement or tilting, providing a stable surface.
- Unstable. The platform simulated a plate with a central pivot, that tilted due to the user's weight shift, while an elastic force field, opposing the user's motion, attracts the platform to the horizontal position.
- Passive. The platform imposed an external perturbation as it moved independently from the subjects' sway, following a pre-programmed circular trajectory (as done in [14]).

These three balance tasks have been combined with the following cognitive tasks that required participants to physically interact with hunova's touchscreen:

- Stroop Color and Word Test. Includes three parts like the oral format: 1. Word Reading: participants are shown a stimulus on the screen, which is a color-word written in black ink. Below the stimulus are four buttons, each containing a color-word (also written in black ink). Participants are asked to press the button that matches the color-word of the stimulus. 2. Color Naming: participants are presented with the four buttons from part 1, but the stimulus now consists of a sequence of 'X's displayed in a specific ink color. They must select the button that represents the color of the ink used in the stimulus. 3. Interference: The same four buttons are used, but the stimulus consists of a color-word printed in a mismatched ink color (e.g., the word "red" written in blue ink). Participants must press the button that corresponds to the color of the ink (in this case, the correct response would be 'blue').
- Trail Making Test: consists of two parts: A and B. In part A participants are asked to connect a sequence of numbered circles in ascending order (e.g., 1-2-3...) as quickly as possible by moving their finger on the touchscreen. In part B participants must alternate numbers and letters in sequence (e.g., 1-A-2-B...). Throughout the whole duration of the test, participants are asked not to lift their finger from the screen when connecting the targets.
- Spatial Span Test: this is an adaptation of the Corsi Block Test [15]. Participants are presented with a visual grid where a specific sequence of squares is progressively highlighted. They are asked to remember and reproduce the sequence in the same order as it was shown. The task starts with a short sequence and gradually increases its length as participants answer correctly.

To avoid repeating the same cognitive exercise multiple times in the different motor configurations, we divided the MCDT activities into two protocols. Each participant was randomly assigned to one of the two protocols (details in Table I). Also, to validate the above presented digital MCDTs we also performed their corresponding traditional versions, either paper-based or oral. More specifically, in the original version of the Stroop test, participants responded verbally without

screen interaction, maintaining the division into three parts (as in the digital version). The Trail Making Test was administered in the paper-based format, mirroring its digital corresponding formats but using pen and paper. For the Spatial test, we selected the Digit Span test, where a clinician reads aloud a sequence of digits that participants must repeat in the same order. The sequence's length increases with each correct response. While the Stroop test was administered while standing on the robotic device across two balance conditions, all other classic cognitive tests were conducted in a seated position external to the device (full details in Table I).

B. Subjects

The study was approved by the local ethical committee of the University of Genoa (protocol n. 2023/93 approved on z14/12/2023). Sixty-one subjects with no history of neurological disease participated in the study: 20 subjects under 35 yo (26±3 yo, 11F), 20 subjects between 35 and 60 yo (51±5 yo, 11 F) and 21 over 60 yo (64±3 yo, 13 F).They were divided into two groups: one group, G1, performed Protocol 1, while the second group, G2, performed Protocol 2. Each group included both subjects under 35, between 35 and 60, and over 60: G1: 13 males (M), 17 females (F); 10 younger, 10 middle-aged and 10 older adults, G2: 13 M, 18 F; 10 younger, 10 middle-aged and 11 older adults.

C. Data and statistical analysis

The robotic device used in this study collects data from the platforms, the inertial sensor placed on the participants' chest, and the participants' interactions with the screen. Within this study, our analysis focused specifically on cognitive performance, prioritizing the data gathered from participants' screen interactions. To address our hypothesis, we calculated standard evaluation indices from the classic test formats as the primary outcome. Additionally, exploiting the advantages of the digital format, we identified secondary outcomes to gain a more comprehensive assessment of cognitive performance, decision-making and motor coordination that are not immediately evident from the primary outcomes . The primary outcomes considered in this study were:

- *Number of correct answers* in the Stroop test*:* the correct answers given, either verbally or by pressing the correct button on the screen, within 30 seconds for each section of the test.

Figure 1: Experimental set up: subjects were instructed to keep an upright stance on the platform beneath their feet. Depending on the task, they either kept their arms relaxed at their sides (during balance tasks) or interacted with the device's touchscreen (during certain dual-task tests) .

- *Completion time* in Trail Making Test*:* the time from the beginning to the end of the exercise.
- *Max span* in the Digit test*:* the number of squares highlighted in the longest sequence recalled by the participant in the Spatial Span test, and the number of digits recalled in the longest sequence.

To gain deeper insights into participants' cognitive performance, we computed secondary outcomes designed to reveal task engagement, information processing efficiency, and strategy approaches. Specifically, we analyzed:

- *Mean reaction* time in the Stroop test: the average reaction time calculated for all correct responses given
- *Number of* pauses during the Trail Making Test: the number of instances where a participant kept their finger in the same spot on the screen for more than one second.
- *Thinking time* during the Trail Making Test: the total time that the participants spent inside the circles.
- *Rate for correct answers* in the Spatial Span Test*:* the number of squares pressed per second, computed by dividing the total number of squares by the total duration of the correct sequence and averaged across all the correct attempts.
- *Rate for incorrect answers* in the Spatial Span Test: As the previous outcome but computed for the incorrect attempts.

To address our first objective, we determined whether there was a correlation between the digital tests and their corresponding oral or paper-based formats. The Spearman correlation coefficients were used for outcome measures (*completion time* and *max span*) not normally distributed according to the Shapiro-Wilk test, while the Pearson correlation coefficients for normally distributed data (*number of correct answers*). Correlation coefficients were categorized as follows: values below 0.20 were considered weak, those between 0.20 and 0.39 as moderate, between 0.40 and 0.59 as relatively strong, between 0.60 and 0.79 as strong, and 0.80 or higher as very strong correlations [16].
For our second objective, to analyze cognitive performance in the Stroop test, we performed a mixed-effects model with *the number of correct answers* and *reaction times* as dependent variables, balance condition, age group and cognitive task complexity factors as the independent

variables, and subject as the random factor. Meanwhile, general linear models were applied to the Trail Making Test, the Spatial and the Digit tests' data. The statistical analysis for these tests included an age factor, and for the Trail Making Test analysis we additionally included a task factor (part A and B).

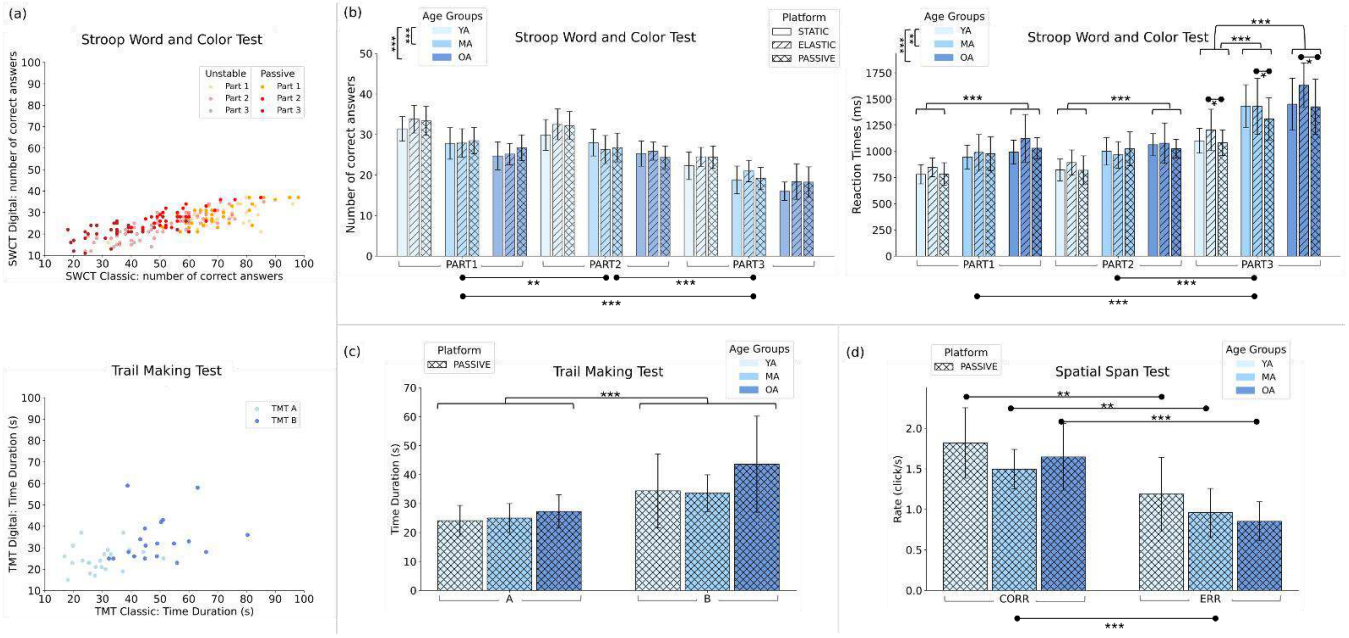

Figure 2: (a) Pearson's correlation between the number of correct answers for the classic and digital version of the Stroop test (top) and Spearman's correlation between the completion time of the classic and digital version of the Trail Making Test (bottom); (b): The number of correct answers (left) and reaction times (right) for each part of the Stroop test, across the three age groups and all three balance conditions; (c): Completion time for part A and B of the Trail Making Test; (d): Rates computed for both correct and incorrect answers for the Spatial Span Test. For all panels: * indicates a significant difference ($p<0.05$), ** indicates $p<0.01$, *** indicates $p<0.00$. Statistical significance for the main effects is indicated either below the bar plots, as in the case of the cognitive task complexity factor (done in (b)), or in the legend, as with the age factor (done in (b)). In contrast, the differences shown above the plots pertain to significant interactions (as for the right plot in (b), and the plots in (c) and (d)).

III. Results

A. Classic and digital tests correlations

Overall, the correlation between the digital versions of the MCDT tests and their traditional counterparts varied across tests. For the Stroop test, the *number of correct answers* revealed a positive strong correlation between the two versions ($r= 0.765$, $p < 0.001$, Fig. 2a - top). For the Trail Making Test, we calculated the correlation based on *completion time*, and results showed a relatively strong correlation ($\rho = 0.538$ and $p < 0.01$, Fig. 2b - bottom). Finally, for the Spatial test (and its classical format, the Digit test), the correlation based on the *max span* indicated a weak positive, not statistically significant ($\rho = 0.224$, $p = 0.24$) correlation between the two tests.

B. Cognitive performance

Stroop Color and Word Test

The Stroop test was administered across all three balance conditions, allowing us to assess the impact of age, cognitive task complexity and balance condition on cognitive performance. Both the *number of correct answers* (Fig. 1b – left) and *reaction times* (Fig. 1b - right) were influenced by age and cognitive task complexity. Specifically, age-related differences were relevant (both $p < 0.001$ for *reaction time* and *number of correct answers*), with post-hoc tests showing that YA consistently performed better, providing more and faster answers compared to both MA and OA (both $p < 0.001$). As expected, cognitive task complexity also impacted *reaction time* and *number of correct answers* (both $p < 0.001$) highlighting that when cognitive demands increased, subjects showed a longer response times with fewer correct responses. More specifically, the *number of correct answers* decreased between part 1 and 2 ($p = 0.009$) with no difference in *reaction times*. Differently, in part 1 to part 3 and part 2 to part 3 transitions, subjects showed both fewer correct answers and significantly longer *reaction times* (both transitions: *number of correct answers*, $p < 0.001$, *reaction time*, $p < 0.001$). In addition, the interaction between age and cognitive task complexity (age*cognitive task) significantly influenced *reaction times*. Post-hoc tests revealed that YA demonstrated consistently shorter *reaction times* compared to OA across all three Stroop test parts (part 1: $p < 0.001$, part 2: $p = 0.005$, part 3: $p < 0.001$). Moreover, in the most complex task condition (part 3), YA exhibited shorter reaction times than MA ($p < 0.001$).

Although both *reaction times* and *number of correct answers* were not directly affected by balance condition ($p > 0.050$), we found a significant interaction between cognitive task complexity and balance condition (*reaction times* $p = 0.005$, *number of correct answers*: $p = 0.045$). The post-hoc analysis

showed a main difference of balance condition in part 3: *reaction times* were longer for the unstable balance.

Trail Making Test

The Trail Making Test was performed only in the passive balance condition, therefore we assessed solely the impact of age and cognitive task complexity (part A and B) on cognitive performance. The *completion time* was only influenced by the task complexity ($p < 0.001$, Fig. 1c). As expected, *completion time* was significantly longer for part B compared to part A, and this difference was consistent across all three age groups (all $p < 0.001$). Similarly to the *completion time*, also the secondary outcomes (*number of pauses* (part A: YA: 1.1 ± 1.3, MA: 1.3 ± 1.8, OA: 2.4 ± 1.5, part B: YA: 5.8 ± 5.7, MA: 4.3 ± 3.2, OA: 7.2 ± 4.7) *and thinking time* (part A: YA: 9.25 ± 3.15 s, MA: 10.8 ± 3.22 s, OA: 12.95 ± 5.22 s, part B: YA: 19.5 ± 4.8 s, MA: 16.85 ± 4.45 s, OA: 25.5 ± 6.45 s), were both influenced only by the task factor (both $p < 0.001$). Consistent with the trend observed for *completion time*, these secondary outcomes were significantly higher in part B compared to part A.

Spatial Span Test

For the Spatial test we found that age significantly impacted the *max span* ($p = 0.006$). More specifically YA showed a larger span with respect to MA and OA (YA: 6.7 ± 0.94, MA: 5.4 ± 0.51, OA: 5.6 ± 1.07), with a significant decrease in *max span* between YA and MA ($p = 0.008$) and between YA and OA ($p = 0.028$). Differently, the secondary outcomes did not have an age effect neither for the *rate of correct answers* nor the *rate of incorrect answers*. However, for all subjects the *rate of incorrect answers* was significantly lower than the *rate of correct answers* ($p < 0.001$), meaning that subjects needed more time when they were unable to recall the sequence correctly.

IV. Discussion

In this study, we assessed cognitive performance using a robotic device that integrated cognitive tasks with both static and dynamic balance challenges. Within this study, we investigated how the cognitive performance is affected by age, cognitive task complexity and balance condition. This methodological approach can be also used to study the effect of cognitive tasks on motor performance. This innovative approach represents a significant advancement in rehabilitation research, as it allows for a comprehensive evaluation of the interplay between cognitive and motor functions. Integrating motor and cognitive evaluations provides deeper understanding of their interaction which is crucial for the definition of tailored rehabilitation strategies, that can focus on enhancing both cognitive and motor performance simultaneously.

A. Classic and digital tests correlations

The first objective of this study was to determine the validity and reliability of the digital MCDTs developed by comparing them to their oral/paper counterparts. Consistent with literature, the digital versions of the cognitive tests faithfully replicated the classic versions. Specifically, results showed a strong correlation for the Stroop test and a relatively strong correlation for the Trail Making Test, while weaker results were found for the Spatial Span test. For the Trail Making Test, the relatively strong correlation was expected, as it is in line with previous studies [15], [16], [17], [18]. In this case the digital version is an exact replica of the classic one, with the only difference that users need to use their finger instead of a pencil. Meanwhile, for both the Spatial Span test and the Stroop test the administration modality was different between the digital and classic versions. The Spatial test, which primarily assesses visual-spatial memory, was compared to the Digit test, which focuses on verbal working memory. Similarly, the digital Stroop test, which requires selecting answers from a screen, was compared to the classical Stroop test, which also involves verbal fluency. Although the administration methods differed in both cases, the Spatial Span test exhibited a weak correlation, whereas the Stroop test displayed a strong correlation, aligning with findings from previous studies [17], [18]. While participants achieved a higher number of correct answers in the original Stroop test format, the strong correlation suggests that the "Stroop effect" influenced participants consistently, regardless of whether they responded verbally or manually on the screen. In contrast, the memory tasks highlighted a key difference: humans tend to rely heavily on visual memory, which is generally considered easier to recall than abstract verbal information, such as numbers [15].

B. Cognitive performance

Overall, we found that age-related effects were evident across various MCDTs, reflecting their broad influence on cognitive performance. In the digital Stroop test, both age and task complexity significantly influenced performance. MA and OA showed a greater decline in *correct responses* and longer *reaction times* compared to YA, particularly in the most challenging task condition. These findings are consistent with previous literature [19], [20], [21]. Similarly, in the Spatial test, *max span* decreased significantly with age, highlighting age-related declines in working memory and processing speed, also in line with previous findings [22]. For the Trail Making Test, cognitive task complexity, rather than age, was the primary factor influencing performance. All groups took longer to complete the more challenging part B, which was also associated with more frequent pauses and extended thinking times. Balance conditions also influenced cognitive performance, particularly in the Stroop test, where unstable conditions resulted in slower *reaction times* but did not affect the *number of correct answers*, indicating that healthy subjects have robust cognitive function even under dynamic conditions.

Building on these findings, future research should further investigate the application of motor-cognitive dual-task (MCDT) exercises combined with the capabilities of robotic devices to potentially identify early cognitive decline in patient populations, including those with mild cognitive

impairment, Parkinson's disease, or dementia. Additionally, future studies should focus on examining the effects of MCDTs on balance performance, as this study primarily explored their impact on cognitive performance.

V. Conlusions

In this study we investigated the integration of digitalized cognitive assessments with dynamic balance tasks by exploiting a medical robotic device, *hunova*. The correlation between the digital and traditional tests confirmed the robustness of our methodology, showing very strong correlations for some tests and weaker ones for others. However, these findings align with the results reported in the literature. Also, by evaluating unimpaired participants across three age groups, we identified significant age-related differences in cognitive performance under various balance conditions. These findings suggest that dynamic balance tasks, combined with cognitive testing, may offer a valuable tool for detecting early cognitive changes. Future research should explore the impact of MCDTs on patient populations, where these assessment tests could be particularly effective in detecting subtle changes associated with cognitive decline.

Arm Activity Feedback for Stroke Survivors – a User Needs Analysis for the Design of a Mobile Application

Laura Mayrhuber [1,†], Lea Roffler [1,†], Chris Awai Easthope [2,3], Roger Gassert [1,4], Olivier Lambercy [1,4]

***Abstract*—Involving end-users early in developing rehabilitation technologies is crucial, especially when designing solutions that aim to provide understandable and instructive feedback on activity or performance. This study explores user needs and preferences for a smartwatch and -phone application (app) to monitor and promote arm activity in stroke survivors. Semi-structured interviews with three stroke survivors and five healthcare professionals (HCPs) identified three key themes using reflexive thematic analysis: feedback, user interface, and motivational strategies. Both groups highlighted the need for an arm movement tracker, as existing commercial options primarily focus on lower limb activity, such as step counting. Stroke survivors preferred simple data representation and real-time tracking with daily and weekly summaries. Feedback was deemed essential, with stroke survivors valuing positive and corrective feedback to increase engagement. Participants emphasized the importance of personalizing the app, advocating for customizable features like font sizes, contrast, and feedback modes to meet varying needs. Moreover, remote HCP supervision was highlighted as a key motivational factor to promote accountability and support therapy planning. Further, incremental goal setting emerged as a potential key motivator. Together, these elements provide a roadmap for implementing more intuitive mobile apps to support arm rehabilitation after stroke.**

I. Introduction

Stroke is a significant cause of upper limb (UL) motor impairments worldwide [1]. Active and repetitive use of the affected arm is a critical part of rehabilitation to regain function, even in the chronic stage [2]. However, a large number of stroke survivors experience learned disuse, where the use of the affected arm is avoided [3]. This pattern becomes more pronounced as stroke survivors transition from rehabilitation clinics to their home environments [3]. The absence of external support through therapists, coupled with the challenges of using the impaired arm during daily life, can consequently lead to a functional decline and reduced motivation, creating a vicious circle of inactivity and further functional deterioration [4]. Therefore, it is crucial to develop supportive strategies that encourage active arm use of the affected side in stroke survivors beyond the clinical setting.

Wearable sensors have shown promise in continuously monitoring arm movements and providing feedback, for example, related to the amount of arm use [5], [6], [7], [8]. Such technology can help improve motivation and increase affected arm use by delivering feedback via different sensory channels. Feedback modalities can include visual displays of the performed activity, vibratory cues as reminders to move, or auditory signals to indicate goal completion [5], [6], [7], [8], [9], [10]. Furthermore, feedback can be provided in "real-time" with information updated during the day or as a summary, where users receive a report at the end of the day. While previous research indicates that activity tracking and feedback devices can effectively promote increased arm use, clinical implementation and usability challenges remain. Most existing solutions rely on dedicated research devices, which are often bulky and overly complex to use, limiting long-term adherence and upscaling [5], [6], [7], [10], [11].

While some studies evaluated the usability of arm activity trackers [10], [12], feedback modalities [9], [13], and report preferences [8], only a few included stroke survivors as the end-users and healthcare professionals (HCPs) as experts in the field, whose experiences with stroke patients of varying impairment levels can provide complementary insights. Specifically, there is a strong need to understand the requirements of stroke survivors regarding how and when feedback on arm use should be given and how these requirements may be fulfilled using consumer-grade devices such as smartphones or smartwatches.

This study focuses on collecting user needs and preferences for a mobile application (app) that processes wearable sensor data to assess and provide feedback about affected UL use. The goal is to improve user acceptance of both the app and the tracking device, thereby promoting consistent adherence to UL therapy at home. Semi-structured interviews with stroke survivors and HCPs explore relevant activity metrics to report (e.g., duration of arm use, activity counts), effective presentation methods and the granularity of the presented information, preferred feedback modalities (e.g., visual, vibratory, auditory), as well as factors for maintaining motivation, such as arm movement goals. These findings can guide the content of future smartwatch- and phone apps. Moreover, insights from the interviews indicate which aspects and motivational strategies are relevant and appropriate for users when designing feedback implementations to promote increased arm use. By engaging end-users early enough in the design and development process, we aim to identify important considerations to create a functional tool that aligns more closely with their expectations for smartwatch and -phone apps designed to monitor and increase the activity of the affected arm.

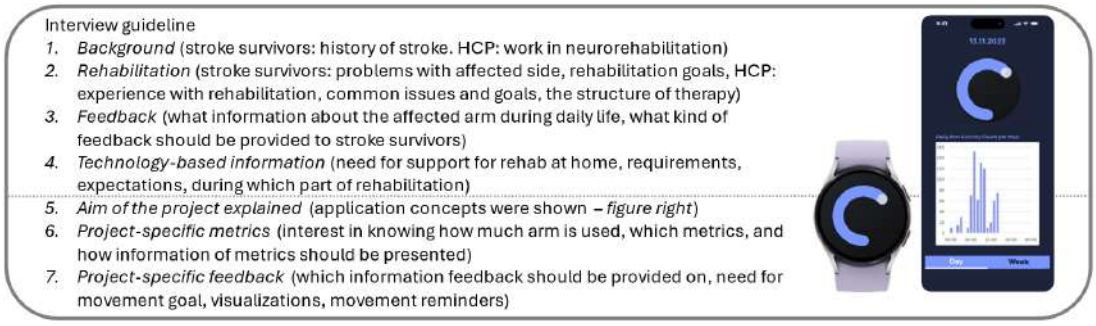

Figure 1. Guideline used during the semi-structured interviews (*left*) and visual representation examples of the application concepts, showing amount of arm activity on both a smartwatch and -phone application (*right*). To minimize bias during the initial part of the interviews, visual representation examples were only shown when the aim of the project was explained (point 5).

II. Methods

A. Study Design

Following a user-centered approach, semi-structured one-on-one interviews were conducted with stroke survivors and HCPs to identify and define user needs and app requirements. The interviews, lasting approximately 45 minutes, were conducted in person between October and November 2024 by LM and LR and were guided using a predefined interview guideline (Figure 1). Topics such as experience with rehabilitation, desired functionalities for a potential smartwatch and -phone app providing feedback on affected arm use, the challenges of smartphone interaction, the type of arm activity metrics to consider, and feedback preferences were addressed. After feedback preferences were identified, the project aim was explained, and the first concept of how the apps could look was presented (Figure 1). Each participant gave written consent for the study and audio recording before the interview started. This study was examined and approved by the Ethical Commission of the ETH Zurich (EK 2024-N-271).

B. Participants

The study population comprised stroke survivors and HCPs, including medical doctors, nurses, therapists, and caregivers. Participants were included if they were (1) above 18 years of age, (2) spoke German or English, and (3) able to provide written informed consent. Additionally, stroke survivors were included if they were in the (1) sub-acute or chronic stage and had a (2) residual unilateral hemiparesis. HCPs were included if they had regular professional contact with stroke survivors who have impairments of the UL following a stroke. Exclusion criteria were (1) major untreated depression, (2) severe cognitive impairment, (3) comprehensive aphasia, and (4) severe comprehension and/or memory deficits. Participants were recruited at the cereneo - Center for Neurology & Rehabilitation (Vitznau/ Hertenstein, Switzerland).

C. Data Analysis

The interview audio data was transcribed in German or English using MS Word Transcribe and checked by LM and LR. For the preparation of this manuscript, selected quotes were translated from German to English. Personal information was excluded from the transcripts to ensure anonymity. With a reflexive thematic analysis (RTA), the data was analyzed to fit the explorative nature of identifying user needs for a smartwatch and -phone app to track arm activity and feedback preferences [13]. RTA, based on Braun and Clarke, is a qualitative method that focuses on identifying, analyzing, and interpreting patterns (themes) within data [14]. A combined approach incorporating deductive and inductive methods was applied to identify themes [14]. Within a deductive approach, themes were established based on previous literature and interview topics. In contrast, an inductive approach involved examining the collected data for emerging patterns to extract themes. The analysis was conducted using the open-source software Taguette [15]. After re-reading the transcripts and familiarizing themselves with the data, LM and LR independently coded interview statements using RTA and subsequently grouped codes into sub-themes based on topic similarity through an iterative process. Corresponding sub-themes were further grouped into themes.

III. Results

In total, eight participants were included in the study (age: 41.5 (±14.7), gender: three females, five males). Three were stroke survivors, one of whom was supported by his son during the interview, and five HCPs. Table 1 provides further details on participants' demographics. The average interview time was 36 minutes (± 7). The RTA identified three themes and six subthemes (Figure 2). Statements from participants incorporated in this section are presented verbatim/direct.

TABLE I. PARTICIPANT CHARACTERISTICS

		Stroke survivors (n=3)	**Healthcare Professionals (n=5)**	
Sex (f/m)[a]	***Age (y)[b]***	***Stroke onset (m)[c]***	***Role***	***Experience (y)[b]***
m	57	8		
m	69	9		
f	36	25		
m	36		Assistant doctor in neurology/ Researcher	0.5/ 9
f	23		Nurse	2
m	43		Occupational therapist	17
m	33		Physiotherapist	4
f	35		Neurologist	6

[a]f = female, m= male, [b] y= years, [c] m= months at time of interview.

A. Theme 1 – Feedback Preferences

This theme provided an overview of what information participants would like stroke survivors to receive about their affected arm (e.g., movement metrics) and feedback preferences.

1) Parameters

Most participants expressed interest in stroke survivors receiving information about their affected arm during daily life. The underlying motivation for this, as reported by HCPs, included that it would give stroke survivors a better follow-up when leaving the rehabilitation clinic, as easy and objective monitoring of arm use is challenging at home, and there is a lack of guidance and feedback. Stroke survivors mentioned a lack of such devices and the importance of tracking progress over time. One stroke survivor mentioned: *"[I have] a manual activity tracker where [I] count [the] activity. [Information on arm use would be interesting] because [many] apps concentrate on the legs and feet but not on the arm or hand. […] I want to see how much I use my hand. Because in my life at home, I don't have the therapist, and I need to have the knowledge."*

The importance of notifying stroke survivors when they perform movements that could potentially cause harm was emphasized by HCPs and stroke survivors. Monitoring compensation movements was mentioned multiple times by HCPs as a critical aspect for stroke survivors to know and receive feedback on. Moreover, stroke survivors voiced that they would like a reminder to use their affected arm if they were inactive for an extended period, if they have not moved enough, and when they would rely too much on the less affected side. HCPs agreed and suggested that feedback should be provided to stroke survivors when the affected arm was not moving enough to meet daily targets or when it was time for a break. Additionally, most HCPs and stroke survivors mentioned that information transfer to stroke survivors on what type of movement was performed, such as grasping or reaching, would be appreciated. One stroke survivor who had almost no residual UL function, however, disagreed. He mentioned that he would not be interested in receiving information about arm use. One HCP supported this, noting that for stroke survivors who have practically no UL function, not much would be seen during the arm tracking.

HCPs suggested that not all detailed information on affected arm activity needs to be presented directly to stroke survivors. Instead, stroke survivors could be remotely monitored, and their data could be accessible to HCPs for clinical purposes. Considering the different use cases, most HCPs would then be interested in receiving detailed information on how stroke survivors performed their movements, whether it was voluntary, which part of the upper extremity was moving, and the variability and quality of the movement. One HCP reasoned: "*[I would like to know] which kind of movement [is performed]. Like if [they] pushed or moved up. Because then you [use] different muscles, and you can know which one has to work more. Because some patients do movements, but they do every time the same. Then you are using always the same muscle[s].*" Several HCPs highlighted their need to receive specific information on various activities of daily living (ADLs), such as the exact activities performed in a daily routine, the time spent on each ADL, the frequency of unilateral and bilateral movements, and whether stroke survivors performed the ADLs independently or required specific techniques or support. Additionally, HCPs addressed their need for information on the arm use ratio of the affected/ less affected side and the intensity of the movement. However, opinions varied on whether they would prefer the duration of arm movement or the number of movements.

2) Modalities

Participants described several possibilities for providing feedback on the affected arm use. Most HCPs agreed that a reminder to move in the form of an encouraging message or smiley emoji on the smartwatch or -phone would be beneficial. One HCP argued that a message on the phone may be more effective than the smartwatch as more people tend to look at their phones regularly. HCPs expected that stroke survivors would appreciate visual feedback to showcase their progress, though they noted that responses to feedback can vary. HCPs and stroke survivors expressed interest in receiving feedback through visual, vibration, and sound modalities.

Further, many stroke survivors elaborated on the benefits of receiving positive feedback when they did a correct movement, as well as negative when they needed to increase their arm activity. One HCP added that even negative feedback should be sent out in a positive format. Most HCPs agreed that positive feedback and an emphasis on reaching a portion of a daily arm movement goal would benefit most stroke survivors. However, it was mentioned multiple times that the feedback preferences are highly individual. One HCP emphasized: "*We generally know that positive feedback is more helpful. […] it's perhaps […] already very motivated by smaller successes, like saying you've only achieved 10% today.*"

Concerning the time and amount of feedback, participants shared a similar opinion. HCPs and stroke survivors both think it is essential that users receive feedback when the arm is not moved enough throughout the day. Participants preferred a gap (2-4 hours) between reminders. Regarding

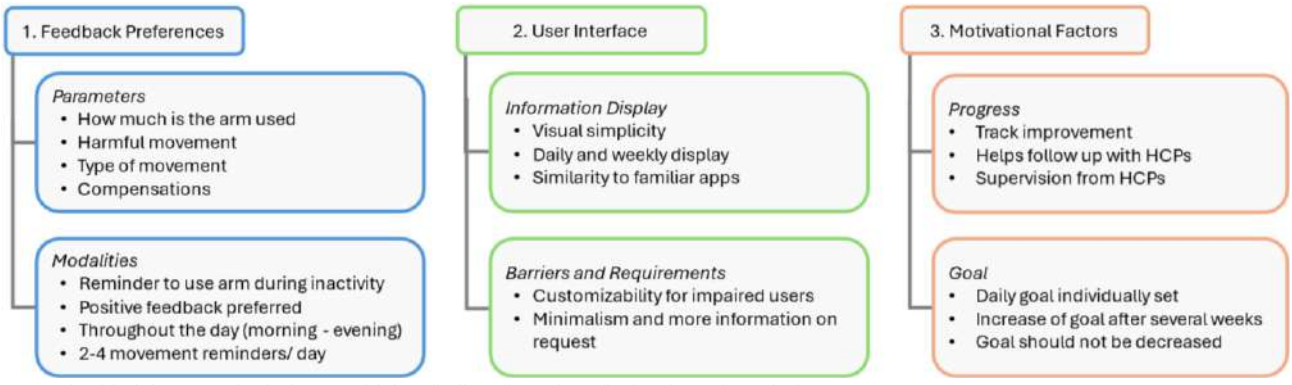

Figure 2. Identified themes and sub-themes with key findings from the reflexive thematic analysis.

when the reminder should be triggered, stroke survivors emphasized that they would like more activity throughout the day, so movement reminders in the morning, afternoon, and evening. Other participants mentioned that they would prefer reminders between 9 am and 5 pm and to have different settings for weekdays and weekends. Contrarily, HCPs suggested providing feedback during the whole wake time, but that stroke survivors should be able to set a time window when reminders are triggered. One stroke survivor remarked that a snooze function would be helpful, as sometimes the time when the reminder is triggered may not be convenient. One participant noted that movement reminders triggered too early in the day lose their effectiveness because they do not give patients sufficient time to move their arm before receiving the first reminder, suggesting that they be scheduled later in the afternoon or evening instead. HCPs indicated that a prolonged inactivity or deviation towards a specific daily arm movement goal should trigger a reminder. One HCP argued: "*If you see that you've maybe only done 200 by lunchtime, how are you going to manage the other 1800 […] by the evening? […] Now, you haven't done anything for half an hour or an hour, […] do your exercise program.*" Participants mentioned that a movement reminder should be triggered twice to four times daily. One HCP added that stroke survivors should be able to decide how many reminders they want to receive.

B. Theme 2 – User Interface

This theme explored what visualizations participants viewed as essential for effective feedback and design considerations critical to accessibility and ease of use.

1) Information Display

Almost all participants reported that they preferred graphical representations (e.g., bar charts and color-coded indicators) to text-heavy displays as they experienced these formats as being easier to understand. Visual simplicity was a key preference among HCPs and stroke survivors, with participants particularly favoring bar charts on an hourly timescale to view progress in real-time. This bar chart should also include the movement goal, as participants found it essential to track progress toward their targets throughout the day. One HCP stated the need for simplicity and visual representations as follows: "*[...]they [want], as I already said, as many graphics as possible [...] Basically very little text, titles maybe or not if they're not needed. And they want colors. They want big things to see and as little buttons as possible and as little windows as possible.*"

HCPs and stroke survivors favored simple metrics to support users' motivation and engagement, such as a daily overview of arm activity and a weekly summary showing which days the users achieved the activity goal. While some HCPs also expressed that stroke survivors may have an interest in monthly summaries for broader tracking, this interest was absent among stroke survivors. However, participants generally agreed that users should be able to interact with the app to get more detailed information if desired. Stroke survivors expressed that it should be similar to other health apps (e.g., Apple Health), as many were familiar with step-counters.

2) Barriers and Recommendations

Most HCPs agreed that too much information on the main display could be overwhelming, mainly since stroke survivors often contend with additional challenges beyond upper limb disability, such as neuropsychological disorders. Moreover, stroke survivors themselves mentioned the importance of customization in the interface, particularly for individuals with additional impairments. This adaptability should include options such as larger font size, adjustable contrast, or switching between visual and auditory feedback modes. One HCP mentioned: "*So it's important to understand for the type of patient […] the interface should be customized. For instance, if it's a patient with visual impairment, you should maybe zoom [in on] some aspects.*" Participants noted that older users could face difficulties with complex interfaces, mainly when the app contains too much information at once. One participant highlighted a common concern that overly complex technology might alienate some users, questioning whether elderly individuals would find smartwatches too challenging. Although some HCPs observed that older adults are becoming increasingly tech-savvy, many agreed that a simple, intuitive design is crucial to keep users from feeling overwhelmed or frustrated. HCPs emphasized simplicity in the design to reduce cognitive load and enhance usability. They advocated for a clear, consistent layout that employs color coding to differentiate essential information, making it easier for users to recognize their progress and goals.

C. Theme 3 – Motivational Factors

Various factors were captured in this theme that can influence the motivation and adherence to a technological rehabilitation intervention. The impact of monitoring the progress and setting a goal to increase motivation was discussed in detail.

1) Progress

Among the stroke survivors and HCPs, tracking the progress of arm use over multiple weeks and months was considered a strong motivational factor. Moreover, HCPs identified that monitoring the progress of arm use right after stroke may be advantageous for stroke survivors as the most significant progress usually occurs at the beginning of rehabilitation. One HCP argued that observing a positive change and seeing the improvement not only motivates but could also help the stroke survivor cope with the consequences of the stroke. The HCP stated: "*Progress is usually visible quite quickly at the beginning, and I think that patients probably get positive feedback from […]the first 3 to 6 months [which] are usually the most successful, and if you always have positive feedback the whole time, that you're always improving a little, I think that's much easier for the patients to deal with or cope with.*" Both stroke survivors and HCPs consider it essential that HCPs monitor the progress of arm use and support follow-ups, especially after discharge. Additionally, it provides information on whether the stroke survivor is improving the use of the affected arm or if it is deteriorating. Stroke survivors mentioned that the remote supervision of an HCP and knowing that someone is checking on their progress would be an additional motivational factor.

2) Goal

Overall, participants agreed that setting a goal value for using the affected arm would be motivating. Stroke survivors said they would like a daily goal to know the amount of arm activity expected and if they have done enough at the end of the day. Several participants further emphasized that the goal should be increased over time toward healthy values, with preferences ranging from expanding the goal every week after several weeks or months. HCPs stressed that the goal should be individually set, depending on patients' abilities, and that it should only be decreased for pathological reasons. One HCP explained: "*Maybe it's a good idea to have a first initial period like one week, two weeks in which you do monitoring and that's your assessment. Then you use that to define that your target is 20% more that over a certain amount of time, and then you see if you can increase [the target] over time.*" Contrarily, another HCP argued that the goal for stroke survivors should be to reach a balance of use between the affected and less affected side.

IV. Discussion and Conclusion

This study explored user needs and preferences to support the development of a mobile app that monitors and provides feedback on the activity of the affected arm in stroke survivors. Interview data from stroke survivors and HCPs offer considerations for the design and development of the apps.

Most participants expressed the need for an arm movement tracker, as few commercial options focus on arm use compared to step counting [15]. Stroke survivors and HCPs agreed on the importance of providing users with information on the types of arm movement performed. Both groups emphasized that stroke survivors should only receive the most relevant parameters on the apps, prioritizing the amount of arm activity. In parallel, HCPs should also be able to access more granular information remotely. Transferring information to HCPs would provide an opportunity for supervision post-discharge, therapy planning, early deterioration detection, and serve as a motivational factor. It has been shown that monitoring by HCPs is a crucial factor for long-term adherence to UL therapy at home, as stroke survivors feel accountable for doing their exercises and improving their progress [16].

Feedback was highly valued, with stroke survivors desiring positive reinforcement for achieving goals and corrective feedback for insufficient or harmful movements. Previous work used a smiley emoji's "happiness level" to indicate arm activity relative to the goal [7]. Positive or promotion-oriented feedback reinforces desirable behaviors, while negative or change-oriented feedback addresses areas that need improvement [17]. HCPs agreed but favored framing feedback positively, as evidence shows it is more effective than negative feedback in rehabilitation [18]. One participant, possibly due to his severe upper limb impairment, could not imagine using such a feedback tool. Literature indicates that stroke survivors with severe impairments often feel that their use of the affected arm is already at its maximum capacity, so additional feedback has a limited effect [8]. Feedback to avoid harmful movements is seen as beneficial, as pointed out by participants' preference for corrective feedback on potentially damaging actions. However, accurately detecting these movements with a single sensor setup can be challenging. Multi-sensor setups could improve harmful movement detection but may reduce practicality and long-term adherence [19].

The importance of visual feedback was emphasized throughout interviews, favoring simple visualizations like bar charts over text-heavy formats to reduce cognitive load [20]. It supports users in quickly identifying and understanding their performance without requiring extensive reading or interpretation [20]. Additionally, users are typically more comfortable using an app resembling familiar technologies, reducing learning barriers and making the app feel intuitive and accessible [21]. Overall, an interface communicating key information effectively using a consistent color scheme is preferred [20]. Simple metrics, like daily arm activity overviews and weekly summaries displaying goal achievement, were suggested to enhance user motivation and engagement. Observing real-time progress in the initial months following a stroke, when significant improvements in arm function often occur, enhances motivation through positive reinforcement [13], [22]. However, while tangible progress can be a strong motivator, a lack of visible improvement, common in the chronic stage, may lead to reduced motivation [16].

For situations requiring immediate feedback, such as inactivity, visual feedback on arm activity can be supported by vibratory or auditory cues [11]. Participants agreed that reminders should be triggered during inactivity or when goals are unmet, as seen in previous work [5], [6]. Different patterns of triggering movement reminders can be observed in the literature. The number of reminders per day ranged from 8 [5], [6] to 36 [13], with times between reminders including 10 minutes [13], 30 minutes [5], [6], or one to four hours [23]. Reminders were either triggered whenever inactivity was detected [5], [6], [23] or in a randomized manner [13]. Contrarily, participants in this study preferred a maximum of four reminders per day, distributed throughout the day, with fewer reminders in the morning and two to four hours between each. This aligns with existing literature showing that reminders in the afternoon tend to be more efficacious [13].

Goal setting emerged as a key motivator, emphasizing personalized movement goals and reminders to take breaks if the activity is excessive [11]. Personalized movement goals could support sustained engagement by fostering a sense of achievement and progress; however, they only seem effective if relevant to the stroke survivor [24]. Daily goals provide structure and reinforce a sense of accomplishment, especially if gradually adjusted based on individual progress [8]. Participants agreed on increasing the goal over time but differed on when it should increase, ranging from every week to several months. Previous literature suggested a daily increase of 3% of the past 30-day mean [5], [6]. Initial goals could be based on an assessment period of arm activity, with proposed increases of 20% over a selected timeframe or aiming for balance between the affected and less affected sides. Literature suggests setting the goal proportional to the impairment level assessed with clinical tests [7].

Developing an app to encourage arm use in stroke survivors must prioritize customization in design, feedback, and goal setting due to varying recovery needs and functional profiles [8]. The results of this study align with the literature,

highlighting that feedback must be tailored to individual recovery goals and daily routines [8]. A customizable approach to feedback, with flexibility in modality and frequency, may optimize user engagement and adherence.

Study limitations include a small sample size and an imbalance in stroke survivors and HCPs, relevant given the frequent differences in their perceptions. Moreover, while indications for developing a mobile app supporting arm use at home were identified, it is crucial to recognize that these generalizations may not reflect the opinions of every stroke survivor and HCP. Due to predefined interview guidelines and the presented app concepts, the interviews were focused on gathering specific insights and implications for an app currently under development, which may have biased some responses (Figure 1). The following steps of this research project involve developing and refining user interface prototypes based on interview insights and literature. Following a user-centered approach, these prototypes will undergo iterative design and usability testing with stroke survivors to optimize usability. Finally, interactive prototypes will be evaluated through task-based navigation assessments and standardized usability measures.

Overall, this study gathered valuable input based on user needs for developing a mobile app to monitor and increase the activity of the affected arm in stroke survivors. Key findings emphasize the need for real-time tracking, simple yet informative metrics, and detailed data for clinical use. Remote HCP supervision was highlighted as a key motivational factor in promoting accountability and supporting therapy planning. Personalization options, such as adjustable features and customizable feedback modes, are essential to accommodate varying impairments. Feedback strategies should balance positive reinforcement and corrective guidance, while incremental goal setting is crucial in maintaining motivation. These findings offer a foundation for developing intuitive and personalized apps to support arm rehabilitation after stroke.

ACKNOWLEDGMENT

The authors thank all study participants, Dr. Meret Branscheidt for assisting with patient recruitment, and Ioulia Barakou for supporting data analysis.

Effects of Exoskeletons on Error between Marker and Markerless Motion Capture in Children with Crouch Gait: A Pilot Study

Noah Rubin[1], Jordan Dembsky[1], Diane L. Damiano[1], and Thomas C. Bulea[1]

Abstract— **This study evaluated if a lower-extremity exoskeleton affects error between marker-based (M^+) and markerless (M^-) motion capture in children with crouch gait. Two participants (P1: female, P2: male, ages 6 and 11 years old, cerebral palsy and spina bifida, both with assistive devices) walked with (Exo) and without (NoExo) an exoskeleton spanning the knee and ankle. Mean absolute difference (MAD) between M^+ and M^- of gait cycle normalized hip, knee, and ankle angles were analyzed. Key outcomes of an ongoing clinical trial including measures of sagittal knee angle and gait speed were also compared. M^- correlated with M^+ kinematics, but MAD ranged 1.57-17.0 deg. Except for sagittal (of P1) and frontal (of P2) hip angles, the Exo increased MAD (range 0.74-8.7 deg). M^- underestimated knee flexion at initial ground contact, peak knee extension in stance, and peak knee extension in swing. No significant difference in MAD (Exo vs NoExo) was observed except for total joint excursion which had distinct trends for P1 and P2. For peak knee extension, a primary endpoint of crouch gait severity, the Exo increased MAD beyond minimum clinically meaningful differences (5 deg). Gait speed was consistent, with MAD <0.03 m/s for all observations (NoExo vs Exo p=0.22). While M^- has potential to ease gait assessment, early results warrant caution for use with wearable devices, highlighting the need for kinematic estimation algorithms to accommodate diverse end users in clinical and research settings.**

Keywords – **Motion capture, markerless, exoskeletons, gait assessment.**

I. INTRODUCTION

Many techniques exist in the rehabilitation field to study biomechanics of human movement, and among them, measuring kinematic and spatiotemporal behavior is a vital, commonly utilized method. By using 3D gait assessment, treatment decisions may improve in accuracy, and with this, targeted interventions may be better informed to further improve patient outcomes [1].

The gold standard method for assessing kinematics in research and clinical settings is marker-based motion capture (M^+), where reflective markers placed on joints and limb segments permit fitting of quantitative models of the body and computation of joint angles in anatomical coordinate frames. While M^+ provides many benefits, it also brings its own set of challenges. Significant time with participants during gait studies is dedicated to precisely and securely placing markers. This burden is particularly amplified when working with individuals who use assistive or wearable robotic devices, as each new physical condition studied (such as walking barefoot with different shoes or orthoses or robotic devices) requires reconfiguration and recalibration. On top of this, marker setups are often cumbersome for individuals to wear and traverse in, especially for young participants. Accuracy can also be affected by marker movement, bumping into objects or other body parts, falling off the body, or being blocked from view, especially in children and those with pathology or devices, rendering some trials unusable. For infants and toddlers, markers may also pose a choking hazard.

To address these issues, many different markerless motion capture (M^∞) systems have been developed over the past several decades as a potential alternative. While open-source models that estimate pose based on video data have gained significant research popularity [2], [3], commercial development of proprietary datasets and algorithms using expert biomechanists for labeling based on multi-camera video data has occurred to streamline clinical gait analysis. These algorithms have shown promise in individuals without neurological or biomechanical impairments [4], [5]. As noted in a recent scoping review, though, few comparisons between M^+ and M^∞ in patient populations exist [6]. Indeed, a recent study showed mixed tracking results depending on which joint angles were observed for children with cerebral palsy [7]. As development of M^∞ for clinical gait assessment progresses, it is crucial to not only account for the impact of patient populations on M^∞ but also to evaluate how wearable devices may further influence these measures. One study examined pose tracking accuracy of M^∞ with a robotic gait trainer in typically developing children on a treadmill [8]. However, to our knowledge, no study has determined how exoskeletons affect M^∞ data during overground walking. Hence, this pilot study sought to determine if walking with a lower-extremity exoskeleton affects the ability of M^∞ to quantify gait biomechanics in children with crouch gait compared to M^+ as the gold standard.

II. METHODS

A. Participant Recruitment

Two participants (P1 female, P2 male, age 6 and 11 years, height 110 and 146 cm, mass 17.9 and 38.9 kg, using a walker and crutches, respectively) diagnosed with crouch gait from cerebral palsy and spina bifida (mid lumbar myelomeningocele and shunt) were recruited for this study. Both participants and their respective parents provided written informed consent prior to conducting study procedures. Data were collected within a larger ongoing clinical trial evaluating effects of training with an exoskeleton outside

This work was supported the by Intramural Research Program at the National Institutes of Health Clinical Center (NIH CC, protocol #001180).

[1]Rehabilitation Medicine Department, NIH CC, Bethesda, Maryland.

the clinic [9]. Data from P1 was included from two different visits three months apart. Data from P2 was from a single visit. Both participants were novice exoskeleton users before the study who acclimated to this device for three days prior to the first assessment. P1 then underwent 12-weeks of training with the device at home prior to the second assessment. Because all data analyzed involved error in kinematics within each trial, data from all visits were combined for later analysis.

B. Data Collection

The marker-based system used 12 infrared cameras (Vicon Vantage, Vicon Motion Systems, United Kingdom), and the markerless system (Theia3D, Theia Markerless, ON, Canada) used eight digital cameras (Sony RX 0II), all placed within approximately three meters of the workspace. Prior to data recording, M^{∞} and M^{+} were calibrated with an extrinsic chessboard and wand, respectively. For M^{+}, a custom 36 reflective marker set was used on the lower-extremities [10]. For the visit with P2, M^{∞} recorded at 60 Hz and M^{+} recorded at 100 Hz. For the two visits with P1, both systems recorded at 120 Hz.

C. Study Procedures

Steady-state walking without (NoExo) and with (Exo) an exoskeleton was recorded for each participant (Fig. 1A-B). In each walking trial, participants traversed an approximately 5-meter path multiple times until they completed at least ten strides for each condition. For the sake of time in setup and ordering of other assessments in the visit, participants always conducted the NoExo conditions first and the Exo conditions thereafter. NoExo conditions included walking barefoot (BF) or with a custom ankle-foot-orthosis (AFO) and shoes used in their daily life. Thereafter, the Exo conditions (always with shoes) were collected. For all conditions, P1 used a walker and P2 used crutches.

The exoskeleton (Fig. 1C-D) is based on a knee-ankle-foot orthosis (KAFO) architecture and therefore attaches to

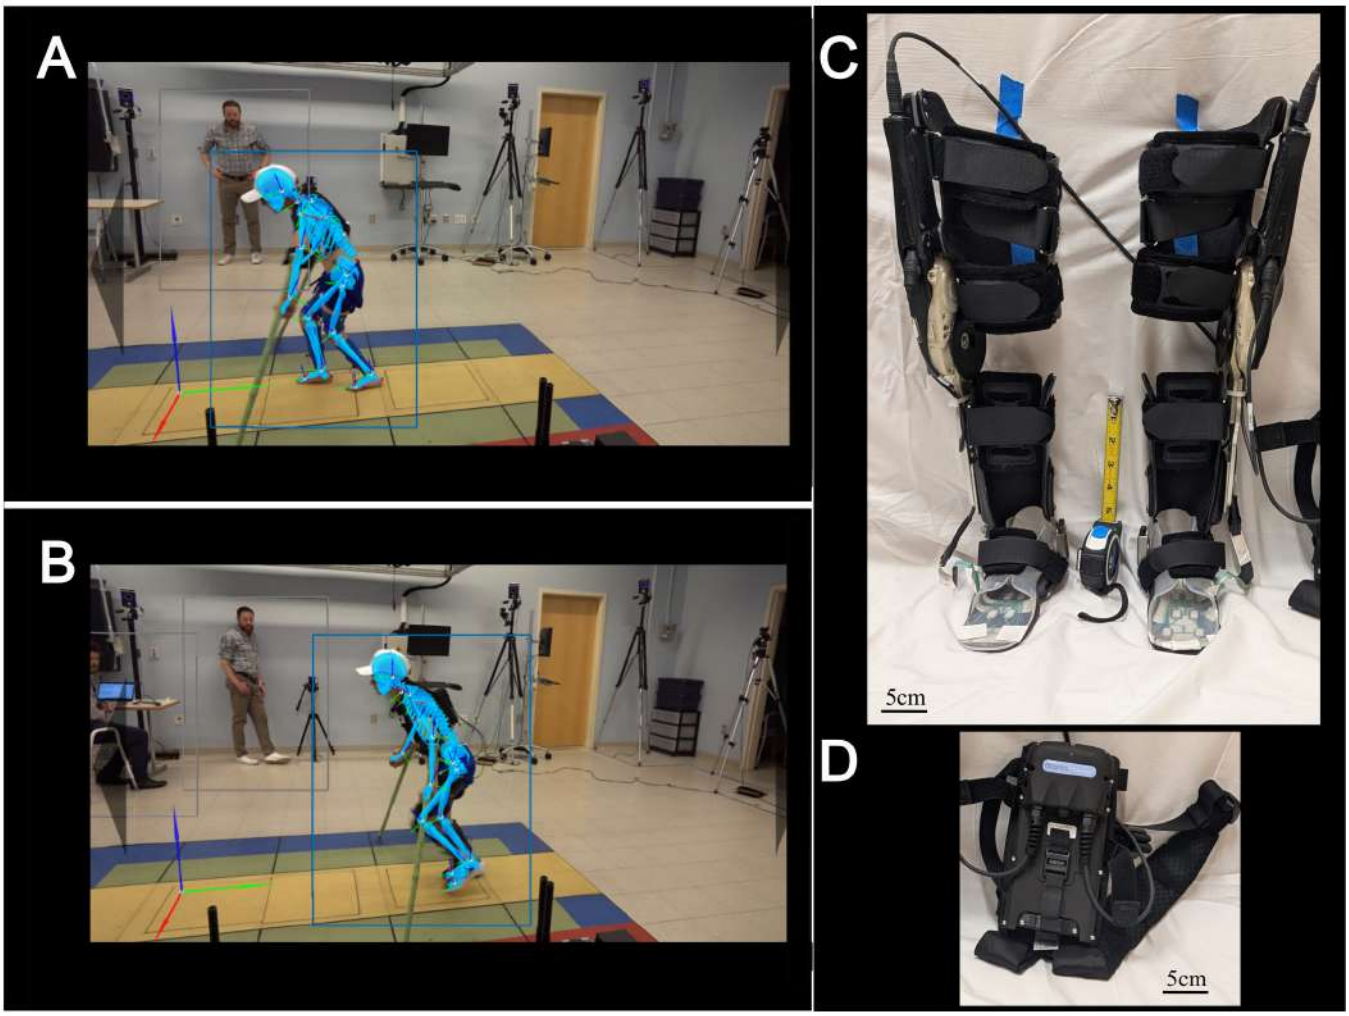

Fig. 1. Experimental setup. Images from one of eight cameras used for the markerless system (Theia3D) with the markerless model overlay are shown for the A) NoExo and B) Exo conditions. The C) bilateral exoskeleton consists of a single actuated degree of freedom at the knee joint in the sagittal plane that applies either flexion or extension torque (Agilik, Bionic Power Inc., Vancouver, Canada). The actuator is connected to a custom-fabricated orthosis (Ultraflex Systems Inc., Pottstown, PA) which has a passive ankle joint with adjustable stiffness independently in the plantar- and dorsi-flexion directions. The system is powered by a D) portable battary in a holster worn as a small backpack. Further device design details can be found in [9].

the thigh, shank and foot segments. The device is worn bilaterally, with a single actuated degree of freedom at the knee joint in the sagittal plane that applies either flexion or extension torque (Agilik, Bionic Power Inc., Vancouver, Canada). The actuator is connected to a custom-fabricated orthosis (Ultraflex Systems Inc., Pottstown, PA) which has a passive ankle joint with adjustable stiffness independently in the plantar- and dorsi-flexion directions. The exoskeleton controller implements a finite-state machine (5 states for early, mid, and late stance and early and late swing) with constant torque applied during each state. State estimation is based on knee angular velocity of an embedded encoder and a force sensitive resistor in the footbed. At least one of three control modes were used in each visit: Zero, Assist, and Interleaved. Zero mode applies a small amount of torque to compensate for inertia such that the device is transparent to the user. Assist mode provides assistive extension torque in both stance and late swing. Interleaved mode applies assistive and resistive torque in stance and late swing, respectively. Because participants must overcome resistance to complete steps, it is employed as a potential gait training tool to strengthen knee extensors and thereby combat knee extension deficiency [11]. Further device design details can be found in [9].

Between conditions, no changes were required for implementing M^{∞}. For M^{+}, markers that would be affected by shoes, an AFO, or the exoskeleton were removed and replaced as needed. Additionally, a 5-sec quiet standing static trial was conducted for each condition to allow for model calibration in post-processing.

D. Data Processing

Raw markerless pose data were processed in Theia3D. Details of the software are proprietary, but the overall architecture consists of a deep convolutional neural network that tracks human movement in 2D video frames to reconstruct 3D motion. The model was trained with over 500,000 images of humans in everyday settings, with at least two experts who labeled each image. Users input synchronized video data, and the model detects 51 anatomical features that are then used to estimate full-body motion through inverse kinematics. The system models the lower body with six degrees of freedom at the pelvis and three at the hip, knee, and ankle [12]. The default filter on pose data of M^{∞} was used (Generalized cross-validation with splines [13], low pass, 20 Hz cutoff). For M^{+}, gap filling of marker trajectories was processed in Vicon Nexus. Exported pose and marker data from each system (.c3d files) were then processed in Visual3D (C-Motion, Kingston, ON, Canada). Raw marker trajectories (prior to angle calculation) were lowpass filtered (4^{th} order Butterworth, 6 Hz cutoff), and joint angles for both systems were exported for analysis in MATLAB.

For each trial, the average delay between three instances of a common visual cue (phone camera flash in the field of view) was used to align the time of recorded frames between systems. Frames of gait events (initial and terminal floor contact of each limb) manually labeled based on digital video review were used to normalize data to each gait cycle with cubic spline interpolation. Individual strides were manually inspected and removed from further analysis if deemed atypical for the given participant or not in steady state. While the exoskeleton actuator applies torque in the sagittal plane, the brace constrains frontal plane motion, and wearing the device inherently changes visual features captured by markerless motion capture used to estimate pose, and by extension kinematics. Hence, mean absolute difference (MAD) between average gait cycle normalized data for each system in all three axes of rotation (sagittal, frontal, and transverse) were computed to evaluate overall performance. Because our current interventional study is evaluating the effect of this exoskeleton on crouch gait [9], we also computed four clinical knee joint kinematic measures (computed at each stride): 1) knee angle at initial ground contact (θ_{init}), 2) peak knee extension during stance (θ_{PKE}), 3) peak knee flexion during swing (θ_{PKF}), and 4) the absolute difference between peak extension and flexion, or total joint excursion (θ_{TJE}). Additionally, gait speed was computed as the mean velocity for pelvis center of gravity in the global Y-direction (along the walkway). Two-sample t-tests (or Mann-Whitney U tests if data not normally distributed, Kolmogorov-Smirnov test) on the absolute difference between M^{+} and M^{∞} in the NoExo and Exo conditions were conducted to determine if wearing the exoskeleton affects accuracy of M^{∞} (α=0.05).

III. RESULTS

The number of strides retained for analysis in each condition can be found in Table I. Both participants walked barefoot and with an AFO. P1 used the Zero and Interleaved modes, while P2 used the Assist and Interleaved modes, with torque magnitudes (normalized by participant body mass) ranging from 0 to 0.085 Nm/kg. Collectively, 116 and 62 strides were retained across both participants for analysis between the NoExo and Exo conditions, respectively.

TABLE I
NUMBER OF STRIDES ANALYZED BY CONDITION

	NoExo		**Exo**		
	BF	**AFO**	**Zero**	**Assist**	**Interleaved**
P1	54	23	8	0	26
P2	16	23	0	14	14

Figure 2 displays gait cycle normalized data from for the sagittal (X), frontal (Y), and transverse (Z) joint angles of the hip, knee, and ankle joints for P1 and P2 in the NoExo and Exo conditions. Across all conditions, kinematic profiles were reasonably correlated, but varied outcomes across the gait cycle were observed, with some angles exhibiting very close tracking while others exhibited large MAD. The sagittal hip angle MAD between M^{+} and M^{∞} for P1 (Fig. 2A) was higher in the NoExo (mean 10.7, range 6.9 to 14 deg) compared to Exo (mean 8.9, range 3.3-13 deg) condition. For P2, while M^{+} and M^{∞} performed similarly in the NoExo condition (mean 1.5, range 1.4-4.2 deg), the Exo amplified

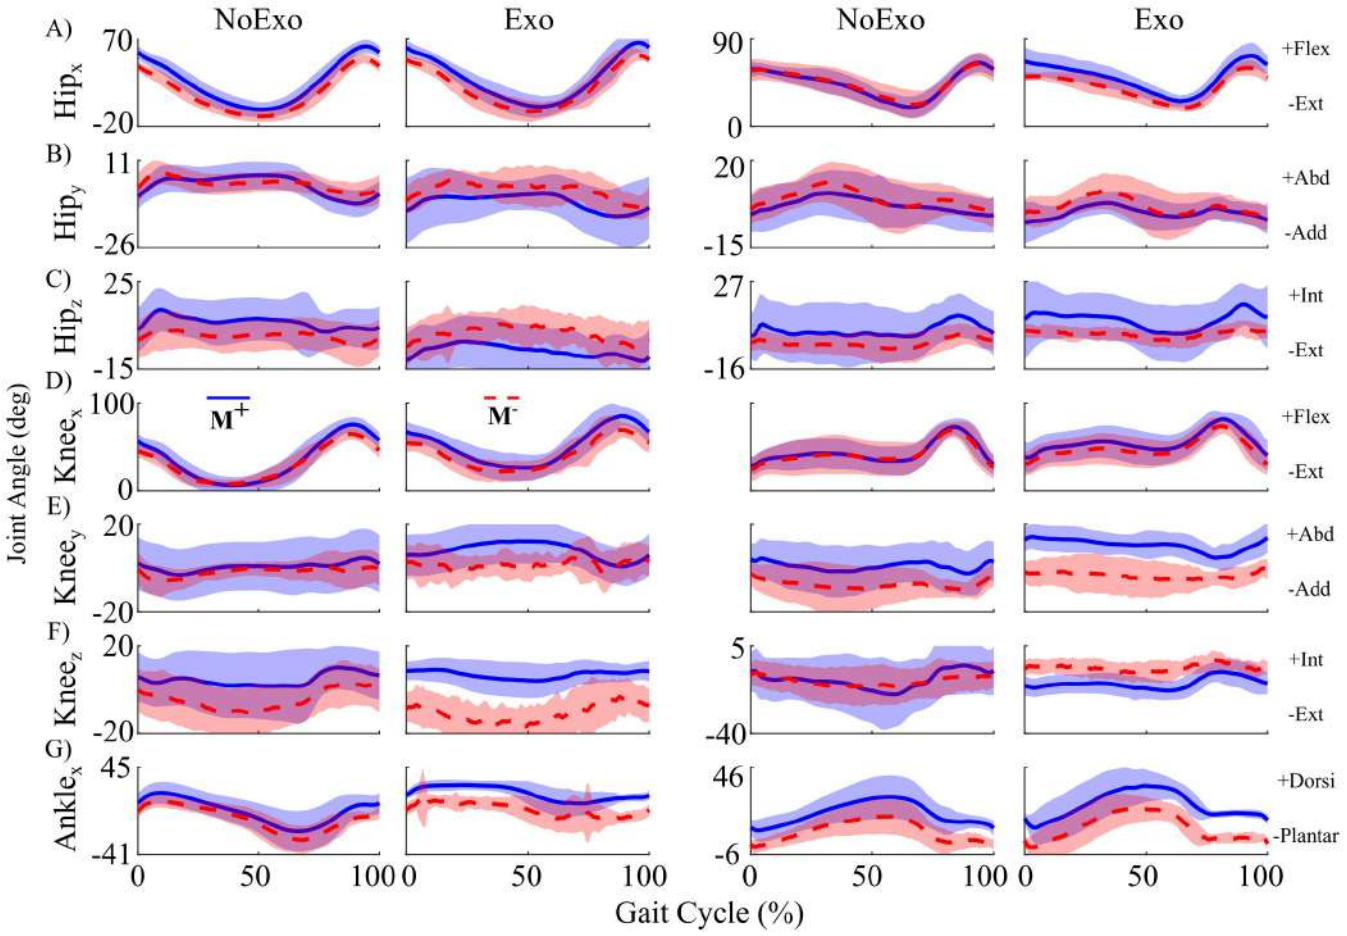

Fig. 2. Gait cycle normalized (0% and 100% initial contact) kinematic data for the sagittal (X), frontal (Y), and transverse (Z) joint angles of the hip, knee, and ankle joints are shown in each row. The first two and last two columns indicate data of the NoExo and Exo conditions from P1 and P2, respectively. Within each panel, the mean of the marker-based (M^+, blue) and markerless (M^-, dashed red) systems across all strides from both limbs are shown, with shades of ±1 standard deviation (SD). Sign conventions for each joint angle are indicated on the right of each row. Y-axis scales are maintained for each joint angle and subject to visualize within-subject differences between M^+ vs M^- and NoExo vs Exo.

MAD (mean 10.2, range 6.2-15 deg). For the sagittal ankle angle (Fig. 2G), M^∞ underestimated ankle dorsiflexion for both participants, where the Exo increased MAD for P1 substantially (NoExo 7.6 to Exo 16 deg) and to a smaller extent for P2 (10.6 to 13 deg). Whereas the Exo resulted in varied effects between participants at the hip and ankle, M^∞ estimated less knee flexion than M^+ with the Exo for both participants (Fig. 2D), and MAD across the gait cycle increased for both participants (P1: 4.3 to 9.5 deg, P2: 1.5 to 7 deg). This amplification was not limited to the sagittal plane of the knee joint. In the transverse plane (Fig. 2F), MAD across the gait cycle nearly doubled from NoExo to Exo for P1 (9.0 to 17.7 deg) and considerably increased for P2 (0.6 to 7.9 deg). Overall, except for the sagittal hip angle of P1 (1.7 deg decrease) and frontal hip angle of P2 (<0.1 deg increase), walking with the exoskeleton increased MAD between M^∞ and M^+ (range 0.74-8.7 deg).

A. Knee Kinematic Outcome Measures

After extracting normalized gait kinematics, clinical outcomes of our ongoing interventional study [9] from the sagittal knee and gait speed were derived for further analysis. For knee angle at initial contact (θ_{init}) in both participants and conditions, M^+ tended to estimate less extension than M^∞ (Fig. 3A). While no significant difference was observed in θ_{init} MAD (p=0.11, Fig. 3E) for both participants, MAD between M^+ and M^∞ slightly increased when wearing the Exo (11.1±4.9 deg) compared to NoExo (10.3±6.4 deg). A similar trend was observed for peak knee extension (θ_{PKE}) during stance phase (Fig. 3B). NoExo exhibited high variation centered near zero for P1 (0.99±7.7 deg) but walking with the Exo yielded overestimation of extension with M^∞ (-7.6±6.1 deg). For P2, a smaller shift in the same direction was seen from NoExo (-3.2±8.7 deg) to Exo (-7.3±5.7 deg). No significant difference was observed (p=0.07), but again θ_{PKE} MAD increased from NoExo (7.0±4.4 deg) to Exo (8.3±4.6 deg, Fig. 3F).

For peak knee flexion during swing (θ_{PKF}), in all cases, M^+ still tended to estimate greater flexion than M^∞. However, wearing the Exo (9.5±5.3 deg) slightly decreased MAD of θ_{PKF} compared to NoExo (10.4±6.0 deg), with no significant difference observed (p=0.29, Fig. 3G). For total

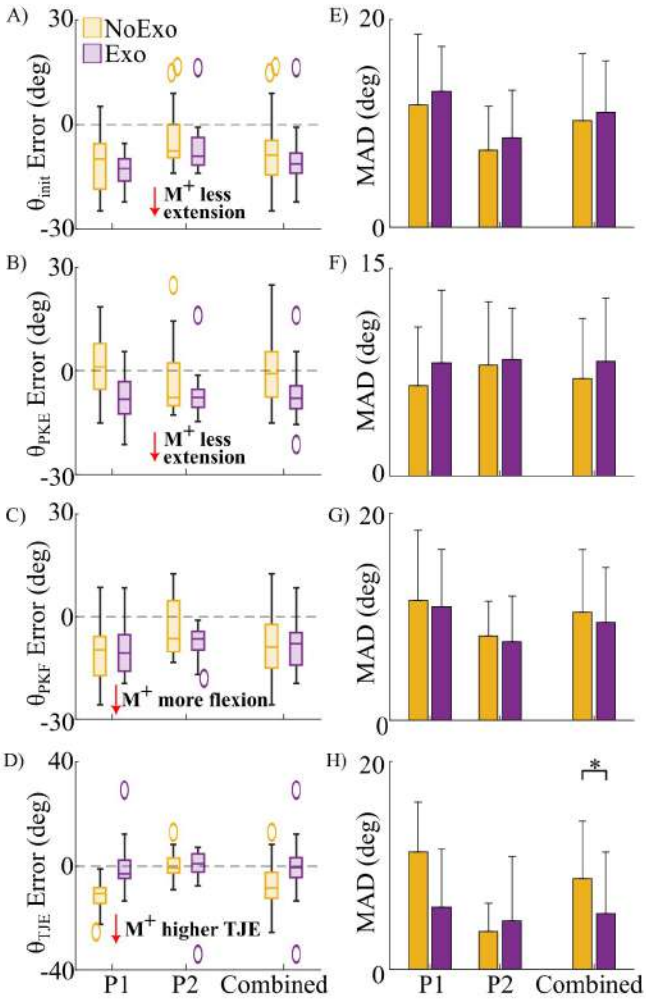

Fig. 3. Errors between motion capture systems for clinical kinematic outcome measures of the knee. Left and column right columns display raw error (M^- minus M^+) and mean absolute difference (MAD) ±1 SD, respectively. Each row corresponds to A) θ_{init}, angle at initial contact, B) θ_{PKE}, peak knee extension in stance, C) θ_{PKF}, peak knee flexion in swing, and D) θ_{TJE}, total joint excursion in the gait cycle. Data shown are from P1, P2, and combined in the NoExo (yellow) and Exo (purple) conditions. Significant differences between Exo and NoExo conditions are indicated with an asterisk ($p< 10^{-4}$).

joint excursion (θ_{TJE}), distinct trends were apparent within participants. M^+ estimated higher excursion in NoExo for P1 (Fig. 3D), but when wearing the Exo, a marked reduction in θ_{TJE} MAD occurred (Fig. 3H). P2, though, displayed similar distributions for both NoExo and Exo centered near zero. Combining participants, wearing the Exo significantly decreased θ_{TJE} MAD ($p < 10^{\infty 4}$).

B. Gait Speed

45 passes were analyzed to compute gait speed in each pass (26 NoExo, and 19 Exo). The MAD observed in gait speed between M^+ and M^∞ was remarkably low (Fig. 4), ranging less than 0.03 m/s across all passes. With this consistency, both systems yielded averages and standard deviations for each participant and condition with differences less than 0.01 m/s. P1 exhibited faster gait speed in the

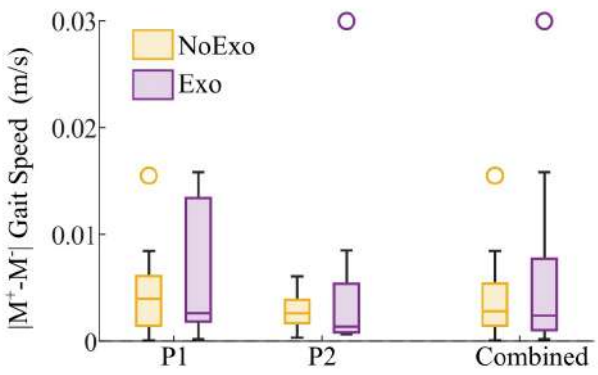

Fig. 4. Absolute difference between M^+ and M^- in gait speed for NoExo (yellow) and Exo (purple) conditions.

NoExo (0.77±0.29 m/s) than the Exo condition (0.57±0.29 m/s), while P2 maintained similar more consistent gait speed between conditions (0.58±0.12 and 0.57±0.07 m/s in NoExo and Exo, respectively). For both participants, no significant difference was observed in absolute difference of gait speed between NoExo and Exo conditions (p=0.74).

IV. DISCUSSION

To our knowledge, this pilot study is the first to evaluate outcomes between marker-based and markerless motion capture with an exoskeleton in overground walking. Given the clinical importance of accurate kinematic measures in gait assessment, we evaluated if wearing a lower-extremity exoskeleton spanning the ankle and knee joints (single knee actuator) affects error between markerless and marker-based motion capture in two children with crouch gait in normalized kinematic profiles, four sagittal knee kinematic outcomes measures, and gait speed.

Comparing normalized kinematic profiles (Fig. 2), M^∞ tended to follow M^+, but mean absolute difference across the gait cycle was highly variable between participants and all joint angles with and without the device (range 1.57-17 deg). In some cases, outcomes aligned with a prior study for children with cerebral palsy, such as consistent underestimation of ankle dorsiflexion with M^∞ [7]. In other cases, such as sagittal knee angle, we observed larger errors. That study recruited mostly individuals who did not require walking aids while both of our participants used an assistive aid (notably, these aids were the same across NoExo and Exo conditions), potentially contributing to this discrepancy. Across joint angles and participants, in most cases, MAD across the gait cycle increased when wearing an exoskeleton. The pose estimation model is a black box proprietary algorithm that to our knowledge has not been trained on data of the target population and has most likely not incorporated wearable devices, leading to possible model underfitting for our application. Incorporating a more diverse training set or implementing adjustable parameters to accommodate wearable device use may reduce potential model bias and improve results.

A primary purpose of quantitative gait analysis is to provide evidence for (or against) the effectiveness of emerging interventions. In this study, for both conditions and participants, M^{∞} consistently measured the knee at a more extended position than M^{+} for knee angle at initial contact, peak knee extension in stance, and peak knee flexion in swing, with MAD increasing when wearing the exoskeleton for outcomes in stance but decreasing for peak flexion in swing. The increased MAD in peak knee extension during stance (averaging 8.3 deg with the Exo) brings critical clinical implications, as this endpoint is frequently used as the primary measure for severity of crouch gait [9], with changes of 5 deg from an intervention often considered clinically meaningful. Thus, our results suggest markerless motion capture does not yet have sufficient accuracy to assess the effect of exoskeletons on crouch gait.

Considering other clinical measures in this study, while total joint excursion significantly reduced MAD with the Exo, distinct trends were observed between participants and differential effects were observed at peak flexion and extension in P1, requiring further investigation to shed light on this outcome. Importantly, the exoskeleton had minimal effect on gait speed, a secondary endpoint in our clinical trial [9]. This is likely due to a larger sampling (data from an entire pass instead of within single strides) which likely reduced variation. Additionally, the exoskeleton in this study does not span the pelvis, giving promise to high reliability in this outcome as reported in prior work [12].

There are several limitations to this study. Different sample rates for M^{+} and M^{∞} were used with P2. It is possible the lower frame rate of M^{∞} contributed to error observed, but given error also consistently increased from NoExo to Exo in P1, this is not likely to be driving observed effects. Movement of markers between conditions may have amplified error. Only two participants with variable physical configurations and device controllers were used. An imbalance in number of strides analyzed was present between NoExo and Exo because data were collected within a larger clinical trial [9]. Future studies with more participants, exoskeleton conditions, and balanced datasets are warranted.

In the long term, the prospect of markerless motion capture offers immense opportunity to ease the burden of clinical gait assessment, especially in children. Our preliminary results suggest strong caution for kinematic analysis with M^{∞} when wearing wearable robotic devices during overground walking. However, spatiotemporal parameters like gait speed may be highly reliable. The markerless system used here (Theia) utilizes supervised machine learning for pose estimation [4]; our results indicate the model's vital need to incorporate labeled gait data from clinical populations and walking with exoskeleton devices directly into the training datasets in order for the full capability of these markerless systems to be realized.

***Abstract*—The recent growth of rehabilitation robots offers new opportunities to improve care for patients with low head control. Traditional cervical spine therapy equipment often restricts neck mobility, inadvertently leading to muscle weakness due to inactivity. This study introduces a novel 1-degree-of-freedom (DoF) Adaptive Robotic Head Support designed to aid recovery during light activity and strength training in head-neck therapy. This study measured the axial forces that simulate the physical human-robot interaction (66.1 ±3.91 N) exerted by the head support in 20 tests as the robot lifts a 2 kg medicine ball until the motor stalls (4.06 ±0.98 s). The Head Support allows full cervical rotation in the transverse plane while providing adjustable support for flexion and extension movements. This study presents a novel head-neck rehabilitation system and tests its ability to support the weight of a six-year-old's head and measure human-robot interaction forces during simulated head-lifting tasks. Our approach aims to address critical gaps in pediatric head neck rehabilitation robotics by reducing the physical burden on clinicians and enhancing rehabilitation capabilities.**

I. Introduction

People with low head control, such as those with Cerebral Palsy (CP) at GMFCS Level V (Gross Motor Function Classification System), struggle to support the weight of their head for extended periods. This limits their opportunities to engage socially and perform activities of daily living (ADLs) [1]–[3]. Conditions such as low head control, dropped head syndrome (DHS), or forward head posture can be caused by weak neck extensor muscles or hypotonia due to neuromuscular disorders, spinal cord injuries, or other neurological and muscular causes [4], [5]. People who experience low head control spend most of their day in a reclined position, with limited rehabilitation options beyond surgery [6], [7].

Children with developmental delays who experience low head control have been a significant focus in head-neck rehabilitation [2]. Studies on pediatric head-neck assistive technology demonstrate improvements in quality of care during ADLs, including reduced head drops, increased active time, and changes in force measurements using a passive HeadPod head support [8], [9]. New physical therapy approaches were studied in games, trunk control, and individual muscle training that noted improvements in posture, ROM, and gaze [6], [10]. Patient outcome measurements have since become the focus of studies on new head-neck therapy tools, although there is no standard for evaluating head-neck rehabilitation technology. Although these studies are of vital importance to understand the benefits of new technology, there is a gap in research studying the physical interactions between the head and neck and the robotics used in therapy.

Preliminary interviews with pediatric physical and occupational therapists revealed that they use foam blocks or their own bodies to hold patients with low head control upright. Therapists are limited by the number of repetitions and intensity of exercises they can assist patients with before becoming fatigued [11]. Assistive technology plays an important role in reducing the physical demand placed on clinicians, allowing them to increase the intensity and number of repetitions necessary for effective therapy sessions [11], [12].

Cervical collars or similar braces designed to restrict cervical range of motion (CROM) are still used to treat patients with low head control [13]. Recent research has developed new robotic head supports for adults with DHS that uses rigid linkages [14]–[16]. However, these robotic solutions are designed for adults and are unsuitable for children because of differences in size and the force applied to the user's head. Exoskeleton head supports thus far are kinematically constrained; the only exception is the cable-driven platform of Bales and Zhang [17]. Bales and Zhang currently set the desired orientation for both torque control and orientation control using a manual joystick controller. Many users would be unable to use the joystick input without a caregiver due to spastic motion or upper extremity limitations.

This research constructs and programs a 1-DoF Adaptive Robotic Head Support system (Head Support) with assist-as-needed capabilities to augment treatment for children (up to age 6) with low head control. The Head Support is designed with parameters similarly outlined in Huang et al to (a) partially support the weight of a child's head, (b) fully support the weight of a child's head, (c) resist volitional motion away from an upright position, and (d) return the child's head to an upright position if the patient loses control [11]. To achieve (a) and (b), the head support simply needs to be able to sustain 20 N of distraction force at a constant strap length, which would act like the passive HeadPod head support [18]. To resist volitional motion (c), the Head

This research was funded by NSF DARE 1706428, Active Head Support for Children with Hypotonia

Support should be able to actuate with force greater than typical head motions (10-40 N) [9]. Returning the head to an upright position (d) can be demonstrated by raising the full weight of the head from an inferior position to a posterior position. Section II discusses other active head supports and some of the scenarios in which they are used. Section III details the novel mechanical design of the Head Support, including hardware components and sensing used to measure user interactions. Section IV outlines methods for prototype validation experiments to test mechanical functionality and usability prior to human-subject testing. Section V presents key results from lab experiments, while Section VI discusses the key findings, advantages, limitations, and clinical implications of the Head Support compared to other head supports. We present a new device with an operating principle not previously reported in the literature in (1) novel head-neck rehabilitation robot design and (2) physical interactions between rehabilitation robots and the human head-neck.

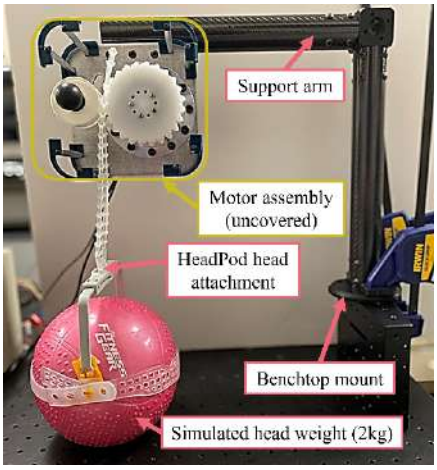
II. Existing Active Head Support Devices

A review of wearable assistive neck devices outlined the control mechanisms and active ranges of motion (AROM) in flexion, extension, and lateral bending for technology used in head and neck rehabilitation up to July 2023 [19]. Zhang et al. created a powered Robotic Neck Brace for adults with amyotrophic lateral sclerosis assists head motions in in-plane and off-plane angles, showing decreased error during prescribed motions with powered assistance compared to baseline support [16]. The position error measurement is used to guide patients through more ideal movement trajectories, which can help if the user controls motion better with some assistance. An active neck orthosis by Lozano et al examines trajectory tracking and the CROM restriction for a parallel robotic device [20]. The percentage of CROM restriction in this study is a common practice which measures the amount of immobilization from head-neck orthoses due to the constraints that rigid linkages have in cervical braces. A flex sensor measures the craniovertebral angle (CVA) for pneumatic artificial muscles with an augmenting force applied to the occiput and cervical vertebrae [21]. CVA measurements could be used to monitor variation from an upright pose while using varying types of head supports. Among the first cable-driven head supports is the CarNeck, which proposes a 3-DoF kinematic model and tension analysis to support head motions within the typical CROM [22]. Many of these studies have shown kinematic feasibility, patient outcome improvements, or a decrease in muscle activity required to move while using their head supports.

III. Construction of the Head Support

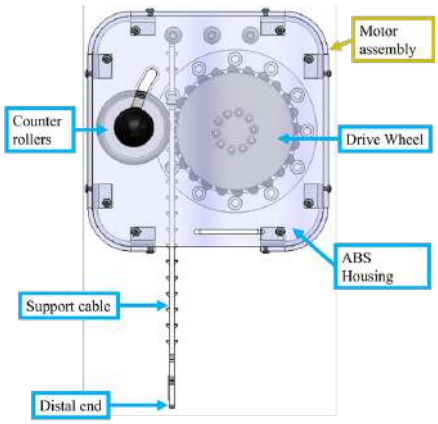
A cable-driven, Adaptive Robotic Head Support (Figure 1) has been designed and constructed to provide variable, programmable support of a 6-year-old child's full head mass (approximately 2 kg) while in a supported sitting position. Additional physical limitations were suggested by some suppliers which were implemented in the prototype design.

A. Design



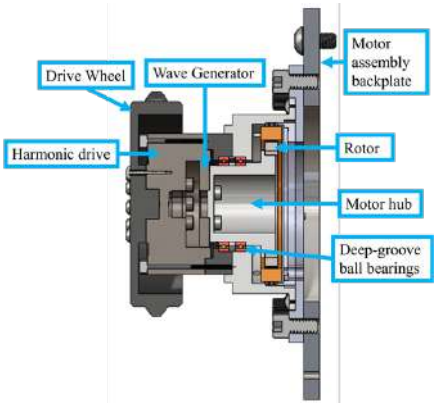
The Head Support utilizes a motor-driven wheel acting through a gear ratio of 100:1 to adjust the amount of tension applied to the user's head. A BLDC motor (Celera ULT-63-A-8-A-H-000) drives the support strap in either direction, with continuous torques (0.082 N-m) and maximum torque (0.245 N-m) that can lift the entire head weight without continuous resistance or overcome momentary resistance at its peak torque. Neck Injury Criteria (N_{ij}), the sum of normalized flexion and extension moment and axial load, is used as a safety measure in vehicle collision testing. The rotor inertia (7.9E-06 kg-m^2) was of particular concern, since an inertia that is too large could cause N_{ij} to exceed a safe value according to NHTSA Standards for vehicle collision safety [23]. Critical intercept tensions (2120 N) and extension moment (27 N-m) were selected from the scaled values to prevent injury in a 3-year-old Hybrid III crash test dummy [23]. Selected critical values are conservative estimates of what would cause injuries in tension, extension moment, or a combination of both.

To ensure that the Head Support moves the drive wheel at a safe speed, a reduction is needed between the motor and drive wheel. The Harmonic Drive (Beverly, MA CSD-14-100-2UH) in the Head Support acts as a compact, back-drivable, 100:1 gearbox with zero backlash. The gear ratio allows the BLDC motor to operate closer to the speed for which it is designed while maintaining continuous support forces up to 205 N with an expected max rpm of 7.5 rpm (3 drive wheel teeth per second). The Harmonic Drive manufacturer describes it as back-drivable, which is a useful feature as the user can temporarily overcome the resistance from the device. The maximum torque of the motor was set accordingly so that the motor torque would not damage the flex spline should the motor malfunction and run at full force. Similarly, the harmonic drive was chosen to minimize size and still output safe speed and sufficient torque to hold the head. A cross-sectional view of the motor assembly is shown in Figure 1c.



Two deep groove ball bearings resist the radial forces of the motor rotor, supporting the rotation of the motor hub, which connects the rotor to the harmonic drive wave generator. Although the rotor should impose only minimal axial forces, the wave generator does apply axial forces along the motor when accelerating, and the use of deep groove bearings is designed to resist these. The axial force (F_{axial}) applied by the wave generator is defined by Equation 1 provided by Harmonic Drive and can be calculated with the output torque of the harmonic drive (τ_{out}) and the size designation provided by Harmonic Drive ($size$).

$$F_{axial} = 2 * \frac{\tau_{out}}{size * 0.00254} * 0.07 * \tan(20^\circ) + 2.1 \quad (1)$$



Using the peak motor torque with the 100:1 gear ratio to calculate the max output torque and the size 14 harmonic drive, a max axial force acting on the deep-groove ball bearings would be 37.2 N. Resisting axial and radial forces and moments are important for ensuring that the rotor does

not run into the stator and that the wave generator of the Harmonic Drive does not leave the flex spline during use.

The drive wheel tooth profile was empirically tuned to match the silicone cable used as the adjustable support strap from the HeadPod device (Siesta Systems, Navarra, Spain). The head attachment consisting of the adjustable arc, occipital mesh, and silicone forehead straps, was conserved from HeadPod because it is designed to be biocompatible and flexible to allow cervical rotation while being able to feed the strap. The drive wheel tooth profile was initially sized based on the D-shaped holes in the strap, and notches were created between the teeth to grip the raised areas of the strap. Various laser-cut prototypes were cut varying the tooth profile parameter among them and each was evaluated for smoothness of feeding and ease of tooth engagement between segments. After settling on the best-performing profile for the drive wheel, the drive wheel was milled from Delrin on a 3-axis HAAS Mini Mill using a 24-segment dividing head. Two rigid skate wheels (McMaster-Carr, Elmhurst, IL) press the strap into the drive wheel.

TABLE I: Design Specifications

Parameter	Requirements	Justification
Motor continuous torque	0.082 N-m	Supports up to 205 N at drive wheel.
Motor maximum torque	0.245 N-m	Overcome momentary resistance without the possibility of injury.
Motor inertia	7.9E-06 kg-m^2	Prevent overcoming N_{ij}.
Motor speeds	750 rpm	Have a max drive wheel speed of 3 teeth per minute.
Harmonic drive gear ratio	100:1	Output safe motor speeds and torque.
Harmonic drive axial forces	37.2 N	Restricts the rotor from crashing into the stator and the wave generator from leaving the flexspline.

B. Mechatronics

An MSP430FR5994 (Texas Instruments, Dallas, Texas, USA) microcontroller controls the Head Support using a TI DRV8317HEVM motor driver. Researchers programmed custom Embedded C code to control the PWM signals to drive the BLDC motor, commutating within the firmware based on Hall sensor states for position or speed control using guidelines provided by Texas Instruments. Commands were sent via serial port from the PC for the testing performed in this study. The motor has a continuous current of 5.6 A, and the DRV8317HEVM limits the current to only 5.0 A as a secondary torque regulator to protect the motor from overheating and additional overexertion prevention during bench-top testing. The position of the drive wheel was controlled by a PID controller, with the PWM duty cycle to the motor being the control input to the system.

IV. Methods

Two main tests were performed to evaluate the performance of the active support device and to verify that it would safely deliver the intended function.

A. Test 1: Axial Loading on the Head

A test was devised to measure the distraction force applied to the head when the Head Support motor is run to stall an initially slack support. The purpose was to verify that sudden loads applied to the head would have a low probability of injury while holding the head. Distraction forces applied to the user's head are especially important, as the Head Support is designed for children with low head control. We assume that for children, there is a smaller range of effective forces (enough to lift the head without applying too much to cause injury) than is typically seen in adults. To measure these distraction forces in axial loading, we modified an MTS tensile testing machine to hold the support strap of the motor assembly in line with the load cell (Figure 2). The Head

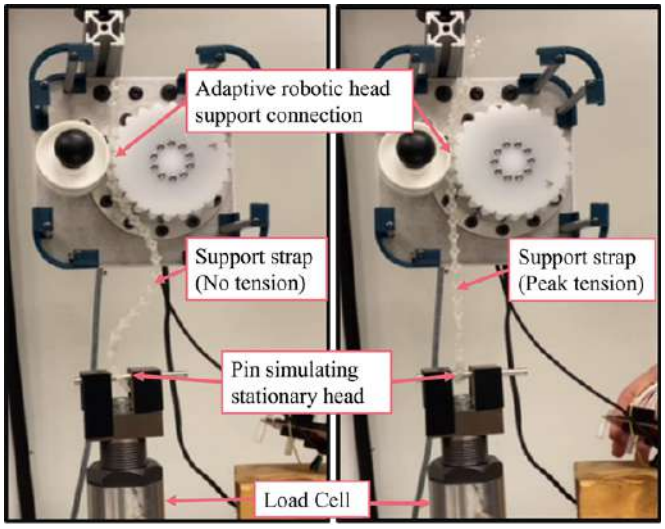

Fig. 2: Head Support mounted with the HeadPod support strap aligned above a load cell to measure axial loads that would be applied to the user's head. The test begins with no tension (left) in the support strap, and the maximum load is measured (right) when the motor stalls at its highest position.

Support positioned directly in line above the user's head to avoid additional moments applied while the patient is sitting upright. We mounted the Head Support to the top crossbeam and raised it 0.2 m above the load cell connection, the designed maximum height above the user's head. The distal end of the support strap is attached to a load cell (25 kN, 5 kHz) to measure the distractive forces that would be applied to the head in an upright position.

Twenty tests were performed from a starting point where the support strap was slack (0 N) and the strap was lifted by running the drive wheel with a simple position controller using the Hall sensor position until the motor stopped. The maximum position was held for approximately 5 seconds before a command returned the motor to its initial position.

B. Test 2: Position Tracking

Test 2 is designed to validate a position tracking method programmed to count Hall sensor events built into the Celera motor. A Polhemus Liberty magnetic motion tracking system (Colchester, VT, 240 Hz) tracked the position of the distal end of the support cable with one sensor in Figure 1b, and another sensor on the 2 kg ball where the user's forehead would be (Figure 3). Polhemus data are used to measure the actual Head Support strap length compared to the Hall sensor position tracking in the firmware. The strap length is calculated as the arc length with the drive wheel radius (44 mm). The difference between the number of Halls and initial position determines the central angle for this calculation.

Using the same Polhemus setup, a dataset for the approximate workspace of the robot was collected to measure the rotational CROM of the Head Support. The medicine ball was manually pushed until the support strap touched the anterior frame for the ABS housing. The medicine ball was then rotated clockwise along the transverse plane until it reached the proximal frame for the ABS housing, then continued the motion back to the anterior position. Workspace size during flexion, extension, and lateral bending will vary based on strap length. This workspace measurement is used to validate that our design can incorporate full cervical rotation within the transverse plane.

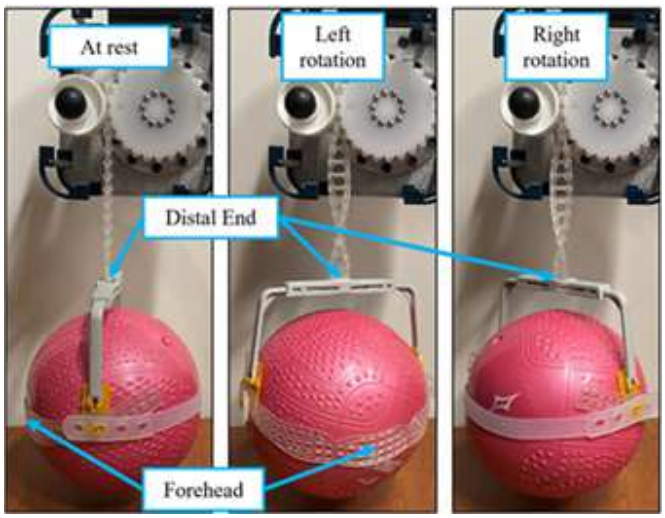

Fig. 3: Sensor probe positions for magnetic motion analysis at the start point of the test. Probes are placed on the forehead and the distal end of the support strap to estimate position.

V. Results

A. Test 1: Axial Loading Measurements

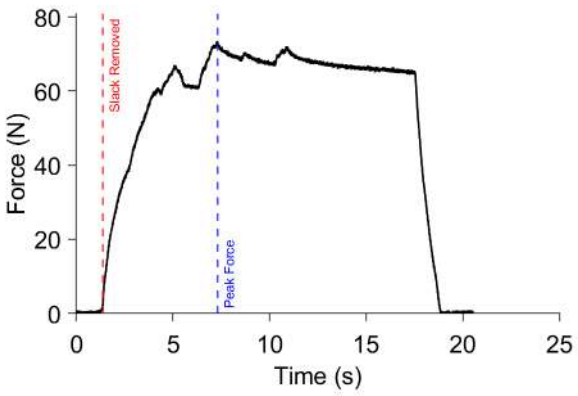

Fig. 4: Axial test 13, which reached the highest overall force magnitude (73.6 N). Constitutive curve of axial loading tests from the Head Support demonstrating the maximum force and time from cable slack to motor stall limit being reached.

TABLE II: Axial loading measurements (n=20) from lifting the Head Support with no tension until the motor stops.

Variable	Mean	Standard Deviation	Min.	Max.
Max Force (N)	66.1	3.91	60.3	73.6
Time to Stall (s)	4.06	0.98	3.31	6.65

The axial load that the device was able to provide was measured at a maximum value of 73.6 N in the 20 tests (Figure 4). The mean maximum force reached before the motor stalled was 66.1 ±3.91 N (Table II). The motor is rated for a continuous torque of 0.082 N-m, so the current limiter on the motor driver further limited the torque in this test. The rise time from when tension was applied to the motor stall was 4.06 ±0.98 s, with an overall maximum of 6.65 s.

B. Test 2: Position Measurements

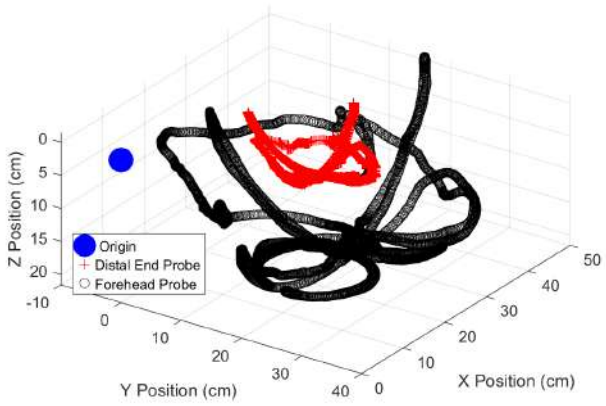

Fig. 5: Approximate workspace of the Head Support demonstrating unrestricted horizontal cervical range of motion due to the flexibility of the support strap.

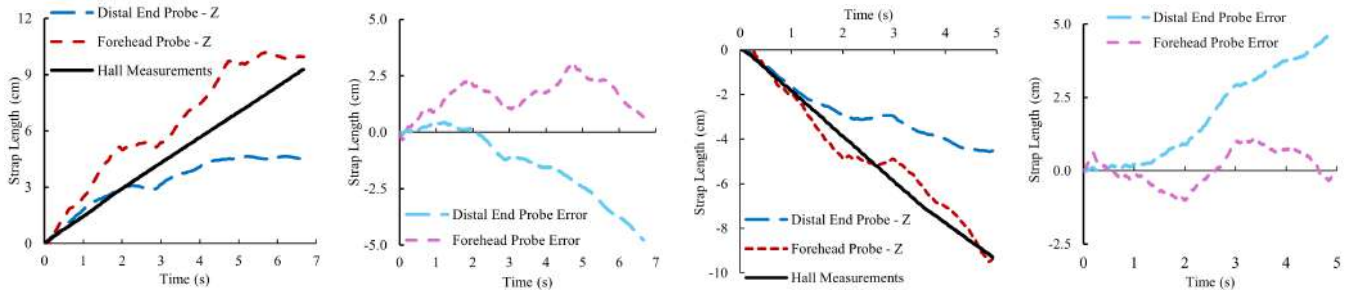
The Head Support lifted (Hall sensor: 9.17 cm, Polhemus: 9.94 cm, Fig. 6a) and lowered (Hall sensor: 9.22 cm, Polhemus: 9.36 cm, Fig. 6c) the 2 kg mass for a 120-degree rotation of the drive wheel (see Figure 3). The Hall sensor position measurements, compared to the external Polhemus position measurements, had errors during lifting from the Distal End probe (-2.34 to 0.44 cm) and Forehead probe (-0.33 to 3.07 cm) (Fig. 6b). While lowering the support strap, errors were present from the Distal End probe (-0.01 to 4.78 cm) and the Forehead probe (-1.01 to 1.08 cm) (Fig. 6d). The Distal End probe error magnitude increased as the Head Support lowered the ball, though the Forehead probe error decreased as the Head Support stopped in both cases.

Additional Polhemus measurements rotated the medicine ball about the vertical axis to estimate CROM. A complete rotation around the vertical axis was performed while the medicine ball was hanging freely (Figure 5).

VI. Discussion

The Head Support needs to independently lift the weight of the head (approx. 20 N). It can supply peak distraction forces ranging between 60.3 and 73.6 N (66.1 ±3.91 N), demonstrating the Head Support's ability to provide a reasonable amount of resistance or the necessary assistance to return the child's head to an upright position. Previous work measured the forces exerted by children on the HeadPod passive head support with peak dynamic loads near 150 N, with typical use ranging between 10-40 N [9]. This means that the Head Support introduced in this research is capable of resisting most expected activity, similar to what children would impart on the device. The motor stopped at least at 60.3 N during our tests in the current control system, which would overcome most expected motions if the ability to resist voluntary or spastic motions is desired in a rehabilitation algorithm. This demonstrates the ability to partially or fully support the sustained weight of a 6-year-old's head. While position control was useful for bench-top experiments, force or torque control would enable higher precision of stall torque, rather than limiting this with electronics. The peak axial loads would fit well within a safe tolerance for use (F_{int}, 2120 N). Polymer creep observed during Test 1 may be a minor source of error.



Preliminary usability testing revealed challenges with the toothed drive wheel when donning the head support. The drive wheel should interface with the HeadPod support strap's ridges and holes. The support strap often slipped when first loaded onto the drive wheel. Future iterations should affix the superior end of the strap to the drive wheel.

Test 2 demonstrates that Head Support Hall readings can approximate changes in height (Figure 6), though out-of-plane motion is not fully defined as in powered neck braces with rigid linkages. The curve deviates more when the medicine ball oscillated during both lifting and lowering. This caused additional out-of-plane movements in the motion capture data that were not captured in the Hall sensor data. The Forehead Probe error was lowest at the initial and final positions, which suggests that these oscillations caused most of the error. In human testing, users would be in a supported sitting position, so we would expect minimal error due to this oscillation. Rotating the medicine ball (Figure 3) with motion capture demonstrates a 180-degree horizontal rotation in both directions (Figure 5). Electric current, force, and torque sensing can be included to implement force and torque control as part of a rehabilitation algorithm.

VII. Conclusions

The Adaptive Robotic Head Support demonstrates mechanical capability to support the full or partial weight of the head, resist typical volitional movements, and assist in returning the user's head to an upright position. While current functionality relies on Hall sensor position tracking, future clinical applications may benefit from additional sensing functionality for better precision.

Future work should explore force and moment control to improve accuracy without relying on current limiting for torque management. Clinical evaluations involving therapists will provide feedback on usability and caretaker fatigue. Human-subject testing is essential to fully characterize the device's ROM in flexion, extension, rotation, and lateral bending. Incorporating activity monitoring, EMG data, intent detection, and patient outcome studies could further advance cervical spine rehabilitation and the role of physical human-robot interactions for head-neck mobility.

ARISE Control of an Uncertain Lower-Limb Hybrid Exoskeleton

Kislaya Mishra*, Sujata Basyal*, Jonathan Ting*, Brendon C. Allen*

***Abstract*—Neurological conditions (NCs) such as spinal cord injury, stroke, and Parkinson's disease have been affecting many individuals by deteriorating their standard of living by not letting them perform physical activities, resulting in inactive lifestyles that cause conditions such as diabetes, obesity, cardiovascular disease, etc. Thus, there is a need to overcome the inactive lifestyle caused by NCs. Many potential solutions have been introduced, but each are limited in someway. For example, functional electrical stimulation (FES), which bypasses typical neurological processes to activate an individual's muscles (active therapy), is one of the capable solutions, but it results in the patient becoming fatigued quicker than normal. In an effort to improve FES-based therapies, this paper develops a novel robust and adaptive control structure for a combined FES and robotic system called a hybrid exoskeleton. Specifically, for the first time, a recently developed ARISE control approach is modified for a hybrid exoskeleton. Furthermore, the control law is augmented with neural networks that learn uncertainties in the dynamic model. To evaluate the performance of the control system, a Lyapunov-based stability analysis is performed.**

***Index Terms*—Lyapunov methods, Nonlinear control, Neural network (NN), Robust and adaptive control.**

I. Introduction

Rehabilitation is vital for individuals suffering from movement disorders caused by neurological conditions (NCs) [1]. An important development in the field of rehabilitation is robot-aided therapy, known as rehabilitation robotics, which has been proven to facilitate recovery from NCs. For example, rehabilitation robots have assisted individuals recovering from a stroke to achieve beneficial health outcomes [2]. Moreover, the design of many rehabilitation robotics are reviewed in [3]. Though there are many advantages of robot-aided rehabilitation, active participation rather than passive movements from the affected individual is necessary for recovery [4]. Thus, finding a balance between the patient's and the robot's contribution is critical. Many techniques have been implemented in an effort to increase the patient's contribution and to achieve an optimal contribution from both the human and robot [5]. Functional electrical stimulation (FES) combined with robotics, also known as hybrid exoskeletons, is one of the more commonly used and actively researched techniques to increase human contribution and to achieve an optimal robot-human contribution split.

Hybrid exoskeletons are particularly effective for individuals with NCs, as hybrid exoskeletons apply FES to ensure muscle contractions while also providing an additional torque from the motor to assist the individual on an as-needed basis, helping to reduce the onset of fatigue. In fact, as shown in [6], hybrid exoskeletons can increase biceps strength by allowing patients to perform more repetitions of biceps curls till fatigue. However, hybrid exoskeletons have highly uncertain nonlinear dynamics with some uncertainties bounded by constants. Designing controllers to compensate for the uncertainties and nonlinearities associated with hybrid exoskeletons can be challenging. Many prior studies have been conducted in the field of nonlinear control theory, particularly for systems with uncertainties (cf. [7]).

One common control method is to combine high gain feedback with adaptive terms, but these methods are less optimal when unstructured disturbances exist that are bounded by constants. Consequently, other methods have been developed that combine robust high-gain terms with additional discontinuous terms, for example, sliding mode (SM) controllers [8]. Though SM often ensures great stability results, it requires an infinite frequency response from the actuator, making it physically unimplementable, or at least, unachievable. Moreover, SM controllers exhibit a chattering effect due to the discontinuous jumps that occur within the control input (typically when an error is driven towards 0), further hindering its practical use [9]. Desirous to develop a continuous controller that would mitigate the chattering effect and could compensate for unstructured terms bounded by constants, the authors developed the Auxiliary Robust Integral of the Sliding Mode (ARISE) controller, which can be implemented for a wide-class of uncertain smooth or nonsmooth dynamic systems [10].

In this paper, an ARISE controller is developed for the first time for a hybrid exoskeleton. To demonstrate the proposed approach, this preliminary work considers a one degree-of-freedom (DOF) leg extension exercise. All prior ARISE developments by the authors have considered a state-space model [10], and an Euler-Lagrange dynamic model [11]. Although the dynamic model presented in this work has similarities to the dynamic model in [11], several distinctions exist. Particularly, hybrid exoskeletons have motor and FES inputs, requiring the design of multiple controllers, and the control effectiveness that maps stimulation to torque output is unknown. Consequently, this work approximates the uncertain FES control effectiveness using a neural network (NN), increasing the optimality of the FES control design

and slowing the onset of fatigue. Furthermore, another NN is designed to approximate additional uncertainties in the dynamic model and ARISE is used to compensate for unstructured and time-varying disturbances, yielding an improved trajectory tracking performance. Additionally, a Lyapunov-based stability analysis was performed to ensure the stability and safety of the proposed control framework, proving semi-global exponential trajectory tracking towards an ultimate bound.

II. Dynamics

In this preliminary work, a lower-limb hybrid exoskeleton for leg extensions will be considered. The dynamics are unknown and nonlinear and can be modeled as[1]

$$M\ddot{x}+P(x,\dot{x})+G(x)+F\dot{x}+d(t) = \underbrace{g_m\left(x,\dot{x},t\right)u_m\left(t\right)}_{\tau_m(x,\dot{x},t)} + \underbrace{g_f\left(x,\dot{x},t\right)u_f\left(t\right)}_{\tau_f(x,\dot{x},t)}, \tag{1}$$

where $x : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is the measurable knee joint angle coordinate, $\dot{x} : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is the measurable angular velocity coordinate, $\ddot{x} : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is the angular acceleration coordinate, $M \in \mathbb{R}_{>0}$ is the unknown constant inertia for the lower-limb about the knee, $P\left(x,\dot{x}\right) : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$ is the unknown passive viscoelastic tissue effects, $G\left(x\right) : \mathbb{R} \to \mathbb{R}$ is the uncertain gravitational effects around the knee joint, $F \in \mathbb{R}$ is an uncertain viscous coefficient, and $d\left(t\right) : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is an uncertain disturbance. In (1), $g_m : \mathbb{R} \times \mathbb{R} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{>0}$ and $g_f : \mathbb{R} \times \mathbb{R} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{>0}$ are a known motor control effectiveness term and an unknown lumped FES control effectiveness term, respectively, $u_m : \mathbb{R}_{\geq 0} \to \mathbb{R}$ and $u_f : \mathbb{R}_{\geq 0} \to \mathbb{R}$ are the motor and FES control inputs, respectively, and $\tau_m : \mathbb{R} \times \mathbb{R} \times \mathbb{R}_{\geq 0} \to \mathbb{R}$ and $\tau_f : \mathbb{R} \times \mathbb{R} \times \mathbb{R}_{\geq 0} \to \mathbb{R}$ are the generalized motor and FES input torques, respectively. Moreover, since muscle forces can only be applied unidirectionally, FES will be applied to the quadriceps and hamstrings muscle groups to enable full control about the knee joint. Specifically, the lumped FES control effectiveness is defined as

$$g_f\left(x,\dot{x},t\right) \triangleq g_q\left(x,\dot{x},t\right)\sigma_q\left(u_f\left(t\right)\right) + g_h\left(x,\dot{x},t\right)\sigma_h\left(u_f\left(t\right)\right),$$

$$\sigma_q \triangleq \begin{cases} 1, & u_f \geq 0 \\ 0, & u_f < 0 \end{cases} \quad \text{and} \quad \sigma_h \triangleq \begin{cases} 0, & u_f \geq 0 \\ -1, & u_f < 0 \end{cases},$$

where $g_q : \mathbb{R}\times\mathbb{R}\times\mathbb{R}_{\geq 0} \to \mathbb{R}_{>0}$ and $g_h : \mathbb{R}\times\mathbb{R}\times\mathbb{R}_{\geq 0} \to \mathbb{R}_{<0}$ are the control effectiveness terms for the quadriceps and hamstrings muscle groups, respectively, and σ_q and σ_h are switching signals for the activation of the quadriceps and hamstrings muscle groups, respectively. Note that the design of the switching signals' values, $\{0, 1, -1\}$, ensures that g_f remains continuous and positive for all time. Furthermore, note that the stimulation inputs into the quadriceps and hamstrings muscles groups are respectively defined as

$$u_q \triangleq \sigma_q\left(x,u_f\left(t\right)\right)u_f \quad \text{and} \quad u_h \triangleq \sigma_h\left(x,u_f\left(t\right)\right)u_f,$$

ensuring that FES inputs are always positive as is required. Additionally, below are common assumptions for the leg extension dynamics in (1).

Assumption 1. M can be bounded such that $c_m \leq M \leq c_M$, $\forall t \geq t_0$, where t_0 is the known initial time, and $c_m \in \mathbb{R}_{>0}$ and $c_M \in \mathbb{R}_{>0}$ are known positive constants.

Assumption 2. $P\left(x,\dot{x}\right)$ can be upper-bounded as $\left|P\left(x,\dot{x}\right)\right| \leq c_{P_1} + c_{P_2}\left|\dot{x}\right|, \forall t \geq t_0$, where $c_{P_1} \in \mathbb{R}_{>0}$ and $c_{P_2} \in \mathbb{R}_{>0}$ are known constants and $|\cdot|$ is the absolute value.

Assumption 3. $G\left(x\right)$ can be upper-bounded as $\left|G\left(x\right)\right| \leq c_G, \forall t \geq t_0$, where $c_G \in \mathbb{R}_{>0}$ is a known constant.

Assumption 4. F can be upper-bounded as $|F| \leq c_F, \forall t \geq t_0$, where $c_F \in \mathbb{R}_{>0}$ is a known constant.

Assumption 5. $d\left(t\right)$ can be upper-bounded as $\left|d\left(t\right)\right| \leq c_D, \forall t \geq t_0$, where $c_D \in \mathbb{R}_{>0}$ is a known constant.

III. Control Development

The control objective of the knee extension system in (1) is to track a bounded and smooth desired limb trajectory $x_d : \mathbb{R}_{\geq 0} \to \mathbb{R}$. The error signal, $e : \mathbb{R}_{\geq 0} \to \mathbb{R}$, can be quantified as

$$e\left(t\right) \triangleq x_d\left(t\right) - x\left(t\right). \tag{2}$$

Furthermore, a measurable auxiliary tracking error, $r : \mathbb{R}_{\geq 0} \to \mathbb{R}$, can be defined as

$$r \triangleq \dot{e} + \alpha_1 e + \alpha_2 e_f, \tag{3}$$

where $e_f : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$ is an auxiliary filtered ARISE signal, and $\alpha_1, \alpha_2 \in \mathbb{R}_{>0}$ are user-implemented control gains. The filtered ARISE term, e_f, is derived by solving the auxiliary differential equation that is defined as

$$\dot{e}_f \triangleq -k_1 \text{sgn}\left(r\right) - k_2 r + \alpha_2 e - \beta_1 e_f, \tag{4}$$

where $\text{sgn}\left(\cdot\right)$ is a signum function (i.e., a SM term), $k_1, k_2, \beta_1 \in \mathbb{R}_{>0}$ are user-implemented control gains, and the initial condition of e_f is defined as $e_f\left(0\right) = 0$. The key feature of the ARISE control method is that the signum function is injected into the closed-loop error system for (3) through $\dot{e}_f$ rather than through the control input. As a result, the control input remains continuous, mitigating chattering and the need for infinite control frequency. Multiplying the derivative of (3) by M and substituting (1), (2), and (4) into the resulting product yields the open-loop error system as

$$M\dot{r} = M\ddot{x}_d + P + G + F\dot{x} + d - g_f u_f - g_m u_m + M\alpha_1\dot{e} + M\alpha_2\left[-k_1\text{sgn}\left(r\right) - k_2 r + \alpha_2 e - \beta_1 e_f\right]. \tag{5}$$

A goal of this paper is to learn uncertainties in the dynamic system. Numerous methods exist to approximate the

[1]For notational conciseness, all explicit dependence on time within the terms $x\left(t\right), \dot{x}\left(t\right), \ddot{x}\left(t\right)$ will be suppressed.

unknown FES control effectiveness. This paper will use a NN to approximate $g_f(x,\dot{x},t)\,u_f(t)$ (and ultimately just g_f); however, the universal function approximation theorem from [12] requires $g_f u_f$ to lie on a compact set to approximate $g_f u_f$ with almost complete accuracy and some residual error. Following a semi-global approach from [13], it will be proven that if x, $\dot{x}$, and u_f are initially bounded, they will remain bounded for all time, proving that they lie in a compact set. Furthermore, although time is unbounded, a nonlinear mapping, $f_g : [t_0,\infty) \to [0,1]$, is defined to map time, $[t_0,\infty)$, into a compact domain as

$$f_g(t) \triangleq \frac{k_g(t-t_0)}{k_g(t-t_0)+1},$$

where $k_g \in \mathbb{R}_{>0}$ is a user-defined constant. Note that time can be re-derived through an inverse mapping, $f_g^{-1} : [0,1] \to [t_0,\infty)$, that is defined as

$$f_g^{-1}(\xi) \triangleq \frac{k_g t_0(1-\xi)+\xi}{k_g(1-\xi)},$$

such that $f_g(t) = \xi$ and $f_g^{-1}(\xi) = t$. Therefore, $g_f\left(x,\dot{x},f_g^{-1}(\xi)\right)u_f$ can be treated as though it lies on a compact set and approximated using a NN. Specifically, the FES torque $\tau_f\left(x,\dot{x},f_g^{-1}(\xi),u_f\right) = g_f\left(x,\dot{x},f_g^{-1}(\xi)\right)u_f$ can be expressed as

$$\tau_f\left(x,\dot{x},f_g^{-1}(\xi),u_f\right) = W_f^T\varphi_f\left(V_f^T\phi_f\right)+\varepsilon_f, \quad (6)$$

where $W_f \in \mathbb{R}^{(F_1+1)\times 1}$ denotes the outer layer weights, $V_f \in \mathbb{R}^{5\times F_1}$ denotes the inner layer weights, $\varphi_f(\cdot) : \mathbb{R}^{F_1} \to \mathbb{R}^{F_1+1}$ denotes the inner layer activation functions defined as $\varphi = \left[\varphi_{f_1},...,\varphi_{f_{F_1}},1\right]^T$, $\phi_f(t) \in \mathbb{R}^5$ denotes the input vector to the NN defined as $\phi_f \triangleq \left[x,\dot{x},f_g^{-1}(\xi),u_f,1\right]^T$, $\varepsilon_f \in \mathbb{R}$ is the function approximation error, and $F_1 \in \mathbb{Z}$ denotes the number of neurons in the inner layer. Based on (6), the estimation of the FES generalized torque $\widehat{g}_f(x,\dot{x},t)\,u_f(t)$ can be represented as

$$\widehat{g}_f(x,\dot{x},t)\,u_f(t) = \widehat{W}_f^T\varphi_f\left(\widehat{V}_f^T\phi_f\right),$$

where $\widehat{W}_f \in \mathbb{R}^{(F_1+1)\times 1}$ denotes the estimated outer layer weights, $\widehat{V}_f \in \mathbb{R}^{5\times F_1}$ denotes the estimated inner layer weights, and $\widehat{g}_f$ is the estimate of g_f. To facilitate the subsequent design of the Lyapunov-based adaptive laws, the mismatch between the ideal and the estimated inner layer weights $\widetilde{V}_f : [t_0,\infty) \to \mathbb{R}^{5\times F_1}$ can be defined as

$$\widetilde{V}_f \triangleq V_f - \widehat{V}_f. \quad (7)$$

Similarly, the mismatch between the ideal and estimated outer layer weights $\widetilde{W}_f : [t_0,\infty) \to \mathbb{R}^{(F_1+1)\times 1}$ can be defined as

$$\widetilde{W}_f \triangleq W_f - \widehat{W}_f. \quad (8)$$

Using (6) and adding/subtracting $\widehat{W}_f^T\varphi_f\left(\widehat{V}_f^T\phi_f\right)$ and $W_f^T\varphi_f\left(\widehat{V}_f^T\phi_f\right)$ in (5) modifies the open-loop dynamics as

$$\begin{aligned} M\dot{r} &= M\ddot{x}_d + P + G + F\dot{x} + d - \varepsilon_f - g_m u_m + M\alpha_1\dot{e} \\ &\quad + M\alpha_2\left[-k_1\text{sgn}(r) - k_2 r + \alpha_2 e - \beta_1 e_f\right] \\ &\quad - W_f^T\left(\varphi_f\left(V_f^T\phi_f\right) - \varphi_f\left(\widehat{V}_f^T\phi_f\right)\right) \\ &\quad - \left(\widetilde{W}_f^T\right)\left(\varphi_f\left(\widehat{V}_f^T\phi_f\right)\right) - \widehat{W}_f^T\varphi_f\left(\widehat{V}_f^T\phi_f\right). \end{aligned} \quad (9)$$

To overcome the challenges associated with the nested structure of NN's, a Taylor series approximation was performed for $\varphi_f\left(V_f^T\phi_f\right)$ to yield

$$\varphi_f\left(V_f^T\phi_f\right) = \varphi_f\left(\widehat{V}_f^T\phi_f\right) + \varphi_f'\left(\widehat{V}_f^T\phi_f\right)\widetilde{V}_f^T\phi_f + \Theta_f,$$

where $\varphi_f' \in \mathbb{R}^{(F_1+1)\times F_1}$ denotes the partial derivative of the inner layer activation functions defined as $\varphi_f' \triangleq \frac{\partial\varphi\left(\boldsymbol{\nu}_f^T\phi_f\right)}{\partial\boldsymbol{\nu}_f^T\phi_f}$, and $\Theta_f \in \mathbb{R}^{F_1+1}$ denotes the higher order terms of the expansion. Adding/subtracting e and $\hat{W}_f^T\left(\varphi_f'\left(\hat{V^T}_f\phi_f\right)\widetilde{V}_f^T\phi_f\right)$, and simplifying (9) results in

$$\begin{aligned} M\dot{r} &= M\ddot{x}_d + P + G + F\dot{x} - g_m u_m + \chi_1 - e \\ &\quad + M\alpha_2\left[-k_1\text{sgn}(r) - k_2 r - \beta_1 e_f\right] \\ &\quad - \hat{g}_f u_f - \left(\widetilde{W}_f^T\right)\left(\varphi_f\left(\widehat{V}_f^T\phi_f\right)\right) \\ &\quad - \widehat{W}_f^T\left(\varphi_f'\left(\widehat{V}_f^T\phi_f\right)\widetilde{V}_f^T\phi_f\right), \end{aligned} \quad (10)$$

where $\chi_1 : \mathbb{R}_{\geq 0} \to \mathbb{R}$, is an auxiliary term defined as

$$\begin{aligned} \chi_1 &\triangleq M\alpha_1\dot{e} + \left(M\alpha_2^2+1\right)e - \varepsilon_f - W_f^T\Theta_f \\ &\quad - \widetilde{W}_f^T\left(\varphi_f'\left(\widehat{V}_f^T\phi_f\right)\widetilde{V}_f^T\phi_f\right) + d. \end{aligned} \quad (11)$$

Now a second NN will be developed to approximate the other uncertain dynamics in the system. To facilitate this NN approximation, the desired system dynamics, $q_d(x_d,\dot{x}_d)$, are defined as

$$q_d(x_d,\dot{x}_d) \triangleq P(x_d,\dot{x}_d) + G(x_d) + F\dot{x}_d, \quad (12)$$

where $x_d : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is the desired angular position and $\dot{x}_d : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is the desired angular velocity coordinate. Adding/subtracting q_d in (10), and simplifying will result in

$$\begin{aligned} M\dot{r} &= M\ddot{x}_d + q_d + S - g_m u_m + \chi_1 - e - \hat{g}_f u_f \\ &\quad + M\alpha_2\left[-k_1\text{sgn}(r) - k_2 r - \beta_1 e_f\right] \\ &\quad - \left(\widetilde{W}_f^T\right)\left(\varphi_f\left(\widehat{V}_f^T\phi_f\right)\right) \\ &\quad - \widehat{W}_f^T\left(\varphi_f'\left(\widehat{V}_f^T\phi_f\right)\widetilde{V}_f^T\phi_f\right), \end{aligned} \quad (13)$$

where S is the difference between the actual dynamics and the desired dynamics and is defined as

$$S \triangleq [P + G + F\dot{x}] - \underbrace{[P_d + G_d + F\dot{x}_d]}_{q_d}, \quad (14)$$

where P_d denotes $P(x_d,\dot{x_d})$ and G_d denotes $G(x_d)$. Considering the theory of universal function approximation from

[12], there exists activation functions and ideal layer weights such that $M\ddot{x}_d + q_d$ can be approximated with almost complete accuracy and some residual error such that

$$M\ddot{x}_d + q_d \triangleq W_l^T \varphi_l \left(V_l^T \phi_l(t)\right) + \varepsilon_l, \tag{15}$$

where $W_l \in \mathbb{R}^{(L_1+1)\times 1}$ is the outer layer weights , $V_l \in \mathbb{R}^{4\times L_1}$ is the inner layer weights, $\varphi_l(\cdot) : \mathbb{R}^{L_1} \to \mathbb{R}^{L_1+1}$ are the activation functions defined as $\varphi_l \triangleq \left[\varphi_{l_1}, ..., \varphi_{l_{L_1}}, 1\right]^T$, and $\phi_l(t) \in \mathbb{R}^4$ is the input vector defined as $\phi_l \triangleq [x_d(t), \dot{x}_d(t), \ddot{x}_d(t), 1]^T$, $\varepsilon_L \in \mathbb{R}$ is the function approximation error, and $L_1 \in \mathbb{Z}$ denotes the number of neurons in the inner layer. To facilitate the subsequent design of the Lyapunov-based adaptive laws, the mismatch between the ideal and the estimated inner layer weights $\widetilde{V}_l : [t_0, \infty) \to \mathbb{R}^{4\times L_1}$ can be defined as

$$\widetilde{V}_l \triangleq V_l - \widehat{V}_l. \tag{16}$$

Similarly, the mismatch between the ideal and estimated outer layer weights $\widetilde{W}_l : [t_0, \infty) \to \mathbb{R}^{(L_1+1)\times 1}$ can be defined as

$$\widetilde{W}_l \triangleq W_l - \widehat{W}_l. \tag{17}$$

Substituting (15) and adding/subtracting $W_l^T \varphi_l\left(\widehat{V}_l^T \phi_l\right)$ into (13) yields a modified open-loop error system as

$$\begin{aligned} M\dot{r} &= S - g_m u_m - e + \chi_1 - \hat{g}_f u_f \\ &\quad + M\alpha_2 \left[-k_1 \text{sgn}(r) - k_2 r - \beta_1 e_f\right] \\ &\quad - \left(\widetilde{W}_f^T\right) \varphi_f\left(\widehat{V}_f^T \phi_f\right) + W_l^T \varphi_l\left(\widehat{V}_l^T \phi_l\right) \\ &\quad - \widehat{W}_f^T \left(\varphi_f'\left(\widehat{V}_f^T \phi_f\right) \widetilde{V}_f^T \phi_f\right) \\ &\quad + W_l^T \left(\varphi_l\left(V_l^T \phi_l\right) - \varphi_l\left(\widehat{V}_l^T \phi_l\right)\right). \end{aligned} \tag{18}$$

Similar to the NN in (6), a Taylor series approximation was performed on φ_l to yield

$$\varphi_l\left(V_l^T \phi_l\right) = \varphi_l\left(\widehat{V}_l^T \phi_l\right) + \varphi_l'\left(\widehat{V}_l^T \phi_l\right) \widetilde{V}_l^T \phi_l + \Theta_l,$$

where $\varphi_l' \in \mathbb{R}^{(L_1+1)\times L_1}$ denotes the partial derivative of the inner layer activation functions defined as $\varphi_l' \triangleq \frac{\partial \varphi_l\left(\boldsymbol{\psi}_l^T \phi_l\right)}{\partial \boldsymbol{\psi}_l^T \phi_l}$, and $\Theta_l \in \mathbb{R}^{L_1+1}$ denotes the higher order terms of the expansion. Adding/subtracting $\hat{W}_l^T \left(\varphi_l'\left(\widehat{V}_l^T \phi_l\right) \widetilde{V}_l^T \phi_l\right)$ into (18) yields the open-loop error system as

$$\begin{aligned} M\dot{r} &= \chi_2 + S - g_m u_m - e + \chi_1 - \hat{g}_f u_f \\ &\quad + M\alpha_2 \left[-k_1 \text{sgn}(r) - k_2 r - \beta_1 e_f\right] \\ &\quad - \left(\widetilde{W}_f^T\right) \left(\varphi_f\left(\widehat{V}_f^T \phi_f\right)\right) + W_l^T \varphi_l\left(\widehat{V}_l^T \phi_l\right) \\ &\quad - \widehat{W}_f^T \left(\varphi_f'\left(\widehat{V}_f^T \phi_f\right) \widetilde{V}_f^T \phi_f\right) \\ &\quad + \hat{W}_l^T \left(\varphi_l'\left(\widehat{V}_l^T \phi_l\right) \widetilde{V}_l^T \phi_l\right), \end{aligned} \tag{19}$$

where $\chi_2 : \mathbb{R}_{\geq 0} \to \mathbb{R}$, is an auxiliary term defined as

$$\chi_2 \triangleq \widetilde{W}_l^T \left(\varphi_l'\left(\widehat{V}_l^T \phi_l\right) \widetilde{V}_l^T \phi_l\right) + \varepsilon_l + W_l^T \Theta_l \ . \tag{20}$$

Using (2), (3), 26-29 Assumptions 1-4, and Assumption 6 (stated below) $\chi_1 + \chi_2 + S$ can be denoted as $\chi \triangleq \chi_1 + \chi_2 + S$ for simplicity purposes and upper bounded as

$$\|\chi\| \leq \Phi + \rho(\|z\|) \|z\|, \tag{21}$$

where $\|\cdot\|$ is the Euclidean norm, $\Phi \in \mathbb{R}_{>0}$ is a known constant, $\rho(\cdot)$ is a positive, radially unbounded, and strictly increasing function, and $z : \mathbb{R}_{\geq 0} \to \mathbb{R}^3$ is a composite error vector defined as

$$z(t) \triangleq \begin{bmatrix} e & r & e_f \end{bmatrix}^T. \tag{22}$$

On the basis of an analysis of the open-loop error dynamics in (19), the control inputs u_f and u_m are designed as

$$u_f \triangleq \frac{1}{\hat{g}_f}(k_4 r), \tag{23}$$

$$\begin{aligned} u_m &\triangleq \frac{1}{g_m}\left(k_3 r - \left(k_2 + \hat{M}\alpha_2\beta_1\right) e_f \right. \\ &\quad \left. + \widehat{W}_l^T \varphi_l\left(\widehat{V}_l^T \phi_l\right)\right), \end{aligned} \tag{24}$$

where $\hat{M}$ is an estimated value for M and is defined by $\hat{M} \triangleq \frac{1}{2}(c_m + c_M)$, and $k_3 \in \mathbb{R}_{>0}$ is a user-defined control gain, and the inertial estimation error is defined as

$$\widetilde{M} \triangleq \widehat{M} - M. \tag{25}$$

Moreover, (25) can be bounded using Assumption 1 and (25) as $\left|\tilde{M}\right| \leq \frac{1}{2}(c_M - c_m) = c_M$, where $c_M \in \mathbb{R}_{>0}$ is a positive constant. Similarly, the NN parameter adaptive laws are designed as

$$\dot{\widehat{W}}_f = -\text{proj}\left(\Gamma_1 \varphi_f\left(\widehat{V}_f^T \phi_f\right) r\right), \tag{26}$$

$$\dot{\widehat{V}}_f = -\text{proj}\left(\Gamma_2 \phi_f r \widehat{W}_f^T \varphi_f'\left(\widehat{V}_f^T \phi_f\right)\right), \tag{27}$$

$$\dot{\widehat{W}}_l = \text{proj}\left(\Gamma_3 \varphi_l\left(\widehat{V}_l^T \phi_l\right) r\right), \tag{28}$$

$$\dot{\widehat{V}}_l = \text{proj}\left(\Gamma_4 \phi_l r \widehat{W}_l^T \varphi_l'\left(\widehat{V}_l^T \phi_l\right)\right), \tag{29}$$

where $\Gamma_1 \in \mathbb{R}^{(F_1+1)\times(F_1+1)}$, $\Gamma_2 \in \mathbb{R}^{5\times 5}$, $\Gamma_3 \in \mathbb{R}^{(L_1+1)\times(L_1+1)}$, and $\Gamma_4 \in \mathbb{R}^{4\times 4}$ are diagonal gain matrices that are positive definite, and $\text{proj}(\cdot)$ defines the smooth projection algorithm in [14] that ensures the bounding of the NN weight estimates. Moreover, the closed-loop error dynamics can be developed by substituting (23) and (24) into (19) to get

$$\begin{aligned} M\dot{r} &= \chi - k_3 r + \left(k_2 + \hat{M}\alpha_2\beta_1\right) e_f - k_4 r \\ &\quad + M\alpha_2 \left[-k_1 \text{sgn}(r) - k_2 r - \beta_1 e_f\right] \\ &\quad - \left(\widetilde{W}_f^T\right) \left(\varphi_f\left(\widehat{V}_f^T \phi_f\right)\right) - e \\ &\quad + \left(\widetilde{W}_l^T\right) \left(\varphi_l\left(\widehat{V}_l^T \phi_l\right)\right) \\ &\quad - \widehat{W}_f^T \left(\varphi_f'\left(\widehat{V}_f^T \phi_f\right) \widetilde{V}_f^T \phi_f\right) \\ &\quad + \widehat{W}_l^T \left(\varphi_l'\left(\widehat{V}_l^T \phi_l\right) \widetilde{V}_l^T \phi_l\right). \end{aligned} \tag{30}$$

The ideal weights of both the NNs are assumed to be bounded by known constants such that $\| V_f \| = \text{trace}\left(V_f^T V_f\right) \leq \overline{V_f}$, $\| W_f \| = \leq \overline{W_f}$, $\| V_l \| = \text{trace}\left(V_l^T V\right) \leq \overline{V_l}$, and $\| W_l \| \leq \overline{W_l}$. Similarly, the activation functions of the NNs and their derivatives, φ_f, φ_f', φ_l, and φ_l' are also assumed to be bounded.

IV. Stability Analysis

A Lyapunov-based analysis is carried out to ensure the safe implementation and the stability of the motor and FES controllers designed for knee extension exercises. A common Lyapunov function candidate is designed such that it is positive definite, and continuously differentiable, denoted by $V_q : \mathcal{D} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$, is given as

$$\begin{aligned} V_q(y,t) \triangleq & \tfrac{1}{2}e^2 + \tfrac{1}{2}Mr^2 + \tfrac{1}{2}e_f^2 + \tfrac{1}{2}\left(\widetilde{W}_f^T \Gamma_1^{-1} \widetilde{W}_f\right) \\ & + \tfrac{1}{2}\text{trace}\left(\widetilde{V}_f^T \Gamma_2^{-1} \widetilde{V}_f\right) + \tfrac{1}{2}\left(\widetilde{W}_l^T \Gamma_3^{-1} \widetilde{W}_l\right) \\ & + \tfrac{1}{2}\text{trace}\left(\widetilde{V}_l^T \Gamma_4^{-1} \widetilde{V}_l\right), \end{aligned} \tag{31}$$

where $\mathcal{D} \subseteq \mathbb{R}^{\upsilon}$ is given as $\mathcal{D} \triangleq \{y \in \mathbb{R}^{\upsilon} \,|\, \|y\| < \gamma\}$, $\upsilon = 3 + (F_1 + 1) + 5F_1 + (L_1 + 1) + 4L_1$, $\gamma \in \mathbb{R}_{>0}$ is a known constant which satisfies the inequality $\gamma \leq \inf\left\{\rho^{-1}\left(\left(\sqrt{k_4}\delta, \infty\right)\right)\right\}$, $\delta \in \mathbb{R}$ is a known constant and is defined as $\delta \triangleq \min\left(\alpha_1, \frac{k_4}{2}, \frac{\beta_1}{2} - \frac{\varepsilon_2}{2}\right)$, and $\varepsilon_2 \in \mathbb{R}_{>0}$ is a user-selectable constant. Based on the subsequent stability analysis, $\mathcal{S}_{\mathcal{D}}$ denotes an acceptable set of initial conditions that is defined as

$$\mathcal{S}_{\mathcal{D}} \triangleq \left\{ y \in \mathbb{R}^{\upsilon} \,\middle|\, \sqrt{\lambda_2 \lambda_1^{-1}} \|y(t_0)\| \leq \gamma \right\}. \tag{32}$$

Additionally, V_q can be bounded such that

$$\lambda_1 \|y\|^2 \leq V_q \leq \lambda_2 \|y\|^2, \tag{33}$$

where

$$\begin{aligned} \lambda_1 \triangleq & \tfrac{1}{2}\min\left(1, c_m, \lambda_{\min}\left\{\Gamma^{-1}\right\}, \lambda_{\min}\left\{\Gamma_2^{-1}\right\}, \right. \\ & \left. \lambda_{\min}\left\{\Gamma_3^{-1}\right\}, \lambda_{\min}\left\{\Gamma_4^{-1}\right\}\right), \\ \lambda_2 \triangleq & \tfrac{1}{2}\max\left(1, c_M, \lambda_{\max}\left\{\Gamma^{-1}\right\}, \lambda_{\max}\left\{\Gamma_2^{-1}\right\}, \right. \\ & \left. \lambda_{\max}\left\{\Gamma_3^{-1}\right\}, \lambda_{\max}\left\{\Gamma_4^{-1}\right\}\right), \end{aligned}$$

where $\lambda_{\min}\{\cdot\}$ is the minimum eigenvalue of $\{\cdot\}$, $\lambda_{\max}\{\cdot\}$ is the maximum eigenvalue of $\{\cdot\}$, and $y : \mathbb{R}_{\geq 0} \to \mathbb{R}^{\upsilon}$ denotes a concatenated error vector defined as

$$y \triangleq \left[z^T, \quad \widetilde{W}_f^T \ , \text{vec}\left(\widetilde{V}_f\right)^T, \widetilde{W}_l^T, \text{vec}\left(\widetilde{V}_l\right)^T \right]^T. \tag{34}$$

Using (34), V_q can be further bounded as

$$\lambda_1 \|z\|^2 \leq V_q \leq \lambda_2 \|z\|^2 + v_1, \tag{35}$$

where v_1 is defined as

$$\begin{aligned} v_1 \triangleq & \tfrac{1}{2}\lambda_{\max}\left\{\Gamma_1^{-1}\right\} \left\|\widetilde{W}_f\right\|_{\max}^2 + \tfrac{1}{2}\lambda_{\max}\left\{\Gamma_3^{-1}\right\} \left\|\widetilde{W}_l\right\|_{\max}^2 \\ & + \tfrac{1}{2}\lambda_{\max}\left\{\Gamma_2^{-1}\right\} \left\|\text{vec}\left(\widetilde{V}_f\right)\right\|_{\max}^2 \\ & + \tfrac{1}{2}\lambda_{\max}\left\{\Gamma_4^{-1}\right\} \left\|\text{vec}\left(\widetilde{V}_l\right)\right\|_{\max}^2, \end{aligned} \tag{36}$$

Theorem 1. *If the knee extension dynamics in (1) satisfy Assumptions 1-4, the control inputs in (23) and (24), and the NN adaptation laws in (26), (27), (28), and (29) yield semi-global trajectory tracking to an ultimate bound in the sense that*

$$\begin{aligned} \|y(t)\|^2 \leq & \tfrac{\lambda_2}{\lambda_1}\|y(t_0)\|^2 \exp\left(-\delta(t - t_0)\right) \\ & + \tfrac{\upsilon}{\lambda_1 \delta}\left(1 - \exp\left(-\delta(t - t_0)\right)\right), \end{aligned} \tag{37}$$

$\forall t \in [t_0, \infty)$, where $\upsilon \triangleq \delta v_1 + \frac{k_1^2}{2\varepsilon_2}$, and ε_2 is a selectable constant, provided that $y(t_0) \in \mathcal{S}_{\mathcal{D}}$ and the following conditions are satisfied

$$c_m \alpha_2 k_1 \geq \Phi, \quad \sqrt{\frac{\upsilon}{\delta \lambda_1}} < \gamma \tag{38}$$

$$k_3 + c_m \alpha_2 k_2 \geq c_M \alpha_2 \beta_1 \frac{\varepsilon_1}{2}, \quad \frac{\beta_1}{2} \geq c_M \alpha_2 \beta_1 \frac{1}{2\varepsilon_1}, \tag{39}$$

Proof: Let $y : [t_0, \infty) \to \mathbb{R}^{\upsilon}$ be a Filippov solution to the differential inclusion $\dot{y} \in K[h](y)$, where $K[\cdot]$ is the differential inclusion operator given in [15], and $h : \mathbb{R}^{\upsilon} \to \mathbb{R}^{\upsilon}$ is defined as $h(y) \triangleq \left[\dot{e}, \quad \dot{r}, \quad \dot{e}_f, \quad \dot{\widehat{W}}_f^T \ , \text{vec}\left(\dot{\widehat{V}}_f\right)^T, \dot{\widehat{W}}_l^T, \text{vec}\left(\dot{\widehat{V}}_l\right)^T \right]^T$. As the closed-loop error dynamics in (30) are discontinuous, there exists a time derivative of V_q almost everywhere (a.e) such that $\dot{V}_q(y) \overset{\text{a.e.}}{\in} \dot{\tilde{V}}_q(y)$, where $\dot{\tilde{V}}_q(y)$ is the generalized time derivative of V_q and is defined based on [16, Equation 13] as $\dot{\tilde{V}}_q \triangleq \bigcap_{\xi \in \partial V_q(y)} \xi^T \left[K[h]^T(y), 1\right]^T$, where $\partial V_q(y)$ denotes the Clarke generalized gradient of V_q. Since V_q is continuously differentiable with respect to y, $\partial V_q(y) = \nabla V_q(y)$, where ∇ is the gradient operator. Thus, taking the generalized time derivative of V_q defined in (31), and substituting the closed-loop error dynamics in (30), the auxiliary error signal defined in (3), the filtered error signal defined in (4), and the NN update laws defined in (26)-(29)

yields

$$\begin{aligned}\dot{\tilde{V}}_q \quad \subseteq \quad & e\left[r-\alpha_1 e-K\left[\alpha_2 e_f\right]\right]+r\left[\chi-Cr\right.\\ & -k_3 r+\left(k_2+\hat{M}\alpha_2\beta_1\right)e_f-k_4 r-e\\ & +M\alpha_2\left[-k_1 K\left[\operatorname{sgn}(r)\right]-k_2 r-\beta_1 e_f\right]\\ & +\left(\widetilde{W}_l^T\right)\left(\varphi_l\left(\widehat{V}_l^T\phi_l\right)\right)-\left(\widetilde{W}_f^T\right)\left(\varphi_f\left(\widehat{V}_f^T\phi_f\right)\right)\\ & -\widehat{W}_f^T\left(\varphi_f'\left(\widehat{V}_f^T\phi_f\right)\widetilde{V}_f^T\phi_f\right)\\ & \left.+\widehat{W}_l^T\left(\varphi_l'\left(\widehat{V}_l^T\phi_l\right)\widetilde{V}_l^T\phi_l\right)\right]\\ & +e_f\left[K\left[-k_1\operatorname{sgn}(r)\right]-k_2 r+\alpha_2 e-K\left[\beta_1 e_f\right]\right]\\ & -\widetilde{W}_f^T\left[-\left(\varphi_f\left(\widehat{V}_f^T\phi_f\right)r\right)\right]\\ & -\widetilde{W}_l^T\left[\left(\varphi_l\left(\widehat{V}_l^T\phi_l\right)r\right)\right]\\ & -\widetilde{V}_f^T\left[-\left(\phi_f r\widehat{W}_f^T\varphi_f'\left(\widehat{V}_f^T\phi_f\right)\right)\right]\\ & -\widetilde{V}_l^T\left[\left(\phi_l r\widehat{W}_l^T\varphi_l'\left(\widehat{V}_l^T\phi_l\right)\right)\right].\end{aligned} \tag{40}$$

Implementing (21) to bound χ, using $-r^T K\left[\operatorname{sgn}(r)\right] \leq -|r|$ and $|K\left[\operatorname{sgn}(r)\right]| \leq 1$, canceling terms, and the definition of $\widehat{M}$ above (25), Assumption 1, and the gain conditions stated in (38) and (39), $\dot{V}_q$ can be bounded as

$$\begin{aligned}\dot{V}_q \quad \overset{\text{a.e.}}{\leq} \quad & -\alpha_1 e^2+r\|\chi\|-k_3 r^2-r\tilde{M}\alpha_2\beta_1 e_f\\ & -M\alpha_2 k_1|r|-M\alpha_2 k_2 r^2-k_4 r^2\\ & +k_1 e_f\left|K\left[\operatorname{sgn}(r)\right]\right|-\beta_1 e_f^2.\end{aligned} \tag{41}$$

Completing the squares and applying Young's Inequality allows (41) to be further bounded as

$$\begin{aligned}\dot{V}_q \quad \overset{\text{a.e.}}{\leq} \quad & -\alpha_1 e^2-\frac{k_4}{2}r^2-\left(\frac{\beta_1}{2}-\tfrac{\varepsilon_2}{2}\right)e_f^2\\ & +\frac{\rho^2\left(\|z\|\right)\|z\|^2}{2k_4}+\tfrac{k_1^2}{2\varepsilon_2}.\end{aligned} \tag{42}$$

Using the definitions of V from the theorem statement, the upper bound in (35), the gain values in (39), the inequality $\|y\| \geq \|z\|$, and the definitions of $\mathcal{D}$ and δ below (31), (42) can then be upper bounded as

$$\dot{V}_q \quad \overset{\text{a.e.}}{\leq} \quad -\delta V_q+v, \tag{43}$$

which can be solved to yield

$$\begin{aligned}V_q(t) \quad \leq \quad & V_q(t_0)\exp\left(-\delta\left(t-t_0\right)\right)\\ & +\tfrac{v}{\delta}\left[1-\exp\left(-\delta\left(t-t_0\right)\right)\right],\end{aligned} \tag{44}$$

provided that $y \in \mathcal{D}, \forall t \in [t_0, \infty)$. A sufficient condition for $y \in \mathcal{D}, \forall t \in [t_0, \infty)$ is that $y(t_0) \in S_D$ and the gain conditions in (39) is achieved. Using (33) with (44) yields the result in the theorem statement. Picking the gains k_1, k_2, k_3, k_4, α_1, α_2, and β_1, appropriately will ensure that $y \in \mathcal{S}_{\mathcal{D}}$ and that all the gain conditions are met in (38)-(39). Additionally, from (22), (34), and (37), combined with (2) and (3), it can be determined that $x, \dot{e}, \dot{x}, \hat{W}_f, \hat{V}_f, \hat{W}_l, \hat{V}_l \in \mathcal{L}_\infty$. It can further be proven that $u_f, u_m \in \mathcal{L}_\infty$. Since $y \in \mathcal{D}, \forall t \in [t_0, \infty)$ is proven to be true provided that $y(t_0) \in S_D$ and the gain conditions are satisfied, the prior assumption that x, $\dot{x}$, and u_f lie in a compact set is proven to be valid. ■

V. Conclusion

In this paper, NN- and ARISE-based controllers were designed for a hybrid exoskeleton that enables leg extension exercises for individuals with NCs, despite the FES control effectiveness matrix and other dynamic terms being unknown. In this work, the FES effectiveness and the dynamics were approximated using NNs. Moreover, Lyapunov-based adaptive laws were developed to estimate the NNs' ideal weights in real-time. A Lyapunov-based analysis was performed to prove semi-global exponential tracking of the knee joint angle to an ultimate bound. Future efforts will focus on experiments and modifications in the stability analysis to remove the ultimate bound from the current stability result.

User field testing for robot wheelchairs: A mixed-method approach

Jorge L. Candiotti, Sivashankar Sivakanthan, Benjamin Gebrosky, Rosemarie Cooper, Rory A. Cooper, *Member, IEEE*

Abstract— **Enhancing mobility and independence for electric power wheelchair (EPW) users is often hindered by architectural barriers. Robotic wheelchairs with innovative mechanisms offer potential solutions, but current technologies are typically confined to lab evaluations with limited user input. This study employed a mixed-method approach to assess the effectiveness of a legged-wheel robotic wheelchair compared to standard EPWs in indoor and outdoor environments. Driving metrics, usability assessments, and user feedback were collected. EPW users found the robotic wheelchair challenging to learn, however, its overall usability and effectiveness in meeting their mobility needs were comparable to their EPWs. The robotic wheelchair also demonstrated improved stability and reduced vibration on uneven terrains. Feedback highlighted the benefits of robotic wheelchair applications when accessibility is not available compared to existing EPWs. Furthermore, participants suggested improvement of seating functions, better maneuverability in tight spaces, and enhanced indoor accessibility similar to EPWs. While standardized tools confirmed the robotic wheelchair's effectiveness compared to existing EPWs, user perceptions are essential to validate these findings. The study concludes that robotic wheelchairs can enhance outdoor safety and comfort but must integrate fundamental functions of existing EPWs to support users' health and indoor mobility.**

I. INTRODUCTION

Electric power wheelchairs (EPW) are essential for people with mobility impairments and the aging population, assisting with indoor navigation and daily activities. Approximately 80 million people need wheelchairs worldwide, with EPW becoming popular with advances in technology [1]. Despite its benefits for indoor maneuvering, architectural barriers in the community limit the mobility of EPW users and increase the risk of injury when navigating uneven terrains, curbs, or inclined surfaces [2-4].

Over the past 20 years, robotic wheelchairs have emerged in both research and market to enhance the mobility and independence of wheelchair users [5, 6]. These robotic wheelchairs incorporate features such as dynamic suspensions, additional degrees of freedom, and expanded ranges of motion to address architectural barriers [7]. Despite significant advances in the field, only a limited number of robotic wheelchairs have successfully transitioned to the market [8]. A key limitation in the development of robotic wheelchairs lies in the insufficient integration of participatory action design, which actively involves end-users in the development process, leading to devices that may not fully address real-world needs [5, 6, 8]. Additionally, much of the testing for robotic wheelchairs has been restricted to controlled laboratory settings, limiting potential evidence of practical use and effectiveness in everyday environments. Assistive technology competitions such as Cybathlon have promoted the innovation of robotic wheelchairs, particularly in navigating architectural barriers [9]. However, the focus on completing tasks in the shortest time may prioritize competition-specific performance over the translation of research into functional and user-centered designs suitable for daily use. Addressing these challenges requires a shift toward more inclusive design processes, real-world testing, and the development of standardized metrics to ensure that robotic wheelchairs meet the mobility and health needs of wheelchair users in everyday life.

The study aims to evaluate the effectiveness and usability of a testing robotic wheelchair, called Mobility Enhancement Robot (MEBot), in real-world indoor and outdoor environments with experienced EPW users. The primary objective is to explore the benefits and design limitations of MEBot through standardized assessment tools, complemented by end-users' feedback. Specifically, we hypothesize that (1) experienced EPW users will rate similar or better scores of usability and effectiveness of MEBot and their EPWs to meet mobility needs in daily environments, (2) MEBot will demonstrate higher stability and less discomfort than participants' EPWs in outdoor environments, and (3) the median NASA-TLX workload scores operating MEBot over curbs will be <40, indicating low workload demand. The findings aim to provide evidence of the MEBot's effectiveness for daily use while identifying potential improvements. The study seeks to refine standard assessment tools tailored to evaluate robotic wheelchairs, focusing on the ability to enhance users' mobility, health outcomes, and overall quality of life.

II. METHODS

A. Testing wheelchair: MEBot

MEBot [10] followed a participatory action design and engineering approach, incorporating feedback from EPW users throughout the design process to address their mobility challenges, particularly when navigating architectural barriers. Previous focus groups confirmed community mobility

challenges, including the risk of tipping on uneven surfaces and steep inclines and restricted sidewalk access due to obstructed or unavailable curb cuts [4, 11]. These findings led to design requirements prioritizing dynamic adaptability to navigate such environments while maintaining stability and comfort [12].

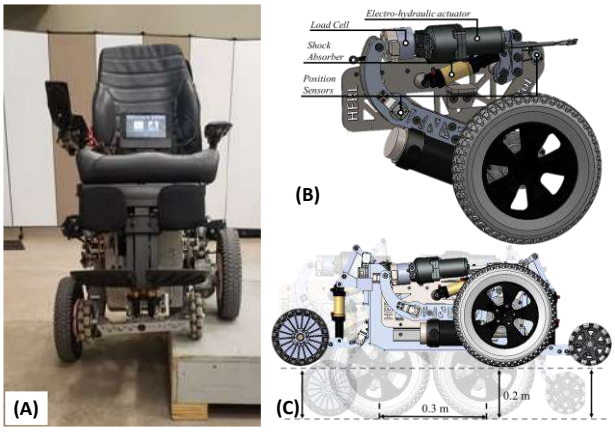

Fig 1: (A) *MEBot leveled* on an uneven surface (B) Side view of MEBot spring-elastic actuator mechanism and (C) MEBot Range of Motion

MEBot features four Series Elastic electro-hydraulic Actuators (SEA) connected to the wheels, enabling vertical motion and dynamic suspension on each side of the base. Two independently mounted driving wheels with separate carriages provide differential drive and horizontal repositioning along the base, allowing efficient maneuvering in tight spaces (Fig. 1). These combined mechanisms enable 5 unconstrained degrees of freedom for rotation and translation in three axes/planes. This design enhances stability on slopes up to 15° slope, shock absorption on uneven terrains, and curbs negotiation up to 20.3 cm high. MEBot also integrates an OEM power seating system, featuring a back and seat air cushion, trunk support, and actuated seat recline, tilt-in-space, and leg rest that can be adjusted by the researcher before the study.

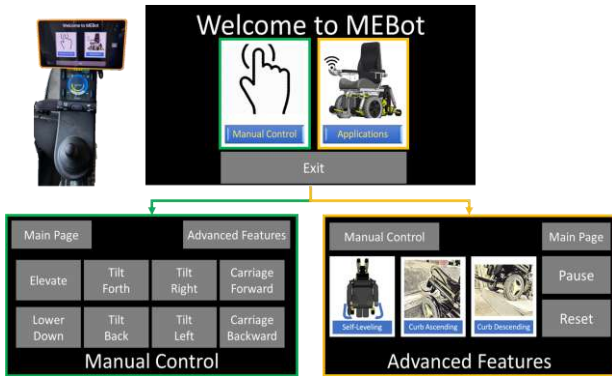

Fig 2. User Interface wireframe of MEBot mobility applications

A graphical user interface (GUI) enables users to select MEBot mobility applications via touchscreen (Fig. 2). The GUI wireframe includes a home screen with options for 'manual' and 'advanced' applications. Manual applications allow users to adjust basic mobility functions, such as wheelchair elevation, back-forth tilt, side tilt, and drive wheel configuration. Advanced applications include self-leveling and curb negotiation features, which users can activate or deactivate as needed. The self-leveling application keeps the seat horizontally level when driving on uneven surfaces by measuring the surface gradient (i.e. pitch and roll) [13] using an Inertial Measurement Unit (IMU) integrated into the frame. These measurements are then processed through a rotation transformation matrix to reposition the SEA mechanisms relative to a horizontal plane.

The curb negotiation application follows a two-step process 1) prompting the user to align perpendicular and adjacent to the curb, and 2) activating the application, allowing MEBot to take control. This autonomous process uses a finite state machine to operate each SEA mechanism, ensuring stability and safety at every stage [14, 15]. A preliminary usability evaluation with EPW users confirmed that MEBot's advanced mobility applications consistently overcome engineered tasks representing architectural barriers in the community [12, 16].

A. Study Procedure

Experienced EPW users were recruited at the National Veterans Wheelchair Games (NVWG) in Portland, Oregon. All participants provided informed consent. The Veterans Affairs Pittsburgh Healthcare System Institutional Review Board approved the study (Study ID: 1690689). After consent, participants completed a demographics questionnaire and information about their wheelchairs. They were then randomized to determine the order of using MEBot or their own EPW in the driving course. Before the study, researchers attached an IMU datalogger to each participant's EPW frame to measure vibration and seat angle changes. If the participants used MEBot, researchers configured its seating and driving parameters to match their EPWs, ensuring comfort and minimizing learning bias. Participants received MEBot training until they and the researcher felt confident in their familiarity with the device. Training for each participant took approximately 15 minutes. This included a checklist of tasks for demonstrating the user interface and applications, having participants replicate the tasks, and a driving session indoors, driving over an inclined surface, and up a curb.

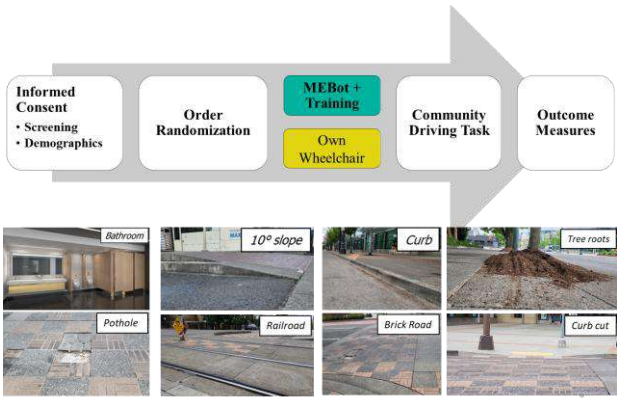

Fig 3. Protocol and Indoor and Outdoor mobility tasks

Participants navigated the driving course using both wheelchairs while maintaining an average speed of 1.2 m/s, comparable to a pedestrian crossing the street [17]. A researcher or clinician accompanied them throughout the course to ensure safety and provide pacing guidance. The driving course included real-world indoor and outdoor mobility tasks from current literature and prior focus groups (Fig. 3) [2, 18-20]. Each task was performed twice. Participants did not perform the last task of navigating a

standard curb height of 15 cm with their EPW due to manufacturer limitations (7.6 cm) and at risk of tipping.

At the end of the study, participants rated the ease of use and effectiveness of each wheelchair in meeting their mobility needs using the System Usability Scale (SUS) and the Assistive Technology Device-Predisposition Assessment (ATD-PA). Participants also rated the NASA Task Load Demand (NASA-TLX) for navigating curbs with MEBot and their daily driving with their EPW to serve as a baseline. Quantitative metrics such as seat angle changes and 3-axis accelerations were recorded throughout the driving course to assess the stability and vibration exposure of each wheelchair. Additionally, follow-up questions were asked about their responses to assessment tools to gather on the benefits, challenges, and areas for improvement of MEBot.

B. Outcome Measures

The SUS measures a device's usability in performing tasks. The questionnaire includes 10 questions rated on a 5-point Likert scale, from 1 (Strongly Disagree) to 5 (Strongly Agree). The overall score ranges from 0 to 100, with a SUS score of 69 considered an acceptable usability score in different studies [21, 22].

The Assistive Technology Device Predisposition Assessment (ATD-PA) tool evaluates user satisfaction with assistive technology based on their needs. It was adapted to assess participants' mobility, accessibility, positioning, and safety in daily environments. The tool included 12 questions rated on a 5-point scale [23].

The NASA-TLX measures the workload imposed by a given task [24, 25]. The short version used in this study consists of six questions, each addressing a unique dimension of workload: mental demand, physical demand, temporal demand, performance, effort, and frustration. Participants rated these six dimensions on a 0-100 scale. Each assessment tool included a comment section in each subscale for participants to describe their responses.

C. Data Analysis

Demographic questionnaire and wheelchair characteristics were described using mean and standard deviation. The SUS, ATD-PA, and NASA-TLX sub-scores were described with median and interquartile ranges since the data were not normally distributed. For hypothesis 1, the SUS and ATD-PA sub-scores were analyzed using a non-parametric Wilcoxon Signed Rank test for pairwise comparisons of usability and effectiveness between wheelchairs. Additionally, a minimum SUS score of 69 was considered an acceptable usability score. To test hypothesis 3, NASA-TLX median scores were calculated to ensure participants' task load demand to climb over curbs with MEBot was <40. A score of 40 falls within the lowest 25th percentile for tasks classified as 'robot operation' and 'medical tasks' [26]. The task load demand associated with their daily EPW driving was also recorded to create a baseline and facilitate a descriptive comparison, despite being a distinct task.

A datalogger with a built-in IMU was placed on the wheelchair frames to record acceleration and seat angles in three axes at a 100 Hz sampling rate for hypothesis 2. Discomfort was measured in terms of vibration exposure by calculating the total root-mean-square (RMS) and vibration dose value (VDV) following the ISO 2631 guidelines: Evaluation of human exposure to whole-body vibration [27]. The total RMS and VDV represented cumulative vibration and shock exposure over time. Seat stability was calculated by measuring the average magnitude of the peak seat angles in the pitch and roll directions during each driving task. The results were averaged and analyzed using within-subjects paired sample t-test to determine if MEBot significantly demonstrated higher seat stability and less discomfort than their EPWs on community driving tasks. The level of significance was set $\alpha = 0.05$ for all analyses. All statistical analyses were performed using Statistical Package for the Social Science (SPSS Inc., Chicago, IL). Participants' feedback was categorized into themes: Dimensions, Safety, Seating Functionality, Discomfort, Ease of Use, and Overall Effectiveness which encompassed SUS, ATD-PA, and NASA-TLX subscales and using NVivo 14 software.

III. RESULTS

A. Subjects

Ten experienced power wheelchair users (9 males, 1 female) aged 61.7 ± 10.9 years, with an average of 6.9 ± 5.4 years of EPW use, were recruited to evaluate the effectiveness and usability of MEBot compared to their existing EPWs in daily environments. Participants spent an average of 10.5 ± 3.3 hours per day in their wheelchairs and had impairments including Spinal Cord Injury (n=6), Multiple Sclerosis (n = 2), Stroke (n = 1), and Guillain-Barre (n =1). Their existing EPWs were evenly split between mid-wheel and front-wheel drive, featuring four seating functions (n = 9) and an EZ-lock mechanism (n =3) located under their EPWs for transportation securement. Participants with pressure injuries or those reporting back, pelvic, or thigh pain were excluded from the study. This criterion helps distinguish between discomfort caused by seating and discomfort from driving on uneven terrain. It also ensures that participants can tolerate sitting for the entire study duration.

B. Usability

Participants reported no significant difference in the usability of MEBot (75.8 ± 11.2) and their EPWs (91.8 ± 13.7) when navigating indoor and outdoor environments, both rated as having 'good' usability on the SUS scale. Participants

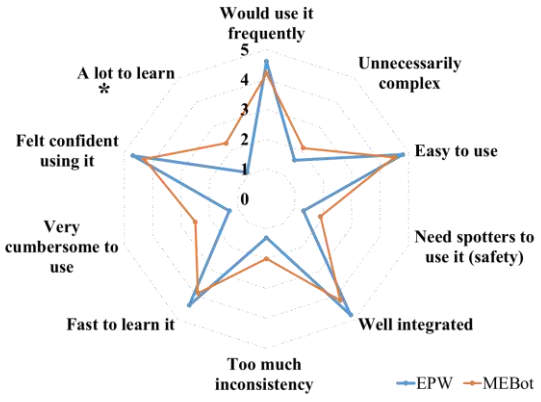

Fig 4. Usability Median sub-scores of MEBot and EPWs. *p <0.05

also indicated the need to learn more about the MEBot interface and applications compared to their EPWs (Figure 4).

C. *Effectiveness of wheelchairs to meet mobility needs*

Results showed no significant differences between MEBot and participants' EPWs in meeting their needs for mobility, accessibility, positioning, and safety in daily environments. Furthermore, participants rated both wheelchairs 4 or higher on each ATD-PA subscale. However, results indicated a coefficient of variation of 10% or higher in the subscales highlighted in Table I, suggesting variability in EPW users' preference to meet their mobility needs.

TABLE I. Effectiveness median and IQR sub-scores of MEBot and participants' EPW to meet users' mobility needs. No significant differences.

This device will	EPW	MEBot
Achieve my primary needs	5.0 [4.8 - 5.0]	5.0 [3.0 - 5.0]
benefit me and improve my Quality of life	5.0 [4.0 - 5.0]	4.5 [3.8 - 5.0]
give me confidence in using its features	5.0 [4.8 - 5.0]	5.0 [4.8 - 5.0]
make me feel more secure (safe) while using it	5.0 [4.0 - 5.0]	4.5 [3.0 - 5.0]
fit well with my routine	5.0 [4.0 - 5.0]	4.5 [3.8 - 5.0]
allow me to use it without stress/discomfort/fatigue	5.0 [4.0 - 5.0]	5.0 [4.0 - 5.0]
offer accommodations to use it successfully	5.0 [4.8 - 5.0]	5.0 [4.8 - 5.0]
physically fit the desired environments	4.5 [3.0 - 5.0]	4.5 [4.0 - 5.0]
make me feel comfortable using it around family	5.0 [4.8 - 5.0]	5.0 [5.0 - 5.0]
make me feel comfortable using it around friends	5.0 [4.8 - 5.0]	5.0 [5.0 - 5.0]
make me feel comfortable using it at work or school	5.0 [5.0 - 5.0]	5.0 [5.0 - 5.0]
make me feel comfortable using it around the community	5.0 [5.0 - 5.0]	5.0 [5.0 - 5.0]

D. *Task Load Demand when climbing over curbs*

Two participants rated a high mental demand, scoring over 40, when using MEBot to negotiate curbs. However, overall, the median NASA-TLX sub-scores met the hypothesis of being below 40. Participants also reported a low task load demand when negotiating curb with MEBot, similar to operating their EPWs in daily environments (Fig. 5).

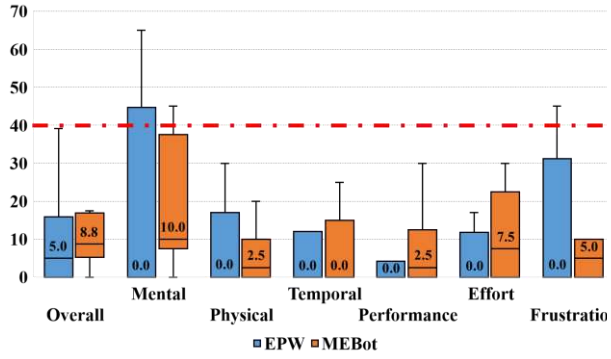

Fig 5. Median task load demand using MEBot to navigate curbs compared to daily EPWs use. Significant NASA-TLX sub scores >40.

E. *Stability and Discomfort Levels*

MEBot significantly reduced pitch and roll seat angle variations and discomfort, showing lower RMS acceleration than participants' EPWs in both indoor and outdoor environments (Table II). Both wheelchairs scored discomfort values below the ISO 2631 health caution safety threshold (RMS < 1.6 m/s^2, VDV < 9.0 m/s$^{1.75}$). Exceeding these values over one hour could pose risks to EPW users. These results were particularly representative of outdoor environments on uneven and inclined surfaces.

TABLE II. Overall stability and discomfort results of MEBot and participants' EPW in indoor and outdoor environments. *p <0.05

Wheel chair	RMS (m/s^2)	VDV (m/s$^{1.75}$)	Max pitch (deg)	Max roll (deg)
EPW	1.1 ± 0.4	6.6 ± 1.8	12.4 ± 4.4	12.7 ± 3.7
MEBot	0. 8 ± 0.2*	5.7 ± 6.6	7.8 ± 3.0*	7.7 ± 2.1*

F. *Participants feedback*

Participants' perception of MEBot's mobility applications and interface were categorized into the themes provided in Fig. 6. These themes combined subscales from the SUS, ATD-PA, and NASA-TLX assessment tools, along with a 'seating functionality' theme. Key codes highlighted areas for improvement in MEBot, including wheelchair footprint constraints, the need for power seating functions, positive feedback on the user interface, and the requirement for more time to assess safety and comfort when using the self-leveling and curb negotiation applications in outdoor environments.

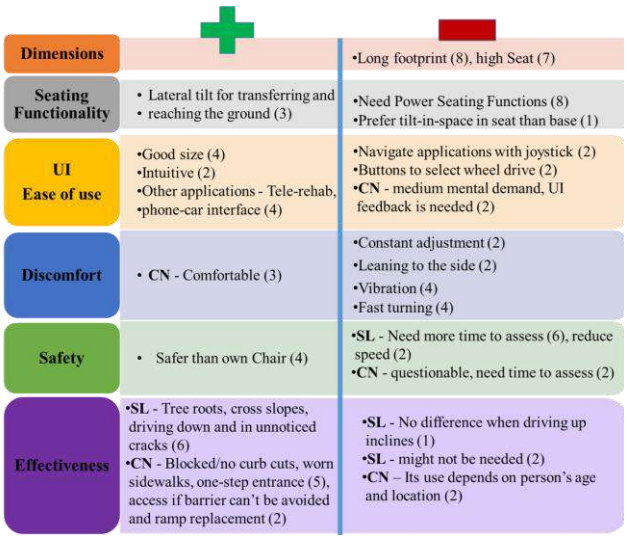

Fig 6. Participants' feedback on MEBot user interface (UI) and its mobility applications: self-leveling (SL) and curb negotiation (CN). Number of participants with similar feedback is indicated in parentheses.

IV. Discussion

The primary goal of the paper was to evaluate emerging robotic wheelchairs in real-world settings with the target population, focusing on their ability to meet mobility needs using both quantitative and qualitative outcome metrics. Specifically, the study assessed the usability and effectiveness of MEBot through a mixed-method approach, which

incorporated adapted assessment tools for robotic wheelchairs and gathered participants' perception of the device during navigation in real-world environments.

Participants reported that MEBot was similarly effective to their existing EPWs in meeting their mobility needs and improving their quality of life at home, work, and in the community. They also expressed high levels of confidence in operating MEBot and its potential to achieve their goals related to mobility, accessibility, safety, and repositioning. These results were further complemented by MEBot's higher stability and reduced discomfort compared to their EPW when navigating community environments. However, follow-up questions revealed additional insights that were not entirely aligned with the assessment tools responses. The findings were presented in themes related to the usability and feasibility of the device.

Dimensions: Although participants generally agreed that MEBot would physically fit desired environments better than their EPWs, eight out of ten participants experienced challenges maneuvering MEBot in indoor spaces such as toilet stalls and elevators due to its large footprint. In contrast, they were able to maneuver their EPW without issues.

Seat Functionality: Additionally, MEBot's seat height and lack of seating functions restricted participants from reaching bathroom sink counters. Although MEBot included seating functions available from the base using the 'manual screen'; its range of motion was comparatively less than their existing EPWs. This highlights the need for robotic wheelchair designs to incorporate the beneficial features of existing EPWs, including power seating functions and seating accommodations to meet user needs.

User interface Ease of use: MEBot demonstrated similar usability responses to participants' EPWs for operating its mobility applications and interface in indoors and in the community. Despite no statistical difference in SUS results, participants favored using their EPWs, likely due to their extensive experience using their wheelchair interface compared to the novelty of the MEBot interface. For example, while two participants found the MEBot interface intuitive to learn, three reported that it had complex features, indicating variability in preferences. Suggestions included reducing the number of screens and integrating all mobility applications into one screen. Additionally, dexterity is a crucial factor when developing touchscreen interfaces, as wheelchair users may have difficulties interacting with them. Two participants recommended alternative options for operating the MEBot interface, such as navigating and selecting applications with a joystick or using physical buttons, similar to the operation of their power seating functions.

Unexpected findings revealed that participants were comfortable with the dimensions of the 18 cm interface for visualizing options and did not expect physical interference with their daily activities. Furthermore, participants suggested that the large interface might offer additional applications for telerehabilitation or phone-car connection, similar to personal vehicles using Android Auto and CarPlay.

Effectiveness to meet mobility needs: When navigating in the community, more than half of the participants highlighted the potential benefits of self-leveling and curb negotiation applications enhancing safety and accessibility in challenging daily environments. More than half of participants suggested that the self-leveling can be useful for navigating over cracked sidewalks due to tree roots, cross slopes caused by driveway architecture, and for feeling safer and more stable when driving down steep streets. However, two participants felt that the self-leveling application was unnecessary due to the accessibility of their community, implying that MEBot applications might be less critical in urban areas with accessible infrastructure. On the other hand, participants who lived in rural areas acknowledged the benefits of MEBot applications where curb cuts are not commonly available and the likelihood of encountering uneven surfaces is higher.

Regarding the curb negotiation application, participants reported a great benefit of the application, specifically when curb cuts are less available due to construction or obstructed by crowds (e.g. at schools).

Safety and Discomfort: Participants concur with the autonomy of MEBot to complete the negotiation process but suggested visual or audio feedback when MEBot approaching the curb and while navigating over curb to reduce their mental demands and for situational awareness. Furthermore, one participant suggested locking the joystick to prevent unintentional use and human error.

Regarding the self-leveling application, participants suggested reducing the speed when descending slopes to minimize the risk of tipping forward. One participant noted no difference when driving up inclines compared to their EPW, suggesting that the actuation of the self-leveling application could be minimized in these scenarios. Participants did not report discomfort when operating the curb negotiation application but highlighted the constant adjustment and vibration sensation when driving outdoors with the self-leveling application activated. It was observed that the nature of the omnidirectional caster wheels to have gaps between their smaller wheels amplifies the vibration. The constant adjustment of the self-leveling can be optimized by increasing the tolerance of the inclination while keeping stability.

Most participants were not confident enough to assess the safety of both mobility applications in the driving course due to the limited time for the study and participants availability. This is a common concern for pilot studies evaluating the feasibility of the device. After addressing participants' feedback, the feasibility of the robotic wheelchair can be evaluated in participants' own environments for a longer period of time.

Limitations: The findings demonstrated that assessment tools may offer quantitative evidence to meet users' needs; however, there is evidence of ceiling effects, with participants rating high scores that reduce the tools' discriminatory power. Therefore, follow-up questions are important to gather the rationale of their responses, particularly to meet users' needs with different levels of impairment and living conditions.

The limited time and a small sample size were limitations in gathering in-depth feedback to address the mobility needs in their own environments and for people with different levels of impairment. For example, receiving only 15 minutes of training for a complex robotic wheelchair is likely inadequate.

Users may not have had sufficient time to become familiar with MEBot's controls and features, affecting their performance and perceptions. Furthermore, the novelty of MEBot compared to participants' EPWs could result in initial difficulties that skewed usability assessments unfavorably.

Existing EPWs are limited to overcome shallow curbs, restricting an effective assessment of MEBot curb negotiation application. For this case, efficacy and usability evaluation could be conducted a following a list of design criteria and through adapted standardized tools and new usability tools to evaluate novel mobility applications. With new technology rising, comparison could be performed between novel robotic wheelchairs

V. Conclusion

The findings highlighted the use of a mixed-methods approach to assess the usability and effectiveness of a robotic wheelchair in real-world environments. This study provides evidence of translational research addressing mobility needs unmet by existing EPWs, while also acknowledging the importance of incorporating the beneficial features of EPWs into the design of emerging robotics wheelchairs.

Future research should focus on developing adapted assessment tools tailored to individual mobility applications of this technology. Furthermore, longitudinal studies could offer deeper insight into the long-term effectiveness of robotic wheelchairs in enhancing the quality of life of wheelchair users.

Pilot Testing of Dynamic Bayesian Optimization for Exoskeleton-Assisted Training of Propulsion Mechanics

GilHwan Kim, Haider Chishty, and Fabrizio Sergi

Abstract— **Human-in-the-loop (HIL) optimization has proven effective in assistive paradigms, but has yet to be translated to training paradigms. One challenge towards the implementation of HIL algorithms for training relates to the inability of conventional HIL optimization methods to account for neuromotor learning that can occur during training.**

In this work, we present our implementation of dynamic Bayesian optimization (DBO) in a single-parameter HIL optimization experiment targeting changes in propulsion mechanics - specifically an increase in the trailing limb angle (TLA). Five participants were exposed to exoskeleton-applied hip torque pulses while walking on an instrumented treadmill in user-driven walking conditions. Outcomes from this experiment were validated against an active control condition, where conventional Bayesian optimization (BO) was used.

Experimental results showed significant increases in TLA in both the early and late portions of the no torque, post-training session, under the DBO paradigm, while no significant increases were observed under BO; however, no significant increases in TLA were observed during training at the group level. A linear mixed model revealed a weak, albeit significant, effect of applied torque on the change in TLA relative to baseline, suggesting that modulation of TLA is not easily achievable under this paradigm. Future work will expand the optimization paradigm to use more parameters or target different metrics of propulsion mechanics.

I. INTRODUCTION

Robot-assisted gait training is attractive due to increased consistency, efficacy, and repeatability compared to standard approaches [1], [2]. During training, target outcomes can be met by applying a specific amount of assistance to the user; the optimal level of robotic assistance is often estimated based on previous observations of participant responses. The identification of this input-output relationship requires a large amount of observations; a primary limitation is efficiently gathering enough participant observations without inducing fatigue.

Previous approaches resolved the requirement for many observations by using group-averaged data to estimate participant responses [3]; unfortunately, group-averaged data eliminates the variability between participants, resulting in sub-optimal levels of assistance being applied during training to a specific individual. Human-in-the-loop (HIL) optimization has been introduced as a method to identify participant-specific optimal conditions in fewer observations by tuning control parameters in real time [4], [5]. This strategy has been successfully implemented using different optimization methods [6], [7], [8], [9].

HIL optimization has previously been implemented in assistive paradigms, seeking to minimize metabolic cost by modulating robot assistance; such paradigms require longer bouts of walking due to long measurement times required to establish metabolic-based metrics at each iteration [4], [6], [7], [8]. HIL optimization may also be beneficial in training paradigms that seek to modify motor coordination in desired directions with immediate outcomes established based on fewer observations. However, a limitation of conventional optimization techniques with regards to motor training and rehabilitation is that the dependency of participant response on training history is not considered. This flawed assumption limits the capacity of optimizers to account for changes in participant responses due to neuromotor learning, whereby participants modify their actions in response to external stimuli, resulting in changes that may persist when the stimulus is removed [10]. Therefore, there is a need to augment HIL optimization techniques to account for human learning dynamics, and to validate such techniques in walking-related outcomes [11].

One method for adapting existing HIL optimization algorithms to dynamic cases is to allow the optimizer to learn the time-dependence of the input-output relationship for a specific optimization problem. Dynamic Bayesian optimization (DBO) is a modification of Bayesian Optimization (BO) that heuristically corrects the covariance between different inputs based on when the inputs were applied in time [12], [13]. While DBO had previously been validated to address time-varying systems, it has yet to be validated for a HIL optimization training paradigm [12], [13], [14]. We have previously presented the application of DBO in simulated paradigms in the presence of learning [15]: our results suggest that DBO may improve the performance of HIL optimization over BO once a sufficient number of iterations had been evaluated.

The work presented here is an extension of our previous work on HIL optimization that also includes an experimental validation via a training paradigm with human participants. A suitable target for a robot-assisted training paradigm should be an indicator of walking function. In this work, we selected to target the kinematic component of propulsion, quantified by the trailing limb angle (TLA) [16]. We validate the efficacy of DBO by implementing it in an optimization algorithm seeking to increase participant TLA during training relative to a baseline.

II. METHODS

A. Dynamic Bayesian Optimization

A detailed description of DBO is provided in our previous work [3], [15], but will be synthesized in this section. BO is a probabilistic approach to determining an (optimal) input value that minimizes a cost function based on the output of a system that is observed with measurement error [17]. Given these observations and a covariance function describing the relationship between changes in input to output, BO constructs a Gaussian process (GP) model which estimates outputs resulting from unobserved inputs. The GP model is used iteratively to identify the next input most likely to maximize some acquisition function, towards determining the optimal input relative to the cost function.

BO assumes the system to be stationary; i.e., repetitions of inputs are expected to result in similar outputs, an assumption that is inaccurate for the case of neuromotor learning. Thus, BO was augmented as DBO to account for system responses that may change with time. To that end, the covariance function $k(u, u')$ between inputs u and u' is modified by introducing the time variable t as $k((u,t),(u',t'))$, where t and t' are the corresponding time instances of inputs u and u' respectively. Assuming the time component of the covariance function to be separable [13], [18], the overall covariance function is described as a multiplication of the static component of the covariance function k_u with a dynamic component k_t, as

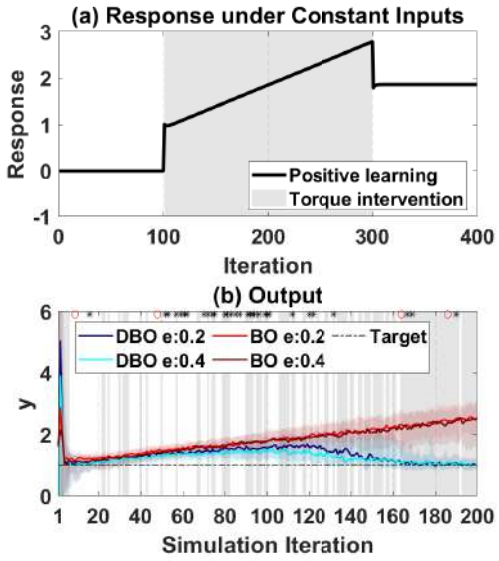
$$\begin{aligned} k((u,t),(u',t')) &= k_u(u,u') \cdot k_t(t,t') \\ &= \sigma^2 \cdot \exp\left[-\sum_{p=1}^{r} \frac{\tilde{u}_p^\top \cdot \tilde{u}_p}{2 \cdot l_p^2}\right] \cdot (1-\alpha)^{|t-t'|} \end{aligned} \quad (1)$$

where r is the number of input/control parameters and $\tilde{u}_p$ is the difference between the p-th input parameter of the input parameter arrays u and u' ($u_p - u'_p$). l_p is the p-th length scale hyperparameter, which influences the function's sensitivity to differences in parameter inputs, and σ^2 is the measurement variance. Finally, $\alpha \in [0, 1)$ is a hyperparameter that defines the time scale of the dynamic component of the covariance function.

B. Validation in Simulation

Validation of DBO was done in HIL simulations featuring a virtual human response based on a state-space model that we have previously established, capable of accounting for key features of human responses to exoskeleton-assisted training of propulsion [19], referred to as the modified use-dependent learning model (modified UDL). The validation will be summarized from the original paper [15].

HIL simulations were performed towards validating the performance of DBO relative to BO. Performance was defined in terms of convergence, by examining at which iterations error metrics using DBO became significantly lower than those using BO, if at all. In all simulations, the optimizers were only privy to system outputs, i.e., the optimizers were not aware of the true structure of the systems.



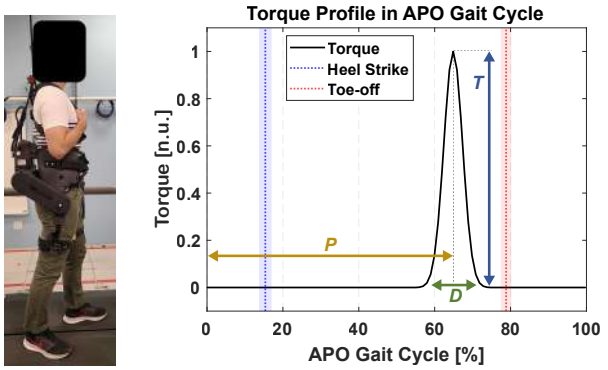


Fig. 1: Simulation results for the modified UDL model with "positive learning". (a) Model response before, during, and after constant input (u = 1) (b) Observed model output to HIL simulations: Solid lines represent the median output of each optimizer; corresponding shaded regions represent the 20th to 80th percentile over all repetitions. Shaded gray regions indicate iterations where optimizer type exhibited a significant difference ($p_{unc} < 0.05$). Different exploration-exploitation ratios (e:0.2 or 0.4) were also investigated during this validation.

One of the simulation models, "positive learning" model - where the response continuously increases with positive stimulus used in simulation - is presented in Fig. 1a for case where a continuous constant input is applied. 50 simulations were performed for the "positive learning" modified UDL model, each lasting for 200 iterations following three initial inputs, selected randomly but consistent across simulations. The goal of these optimizations was to achieve a response of $y = 1$ (i.e., minimize the cost function $g = (y-1)^2$). The response y can be interpreted as the hip extension or trailing limb angle of a participant during gait training. Fig. 1b shows the results of this validation: as is seen, DBO-based HIL optimization simulations eventually converged to the desired output value, in contrast to BO-based optimization simulations which continuously diverged from the desired output in presence of learning.

C. Experimental Methods

1) Equipment: Robot-assisted training was provided through an Active Pelvis Orthosis (IUVO, Pisa, Italy), or APO, a bilateral hip exoskeleton (Fig. 2a) with a weight of 6 kg. The APO features an onboard encoder used to measure the hip flexion/extension angle (resolution: 0.015 deg, log rate: 100 Hz).

Based on the measured hip joint angle, the APO predicts the participant's gait phase and total hip joint angular profile using adaptive oscillators [20], [21]. The gait phases are estimated individually for the left and right leg. Based on these predictions, the APO applies assistive/resistive torques to the hip joint as Gaussian shaped profiles. These profiles

(a) (b)

Fig. 2: (a) Experimental setup including the APO, instrumented treadmill, motion capture system, and safety harness. (b) Commanded torque profile in the APO Gait Cycle domain (0%: peak of hip flexion). Mean and std. of heel-strike and toe-off timings are provided by the blue and red distributions respectively. Control parameters that define the assistive profile are labeled.

are defined by three parameters: pulse amplitude (T), peak timing (P), and pulse duration (D) (Fig. 2b).

In this experimental study, participants experienced a single torque pulse profile on the right side at each stride. The duration of the applied torque profile D was set to 10% of the gait cycle, generating a brief torque pulse (pulse-width at half maximum: 5.9%). Timing of peak torque P was set to be 65% in the APO gait cycle (0%: peak of hip flexion), corresponding to the torque pulse being applied at the end of the stance phase. The amplitude of the torque pulse T was updated iteratively via a real-time controller in Simulink (MathWorks Inc., Natick, MA, USA) which communicated with the APO via a Serial Peripheral Interface connection at a frequency of 400 Hz; the update was performed during the swing phase (no torque applied), ensuring that it would be executed by the APO in the ensuing stance phase.

An instrumented, split-belt treadmill (Bertec Corp., Columbus OH, USA) was used to collect analog force/torque data via two force plates embedded within the treadmill. Control signals for the treadmill were sent from a Simulink-based controller running at a frequency of 400 Hz. To measure effects on propulsion mechanics in ecological conditions, we implemented a user-driven treadmill controller such that treadmill velocity changed in response to participant walking behavior [22].

Gait kinematics were assessed via motion capture, using a ten T40-S (Vicon Motion Systems Ltd, Oxford, UK) camera system, which tracked four retroreflective markers located on the right and left malleoli of the participant, and on the right and left side of the APO, coinciding with the exoskeleton's (and thus the user's hip) axis of rotation. Real-time marker location was recorded at 100 Hz and communicated in real-time to the Simulink-based controller for processing and optimization purposes. For safety, a harness system (Solo-Step Inc., North Sioux City, SD, USA) installed with an overhead track was used during all experiments.

2) Study Participants and Experimental Procedure: 5 healthy participants (3 female) of age (mean $\pm$ std) 25.4 $\pm$ 2.5 yrs, height 167.6 $\pm$ 8.6 cm, and mass 70.0 $\pm$ 14.7 kg were recruited for this study (protocol approved by the University of Delaware Institutional Review Board, protocol no. 1755609-7). Participants performed the experimental paradigm twice within the same day, separated by at least ten minutes of rest to avoid fatigue and reduce leftover training effects. The two experiments differed by which optimizer was used (DBO vs. BO), with the order randomized between participants.

Prior to the first experiment, the APO was fit to the participant such that the rotational axis of the device aligned with the user's hips. The device was secured once the participant confirmed comfort. Reflective markers were placed on the user and device, and a safety harness was secured. Participants then began a familiarization procedure to acclimate to walking with the exoskeleton on the user-driven treadmill.

Familiarization occurred for at least 150 strides. The treadmill was initially set to a constant speed of 1 m/s, switching to user-driven mode once 10 strides had been completed. During this session, the exoskeleton was set to transparent mode, minimizing interaction forces/torques between the user and device.

The experiments began once familiarization had been completed. Each experiment consisted of three consecutive sessions: a baseline session without robotic interventions, a training session featuring torque input from the exoskeleton, and an post-training session to evaluate post-training effects, in absence of robot input. During the baseline session, participants walked on the user-driven treadmill for 100 strides. The last 20 strides of this session were used to quantify baseline values for metrics of propulsion mechanics.

During training, the exoskeleton applied extension torques to the right hip joint towards increasing the trailing limb angle of the right leg relative to baseline. This session lasted for 40 iterations of optimization, with each iteration lasting for 6 to 7 strides (depending on HIL algorithm execution time). The torque applied to the user within each iteration was constant.

Following torque intervention, the post-training session lasted for 100 strides, with no torque being applied to the user, to quantify residual training effects left over from the robot assistance. Upon completion of this session, participants removed the exoskeleton and harness, and rested for at least ten minutes, before repeating the experimental procedure with the alternate optimizer.

3) Optimizer Setup: The objective of this HIL optimization paradigm was to increase the TLA of the right leg during stance by a target amount relative to baseline, ΔTLA^*, set to +3 degrees for this experiment. Thus, the optimizer cost function was defined as $c_i = |\Delta\text{TLA}_i - \Delta\text{TLA}^*|$, i.e., at iteration i, the absolute difference between the current change ΔTLA_i (relative to baseline), and the target change ΔTLA^*. Only the average of the first five strides at each iteration were considered for calculating ΔTLA_i, with the exoskeleton continuing to apply the same input later until the optimizer

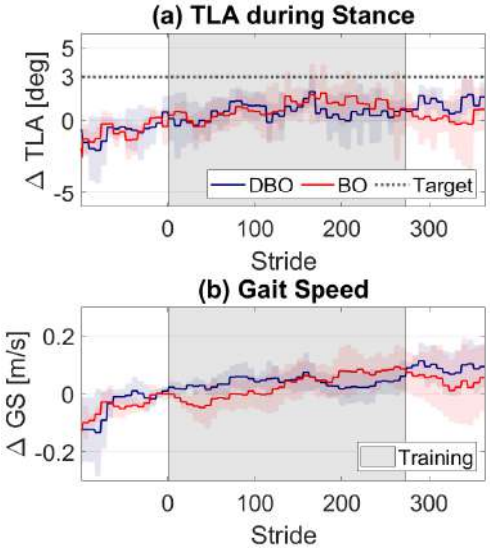

Fig. 3: Group analysis of the changes in (a) TLA, and (b) Gait speed (GS) compared to baseline for each stride. The solid line indicates the group mean at each iteration, repeated over strides, and the shaded area extends by one std. Stride numbering begins during the Training Session.

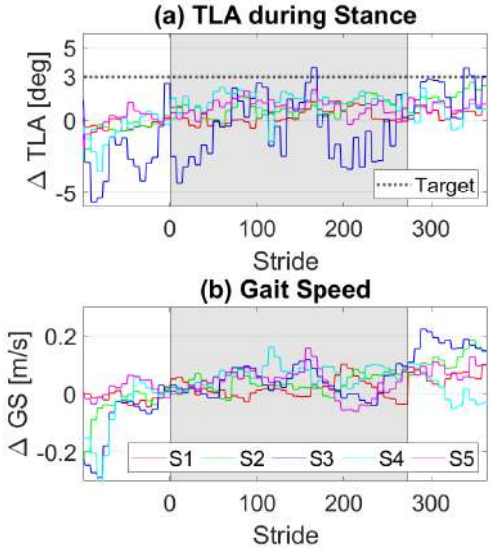

Fig. 4: Individual participant data under DBO for the change in (a) TLA, (b) GS, relative to baseline. Each color represents response from a participant.

identified a new solution for the new optimizer iteration. Computation of the following inputs took an additional 1-2 strides in our current setup.

The optimization pursued in this study was a single-parameter optimization with the only tunable parameter being torque pulse amplitude T, with bounds of 0 and 9 Nm, applied in the extension direction. To initialize the optimizer, the inputs applied in the first three iterations were fixed, such that the applied torques at these iterations were 0, 7, and 3 Nm respectively. Expected improvement was selected as the acquisition function of the optimization based on previous simulations [3]. Further, the exploration-exploitation ratio (e-ratio) was set to 0.4, also based on previous analysis [15]. This tunable ratio is bounded at [0 1], and promotes the optimizer to favor one optimization strategy over the other; a higher e-ratio results in greater exploration.

4) Data Processing and Analysis: Forceplate and retroreflective marker data were filtered in real-time during the experiment with low-pass Butterworth filters with cutoff frequencies of 100 and 60 Hz, respectively. Forceplate data were used in real-time to identify gait events and distinguish strides; kinematic marker data was used in real time to calculate TLA for each stride.

The angle between the vertical axis and the line connecting the hip and ankle markers in the sagittal plane [23] was calculated as a timeseries for each stride; we used the maximum angle over the stance phase of this time series as our measure of TLA.

Outlier removal was performed by removing TLA measurements outside of a $\pm$ 35 degrees range; after removing outliers, a median filter with 51 sample window size (127.5 ms) was applied.

Hip extension angle (HE) was determined based on encoder measurements from the APO, and the peak value during the stance phase was identified. Participant gait speed (GS) was defined as the average treadmill speed over each stride.

Baseline values of the above metrics of propulsion mechanics were defined as the average over the last 20 strides of the baseline session. Baseline values were subtracted from measured metrics to determine outcomes relative to baseline: ΔTLA, ΔHE, and ΔGS.

Individual participant responses were averaged within each iteration during training. For baseline and post-training sessions, responses from 7 strides were averaged for visualization. Individual participant responses were then averaged to construct group mean responses.

Baseline values were compared to the final 3 iterations of training, and both the initial and final 3 iterations of post-training to establish if either optimization algorithm induced changes in propulsion mechanics during and after training.

To study the mechanism under which robot-applied hip torque modulated TLA, we investigated the association between T and the change in TLA relative to baseline (ΔTLA) - the input and output of the training paradigm respectively - while controlling for changes in participant GS relative to baseline (ΔGS), as GS is a known covariate of TLA [24], [25]. This was done by building a linear mixed model with T, ΔGS, and their interaction as fixed effects, and participant as a random factor, which allowed us to study how these factors influence the outcome - ΔTLA.

III. Experiment Results

A. Training-induced changes in propulsion mechanics

Group level measures of changes in propulsion mechanics relative to baseline (ΔTLA and ΔGS) over each experimental session are displayed in Fig. 3.

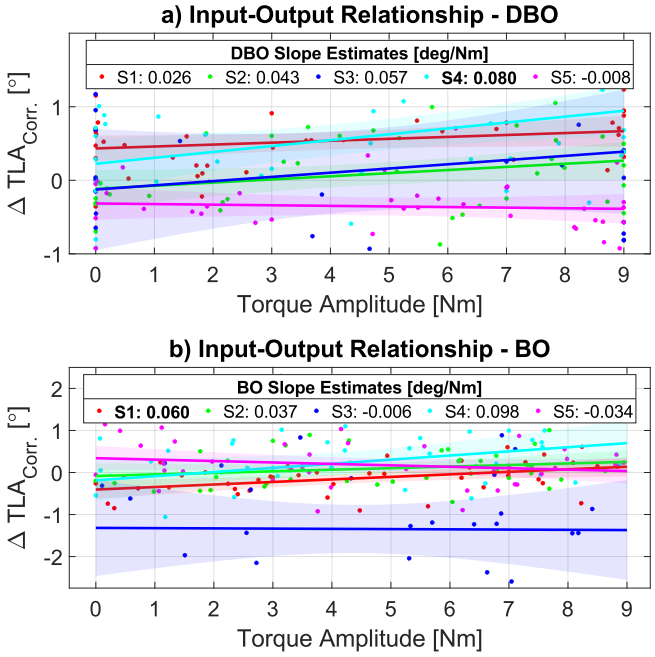

Fig. 5: Relationship between changes in TLA relative to baseline, corrected for the linear effect of GS, and T, for each iteration. Bolding in legends indicate which estimates are significant at the single-participant level ($p < 0.05$).

As is visible, neither optimizer was able to achieve the targeted 3 deg increase in TLA during training at the group level; however, significant increases were found in the post-training session. Notably, under DBO, TLA increased relative to baseline in both early and late portions of the post-training session (ΔTLA mean $\pm$ s.e.m: 1.039 $\pm$ 0.139 deg, $p = 0.002$, and 1.485 $\pm$ 0.367 deg, $p = 0.016$, for early and late post-training respectively). No significant effects were found under BO. Across optimizers, TLA significantly increased compared to baseline only during the early portion of post-training (0.721 $\pm$ 0.279 deg, $p = 0.029$).

Individual participant responses to DBO optimization are visible in Fig. 4, where the large variability of ΔTLA between iterations can be observed, even in the absence of torque inputs. It can also be observed that the desired increase in TLA was in fact achieved within a 1 deg accuracy in 4 out of 5 participants at some point during training. The largest participant-specific change in TLA observed during training under each optimizer is provided in Table I.

The effects of training on GS were qualitatively similar to those as TLA, in part as expected given that TLA scales positively with GS [24], [25]. Across optimizers, GS increased in the late portion of the training session (ΔGS mean $\pm$ s.e.m: 0.070 $\pm$ 0.018 m/s, $p = 0.004$), and the early portion of the post-training session (0.085 $\pm$ 0.018 m/s, $p = 0.001$).

At the optimizer-specific level, GS under DBO only significantly increased compared to baseline during the early portions of the post-training session (0.102 $\pm$ 0.016 m/s, $p = 0.003$), and under BO only significantly increased during the later portion of the training session (0.088 $\pm$ 0.030 m/s, $p = 0.041$).

TABLE I: Largest Change in TLA during Training for Participants

Participant	1	2	3	4	5
DBO (deg)	1.391	2.017	3.703	2.919	2.286
BO (deg)	2.414	1.846	7.144	3.438	1.432

B. *Effect of Torque Amplitude on Propulsion Mechanics*

The linear mixed model highlighted significant effects of both T and ΔGS on ΔTLA (Table II). This indicates that even after controlling for the known association between TLA and GS, the exoskeleton control input had an effect on the outcome. However, the strength of the association, while statistically significant ($p = 0.047$), was not very strong (slope = 0.032 deg/Nm, implying that even with a maximum applied torque of 9 Nm, TLA is only predicted to increase by about 0.3 deg after controlling for a linear effect of speed). For comparison, the same linear mixed model applied to the outcome of peak HE, yielded a stronger effect of T (p <0.001, slope = 0.801 deg/Nm).

Fig. 5 shows participant-specific associations between the T and ΔTLA, after correcting for changes in ΔTLA due to changes in ΔGS. This relationship was significant in only 1/5 participants when DBO was used, and 1/5 participants under BO.

TABLE II: Mixed Model Results: Fixed Effects for ΔTLA

Factor	Estimate	t ratio	Prob> $\|t\|$
T	0.032 [deg/Nm]	1.99	**0.047**
ΔGS	12.058 [deg·s/m]	12.72	**<0.001**
$T \cdot \Delta GS$	0.355 [deg·s/Nm^2]	1.31	0.189

IV. Discussion and Conclusions

This study builds upon our previous work towards validating the use of a dynamic HIL optimization algorithm (DBO) for robot-assisted training of propulsion. In this experiment, training was delivered by a hip exoskeleton that applied hip torques to the user's right leg. Training effects were compared to a no-torque baseline session, as well as a post-training session with no torque perturbations, to evaluate the effect of robot-training on the selected outcome measure.

Results of this pilot study indicate that the training paradigm was able to induce a positive increase in TLA in most participants during training, though this increase was not of the desired amplitude, nor was sustained during training. After training, TLA was significantly increased at the group level: across optimizers, TLA was significantly increased relative to baseline in the early portion of the post-training session, and under the DBO paradigm was significantly increased in both the early and late portions of the post-training session.

Statistical results from the linear mixed model indicate that the association between T and TLA is quite weak,

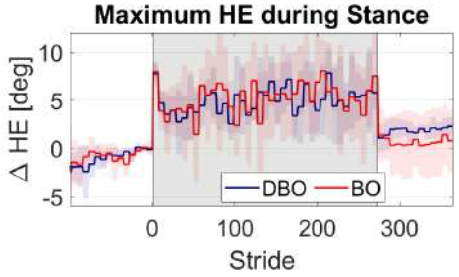

Fig. 6: Group analysis of the change in HE measured at each iteration, for both optimizers.

as evidenced by small estimated slopes and by the few significant cases at the participant level. This could indicate that the current target increase in TLA is too large for the current paradigm, and thus experimental modifications must be made before DBO can thoroughly be experimentally validated in a paradigm targeting TLA. One option is to open the optimization problem to more parameters, such as torque pulse timing (P) and duration (D) described in Fig. 2b, as done for assistive applications, which may lead to a stronger input-output control capability.

Alternatively. based on the strong association of T and increase in participant HE angle during training (Fig. 6), it may be beneficial to alter the paradigm to target HE instead. Performing the DBO validation on an HIL optimization paradigm with an output that is more reasonably sensitive to the applied inputs could better serve to evaluate the efficacy and necessity of using a history dependent optimizer.

One limitation of this study results from the lack of cross-validation trials, which prevented us from obtaining a direct comparison across optimizers that was not affected by the specific optimizer strategy at a given iteration. Cross-validation trials are critical for all applications of machine learning, but currently under-utilized in human-in-the-loop optimization methods [5]. In this work, online cross-validation can be done by incorporating sporadic validation iterations during training, where the estimated optimal input at that iteration is applied. This would allow for independent outcomes that can be compared across optimizers and will be explored in future work.

Multi-Linear Regressor for Static Posturography Estimation Through an Instrumented Cane

Max Burns, Kaymie Shiozawa, and Neville Hogan, *Member, IEEE*

***Abstract*—Measuring static postural sway outside of the clinic could provide clinicians with long-term, continuous data on patient balance, offering a comprehensive view beyond infrequent in-clinic assessments. This paper presents a novel method to quantify balance ability through a regression algorithm that predicts postural sway velocity using only motion and force sensors. Data is acquired through sensors onboard an instrumented cane. The prediction algorithm's validity was demonstrated in a study of eight young unimpaired subjects and eight adults over 65. The subjects' balance was challenged with different stance widths and sight conditions while using an instrumented cane. In the younger subject cohort, balance was further challenged through an unstable platform. Together, these conditions allowed for variation of the tasks' difficulty levels and thus the range of measured sway velocity. Across subjects, sway velocity was demonstrated to be highly predictable (Younger Subjects $R^2 = 0.73$, Older Subjects $R^2 = 0.47$) using just the sensors onboard the instrumented cane. In particular, hand motion was shown to be important in predicting sway velocity. We also demonstrated the use of data features to estimate Romberg quotients of the older participants, suggesting the method's potential to track proprioceptive function over time (Correlation r = 0.82). This method offers a promising approach to continuous patient monitoring and could provide a long-term, quantitative assessment of balance ability.**

I. Introduction

Falls pose a serious threat to the health and autonomy of people. Persons over 65, a demographic that is rapidly growing, are disproportionately affected by fall-related injuries and fatalities and have greater difficulty recovering from fall injury [1, 2]. Younger adults also suffer from falls and resultant injuries but recover faster and are generally more robust [3, 4]. In 2018, 27.5% of American adults over 65, or 35.6 million people, reported at least one fall [5]. These falls led to 8.4 million injuries and approximately 32,000 deaths [5]. Falls are also the most common cause of traumatic brain injury [6] and can result in bone fractures and other bodily trauma [1].

Timely and accurate assessments are crucial to identify people with acute fall risk. Although many falls occur while the body is in motion, static balance analysis has been shown to be a valuable predictor of future fall risk [7-9]. The three most common functional balance and mobility tests administered by clinicians are the Timed Up and Go (TUG) test, the 30-second chair test, and the 4-stage balance test [10]. Unfortunately, recent work has suggested that the TUG and 4-stage balance tests are not adequate predictors of fall risk [7, 11]. Furthermore, clinical assessments require a clinician to be present to conduct the analysis, limiting the frequency at which a patient can be assessed.

Instead, static postural sway analysis has been shown to yield more effective predictions of fall risk [7-9]. This analysis is traditionally performed by measuring the center of pressure (CoP) with a force plate in different conditions. In particular, the velocity of the CoP (sway velocity) has been found to correlate with fall risk [7-9]. When subjects stood with their feet shoulder-width apart, Lin et al. observed an average sway velocity of 2.26 ± 0.95 cm/s in older adults compared to 1.43 ± 0.41 cm/s in younger adults [12]. Higher sway velocity is observed in older adults and younger adults when balance is challenged.

Romberg quotients can be calculated as part of postural sway analysis. A Romberg quotient is computed by dividing a measure of balance when a subject's eyes are closed, by the same measure when eyes are open. The ratio can highlight abnormal increases in instability when vision is removed, which can indicate poor proprioception [13]. Prior studies have shown that sway velocity Romberg quotients effectively classify populations with various balance-affecting conditions [13]. A sway velocity Romberg quotient over 2.0 may indicate a proprioceptive deficit; for adults without balance issues, the quotient is expected to be 1.2±0.3 [14].

Postural sway velocity and Romberg quotients can be combined for fall risk prediction [8]. A fall-risk classifier proposed by Howcroft et al. used the anterior-posterior (AP) component and magnitude of sway velocity, and the two corresponding Romberg quotients in a linear classifier [8]. The model achieved a classification accuracy of 84.9% for 47 fallers and 42 non-fallers, based on follow-up surveys six months after data collection [8].

However, similar to clinical balance assessments, sway velocity and Romberg quotient analyses are typically confined to a clinic or lab setting, as they require stationary equipment (a force plate). At the same time, the frequency of clinic visits by older adults has been declining over the past two decades [15], highlighting the necessity for continuous

balance monitoring tools to be used outside the clinic.

Instrumented mobility aids offer a promising solution for continuous balance assessment. Patients with poor balance are already prescribed walking aids, such as canes or walkers, to reduce their fall risk. As a result, nearly six million people in the United States use a walking cane, the most popular mobility aid [16]. Given the growth of the 65+ demographic, the number of cane users is projected to increase significantly by 2035 [2].

Instrumented walking canes in prior work typically feature an accelerometer near the handle, an axial force sensor in the tip, and sometimes a measure of handle grip force [17-20]. Instrumented walking canes have demonstrated near-perfect rates of fall identification after a fall has occurred using accelerometer readings [19, 20], classified the user's motion (walking, running, stair climbing, etc.) using machine learning [18], and found correlations between cane sensor data and functional gait assessment scores given by physical therapists [17]. However, as far as the authors are aware, instrumented canes have not been used for quiet balance assessment or for future fall prediction. For in-home assessments, static, rather than dynamic, analyses may be safer for the user, as they only require standing in place.

The work presented here aimed to predict both sway velocity and the Romberg quotient, which are typically measured with a force plate during quiet stance, using a novel data processing pipeline and regression model. The data were collected using the instrumented cane first described by Shiozawa et al. [21]. As a preliminary test, a healthy young subject was asked to balance on an unstable platform while using the instrumented cane under various quiet balance conditions. When the subject was more unstable, the instrumented cane demonstrated a greater mean acceleration in the plane parallel to the ground. This result suggested that instability could be assessed using data from the cane [21].

Machine learning methods have been used successfully to quantify stability in the past. Greene et al. used a combination of body-mounted inertial measurement units (IMUs) and data about the user's physical characteristics to improve the accuracy of the TUG test from 60% to 80% for 226 fallers and non-fallers [22]. The authors used a logistic regression model for the classifier and set a cutoff value which could classify patients as "at-risk" [22]. Sway Medical Inc. used smartphone sensors to assess postural sway, but the sway measurement accuracy is not publicly available [23].

In this work, we describe the design and validation of a novel regression algorithm which uses instrumented cane data features to predict postural sway velocity and estimate Romberg quotients in static balance. To evaluate the accuracy of these measurements, eight unimpaired young subjects and eight subjects over 65 were evaluated under four balance conditions while using the instrumented cane. The data gathered from these experiments were used to train our regression model and estimate Romberg quotients. This is the first algorithm that has been shown to predict postural sway ability using just the sensors in an instrumented mobility aid.

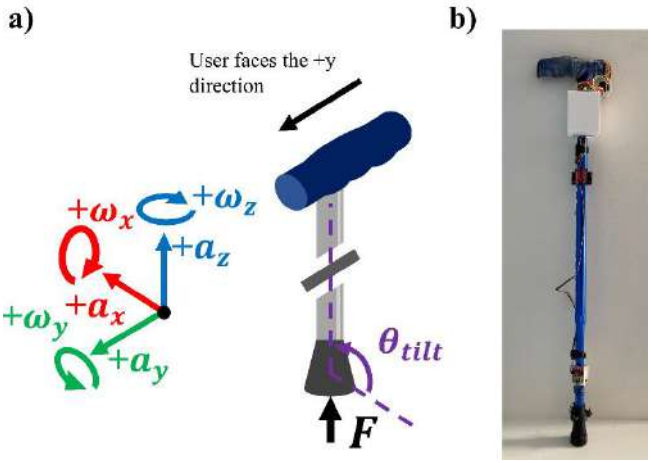

Fig. 1. a) An overview of cane sensor data outputs. Linear acceleration (a), angular velocity (ω), and orientation of the handle were collected from a 9-axis IMU. Absolute angle from the vertical axis (θ_{tilt}) was computed from the IMU's outputs. Axial force (F) was collected from a load cell inside of the cane tip. b) A photograph of the instrumented cane used in this study.

TABLE I. DATA VECTORS COMPUTED FROM COLLECTED DATA

Computed Data Vector	***Formula***

Tilt Angle, θ_{tilt}	*Quaternion Conversion*

II. CANE SYSTEM OVERVIEW

The design of the MIT Instrumented Cane and the data processing methods were based upon the instrumented cane system developed by Wade et al. [18]. A 1-axis load cell force sensor with a range of 0-250 N (FC2311-0000-0250-L, TE Connectivity Measurement Specialties) was connected to an amplifier (NAU7802 SparkFun Qwiic Scale) and installed within the ferrule of a commercially available walking cane to measure the force applied along the shaft of the cane. The range of the load cell was selected to encompass approximately 30% of a standard 75 kg subject's body weight [21]. A 9-axis inertial measurement unit (IMU) (SEN-14686 SparkFun VR IMU breakout) was fastened to the shaft next to the handle, which recorded 3-D linear acceleration, angular velocity, and orientation of the cane. Data were collected with a sampling frequency of 50 Hz. The raw data vectors gathered from the cane and their respective directions are indicated in Fig. 1. Four data vectors, which are outlined in Table I were computed with Python.

Data from the cane were recorded by an Arduino Leonardo, which transmitted the information to a nearby PC through USB Serial. A Python script on the acquisition PC was used to collect and organize the USB Serial input.

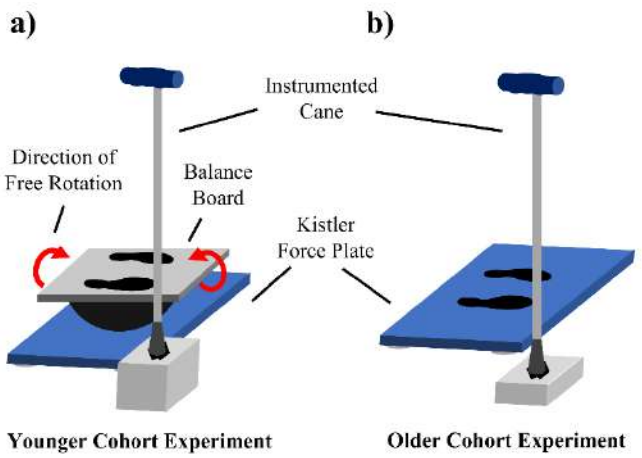

Fig. 2. Experimental setup. a) Young subjects were tasked with standing on an unstable balance board, which was placed on top of a force plate. b) Older subjects balanced directly on the force plate.

III. Experimental Data Collection

In this study, a measure of postural sway velocity and an estimate of a subject's Romberg quotient were sought. To validate that our algorithm can produce effective predictions of these measures, subjects participated in a balance experiment with the instrumented cane.

A. Participants

Eight young unimpaired human volunteers were recruited for this study, between the ages of 19 - 49 (Average: 25.4 ± 9.8 years). Young subjects were recruited to initially determine the validity of the prediction algorithms. All subjects in the younger cohort were inexperienced with using a cane and did not report any neurological or muscular issues which affected their balance. Subjects varied in height (1.65 ± 0.09 m) and mass (65.3 ± 13.2 kg), based on self-reported data. This experimental protocol was reviewed and approved by the Institutional Review Board of the Massachusetts Institute of Technology (protocol number 1912000067) on January 16, 2020.

Eight individuals over the age of 65 were also recruited to participate in a similar balance experiment to validate the instrumented cane's ability to quantify balance measures of the target population. Only community-ambulating individuals, who were able to walk a distance of 10 meters without assistance and stand in place for 5 minutes, were considered eligible for this study. Among these subjects, two were male (Age: 81.5 yrs, Mass: 77.3 kg, Height: 1.84m) and six were female (Age: 79 ± 6.9 yrs, Mass: 62.0 ± 7.1 kg, Height: 1.56 ± 0.12 m). Subjects ranged widely in age from 69-92 years at the time of collection. Six of the eight subjects were not affected by any self-reported balance conditions. Subjects varied in height (1.61 ± 0.12 m) and weight (67.3 ± 7.6 kg), based on self-reported data. This experimental protocol was reviewed and approved by the Institutional Review Board of the Massachusetts Institute of Technology (protocol number 2305000991) on June 15th, 2023.

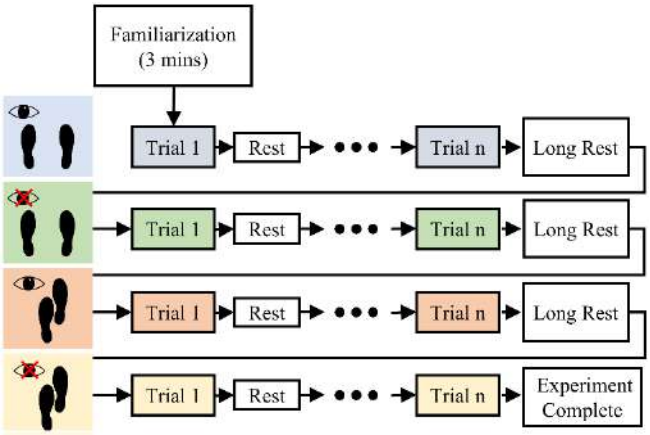

Fig. 3: The experimental protocol used in this study. Balance challenges are noted on the left, where the icons indicate the status of the eyes and positioning of the feet. A different number of trials, n, for each condition were performed by some subjects, based on subject ability and fatigue, summarized in Table II.

Younger Cohort	10 ea.	10 ea.	10 ea.	10 ea.	**240 ea.**

B. Experimental Protocol

In the experiments, subjects in the younger cohort stood on top of an unstable platform with the cane in their dominant hand, which was placed on top of a Kistler force plate. The platform was free to rotate within the subjects' sagittal plane, allowing them to rock forward and back, as shown in Fig. 2. The unstable platform was used to artificially inhibit the balance ability of the participants, and not to imitate a specific balance condition. Subjects over 65 stood directly on the force plate with the cane in their dominant hand, as shown in Fig. 2. The distance between the cane and the center of the base of support was kept constant across trials and subjects.

During the experiment, all subjects were asked to assume two stances, the first with their feet shoulder-width apart and the second in the half-tandem orientation, where feet are close together and slightly offset in the sagittal plane. Subjects were instructed to stand in both stances with eyes open and then closed, yielding four experimental conditions. These conditions were selected to induce a high variation of stability and sway velocity. The condition order is shown in Fig. 3 and was not randomized because preliminary experiments suggested that transitioning between conditions too frequently decreased subject consistency. The number of trials and conditions varied for each subject, depending on their physical ability and fatigue, and is summarized in Table II. Each trial duration was 36 seconds, which was selected

based on preliminary data to maximize the number of data windows extracted without exhausting participants.

For each trial, center of pressure (CoP) data were collected from the force plate at a sampling frequency of 50 Hz. Then, the average speed of the subject's CoP, sway velocity, was calculated over a ten second time window. The CoP computation did not include the force on the cane, as it was small enough to be neglected (an average body weight borne of $3.08 \pm 2.07\%$ for the younger cohort, $2.26 \pm 1.18\%$ for the older).

IV. Balance Measure Prediction Algorithm

To predict body sway velocity using motion and force data from the instrumented cane, we used a feature extraction pipeline and linear regression model to fit data to true sway velocity collected with a force plate.

A. Linear Regression Model for Sway Velocity Prediction

The preparation of data for use in a linear regression model is summarized in Fig. 4. To create test and train sets, stratified three-fold cross-validation was used to divide each subject's trials into three equal bins. Data were divided by trials to avoid pollution between folds. In three-fold cross-validation, each bin (33% of data) is used once as the test set for a model trained with the two remaining bins (67% of data). The stratification process was applied to avoid class imbalance between the four balance challenges, which would interfere with model training due to the dissimilar test and train datasets.

1) Windowing

For each trial, a ten second sliding window was applied, with 48% overlap between windows. This overlap was selected based upon prior work to maximize the number of data points produced per trial without causing overfitting [18]. The sliding window produced six windows for each 36 second trial. The total number of windows varied by subject and is summarized in Table II.

Window length and number of features used were selected through a parameter sweep using the MIT SuperCloud computing system [24]. Window lengths between 2 and 17 seconds and total feature counts between 3 and 16 features were examined in a 2-dimensional parameter sweep. A window length of 10 seconds and a feature count of 10 produced acceptable and stable R^2 values across subjects.

2) Feature Computation and Selection

Features were extracted from the raw data recorded by the instrumented cane [18]. Each feature was computed by applying a statistical method to one window of raw data. For instance, the "mean axial force" feature was computed by applying the "mean" method to a window of "axial force" data. Each method was applied to each raw data vector such that 108 features (9 methods for each of the 12 raw data vectors) were extracted for each window. The functions used for feature production are summarized in Table III.

For each model, a feature selection process was employed to minimize overfitting and eliminate ineffective features. An optimizer was used to select features from the training data

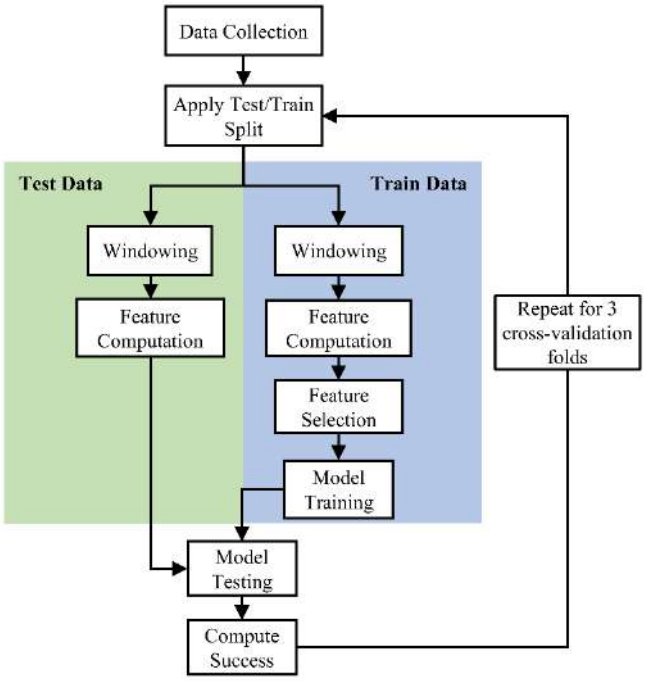

Fig. 4. A summary of the steps required to compute and evaluate the sway velocity regression model.

TABLE III. Data and Methods for Feature Computation

Data Vectors	Methods
X Acceleration, a_x	Mean
Y Acceleration, a_y	Median
Z Acceleration, a_z	Minimum
X Angular Velocity, ω_x	Maximum
Y Angular Velocity, ω_y	Range
Z Angular Velocity, ω_z	Interquartile Range
Axial Force, F	Standard Deviation
Tilt Angle, θ_{tilt}	Mean Absolute Deviation
Acceleration Magnitude, a_{mag}	Signal Energy
X-Y Acceleration, a_{xy}	
Angular Velocity Magnitude, ω_{mag}	
Tilt Angular Velocity, ω_{tilt}	

that strongly correlated with sway velocity while penalizing those that were closely correlated with each other, as described in Wade et al. [16]. This approach reduced redundancy and ensured that the chosen features were strong predictors of sway velocity. Feature selection was performed for each cross-validation fold based upon only training data to prevent contamination of test data. Using the methodology above, ten features were selected for use in linear regression. The feature selection process was conducted separately for the two cohorts, and training data from all subjects in a given cohort was used to select features for that cohort.

3) Model Training and Testing

Linear regression models were trained using each subject's feature data. While the training was specific to each individual's dataset, feature selection was based on data from the entire cohort for each cross-validation fold. Each model was then applied to the corresponding subject's test data set, and the predicted sway velocity was compared to the true sway velocity. Due to the random nature of the test-train split,

TABLE IV. PREDICTION RESULTS: 250 MODEL ITERATIONS

	Younger Cohort		Older Cohort	
Metric	R^2	$RMSE\left(\frac{mm}{s}\right)$	R^2	$RMSE\left(\frac{mm}{s}\right)$
SV (Mag)	0.73 ± 0.04	8.29 ± 0.51	0.47 ± 0.09	5.88 ± 0.37
SV (ML)	0.73 ± 0.04	6.43 ± 0.40	0.45 ± 0.09	4.71 ± 0.31
SV (AP)	0.57 ± 0.05	5.60 ± 0.36	0.36 ± 0.12	3.80 ± 0.24

TABLE V. "STRONG" FEATURES OBSERVED IN YOUNGER COHORT

Feature	Subjects with Correlation > 0.8	Avg. Correlation with Sway Velocity
ω_{tilt} Mean	8	0.88 ± 0.05
ω_{mag} Median	8	0.87 ± 0.05
ω_{tilt} Median	7	0.87 ± 0.05
ω_y Mean Abs. Deviation	7	0.84 ± 0.05
ω_y Interquartile Range	7	0.84 ± 0.05

TABLE VI. "STRONG" FEATURES OBSERVED IN OLDER COHORT

Feature	Subjects with Correlation > 0.8	Avg. Correlation with Sway Velocity
ω_{tilt} Mean	8	0.70 ± 0.10
ω_{tilt} Mean Abs. Deviation	8	0.69 ± 0.12
ω_{tilt} Interquartile Range	8	0.68 ± 0.13
ω_{tilt} Median	7	0.71 ± 0.12
ω_y Mean Abs. Deviation	7	0.66 ± 0.16

250 linear regression models were prepared for each subject, using test and train sets randomized through cross-validation. Average RMSE and R^2 values for the test data of each subject were calculated based on test set performance. [16]

B. *Identifying Common Important Features*

The selected features varied between models due to the variability of the test-train split. This variability made identification of common important features difficult. Instead, the Pearson correlation coefficient between sway velocity magnitude and each feature was computed for each subject. This correlation was not used for sway velocity prediction, so a test-train split was not applied. A feature with an absolute correlation of greater than 0.8 for the younger cohort, or 0.5 for the older cohort, was considered a "strong" feature for that subject. This process was repeated for each subject, and the strong features were recorded.

C. *Romberg Quotient Estimation*

Romberg quotients were obtained for the older subject cohort using the data from the instrumented cane. For this correlation analysis, no test-train split was applied. Romberg quotients were computed for all features, by dividing the feature vectors obtained during the eyes-closed trials by the feature vectors obtained during the eyes-opened trials. The correlation of these feature Romberg quotients to the true Romberg quotient (computed with the force plate sway velocity data) was evaluated for each subject. This analysis was confined to the shoulder-width stance condition, based on methods presented in prior work [13]. The quotient with the highest correlation was reported.

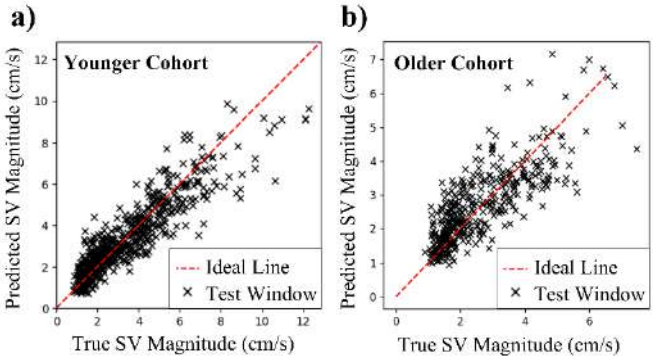

Fig. 5. Representative plots of the prediction of sway velocity magnitude for the a) younger and b) older subject cohorts. Each point is from one 10s window of test data from a subject. The diagonal line represents the ideal output, where the prediction error is zero.

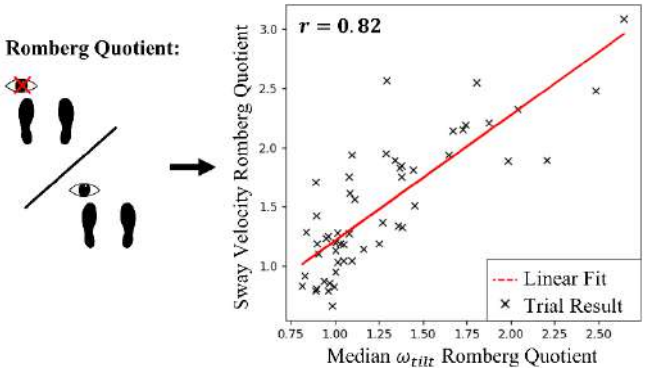

Fig. 6. A comparison between Romberg quotients computed from measured mean sway velocity and mean ω_{tilt} for older subjects in the shoulder-width stance. Each x icon represents the quotient computed from an eyes-open and eyes-closed trial for one subject. Data from all older subjects is displayed and used to compute the Pearson's correlation of $r = 0.82$ (p = 4e-14). A line of best fit, of which the slope was 1.06 ± 0.10 and the intercept was 0.15 ± 0.04, is shown.

V. RESULTS

Table IV summarizes the R^2 and RMSE values for each component of sway velocity, averaged across all subjects. For the younger cohort, an average R^2 value of 0.73 ± 0.04 was found between the linear regression result and the mean magnitude of sway velocity. For the cohort of subjects over 65, an average R^2 value of 0.47 ± 0.09 was observed for sway velocity magnitude. For the younger subjects, the highest average R^2 for sway velocity magnitude of an individual subject was 0.86 ± 0.05, while the lowest was 0.60 ± 0.12. For the older cohort, the highest average R^2 for a subject was 0.67 ± 0.13, and the lowest was 0.34 ± 0.31.

Fig. 5 demonstrates example models for the older and younger cohorts, which compared the predicted sway velocity magnitude of each data window to the true sway velocity magnitude for the younger and older cohorts respectively.

Tables V & VI summarize the features that displayed high Pearson's correlation with sway velocity magnitude for the two cohorts. Notably, features which described the magnitude and variability of ω_{tilt} (the angular velocity about the instrumented cane's base) were particularly well correlated with sway velocity magnitude for both subject cohorts.

For the older cohort, ω_{tilt} correlated most strongly (r-value of 0.82) with the true Romberg quotient in the shoulder-width stance. This Romberg quotient correlation across all older subjects is shown in Fig. 6.

VI. Discussion

Postural sway analysis can be used to estimate fall risk [8, 9] and quantify proprioceptive changes [13]. To our knowledge, this study is the first to estimate a user's sway velocity and Romberg quotient during quiet stance using only sensors onboard an instrumented mobility aid. Our results demonstrated that our algorithms were sufficient to both predict sway velocity and estimate the Romberg quotient across all participants using just instrumented cane data. Furthermore, aspects of the participants' hand motion were closely tied to body motion for all subjects. The Romberg quotients computed from instrumented cane metrics were found to have strong correlation with true Romberg quotients computed from sway velocity. This work provides support for future analysis of fall risk based upon long-term, continuous data from a portable, instrumented device.

In prior work, algorithms have been developed to classify activities or detect falls with instrumented cane data, but not to provide measures of balance health. The regression algorithm and Romberg estimation presented in this paper rely primarily on measurements from an IMU, and could be used to evaluate a user's balance throughout everyday life. This technology could bring dramatic change from the current standard of care, in which at-risk patients are evaluated for risk of falling a few times per year, if at all [10]. These estimations are accomplished by extracting useful feature information from the instrumented cane's data, which makes the models both easy to interpret and effective predictors of balance metrics. The features used in this work are static balance measures, but assessment of dynamic balance is a promising avenue for further investigation which could provide additional information. Future work could also conduct user-focused studies to assess adoption rates and preferences within older populations for this technology.

A promising relationship between predicted and actual sway velocity was observed, but predictions were strongest when sway variance was high. The younger cohort, likely more challenged due to the presence of the unstable platform and therefore exhibiting greater sway variance, achieved the highest average R^2 for sway velocity magnitude of 0.86; meanwhile, the older cohort's highest average R^2 was 0.67. Although older subjects displayed a smaller RMSE than younger subjects, their average R^2 values were lower. Similarly, the prediction accuracy for the AP sway velocity component was lower than for the medial-lateral (ML) component for all subjects. This result is also likely due to the greater variance of ML sway velocity across subjects and conditions. When sway velocity variance is low, the inherent noise between the true sway velocity signal and the interaction with the instrumented cane likely dominates. To improve predictive accuracy, future studies could collect more data to extract further useful feature information.

In both age cohorts, when subjects swayed more rapidly, it resulted in larger and more variable hand motion. Features with high correlation to sway velocity were primarily computed from ω_{tilt}, a measure of the planar motion of the hand. For example, mean ω_{tilt} had a very strong correlation with mean sway velocity (0.88 ± 0.05 for younger, 0.70 ± 0.10 for older), a finding that was consistent across all subjects (Tables V and VI). Three of the five strong features were shared between the two subject groups as well, and all strong features were computed from angular velocity components measured by the IMU. This is compelling evidence that hand motion and body sway are closely linked, and that this behavior is consistent across age and experience with assistive devices.

Median ω_{tilt} was found to correlate strongly with sway velocity magnitude for seven of the eight older subjects with an average correlation of $r = 0.71 \pm 0.12$ (Table VI). The Romberg quotient was computed for the older cohort, yielding an even stronger correlation of $r = 0.82$ between the Romberg quotients of mean sway velocity and the median ω_{tilt}. The Romberg quotient is a useful measure of abnormal proprioception. Therefore, the results suggest that data from the instrumented cane could quantify long-term proprioceptive trends, potentially signaling the need for intervention before a fall occurs. The older cohort's average Romberg quotient found from sway velocity (1.46 ± 0.52) was lower than the expected average for this population (1.94 ± 0.58, [13]), likely due to the cane's stabilizing effects.

Hand motion rather than force exerted on a cane may provide greater insight into the user's balance. Axial force features were not a strong indicator of sway velocity, and Romberg quotients computed from axial force exhibited poor correlation with true Romberg values. Since large forces applied to a walking cane are not necessary to provide greater stability [25], balance assessments using handheld assistive devices could focus on hand motion rather than force. The findings also agree with the work of Shiozawa et al., in which the mean acceleration, but not the mean axial force, of an instrumented cane was determined to be significantly different between various stability conditions [21]. Taken together, these insights suggest that the algorithms presented in this paper may only require IMU data to provide stability estimates.

One limitation of this study is that fewer trials were conducted for older adults compared to their younger counterparts to avoid fatigue. An average of 25.75 trials were collected per older subject, compared to 40 trials per younger subject. The larger dataset for younger subjects may have contributed to the higher variance accounted for compared to that of the older participants. Future studies could benefit from conducting multiple sessions with the same subjects to gather larger datasets and stronger predictions. Another limitation of this methodology is that using a cane artificially improves observed balance due to the physical support and haptic cues it provides [26]. Thus, it is important to note that this sway velocity estimate would be best applied by observing changes over time, rather than being used as a

stand-in for unsupported sway velocity.

Preliminary tests with nonlinear regression resulted in overfitting of the data and poor performance during test data evaluation. More advanced models trained with time series data may provide greater predictive ability for a larger dataset and are promising avenues for future work. Furthermore, the rate at which balance changes occur in an individual is a crucial area of future research. The algorithm presented in this work could be used to study daily changes in balance among a population of older individuals over months or years.

VII. Conclusion

This work demonstrated that the outputs of sensors onboard an instrumented cane can reliably estimate a user's postural sway velocity and Romberg quotient. Using a novel regression algorithm, the cane's motion data was crucial in predicting these measures for both unimpaired young subjects and those over 65.

Although the nature of falls is complex, postural sway velocity and the Romberg quotient are both important markers of a patient's balance health and can be incorporated into models to predict future fall risk [8]. The Romberg quotient, in particular, can indicate poor proprioception and overreliance on visual feedback for balance. Validating the proposed algorithm's ability to predict and compute these measures provides promising support for its eventual use as a tool to assess changes in balance ability. Equipped with the ability to predict balance performance via our custom regression model, the instrumented walking cane is envisioned to be an at-home monitoring device which measures a user's stability over the course of months or years, rather than during infrequent clinic visits. Such continuous monitoring could provide advance warnings of declining balance, potentially preventing falls. The proposed methods could complement a comprehensive balance assessment, informing physicians in developing treatment plans or determining the need for intervention.

Development and Validation of a Low-Cost Open-Source Force Myography Band for Hand Gesture Recognition

Giancarlo K. Sagastume, Peyton R. Young, and Jonathon S. Schofield, *Member, IEEE*

Abstract— **Wearable systems for hand gesture recognition have gained significant attention in research and clinical applications due to advances in many hand-centric control interfaces for technologies such as upper limb prostheses, hand exoskeletons, and virtual reality for rehabilitation. However, common hand gesture recognition techniques are often associated with high costs and proprietary software which can reduce the accessibility of these devices. Thus, in this work we developed, and feasibility tested a low-cost open-source alternative in the form factor of a wearable forearm band. Our system leverages force myography (FMG) which recognizes patterns in the radial muscle forces at the skin's surface on the forearm when different hand gestures are performed. Our FMG band was validated through a participant-based study (N=15) where able-bodied individuals were instructed to perform repetition of 10 hand gestures. Offline classification analysis of the resulting muscle force data using a linear discriminant analysis showed the band achieved an average of 94.28% accuracy among all gestures across all participants. These results suggest that despite the FMG Band's low cost, its performance is comparable to similar gesture recognition technologies currently available for research, clinical, and consumer applications.**

INTRODUCTION

The recognition of hand gestures is a critical component in controlling many emerging rehabilitative and assistive technologies, such as upper limb prostheses, exoskeletons, and virtual reality rehabilitation systems [1], [2], [3]. Effective operation of these technologies can be facilitated by human-centric control interfaces—those that are intuitive and non-intrusive for the user. Various human interface technologies exist to decode user intentions from naturally occurring biological signals during attempted hand motions, enabling accurate prediction of hand gestures. These technologies can use a variety of sensing approaches, including electrophysiological [4], acoustic [5], and optical [6] methods, among others. However, despite increasing demand for intuitive hand-gesture decoding strategies, many techniques remain experimental. Those that are commercially available are often cost-prohibitive and rely on proprietary software, which can further limit their accessibility and utility in research and clinical environments. This is particularly true when constrained by research or clinical budgets or when requiring access to customize signal acquisition methods to meet specific data collection and equipment integration needs.

One relatively new approach with the potential to address accessibility limitations is Force Myography (FMG), the measurement of radial muscle forces at the surface of the forearm. Unlike Electromyography (EMG), a popular sensing modality which requires stable skin-electrode contact [4], FMG is a non-electrophysiological method that captures muscle activity through mechanical deformation. The surface of the forearm changes in response to the contraction and relaxation of underlying muscles when hand gestures are performed, resulting in unique force profiles that can be detected along the forearm's circumference. To capture these profiles and use them as control signals, FMG typically employs a series of pressure (or force) sensors placed around the circumference of the forearm. Although a variety of different pressure or force sensors can be used to accomplish the task of measuring these radial forces, the most common is the force sensitive resistor (FSR). FSRs are thin-film components that decrease in resistance as force is applied. Their popularity in numerous commercial and hobbyist applications has resulted in a low unit price when compared to other sensing modalities. Thus, FMG presents a low-cost sensing technology for potential applications in hand gesture recognition systems.

However, as an emerging technology, FMG remains a largely experimental control modality with few to no clinical or consumer systems available for purchase. As a result, those wishing to leverage FMG technologies in research or clinical applications are left to create custom systems drawing upon scientific literature reporting disparate quantities of force sensors, amplification and signal conditioning circuitry, and fitment solutions [7]. Thus, in addressing accessibility challenges, the objectives of this work are to develop and evaluate a low cost, open-source FMG system that takes the form factor of a wearable forearm band.

I. DESIGN METRICS

A literature search was conducted to survey trends in wearable technologies for hand gesture recognition. From this, three key design characteristics guided the development of our FMG band: *fitment*, *accessibility*, and *modularity*. These factors and their implications are further defined below and their impact on our prototype design are highlighted

throughout the Electrical and Mechanical design section of this paper.

Fitment refers to how well a wearable device conforms to the users' anatomy. In the context of a wearable FMG system, fitment is critical because it directly affects the quality of contact between the force sensors and the user's forearm, which in turn impacts device performance. For instance, a band that fits too loosely may result in sensor contact loss or slippage on the forearm, leading to inconsistent or unreliable force measurements. Conversely, a band that is too tight may cause user discomfort and potentially saturate the sensors as they press with excessive force into the forearm tissue. These factors accentuate the impact of external forces and motion artifacts, making it a key quality to ensure signal reliability.

Accessibility was a primary consideration in our design and development process. We aimed to create an FMG device that leverages low-cost, off-the-shelf components and integrates existing open-source computational methods [8]. This approach ensures that the device remains affordable and widely accessible for various users and applications.

In the FMG literature, a range of force sensing modalities and fitment solutions have been reported [9]. To address this diversity, we prioritized modularity in our design. A modular system allows for easy removal and modification of sensor units, enabling compatibility with different sensor types, circuitry, and data acquisition systems. This flexibility supports the potential diverse needs of research and clinical applications. Furthermore, our design ensures that adjustments to fitment and mobility can be made with minimal effort by the end user (as described below).

II. Electrical and Mechanical Design

A. Electrical Design

FMG systems inherently rely upon force or pressure sensors to derive control signals from muscle activity. In literature, a variety of different sensor modalities have been reported to achieve this task. Barometric [10], capacitive [11], and strain transducer [12], technologies among others have all been used in previous works. However, we chose to develop our FMG system around force sensitive resistors (FSRs). FSRs are thin film, two-terminal sensors that decreases in resistance as force is applied to its surface. They are among the more common sensors in FMG applications owing to their widespread availability, low unit cost, low power draw, and reduced demand for complex circuits and signal conditioning when compared to other sensors [7], [13].

Toward the goal of designing an *accessible* system, our design used Interlink Electronic's FSR400. This choice was driven by the low cost and commercial availability of these sensors across multiple vendors internationally. Because FSRs are not active sensors, additional circuitry was required to acquire an analog output signal from these sensors. To obtain the difference in electric potential between ground and the FSR output, a voltage divider (VD) circuit was employed. The VD configuration comes with several benefits for use in FMG systems, such as its flexible voltage range, minimal-complexity design, and ease of tuning. In this configuration, an FSR is tied to the positive input voltage and its secondary lead is connected in series to a grounded reference resistor. The reference resistor controls the behavior of the FSR through limitation of current flow. Per manufacturer guidelines, a 7.5 kOhm reference resistor was selected to leverage the improved linearity in output voltage in response to an input force (force range 0-4N, pressure-voltage curve shown in [14]). Because of the VD's passive nature, input voltage was limited only by the FSR and resistor. While in this work we opted to use +5V, the FMG system can be powered through a wide range of voltage sources, including 3.3V. This further promoted our device's *modularity* by being capable integration with a wide variety of microcontrollers operating across this voltage range (Arduino, MSP432, etc.). An itemized bill of materials can be found in table 1, demonstrating the overall component cost of our system, being $162.60 USD.

B. Electrical Construction

Translation of the theoretical circuit design was done with consideration to reduce complexity. Following prior FMG literature, we opted to use 8 sensors [15] and thus, 8 VD channels (Fig. 1). The circuit was fabricated on a through-hole protoboard with accompanying resistors of the same style. Solder traces within the protoboard and jumper wires connected the components together. Two 10-pin DuPont connectors laid on the top and bottom of the board for quick connection of the FMG band and its analog output. Positive and ground jumper pins were soldered in place to feed the power supply voltage. A key aspect of this design is that the device can be used both in tethered or untethered fashion. This means that the analog output pins of the circuit can be fed to either a self-powered microcontroller or a benchtop power supply and data acquisition device (DAQ). In our validation study (described below), we chose to use the device in the tethered configuration. With the electrical portion completed, the FMG band itself could be constructed.

A. Mechanical Design

The mechanical design of the FMG band had the greatest impact on *fitment* and *modularity*. These two aspects governed the band's design as it needed to be able to fit a wide range of forearm sizes and accommodate other potential sensors.

The thin film composition of the FSR400 sensors lends to its small physical size and unobtrusive footprint. While this is helpful for physical space considerations and thus increasing the ability to incorporate additional sensors around a forearm, their construction required a custom designed housing to ensure effective measurement of forearm muscle forces. Sensor "cradles" were designed in SolidWorks to act as a hard backing for the FSRs, ensuring applied muscle forces would be directly translated into the FSR's sensing surface (Fig. 2). The cradles were designed with consideration to wiring management as each FSR requires a ground, voltage supply, and signal lead. This resulted in a T-shaped groove on the back of the cradles rear side and a negative shape of the FSR400 was cut from the front side of the cradle such that an FSR could rest flush with the top of the unit.

B. Mechanical Construction

Once printed, the cradles were outfit with FSR400 pressure sensors and accompanying wiring. To ensure consistent sensor

Item	Quantity	Cost Per Unit	Total Cost
FSR400	8	$2.99	$23.92
Velcro Strap	1	$8.49	$8.49
Velcro Adhesive Tape	1	$8.99	$8.99
30 AWG Flexible Cable	1	$12.99	$12.99

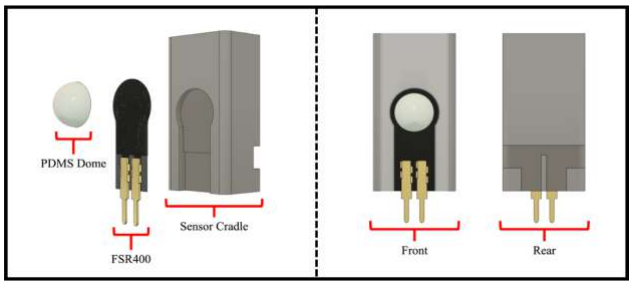

Fig. 2. Sensor cradle construction. From left to right: the exploded view of a single sensor cradle constructed of a PDMS dome, FSR400 sensor, and 3D printed housing; the front and rear view of an assembled sensor cradle.

placement, liquid adhesive was applied to affix the FSR in the appropriate position on the cradle. The sensing surface of each FSR was carefully fit with a small adhesive polydimethylsiloxane (PDMS) dome. This was done to ensure the even spread of applied forces across the sensor's active sensing region [16]. The FSR's solder tabs were bent at a 90-degree angle, laying on top of copper tape leading to the cradle's rear. This helps not only with wiring management but also to prevent solder joint damage from wire tension. On the rear, input and output wires are soldered to the copper tape and a thin layer of hot glue is applied to prevent unwanted movement. One inch Velcro adhesive backings were applied to the rear of the sensor units for individual sensor adjustment. Velcro was used as the band's base to allow for quick removal and replacement of sensor cradles, reducing the burden of resizing the device improving *fitment* by accommodating varying forearm sizes. In this work, our device was tethered to our data acquisition system. A bus cable of 9 wires was attached via DuPont connector to the outmost layer of the Velcro band. Fig. 3 shows the overall assembly. After final connections were made between the band, circuit, and benchtop equipment, the band was ready for feasibility testing.

III. Feasibility Testing

A hand gesture task was performed to evaluate the feasibility of our FMG band as a tool for hand gesture recognition. This offline hand gesture classification study required participants to complete a series of hand gestures while wearing the FMG band and we evaluated the accuracy to which a machine learning classifier could use the collected data to predict the performed gesture (described further below).

A. Experimental Setup

15 able-bodied subjects, aged 20 to 32 years old (mean age 23 ±3.2 years), participated in our study. 9 participants identified as male and 6 as female, with the majority (14) identifying as right-handed and 1 identifying as ambidextrous using the Edinburgh Handedness Inventory [17]. Study protocols were approved by the UC Davis Institutional Review Board (IRB) and all participants provided written informed consent.

Participants were seated at a table and were fit with the FMG band on the forearm of their dominant hand. Their hand and forearm were supported for comfort, but care was given to minimize limb movements during testing and ensure the FMG band was not in contact with any objects other than each participants' forearm. The FMG band was connected to the tethered VD circuitry resting on the table via bus cable connections. Following this, a +5V connection was made between the benchtop DC power supply (TekPower TP-3005D-3) and the VD circuit, and the signal outputs were sent to a National Instruments USB-6210 Data Acquisition System (NI DAQ). Following, a brief verification of sensor placement was conducted through a MATLAB test script in which the real-time sensor output was monitored and the investigators adjusted the band to maximize the sensor output when the participant contracted their muscles by making a fist. Fig. 4 shows the experimental setup. Once completed, the primary experiment began.

B. Experimental Procedure

Participants were tasked with performing a series of hand gestures. The 10 gestures seen in Fig. 5 [18]: Cylindrical Rotation (CR), Cylindrical Wrap (CW), Index Flexion (IF), Index Point (IP), Key Pinch (KP), Pulp Pinch (PP), Tripod

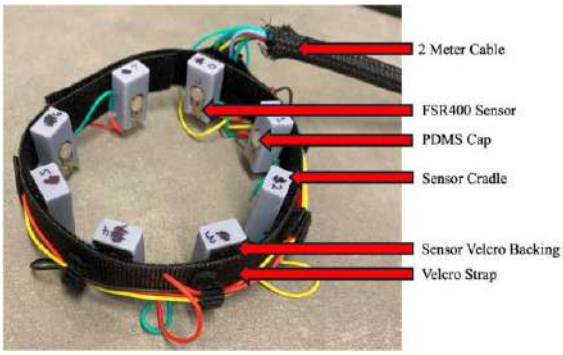

Fig. 3. The designed FMG band, comprised of a 2-meter long bus cable, 8 FSR400 sensors capped with PDMS domes, 3D printed cradles to house the sensors, and attachments to an outer Velcro band

Pinch (TP), Wrist Extension (WE), Wrist Flexion (WF), and Wrist Rotation (WR) are common to daily living. Testing began with the initial gesture being chosen at random. A MATLAB script would play an auditory tone for 3 seconds, indicating to the participant to perform the gesture, followed by silence, indicating a rest period (3 seconds long). During times of muscle contraction, the script would record FSR voltage responses through the NI DAQ's analog inputs at a rate of 2000 Hz. This sample rate was chosen as it was the most prevalent in FMG literature to captured appropriately rich data sets for gesture classification [7]. Each gesture was repeated 3 times; after which the next gesture was selected at random and this process repeated until all gestures were completed. In total, 10 MATLAB data files were generated (1 for each gesture), each time stamped data labels and the corresponding FSR voltages for each sensor in the FMG band.

C. Data Analysis

We employed an offline analysis approach in which participant FMG (voltage) data was processed through a classifier after the data collection had ended. While many metrics could be extracted from participant data, we chose to focus on hand gesture classification accuracy as our primary feasibility evaluation metric. Hand gesture classification accuracy refers to the accuracy at which our employed machine learning algorithms (described below) were able to use the voltage data collected using our FMG band to predict the user's performed hand gestures. Similar data collection and testing schemes are common in FMG literature [19] and reflect the FMG system's ability to measure relevant muscle forces generated during hand gestures for the specific context of hand gesture recognition in future real time device control applications. Our classification approach utilized a linear discriminant analysis classifier (LDA) paired with leave-one-out cross validation (LOOCV). To achieve this, MATLAB data files were input to a python script that isolated individual FSR voltage responses for each channel. These channels were then segmented into 200ms overlapping windows with 50ms time increments such that minute changes between points in time could be observed [20].

The mean absolute value (MAV) was calculated for each window, which served as the primary feature vector to train and test the LDA classifier using LOOCV [4], [21].

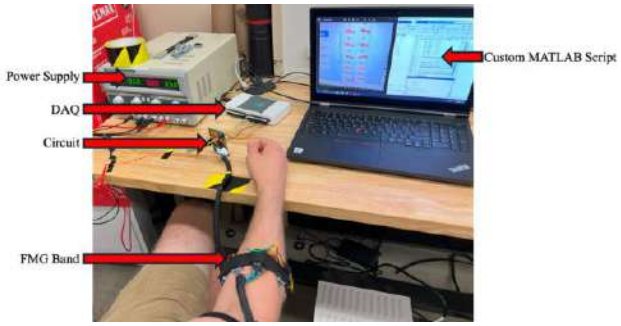

Fig. 4. The experimental setup of the FMG band validation testing. The FMG band is fit 2/3 the length of the participants forearm at a comfortable tension. A custom MATLAB script records the data for offline analysis and a TekPower TP-3005D-3 DC power supply powers the chosen circuit.

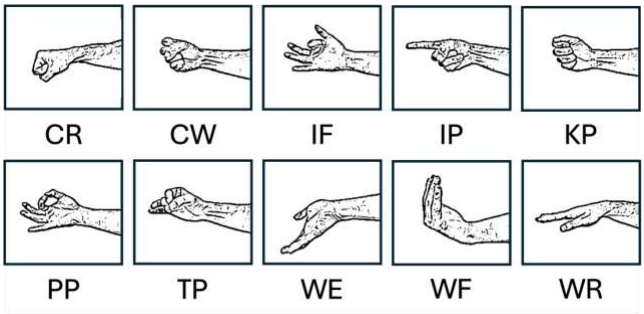

Fig. 5. The hand gestures participants were instructed to perform common to daily living. From left to right, top to bottom: Clockwise Rotation (CR), Cylindrical Wrap (CW), Index Flexion (IF), Index Point (IP), Key Pinch (KP), Pulp Pinch (PP), Tripod Pinch (TP), Wrist Extension (WE), Wrist Flexion (WF), Wrist Rotation (WR).

These feature vectors represented specific hand gestures and were labeled as such for use as the ground truth of the model. The LDA classifier was trained using the open source sklearn python package. A single feature vector (data from the completion of one single hand gesture movement) was removed from the dataset at random and the remainder were used to train the LDA classifier. Following a conventional LOOCV scheme a prediction using the removed data was then made, and this process was then repeated each time leaving a different hand gesture movement out and using it to test the prediction accuracy. The output of this pipeline was a series of predictions which were compared to the ground truth and used to create a confusion matrix. The classification accuracy of this confusion matrix was obtained to find the overall accuracy of the FMG system (Fig. 6).

The average accuracy across all participants for all hand grasps served as the summarizing metric of this work. This was found by summing the classification accuracies for each correctly predicted gesture (the diagonal elements of the confusion matrices), and dividing by the number of gestures performed (10), repeated for all participants. Standard deviations of this metric were also calculated.

IV. Validation Statistics

A. Classification Accuracies

The average classification accuracy of the FMG system was found to be 94.28% with a standard deviation across gestures

of ± 6.88%. Among all participants, the highest overall accuracy achieved was 100% (± 0%) for all hand gestures, and the lowest was 72.11% (± 31.39%). Fig. 6 illustrates the averaged confusion matrix and the average of the diagonal.

To evaluate the feasibility of our system in predicting hand gesture accuracy, we compared its performance to values reported in prior FMG literature as well as other modalities, including electromyography-based systems. While FMG systems—and other sensor modalities—represent heterogeneous datasets spanning diverse participant cohorts, sensing elements, circuitry, and even the underlying muscular phenomena being measured, FMG literature reports accuracy ranges from 91-96% [22]. EMG, a more mature measurement modality for hand gesture applications, has been suggested to require an accuracy threshold of >90% for reliable real-time control of external devices such as prostheses [23]. While FMG is more experimental, studies have shown it can produce classification accuracies similar to that of EMG-based control systems with less signal variance for participants with and without upper limb prostheses [7], [24]. Based on these benchmarks, the average performance of our FMG system meets or exceeds these values, supporting its feasibility as a low-cost, open-source option for hand gesture classification.

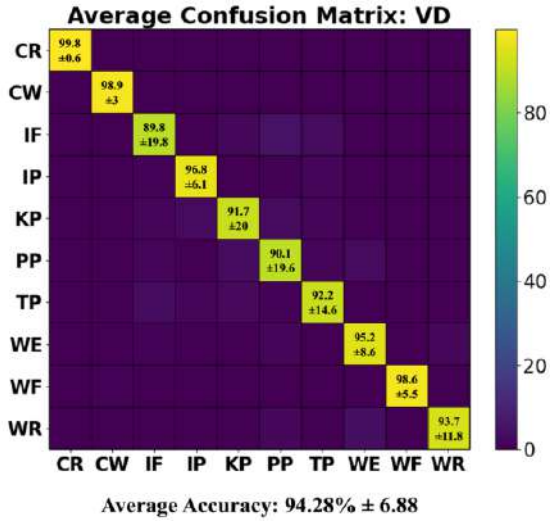

Fig. 6. Averaged classification accuracy in the style of a confusion matrix for the VD circuit. The hand gestures, Cylindrical Rotation (CR), Cylindrical Wrap (CW), Index Flexion (IF), Index Point (IP), Key Pinch (KP), Pulp Pinch (PP), Tripod Pinch (TP), Wrist Extension (WE), Wrist Flexion (WF), and Wrist Rotation (WR), display their actual (horizontal) versus predicted (vertical) classification accuracies within the matrix.

V. Discussion and Concluding Remarks

This work contributes an open-source low cost FMG wearable system designed to predict use's hand gestures from the radial muscle forces present in the forearm. To further promote the accessibility of our device, design files, a bill of materials, and accompanying fabrication documentation is available at https://github.com/BEAR-Labs.

Our prototype prioritized 3 primary considerations in shaping design decisions: *fitment, accessibility,* and *modularity*. Often, the *fitting* of a wearable system to a participant presents significant challenges in comfort and signal acquisition. Although the design of our FMG band still presents opportunities for further refinement, it was able to accommodate a wide range of forearm sizes across our participant cohort (circumference ranging from 21.5-29 cm). During our testing, it was anecdotally noted that no participants reported discomfort and all were successfully able to complete our study (approximately 45 minutes while wearing the FMG band) without any fit related or comfort related issues. Upon reviewing FSR voltage data, we found that voltages at the rest and contraction phases were clearly visually discernable. Distinct contraction and relaxation periods are a requisite condition needed to perform hand gesture classification analysis and further supporting that the FMG fitment allowed for appropriate sensor contact on the forearm skin and underlying muscle.

FSRs are one of many possible sensor types and sensing modalities used for hand gesture classification. Our system was designed to be *modular*, enabling integration with sensor technologies, circuitry, and data acquisition systems. Most significantly, the band can have its signal acquisition circuitry substituted for others that are commonly used in literature, such as the transimpedance amplifier or unity gain amplifier [25], [26]. This allows for the testing of unique signal profiles found from different circuit configurations. Furthermore, the Velcro-based band and mounting of sensors allows for the possible implementation of other force sensing modalities, sensory feedback or haptic actuators, sensor types, and more. This is of growing significance especially in research applications investigating sensor fusion and the impact of closed-loop feedback from wearable devices [27].

The overall component cost of the device was an important factor in making it *accessible*. Selection of readily available and off-the-shelf components resulted in the low cost of $162.60 USD (table 1). However, our feasibility data suggests that this low cost of componentry does not translate to poorer device performance when compared to other gesture recognition alternatives. Our offline classification analysis found an average classification accuracy upwards of 94%. While offline classification tends to produce more accurate results than real time classification, offline procedures are still highly prevalent in hand gesture classification research [23] and often reflective of efficacy in real time control applications. The *accessibility* of our system compounds with its *modularity* such that its low cost and ease of integration offers flexibility to accommodate a variety of clinical and research study demands.

For these reasons, future work aims to expand this study to a larger participant population to assess the device's efficacy across a greater range of physiological variances. Additionally, we aim to validate the device's ability to perform in real time control applications in an untethered fashion. This requires the creation of an adapted Python control script with optimized delay to overcome inaccurate classifications and motion artifacts, common in real time control. Collectively these changes could further promote the utility of our system and flexibility for use in a variety of

environment requiring larger dynamic movements and greater range of motion of the limbs, among many others.

SpasticMyoElbow: Physical Human-Robot Interaction Simulation Framework for Modelling Elbow Spasticity

Hao Yu[1,2,†], Zebin Huang[1,2], Yutong Li[3], Xinliang Guo[4], Vincent Crocher[4], Ignacio Carlucho[1], Mustafa Suphi Erden[1]

***Abstract*— Robotic devices hold great potential for efficient and reliable assessment of spasticity in post-stroke patients. However, the limited experimental data from patients with variable conditions has long posed a major barrier to quantitatively modelling spasticity with robotic measurements and fully validating robotic assessment techniques. As a result, spasticity is still assessed manually in current clinical settings. This paper presents a simulation framework developed to support the design and validation of elbow spasticity models and mitigate data problems. The framework consists of a simulation environment of robot-assisted spasticity assessment, two motion controllers for the robot and human models, and a stretch reflex controller. Our framework allows simulation based on synthetic data without experimental data from human subjects. Using this framework, we replicated the constant-velocity stretch experiment typically used in robot-assisted spasticity assessment and evaluated four types of spasticity models. Our results show that a spasticity reflex model incorporating feedback on both muscle fibre velocity and length more accurately captures joint resistance characteristics during passive elbow stretching in spastic patients than a force-dependent model. When integrated with an appropriate spasticity model, this simulation framework has the potential to generate extensive datasets of virtual patients for future research on spasticity assessment.**

I. Introduction

Statistics from the Global Burden of Disease Study show that there were approximately 12.2 million new stroke cases and 101 million prevalent cases worldwide in 2019 [1]. Spasticity is a common complication following stroke, referred to as a type of abnormal neuromuscular activity, with an incidence of 17%-38% in post-stroke patients [2]. Given the large number of stroke cases, the prevalence of spasticity is significant in society. The cost of treating stroke might be four times due to the influence of spasticity, making the assessment and therapy of spasticity an important research direction in post-stroke rehabilitation [3].

Pandyan et al. defined spasticity as a symptom of disordered sensorimotor control caused by an upper motor neuron (UMN) lesion, featuring intermittent or sustained involuntary activation of muscles [4]. They stratified the all-encompassing definition into multiple positive features of the UMN syndrome for practical study or measurement, including abnormal activation of muscles to an externally imposed stretch, spasms, clonus, and spastic dystonia [4]. In this paper, the term *spasticity* specifically refers to abnormal muscle reflexes to external stretches in the elbow.

In current clinical settings, clinicians use manual scales, e.g. the Modified Ashworth Scale, to assess spasticity, but these scales struggle with subjective judgement, ambiguous terminology, measurement errors, and inconsistencies in assessment results [5]. Consequently, a variety of robotic devices and instrumented assessment approaches have been developed to evaluate spasticity using biomechanical and neurophysiological measures [6], [7]. Beyond merely extracting statistic features from sensor measures, many physical models of spasticity were proposed to describe spasticity conditions with model parameters [8]. For example, impedance models can identify the viscoelasticity of spastic joints [9], [10], and threshold models represent the impaired ability to regulate the tonic stretch reflex thresholds [11].

Aiming to provide a more explainable approach to the characterisation of spasticity, some studies proposed neuromuscular spasticity models grounded in pathophysiology and realised numerical simulation. He et al. [12] developed the first neuromusculoskeletal model to simulate the pendulum test for knee spasticity, incorporating musculotendon actuators, motoneuron activation, and stretch reflex. Feng et al. [13] adapted He et al.'s model to simulate the pendulum test for elbow spasticity, and validated their simulation through experimental data of joint trajectories and muscle reflex activations from spastic patients. However, the models based on pendulum tests are unsuitable for patients with severe spasticity [14], as high muscle tone often causes their elbows to remain flexed. Consequently, Koo et al. [15] developed a neuromusculoskeletal model to simulate the stretch reflex response triggered by constant-velocity stretches in a spastic elbow.

With the advent of OpenSim [16], which offers well-developed musculoskeletal models and human motion simulation tools, researchers have developed feedback-dependent spasticity models in OpenSim to simulate the effects of spasticity during both passive and active leg movements. Krogt et al. [17] proposed a velocity-dependent reflex model to simulate the joint trajectories of a spastic knee during passive stretches, while, in subsequent research, Falisse et al. [18] demonstrated that a force-dependent reflex model outperformed a velocity-dependent model, as it better aligned

estimated muscle activity with experimental data of passive stretches and walking in children with spasticity. More recently, Veerkamp et al. [19] contradicted these findings, reporting that a velocity-dependent model outperformed a force-dependent model in simulating gait patterns of spastic patients. We did a detailed comparison of these modelling approaches and open-source code and found that, while all these studies used OpenSim, they used distinct optimisation algorithms in different simulation frameworks [17], [18]. Krogt et al. [17] obtained the optimal model parameters by matching predicted muscle excitability with experimental data, while Falisse and Veerkamp et al. [18], [19] realised the optimisation by fitting joint trajectory data. It is likely that their models achieved only a 'local optimum' within their respective datasets, optimisation targets, and simulation frameworks. To evaluate the optimised models, they also calculated the root mean square errors (RMSE) between the measured and predicted joint trajectories or qualitatively compared the real and simulated muscle activities, but the experimental data used for evaluation had been used in the optimisation process. In addition, these OpenSim-based spasticity simulation methods have been implemented and tested to date only on leg models, and they were computationally expensive, especially for testing combinations of spasticity model types [19].

In this paper, we present SpasticMyoElbow[1], a simulation framework that allows forward simulation of physical human-robot interaction in robot-assisted spasticity assessment, providing a transparent and physiologically grounded platform for validating and comparing different elbow spasticity models. This framework was implemented using MyoSuite [20], the latest simulator for musculoskeletal motion. We integrated a robotic controller and a stretch reflex controller into an exoskeleton-elbow environment provided by MyoSuite to simulate physical interactions occurring during robot-assisted elbow spasticity assessments (see Fig.1). With this simulation tool, we reproduced the constant-velocity stretch experiment and evaluated four types of elbow spasticity models. The main innovations of this study include:

- Developing an open and flexible simulation framework for testing and comparing elbow spasticity models;
- Comparing the performance of four prior models in describing the passive stretch resistance of spastic elbows;
- Exploring the application of physical interaction simulation between virtual patients and rehabilitation robots.

II. Methods

This work expanded on our prior study [21], in which we built a simulation tool for the physical interaction between an elbow and an exoskeleton in MyoSuite. We newly added a stretch reflex controller unit to the simulation tool to enable simulation of spasticity models on the virtual elbow. Afterwards, we simulated the robot-assisted constant-velocity stretch experiment for four types of elbow spasticity models.

[1]The repository can be accessed at: `https://github.com/myo-manipulation/SpasticMyoElbow.git`.

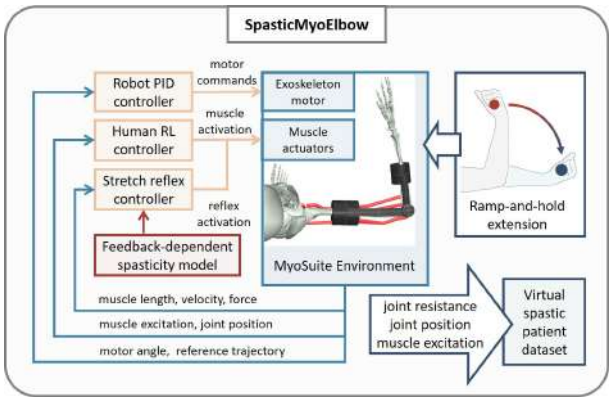

Fig. 1. Framework diagram of SpasticMyoElbow. The physical interaction between the robot and the musculoskeletal model during a ramp-and-hold extension can be simulated through the parallel control of the robot and human controllers in the simulation environment. The stretch reflex controller allows the elbow model to exhibit spasticity symptoms, simulating a virtual patient in the interaction. This setup provides a validation dataset for evaluating spasticity models.

A. Simulation framework

The foundation of the simulation framework is a simulation environment of a typical clinical setup for upper extremity rehabilitation [14], [15], [22], in which a seated person's elbow interacts with an exoskeleton robot, as shown in Fig.1. This simulation environment was adapted from the elbow-exoskeleton model provided by MyoSuite [23], which contains a human elbow skeleton with six muscle actuators (the long, lateral, and medial heads of the triceps brachii; the long and short heads of the biceps brachii (LHB, SHB); and the brachioradialis (BRD)) as well as a CAD model of the exoskeleton robot with a joint motor. In real-world laboratory settings, researchers might use other types of rehabilitation robots to apply controlled rotational motion to the elbow joint [14], [15], [22]. Nevertheless, the effect of other robots would be similar to that of the exoskeleton in the simulation.

The prior simulation tool [21] incorporates two controllers: a robot PID controller and a human controller, which respectively modulate the motor of the exoskeleton and the muscle activation of the elbow. The elbow musculoskeletal model, guided by its reinforcement learning (RL) controller, can simulate movements similar to those of a healthy real elbow. Meanwhile, the robot PID controller enables the exoskeleton to precisely track trajectories in position control or apply specific external torques in force control. This parallel control of the elbow and robot facilitates the simulation of their physical interactions in typical rehabilitation experiments, such as perturbation-based joint impedance identification experiments [21]. As the exoskeleton linkage is fixed on the arm model, there is no contact force interaction between them.

Building on this framework, we developed and integrated a stretch reflex controller into the simulation control loop. During each control cycle, the stretch reflex controller receives inputs of muscle fibre length, velocity, and force, simulating proprioceptor functions within muscles. It then generates a muscle reflex response based on proprioceptive feedback,

simulating the action of spinal motor neurons. This reflex is calculated using an equation-based model that describes the mechanics of muscle spasticity. The resulting spasticity-related muscle reflexes are then fused with the muscle activation outputs of the human RL controller, producing the final control commands for muscle actuators in the simulation environment. Muscle actuators produce torques around the elbow joint following the Hill-type musculotendon dynamic model [20]. When the human RL controller is disabled to simulate a completely relaxed elbow without voluntary control, muscle activations are driven solely by the stretch reflex controller, allowing for an isolated analysis of reflex-driven muscle behaviour.

B. Spasticity model and stretch reflex controller

Although no universal model can precisely describe the connections between spasticity pathophysiology and clinical symptoms, it is generally accepted that the abnormal stretch reflex in spasticity can be modelled as a dynamic function of exaggerated muscle excitation driven by proprioceptive feedback [8]. Spasticity is thought to arise from reduced inhibition of stretch reflex within the spinal cord, along with an increased reflex gain due to changes in the intrinsic properties of motoneurons [24]. On the one hand, the neural excitation underlying the stretch reflex originates from the firing rates of the muscle spindles, which are influenced by both the muscle length and the muscle velocity feedback. For a given spindle firing rate, a reduction in inhibitory inputs to the motoneurons can lead to higher levels of excitation [25]. This heightened excitation causes the stretch reflex to be elicited at lower velocities and shorter stretch distances. On the other hand, following a neurological injury, disrupted inputs to the motoneuron pool would activate persistent inward currents, which amplify inputs to motoneurons and cause self-sustained firing [24]. This process results in an exaggerated motoneuron response to incoming signals, contributing to the excessive reflex activity characteristic of spasticity.

In addition, there is evidence showing that spindle firing is proportional to muscle force and its derivative during passive stretches [26], so some researchers believed that spasticity could be related to the exaggerated response to spindle firing turned by the feedback of muscle force and its first-time derivative [18]. Given that, we implemented and tested force-, velocity- and length-dependent models of muscle spasticity and their combinations to comprehensively compare their capability to describe the characteristics of passive stretch resistance observed in elbows with spasticity.

To describe spasticity models incorporating different feedback mechanisms, we adapted the hybrid model equation for the muscle activation of a motoneuron proposed in [19]:

$$E(t) = C + G_l \cdot R_l(t) + G_v \cdot R_v(t) + G_f \cdot R_f(t) \quad (1)$$

where $E(t) \leq 1$; C represents the supraspinal drive modulated by the human RL controller, which is set to zero when simulating a completely relaxed elbow; R_l, R_v, and R_f denote the reflex activations contributed by muscle length, velocity, and force feedbacks within the afferent pathway; G_l, G_v, and G_f are the reflex gains of spasticity models, which can disable the corresponding model when set to 0. Similar to the modelling method of reflex thresholds used by He et al. [13], [27], the feedback-dependent reflex activations are calculated through normalisation functions with thresholds of corresponding feedbacks:

$$R_l(t+\tau) = \begin{cases} (l(t) - l_t)/(l_0 + l_r), & \text{if } l(t) \geq l_t \\ 0, & \text{if } l(t) < l_t \end{cases} \quad (2)$$

$$l_t = l_0 + \lambda_l \cdot l_r,\ 0 \leq \lambda_l \leq 1 \quad (3)$$

$$R_v(t+\tau) = \begin{cases} A \cdot (v(t) - v_t)/v_{max}, & \text{if } v(t) \geq v_t \\ 0, & \text{if } v(t) < v_t \end{cases} \quad (4)$$

$$v_t = \lambda_v \cdot v_{max},\ 0 \leq \lambda_v \leq 1 \quad (5)$$

$$R_f(t+\tau) = \begin{cases} A \cdot (f(t) - f_t)/f_{max}, & \text{if } f(t) \geq f_t \\ 0, & \text{if } f(t) < f_t \end{cases} \quad (6)$$

$$f_t = \lambda_f \cdot f_{max},\ 0 \leq \lambda_f \leq 1 \quad (7)$$

$$A = 3 \cdot l_r/(l_0 + l_r) \quad (8)$$

where $l(t)$, $v(t)$, and $f(t)$ are the proprioceptive feedbacks of fibre length, velocity, and tension force; l_t, v_t, and f_t are the reflex thresholds of muscle stretch length, velocity, and force; λ_l, λ_v, and λ_f are the factors to adjust the thresholds of the stretch reflex; l_0 is the starting muscle length of stretches; l_r is the range of muscle stretch; v_{max} is the maximal contracting velocity of a muscle, which was set as 1.5 times the optimal resting length of the muscle per second [28]; f_{max} is the maximal muscle force, which was set as 1.2 times the static maximal force [28]; τ is the stretch reflex delay, which was set as 30 ms [15]; A is the scaling factor that balances the reflex magnitudes of different models at a same level. In our simulation tool, we deployed three separate stretch reflex controllers based on the aforementioned feedback-dependent spasticity model to the LHB, SHB, and BRD muscles, respectively. As we only focused on the abnormal muscle reflexes to external stretches occurring in a relaxed elbow, the reflex mechanisms involved in voluntary movements, e.g. reciprocal inhibition, were not take in to account.

C. Robot-assisted elbow stretch experiment

The constant-velocity elbow stretch experiment is a typical biomechanical measurement method used in spasticity assessment research [14], [15], [22], [29]. This method involves using a robotic device to exert slow to fast constant-velocity stretching on the relaxed limb joint while recording the joint position and resistance over time. A fundamental assumption of this method is that when the stretching speed exceeds a threshold value, a spastic elbow will exhibit velocity-dependent stretch reflexes, demonstrating a lower reflex threshold and greater resistance compared to healthy individuals [29], [30]. In the early study proposing this

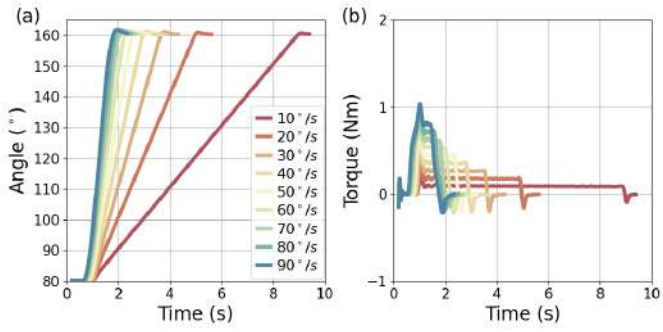

Fig. 2. Simulation data of the robot-assisted constant-velocity elbow stretch experiments: a) the angle profiles of the ramp-and-hold extension movements; b) the driving torques collected in the simulated elbow stretch experiment.

TABLE I

SPASTICITY PARAMETERS SET IN THE SIMULATION

Model	G_l	G_v	G_t	λ_l	λ_v	λ_f
Len.	$1 \sim 3$	0	0	0.1	0	0
Vel.	0	$1 \sim 3$	0	0	0.1	0
For.	0	0	$1 \sim 3$	0	0	0.1
Hybrid	$1 \sim 2$	$1 \sim 2$	0	$0.1 \sim 0.4$	$0.1 \sim 0.4$	0

method, researchers used a motor-driven beam connected to the forearm to apply ramp-and-hold extension and flexion movements to the elbow joint [14]. A ramp-and-hold movement includes a start phase that fixes the elbow at the initial position, a ramp phase that moves the elbow to the target position at a constant velocity, and a hold phase that stops the elbow at the target position. In recent studies by Guo et al. [22], this method was followed, but they used a planar forearm rehabilitation robot to conduct the experiment.

We reproduced Guo's experimental protocol in the simulation environment. The arm was attached to the robot with an initial posture of approximately 90° shoulder elevation and 70∼90° elbow angle (completely extending the elbow is 180°). The human RL controller was disabled to simulate a relaxed elbow, while the robot extended the elbow from the initial position to full extension at nine different angular velocities (ranging from 10 to $90°/s$). A sample of the experimental data is depicted in Fig.2. The stretch experiment was repeated on the virtual elbows with different model parameters in the simulation tool. The model parameters of the stretch reflex controllers set for the simulation are provided in TABLE I. By setting different combinations of gains and thresholds, the general spasticity model described by Eq.1 was transformed into the length-dependent model, velocity-dependent model, force-dependent model, and hybrid model of length and velocity muscle feedbacks. The muscle parameters used in all simulation experiments are the same, as listed in TABLE II, which were calculated by the internal parameters of the MyoSuite elbow model.

In the simulated experiments, virtual sensors within the simulation environment recorded the angle of the elbow joint θ and the driving torque T_{total}. According to Newton's third law, this driving torque represents the stretch resistance of the joint, which can be described as a function of joint angle.

TABLE II

MUSCLE PARAMETERS SET IN THE SIMULATION

Muscle	$l_0[m]$	$l_r[m]$	$v_{max}[m/s]$	$f_{max}[N]$
LHB	0.36	0.054	0.18	729
SHB	0.28	0.054	0.20	508
BRD	0.12	0.024	0.13	1171

For a spastic elbow joint, the stretch resistance is divided into passive resistance T_p contributed by the mechanical property of body inertia and soft tissues (muscles, tendons, ligaments, etc.) and reflex resistance T_s elicited by spasticity models [14]. The passive resistance can be further decomposed into the elastic torque T_e related to the joint displacement, viscous torque T_v dependent on the joint velocity, and inertial torque T_i [15], which accounts for accelerating and decelerating the body inertia:

$$T_{total}(\theta) = T_p(\theta) + T_s(\theta) \tag{9}$$

$$T_p(\theta) = T_e(\theta) + T_v(\theta) + T_i(\theta) \tag{10}$$

During the constant-velocity phase of each passive extension movement, the acceleration is zero, so inertial resistance is zero. The reflex torque elicited by the elbow flexors over this constant angular velocity range can be estimated by subtracting the passive elastic and viscous torques from the driving torque [15]. As shown in Fig.2(b), when the stretching speed increases, the joint resistance increases due to the increased viscous component, but the maximum peak viscous torque is approximately 1 Nm, which is relatively small compared to the reflex-induced torque in Fig.3. Although a more accurate value of the viscous torque can be estimated as the sum of the viscous components of all involved muscles using the method of Koo et al. [15], in our case, the viscous component is too small to influence our analysis results, so it is simplified. The passive elastic torque was estimated by the driving torque recorded at the lowest extension velocities when the reflex controller was disabled. We analysed the performance of different spasticity models by examining the reflex torque curves obtained in the simulation experiments.

III. RESULTS

We compared the reflex torque curves of the length-, velocity-, and force-dependent spasticity models, with reflex gains incrementally varying from 1 to 3. The results of the length-dependent spasticity model are shown in Fig.3 (a-d). As the elbow muscles are lengthened, the reflex torques gradually increase, reaching a plateau or slightly declining. This behaviour aligns with the intuitive understanding of a length-dependent model: as muscle length initially increases during stretching and then stabilises, the muscle excitation proportional to fibre length follows a similar pattern. The slight reduction at the end is attributable to the decreasing muscle velocity, as the force in a Hill-type muscle model is determined by the product of the length-tension and velocity-tension functions.

Fig.3 (e-h) presents the simulated results of the stretching experiment using the velocity-dependent spasticity model. It is evident that the peak of the reflex torque increases as

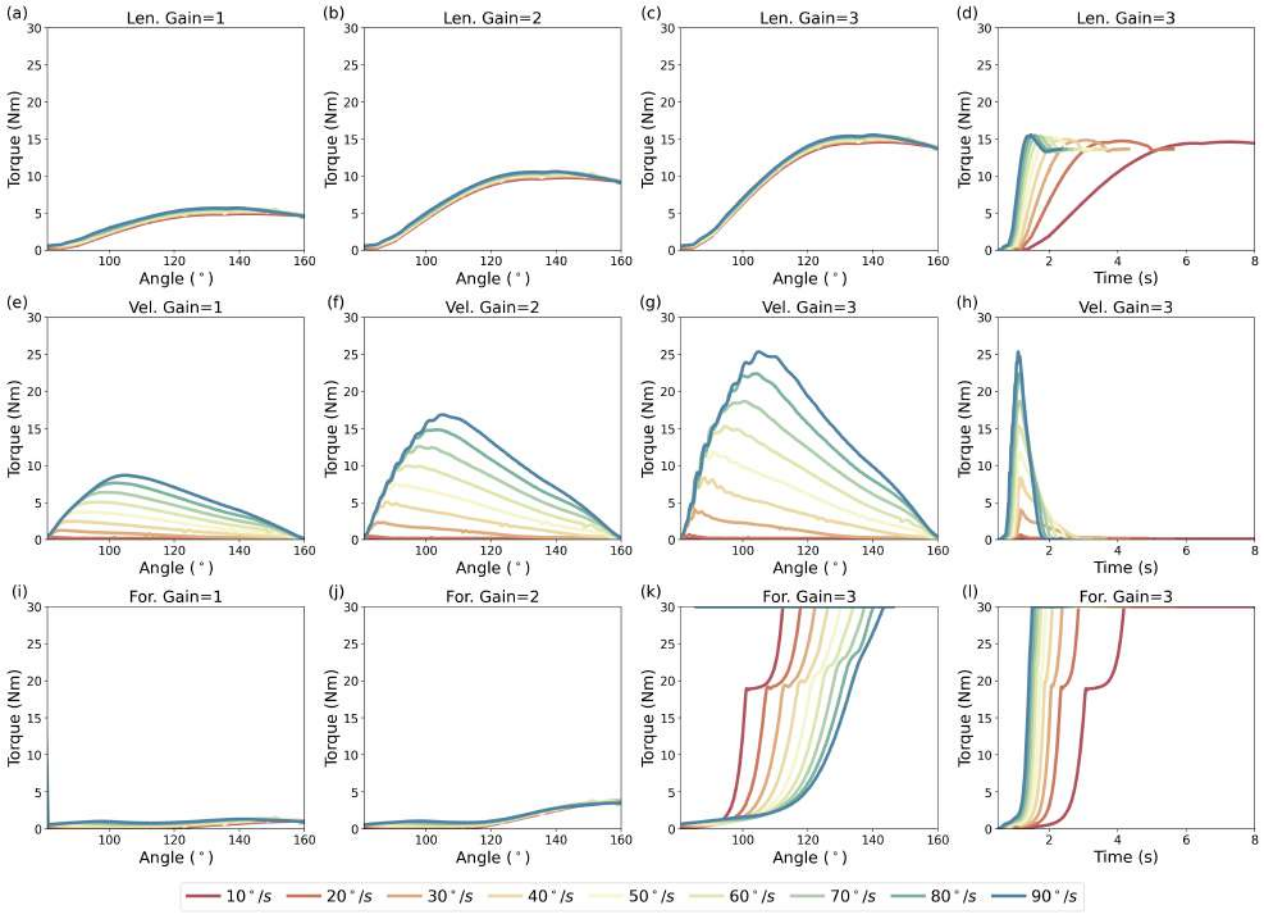

Fig. 3. (a-c) Reflex torque curves plotted against joint angle for the length-dependent spasticity model, with reflex gains ranging from 1 to 3. (e-g) Reflex torque curves plotted against joint angle for the velocity-dependent spasticity model, with reflex gains ranging from 1 to 3. (i-k) Reflex torque curves plotted against joint angle for the force-dependent spasticity model, with reflex gains ranging from 1 to 3. (d, h, l) Evolution of reflex torques over time for the length-, velocity-, and force-dependent spasticity models, with a reflex gain of 3.

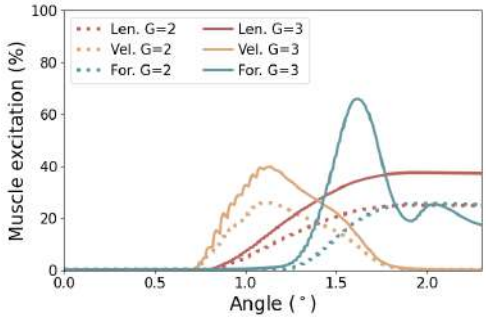

Fig. 4. Muscle excitations of the long head of the biceps brachii modulated by the length-, velocity-, and force-dependent spasticity models under a $90^{\circ}/s$ elbow stretch.

velocity increases. In addition, the resistance of the joint decreases after reaching the peak, even though the joint continues to move with a constant velocity. This reduction may be attributed to the decreasing stretch velocity of muscles as their moment arms change.

Fig.3 (i-l) shows the results of the extension experiment for the force-dependent spasticity model. When the gain is small, the force-dependent model induces an increase in resistance during the second half of stretching. However, when the spasticity gain is large, the reflex torque rapidly increases toward the limit value of the muscle force. It may be explained by the mathematical description of the model. The spasticity model causes greater reflex muscle forces and greater muscle forces also produce more intensive reflexes, so the elbow system cannot reach a stable state. We further plotted Fig.4 to compare the muscle excitation levels regulated by different models when G=2 and G=3. It can be observed that at G=2, the excitation peak values generated by the three models are quite close. However, at G=3, the force-dependent model shows a sharp increase and fluctuation in muscle excitation.

Previous studies have clearly analysed the trend of stretch reflex resistance in spastic elbows, where the most common pattern of resistance profiles is an initial increase followed by a plateau phase [14], [29], [30]. The rate of increase in resistance relative to joint angle (commonly referred to as reflex stiffness) and the onset of abnormally elevated resistance (typically called the reflex angle or catch angle) are both related to the severity of spasticity and the stretching velocity. In our simulation results, the length-dependent model does not exhibit velocity dependence, while the velocity-dependent model lacks a plateau phase in the resistance curve. As a result, we ultimately adopted a length-velocity

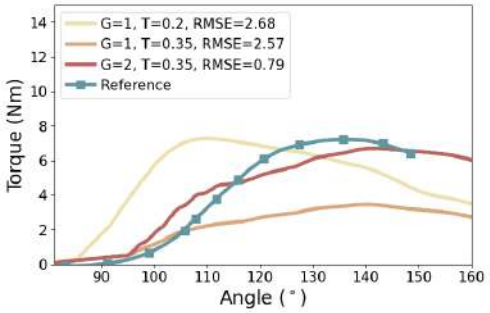

Fig. 5. Reflex torque curves plotted against joint angle for the hybrid spasticity model with different model parameters (G: gains, λ: threshold factor) at $90°/s$. The reference torque curve was extracted from McPherson et al. [29].

hybrid spasticity model and conducted simulation experiments using different model parameters listed in TABLE I. The gains and thresholds for length and velocity were set at identical values for simplification (G_l=G_v, λ_l=λ_v). As shown in Fig.5, when the gains are kept constant and the thresholds are increased, the onset of torque increase occurs later and the magnitude of the torque peak decreases. In contrast, increasing the gains while keeping the thresholds unchanged results in an obvious increase in the peak magnitude of the reflex torque curve. With appropriately selected model parameters (G=2, λ=0.35), the RMSE between the simulated and experimental data can reduce to 0.79 [29].

IV. Discussion

In this study, we proposed a simulation framework for modelling spasticity through passive stretch experiments based on the simulation of physical interaction between a rehabilitation robot and a human elbow. Unlike previous simulations of spasticity models, the realisation of the simulation in our framework does not rely on motion or electromyography data from real-life experiments, nor does it generate the simulation depending on optimal fitting to limited sample data. Instead, it leverages the advantages of the robotic simulator, combined with validated spasticity models, to perform forward simulations purely according to the physiological mechanism.

Our simulation examined length-, velocity-, and force-dependent models separately, all of which demonstrated unique characteristics, but none of the models alone could capture the full passive resistance curve observed in elbow stretches of spastic patients. Only when combining both velocity and length dependencies did the hybrid model display passive resistance patterns seen in a real spastic patient's elbow. This can be explained by the physiological origin of the stretch reflex, the muscle spindle, which contains Ia and II sensory fibres sensitive to muscle velocity and length, respectively. The activation of these sensory fibres in response to external stretch increases the afferent firing rate of the motoneuron, which can induce the stretch reflex [15]. Previous experimental evidence has shown that the muscle spindle in a spastic patient is not more sensitive than in a normal individual, and spasticity is more closely associated with a reduction in inhibition of motoneuron excitability within the spinal cord [24], [25]. Therefore, we infer that the weakening of afferent-related neural inhibition may lead to an abnormal stretch reflex exhibiting length- and velocity-dependent excitation originating from the muscle spindle.

In the study by Falisse et al. [18], spasticity models were described by state equations that incorporated reflex threshold and gain, with state variables of muscle feedbacks (length, velocity, acceleration, force, and force derivative), while the time course of muscle excitation was the simulation output. Optimisation of model parameters was performed to fit the simulated time course of muscle excitation with the electromyography data from real patients. However, the muscle force input of the model in their optimisation framework was generated from the real electromyography data, which might result in a fitting bias in that the force-dependent model has better optimisation results than the model based on other feedback. In contrast, our study directly simulates the force-dependent model without employing any optimisation techniques, allowing us to observe the model's behaviour without any pre-set bias from fitted data. Our findings reveal that models based solely on force variables lead to muscle system instability, producing physiologically unrealistic results.

Veerkamp et al. compared the velocity-dependent and force-dependent spasticity models in reproducing spastic patients' gait patterns [19]. Similar to our findings, the velocity-dependent model outperforms the force model under their simulation goals. Their simulation method consists of two layers of internal and external optimisation loops, and therefore the simulation is computationally intensive, so they failed to validate the spasticity model with multiple feedback combinations. In terms of computational cost, our proposed simulation tool is advantageous. It is true that adding optimisation of model parameters to our simulation tool to make it fit to the experimental data will introduce new computational costs. However, our simulation framework only requires one optimisation loop. Moreover, the simulation efficiency of MyoSuite is higher than that of OpenSim [20]. Therefore, we believe that the presented simulation tool has the potential to improve the computational efficiency of simulation of the spasticity model.

Due to space limitations, we have not included the simulation results for the full model incorporating all three reflex mechanisms in this paper. Our preliminary trial-and-error investigations indicate that the force-dependent reflex model actually degrades the agreement between model predictions and experimental data. Specifically, when the force gain is set to a low value, its contribution to the overall resistance torque is minimal; however, as the force gain increases, the total torque escalates to unreasonably high levels, corresponding to the phenomenon observed in Fig.3(i-k). In future work, once optimization techniques are employed, a more comprehensive search will be done to test the force-based feedback and and identify the most realistic reflex model.

V. Conclusion

It is undeniable that, due to the lack of clinical trial data, this study does not propose a rigorously validated spasticity model. The musculoskeletal model of the elbow requires improvement as it excludes the Brachialis muscle. However, our simulation framework provides new approaches and insights into some of the ongoing debates in spasticity modelling. The framework enables easier comparison of stretch resistance at the elbow joint across different types of spasticity models. The preliminary qualitative analysis results demonstrate the superiority of the length- and velocity-dependent hybrid spasticity model in explaining the abnormal elbow resistance caused by spasticity. Furthermore, while not covered in this paper, the effects of spasticity on active human motion can also be simulated, as the simulation tool includes a controller for active motion. In future research, one focus will be on gathering some real-patient data to develop a more precise and reliably validated spasticity model, thereby enhancing the simulation fidelity for spastic patients.

***Abstract*—Partial body weight support during gait training and other tasks is a common practice. Approaches using robotic devices allow for a wide range of functions but at great cost and complexity. Based on constant force springs, we have created a low-cost body weight support system from off-the-shelf parts, with no tools required for assembly or maintenance, and it is easily integrated into any overhead support system. The design is presented as open source for future improvements. We evaluated the hysteresis using two different types of constant force springs, comprising clinically relevant levels of weight support, 61.2 N and 131 N. Force constancy during walking was examined. Hysteresis had noticeable effects on weight support, illustrating a potential challenge for future designs with body weight support through constant force springs. By providing the constant weight support, the most common type of body weight support, this device represents an accessible alternative to robotic dynamic body weight support tools.**

I. Introduction

In the U.S., 12.2% of adults have a mobility disability that makes tasks such as walking or climbing stairs more difficult [1]. To enable repetitive practice of these tasks for recovery, partial body weight support (BWS) devices have been developed for use in clinics [2]. A BWS device is a support system created with suspension that provides vertical support on the patient's pelvis and trunk, reducing the functional weight of the patient while they are training. It reduces mechanical demand on muscles and makes it easier for users to coordinate their movements. A study using body weight support along with standard of care in post-stroke patients found improved Functional Independence Measures over patients who only received the standard of care [3]. There have also been similar benefits of body weight support training seen in individuals with spinal cord injury [4], [5]. More testing on BWS systems in rehabilitation could lead to better outcomes for patients with musculoskeletal and neurological gait disorders.

BWS can be provided passively or actively. Passive BWS systems include the use of a weight stack and pulleys, extension springs, and bungees [6]. These methods have drawbacks. For example, a weight stack adds inertia and must be in a fixed location, and elastic elements provide height-dependent weight support. Active, robotic body weight support has become increasingly popular. A pioneering example is the ZeroG system (Aretech, Sterling VA), which travels actively along a rail with programmable BWS. The Bioness Vector (Bioness, Valencia, CA), based on Aretech's design, operates similarly. These devices cost approximately $200,000, not including the approximate $30,000 of renovation costs [7], making these inaccessible to most clinics.

Constant force springs, made from coiled stainless steel, provide a passive, low-cost cost alternative to BWS unhindered by inertia or changes in height. MacLean and Ferris used an arrangement of constant force springs to create a novel, low-cost BWS system. Their device can support up to 79% of the patient's body weight, and parts cost about $4000 [8]. A recent commercial device, the Levity by Ora Medical (Montreal, QC), integrates constant force spring modules of predetermined strengths into a novel pediatric gait trainer, as opposed to an overhead support. As a result, this device uniquely enables squatting, and other activities at different heights anywhere the gait trainer can travel at a cost of approximately $8000 [9].

The approach outlined in this paper moves further towards low cost and simplicity [10]. Our goal was to focus on easily sourced, off-the-shelf parts, versatility in usage, affordability to any clinic, no machining required, and easy adjustment and assembly by a non-expert. Our result is a device that costs under $100 in parts sourced from accessible vendors such as Amazon, McMaster-Carr, and Home Depot, can be assembled in under 10 minutes by a non-expert without tools (with the exception of sawing a PVC pipe), can adjust resistance just as easily, and can be used with any typical overhead support. Here, we describe the design, provide details on where to source the parts and perform a performance evaluation of the system. While robotic BWS has distinct advantages, including the ability to adjust BWS dynamically, the philosophy of this work is to prioritize accessibility, versatility, and ease of use when functionality lacks strict requirements.

II. Methods

A. Device Design

This project aimed to design an affordable BWS device that can be constructed with off-the-self parts that will require little to no additional machining. All components of this device, Table 1, can be bought off the shelf or delivered within 24 to 48 hours.

Constant force springs (McMaster-Carr) were chosen to provide the BWS due to their affordability, ease of replacement, and range of available force options. The system was designed to house the constant force springs to reduce the risk of the user coming into contact with the springs while also being easy to take apart to replace the springs at their end of life or change the level of assistance the device is providing. The component breakdown can be seen in Fig. 1, and the assembled device can be seen in Fig. 2. Two constant force springs are placed back-to-back, a configuration that prevents twisting and improves stability. The springs rotate around hex bolts that pass through mounting plates, with PVC pipe sections providing rigidity and preventing wear on the inner diameter of the springs. The mounting holes on the ends of the springs are connected with an S-hook, which then connects to a carabiner and eventually to the harness. A carabiner with a

[c] Cost of spring depends on force and excursion properties

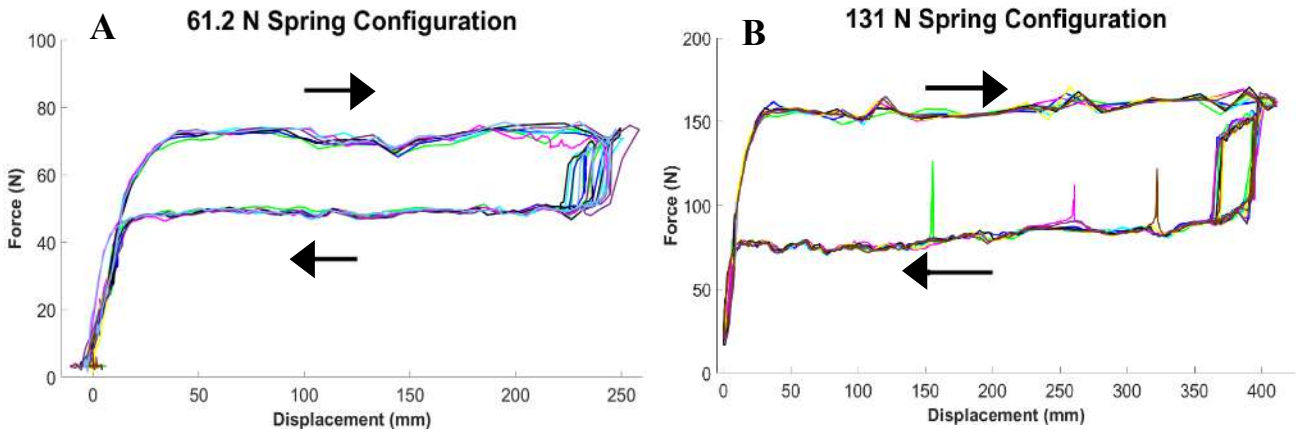

Fig. 3 (A) Hysteresis plot for the 61.2 N configuration (two 30.6 N springs), red arrows indicate the direction of motion of the applied force. (B) Hysteresis plot for the 131 N configuration (two 65.7 N springs). An increase in force over the initial, approximately 35 mm of the spring unraveling before leveling out to the constant force can be seen in both configurations. There is a decrease of force seen when the load begins to return to its starting point, with a quick decrease seen over the final, approximately 35 mm.

swivel connects to the top hole of the mounting plate via a hex bolt to connect to the overhead support. Wingnuts tighten the bolts by hand, and oversized washers prevent the springs from rubbing against the mounting plates. A full bill of materials and assembly instructions can be found on GitHub [11]. When weight is applied to constant force springs, there is no limit to their motion, and they will reach the end of the range of their excursion, so it is necessary to have a fall arrest lanyard parallel to the device for safety purposes.

B. Testing protocol

To validate the design of our device, we performed tests with two constant force spring strengths: 30.6 N and 65.7 N. Since the design requires a pair of springs, the two configurations account for 61.2 N and 131 N, respectively. The measurements, with the purpose of examining the mechanical properties of the device, were performed on author W.K. Given the design and goals of the study, no ethics approval was necessary according to local Institutional Review Board policy.

We first performed hysteresis testing on the device, where we applied a load to the springs over a distance to ensure the springs returned to their rest length. For the test, a known weight was attached to the springs, released to fall a distance, and then manually returned to the starting point; this was repeated 10 times for each spring strength. For the smaller springs, a load sufficient enough to extend the springs (75.6 N) was used, and for the larger springs, a load sufficient enough to extend the springs (164.6 N). An inline load cell, placed in series with the BWS device, measured the spring force (Futek, Irvine, CA). Data from the load cell were recorded using an NI USB-6009 and LabView 2024 (National Instruments, Austin, TX). The displacement of the springs was tracked using motion capture. Four reflective markers were placed on the device, with one being placed on the S-hook at the end of the springs. Motion capture data were recorded using Vicon Nexus 2.12 (Vicon Motion Systems Ltd., Oxford, UK). Both motion capture and the load cell readings were captured at a rate of 200 Hz.

We then performed a functional test of the device while walking on a Bertec instrumented treadmill with an overhead support structure (Bertec, Columbus, OH). A load cell was placed in line with the device during the trials where the BWS device was used in the same manner as during the hysteresis tests. The BWS device was then attached directly to a safety harness worn by a single participant. Fall arrest lanyards were also placed in parallel with the BWS device to allow the wearer to have enough movement so as not to alter their normal gait pattern but still prevent the springs from fully extending. The participant then walked on the treadmill at a comfortable walking speed of 1.0 m/s. Force plates embedded under the treadmill belts gathered ground reaction forces. Data from the treadmill were recorded at rate of 1000 Hz using Bertec Fit5 (Bertec, Colombus, USA). The participant walked at the speed of 1.0 m/s for three one-minute walking trials. The first trial was with no BWS; the following two trials were with the BWS device with the two different spring strengths mentioned previously.

C. Data Analysis

All analyses were performed using Matlab R2024b (Mathworks, Natick, USA). The data from the load cell and motion capture system were synchronized for analysis of the hysteresis data. The data from the displacement and force data were divided into cycles, with a cycle being defined starting when the marker starts moving (load is applied) and ending when the marker returns to its starting point (load has been removed).

For analysis of the functional walking data, the data from the force plates was down sampled to the load cell data. The load cell and force plates were then synchronized using a trigger point. The data were then divided into gait cycles using the heel strike of the participant's right foot. The average and standard error of the mean (SEM) were taken across the gait cycles for the left and right vertical ground reaction forces and the load cell. The mean was then plotted

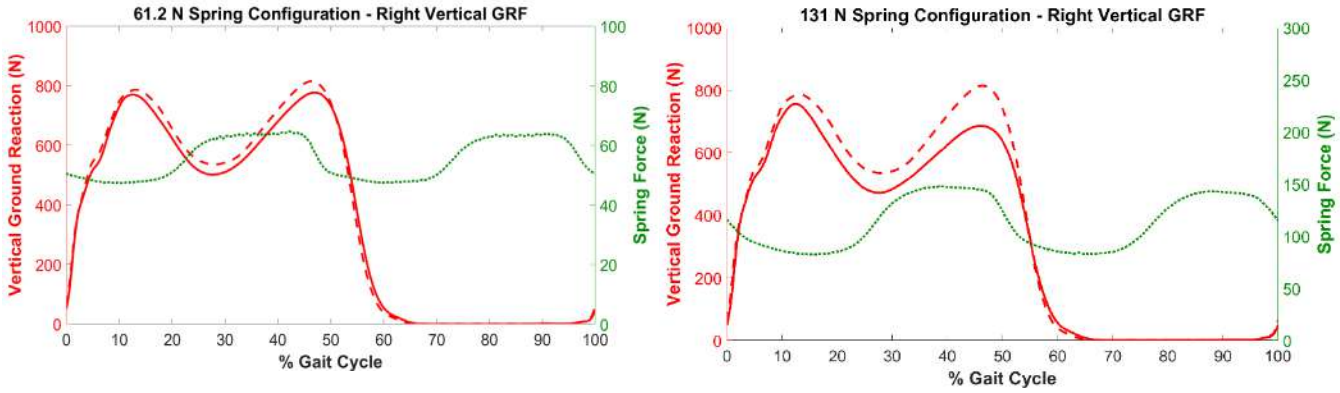

Fig 4 Average vertical ground reaction forces during gait of the right leg during unassisted walking (red-dashed) and assisted walking (red-solid) for the 61.2 N spring configuration (right) and 131 N spring configuration (left). The average force from the springs during the assisted walking (green-dotted) can also be seen throughout the gait cycle.

for the right and left vertical ground reaction forces along with the mean of the load cell.

III. Results

Both sets of springs showed hysteresis. The force vs. displacement graphs for the hysteresis tests can be seen in Fig. 3. In the small springs, Fig. 3A, a sharp increase in the force applied can be seen over the initial 35 mm of the spring unraveling before leveling out to the constant force. There is a decrease of about 20 N seen before the load begins to return to its starting point, with a quick decrease seen over the final 35 mm. A similar trend is seen in the hysteresis test of the large springs, Fig. 3B. There is, however, a larger decrease seen when returning the load to its starting point; this is a variation of about 60 N. There are also a few cycles that appear to have a spike in the applied load when returning to the start of the cycle. We attribute this to the experimenter's readjustment of the grip on the weight when moving it back to the beginning of the cycle.

The BWS device reduces the vertical ground reaction forces during walking, but the reduction varies (Fig. 4). The variation can be clearly seen after the loading response, but the decreased load is at the level that is expected until shortly before midstance when the unloading response begins. The load cell shows fluctuation in the support provided by the springs on the participant. The pattern seen by the load appears to follow what is seen in the vertical displacement of the center of mass (CoM) during walking [12].

IV. Discussion

This project aimed to develop a body-weight support device that was accessible, versatile, and easy to use. The product described in this paper meets these requirements. All components of our BWS device can be purchased off-the-shelf and delivered within 48 hours for less than $100, including shipping. The device can be assembled without tools by a layperson, with the only adaptation to any component being cutting PVC pipe to size. The springs can be easily replaced if worn out or other force levels are desired in minutes without tools. Due to its compact size, the device can be integrated into any overhead support frame. Unlike weights or bungees, the constant weight support does not suffer from inertial effects or displacement-dependent forces. In comparison to a similar device using constant force springs [8], the device of this paper costs an order of magnitude less, does not require any special manufacturing or custom parts, and has greater versatility of placement. Further, the design is open source, meaning that if others find better off-the-shelf solutions, the design can be updated. The low cost means that any clinic could easily purchase and manufacture this device, including individuals at home.

There is room for improvement in the design. While the S-hooks hold the springs, they sometimes require a crimp to ensure the springs remain in place. The springs are sheet metal, meaning that they have an exposed edge. We deal with this by connecting the device to the overhead support and then an inelastic lanyard in series connects to the user such that the exposed spring is far from the clinician or individual. A flexible cover, however, could help improve safety. The force adjustments are limited to the availability of springs with a geometry that fits within the mounting plate. Some versatility in spring force adjustments can be made by stacking the springs and using a longer hex bolt. It is also important to note that because the springs provide constant force, the springs can unwind with sufficient force. As such, a fall arrest lanyard must be used in parallel in any clinical setting. Since overhead support systems already have fall arrest lanyards, all that is required is setting the lanyard to a level of slack so that the BWS device has a range of operation. We tested a limited range of scenarios on a single participant, and it is possible other factors could be revealed through more comprehensive testing.

While we did find that the springs provided nominally constant force for most of their excursion, we observed

significant hysteresis. The force of the smaller springs was reduced by 33% when returning, and the larger springs were reduced by approximately 50%. This hysteresis was evident during walking trials, where spring force lowered by the measured hysteresis values when the vertical center-of-mass (CoM) moved upwards (loading response), and greater spring force was found when vertical CoM was moving downwards (mid-stance/pre-swing) [12]. This represents a potential issue with the functionality of constant force springs as a method of BWS. It is believed that this hysteresis seen in the working portion of the springs is because of friction of the springs. Characterization of constant force springs has shown a relationship between hysteresis and friction:

$$e = f * F_r 2R_d \quad (1)$$

where e is the hysteresis, f is the coefficient of friction in the roller, F_r is the roller reaction force, and R_d is the radius of the drum [13]. Based on these factors, hysteresis could be reduced with design change, for example, including ball bearings within the springs. However, this additional complexity would likely require machining expertise and cost. The clinical tolerance of weight support hysteresis would need to be determined to perform a cost-benefit analysis of making such design changes. There are few, constant force spring BWS systems currently available [8], [9], we are not aware of any published data on hysteresis reported in those devices, it would be interesting to see if they experience the same phenomenon. Likewise, we are not aware of any hysteresis evaluations of passive BWS devices. In its current configuration, due to the imprecise force production due to hysteresis, the device is most fit for clinical application as opposed to research.

One of the major motivations behind this work was to create accessible BWS. While the device itself is accessible, it still requires an overhead system to operate. This could be in the form of an overhead track system (e.g., Solostep, North Sioux City, SD), a two-degree-of-freedom support system (e.g., OASUS by Enliten, Newark, DE), a Universal Exercise Unit, an overground gait trainer (e.g., LiteGait, Tempe, AZ), or other equivalent overhead system. Clinically, BWS is provided as constant or nearly constant weight support [14]. In contrast to a robot that provides dynamic BWS, a passive, low-cost system could account for most of the applied usage at several orders of magnitude lower cost. Clinical trials should clarify in which scenarios such dynamic, robotic BWS is superior to the simpler design presented here.

An accessory like this device would typically be regulated by the FDA as a class I (low-risk) device. Providing the instructions to construct the device would classify one as a "specification developer" if those instructions were provided for commercial gain. However, providing those instructions open source for others to improve upon effectively eliminates the need for FDA regulation. While out of the scope of this work, it raises an interesting question on whether and how to regulate grass-roots "maker" initiatives, created to empower individuals over their own health and reduce undue costs and time using low-risk technologies. An example is a modified ride-on car for use in children with disabilities, a paradigm that has been found to improve socialization and mobility [15] In cases like these, the parent using the car assumes responsibility for its safe use, not the individual posting instructions on how to properly adapt the car. For the device considered here or for other solutions used by therapists, would need approval from clinical engineering, which in most hospitals only governs equipment plugged into the wall.

Delivering Gait Training to Children at Home with a Robotic Knee Exoskeleton: Initial Findings on Feasibility and Patient Satisfaction*

Taylor M. Devine[1], Noah Rubin[1], Afua Asante-Otoo[1], Katharine Alter[1], Jeffrey Fairman[1], Diane L. Damiano[1], and Thomas C. Bulea[1]

Abstract— **Robotic exoskeletons offer the potential to increase gait training dosage by providing therapy outside the clinic. Exoskeleton use in naturalistic settings has been reported but under researcher supervision and for the purposes of assisting mobility. Here, we examined the feasibility of delivering a resistance-based exoskeleton gait training paradigm in the community setting. Five children aged 6-15 years with crouch gait/knee extension deficiency completed 12-weeks of gait training (5 days/week) at home with the exoskeleton as part of an ongoing interventional trial. Weekly telehealth check-ins were completed. Feasibility was assessed using patient-reported adherence to the prescribed dosage, number of adverse events, and exoskeleton hardware and software robustness during the intervention period. User satisfaction was assessed using the QUEST 2.0. No serious adverse events were reported. Participants completed between 44-57 of the targeted 60 sessions of gait training. Exoskeleton hardware and software were reliable with the most common controller adjustments involving tuning of underfoot sensing thresholds to detect stance and swing. Participant satisfaction with the exoskeleton (mean: 3.65/5) and service (4.7/5) were high. Thus, our findings indicate that resistive gait training with an exoskeleton in the real-world is safe and tolerable in children with neuromotor disorders and should be further investigated to determine effectiveness for improving functional mobility.**

Keywords - Exoskeletons, Wearable robotic systems, Usability

I. INTRODUCTION

Device-assisted gait training in children with neuromotor disorders, including full weight-bearing, body-weight support or guided robotic assistance paradigms, range in effectiveness with some studies reporting improvements in posture, gait speed, and endurance [1, 2]. Robotic-assisted gait trainers have gained prominence but are limited to the clinical setting, often coupled to a treadmill [3-5]. These challenges led to the expansion of wearable robotic exoskeleton technology to pediatric populations [6]. Initial cohort studies, conducted in clinical settings, demonstrated efficacy of exoskeletons as assistive devices for children with cerebral palsy (CP) [7-10]. Reduced muscle strength in children with CP is correlated with less locomotor ability [11]. Resistance training can be effective for improving knee extension deficiency [12]. Utilizing robotic exoskeletons and other wearable devices to apply resistance training during walking in clinic-based pilot studies has improved step length and knee extension among other measures [13-16]. These findings support use of robotic exoskeletons for gait therapy outside of the clinical setting to address the limitations of dosage and intensity.

Delivery of exoskeleton-based gait training outside the clinical environment has been very limited to date, especially in children. The Trexo Home (Trexo Robotics, Ontario, Canada), which combines a robotic exoskeleton spanning the hip and knee with an overground walker for safety and stability, was piloted for a non-ambulatory child with CP in the community setting [17]. The case study reported a high number of non-use days suggesting limitations in feasibility. Change in functional outcomes, including range of motion and spasticity, were variable suggesting the need for more controlled studies. The Trexo Home was subsequently analyzed in 70 elementary school age, non-ambulatory children with CP [18]. Usage was highly variable, ranging from 284-1795 steps/week split over 2-5 sessions. Nevertheless, this study indicates at least partial feasibility of exoskeleton use outside the clinical setting, potentially removing a major barrier to more frequent training.

Exoskeletons which target single joints are less encumbering and can be used by more functional individuals, increasing the potential for successful deployment in the real-world. For example, automatic personalized assistance to ambulation has been tested in an ankle exoskeleton resulting in meaningful benefits to gait speed and energetic costs of walking under naturalistic conditions in young healthy people [19]. A different ankle exoskeleton was capable of adapting assistance to real-world settings including uneven terrain [20]. An exoskeleton that assisted hip flexion reduced energy expenditure during uphill, outdoor hiking in healthy individuals and outdoor level walking on a track in adults greater than 60 years of age [21]. Additionally, a recent study of 8 individuals with CP spanning multiple levels of functional mobility (Gross Motor Function Classification System (GMFCS) I-III) demonstrated feasibility of using an ankle exoskeleton outdoors during level, incline and decline, and stair walking [22]. After 4 visits, participants significantly reduced their metabolic cost of walking, increased walking speed or both and all participants stated they preferred walking with rather than without the device. These results demonstrated rapid acclimation to the device with consistent improvement across sessions in most participants. Collectively, these studies demonstrate feasibility of deploying robotic exoskeletons across diverse naturalistic settings and

user populations. Yet, these exoskeletons have all been used to assist, rather than train gait. Further, while experiments were completed in settings that reflected the real world by testing across multiple types of terrain, exoskeleton use was supervised by researchers who were present during each session. Therefore, the suitability of delivering gait training in a real-world setting, without the presence of clinicians or researchers, remains to be investigated.

We previously developed a robotic exoskeleton for over-ground use in children with knee extension deficiency [7, 8, 23, 24]. A next generation wearable robotic exoskeleton (Agilik®, Bionic Power, Inc., Vancouver, Canada) was later developed with an expanded target population to include children with CP, spina bifida (SB), muscular dystrophy (MD) or incomplete spinal cord injury (iSCI). The exoskeleton can apply torque to assist and/or resist knee movement. Initial findings from clinical evaluation of this exoskeleton showed that application of resistance during phases of knee extension was tolerable and increased extensor muscle activity during use, thereby providing the potential to strengthen muscles and improve function if used for an extended time [25]. Further, by interleaving assistive and resistive torques within the gait cycle, the resistance-based therapy could be extended to more affected individuals at elevated risk of mobility loss due to significant weakness and/or diminished motor control.

Based on these preliminary findings, we initiated a randomized interventional trial to evaluate the safety, feasibility and effectiveness of a 12-week resistance-based exoskeleton gait training regimen delivered in the home/community environment in children age 3-17 years with crouch gait from CP or knee extension deficiency from MD, SB or iSCI [26]. To our knowledge, this ongoing trial constitutes the first controlled study evaluating an exoskeleton that challenges users during walking outside of a clinical setting. The study includes primary outcome measures assessing changes in knee extension, gait speed, muscle activity during walking and strength. Importantly, feasibility, assessed as a measure of compliance with study parameters, safety, assessed as recorded adverse effects, and patient-reported usability are secondary or exploratory objectives of the ongoing protocol [26].

This manuscript aims to provide an initial analysis of the safety and feasibility of and participant satisfaction with the 12-week robotic intervention delivered outside the clinical setting. Our analysis encompasses data from five participants who completed the exoskeleton intervention. The goal is to fill the existing knowledge gap regarding suitability of unsupervised exoskeleton mediated gait training in the real world.

II. Methods

A. Intervention Description

The interventional study from which the data here were collected is a randomized crossover trial with two arms lasting 12 weeks each: (1) exoskeleton intervention and (2) standard therapy control. All participants completed both arms but the order in which they were completed was randomized. In this manuscript, only data from the first arm (the 12-week exoskeleton intervention period) was evaluated.

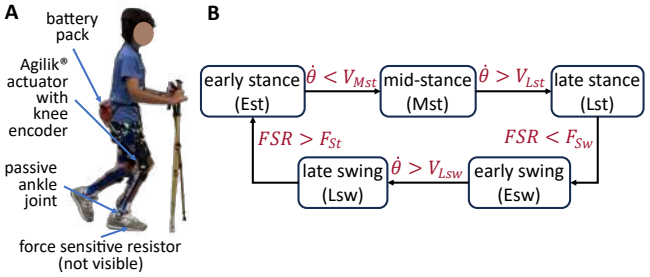

Fig. 1. A. The robotic knee exoskeleton utilized for delivery of gait training outside the clinic. B. The exoskeleton 5-state finite state machine that tracks user walking in real-time to deliver knee torque during walking.

The exoskeleton used for the intervention (Fig. 1) is based on a knee-ankle-foot orthosis (KAFO), with one actuated degree of freedom at the knee in the sagittal plane (Agilik®, Bionic Power, Vancouver, Canada) and a passive adjustable degree of freedom to control dorsi/plantar flexion stiffness and range of motion at the ankle (ADR®, Ultraflex Systems, Pottstown, PA). A custom KAFO is fabricated by a commercial orthotics manufacturer (Ultraflex) for each participant using a digital scan of their legs captured using a Structure Sensor Pro and an iPad. The knee actuator and ankle mechanism are attached to the lateral side of each KAFO. The actuator includes a motor encoder that measures knee angle and angular velocity (by differentiation) and force sensitive resistors (FSRs) mounted within the orthosis footbed detect foot-ground contact. The actuator also includes a Bluetooth modem which can connect to a software application on a laptop to stream, display and save sensor and actuator data at 100 Hz (Fig. 2, Fig. 3).

The exoskeleton parses the gait cycle into five discrete states in real-time (Fig. 1): early stance (Est), mid-stance (Mst), late stance (Lst), early swing (Esw), and late swing (Lsw) [25]. The swing-to-stance (foot contact) and stance-to-

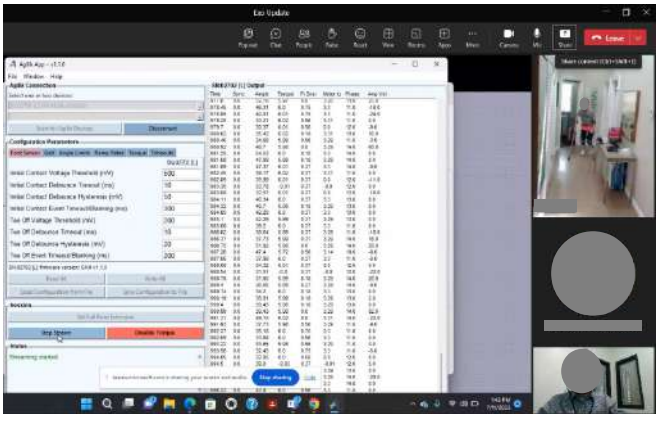

Fig. 2. Screenshot of a weekly telehealth visit. Left: The exoskeleton app streams real-time sensor data over the internet to the clinical team. Right: Live video of a participant walking with the exoskeleton at home while researchers monitor exoskeleton performance. Note: faces and names of the participant and study members have been obscured.

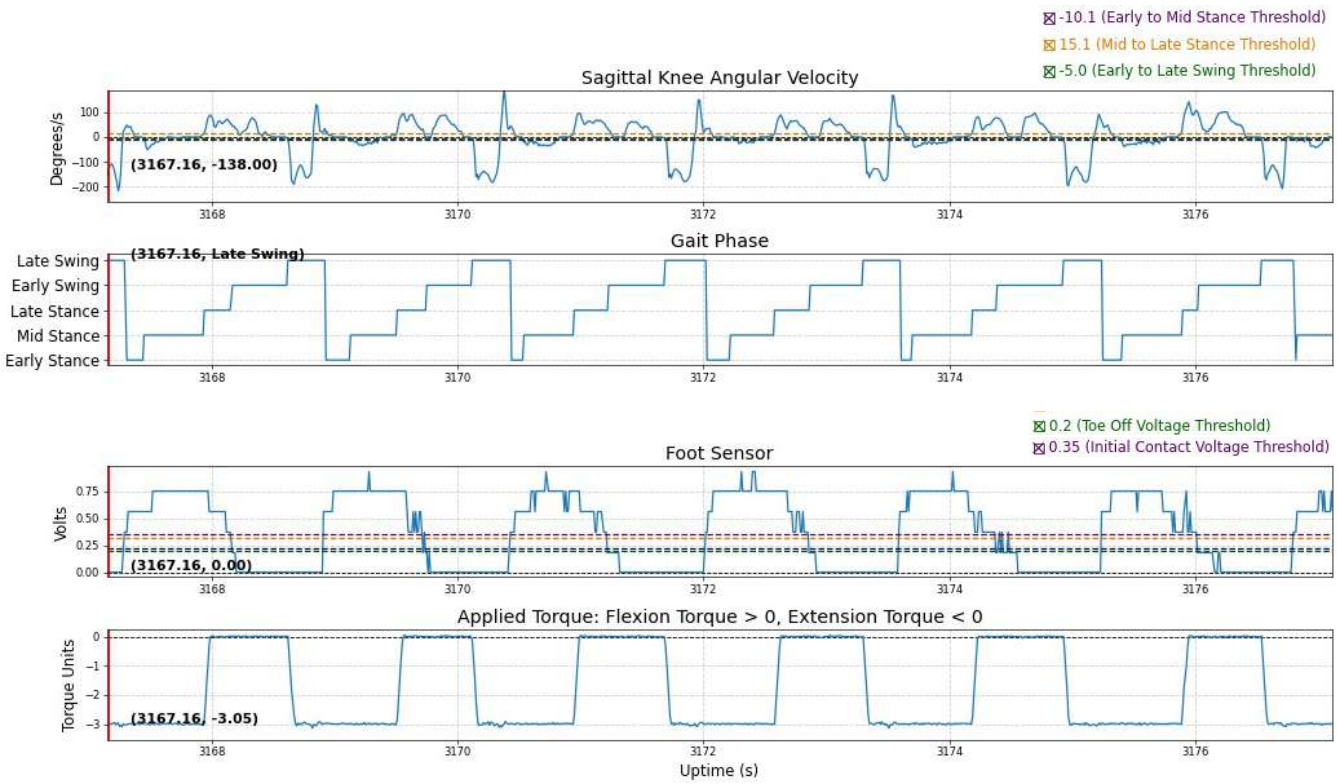

Fig. 3. Screen capture showing example data that are displayed in real-time by the app to facilitate adjustment of exoskeleton parameters if necessary. The top panel shows knee angular velocity in the sagittal plane and the angular velocity thresholds for early-to-mid-stance (V_{Mst}), mid-stance-to-late-stance (V_{Lst}), and early-to-late swing (V_{Lsw}) transitions. The second panel displays the output of the finite state machine. The third panel displays total voltage output of the underfoot FSR sensors and the thresholds for transition for foot contact (F_{St}) and foot off (F_{Sw}) events. The bottom panel displays applied torque.

swing (foot off) transitions are controlled by the underfoot FSR. Two separate thresholds are set for each participant, whereby when the FSR reading exceeds the first (F_{st}), the state machine transitions to stance, and when the FSR reading falls below the second (F_{sw}), it transitions to swing. States within stance and swing phase are determined by separate knee angular velocity thresholds for Est to Mst (V_{Mst}), Mst to Lst (V_{Lst}), and Esw to Lsw (V_{Lsw}) transitions. The Est to Mst and Esw to Lsw transitions occur when the knee angular velocity falls below the threshold governing each (extension velocity negative) whereas the Mst to Lst transition occurs when the angular velocity exceeds the threshold (flexion velocity positive). Within each gait phase, the exoskeleton can apply pre-tuned torque profiles up to 12 Nm in either the flexion or extension direction.

After custom exoskeleton fabrication, each participant completed 3-5 visits (up to 4 hours each) wherein the exoskeleton therapy was personalized to each individual and each family was educated on proper use of the device. The goal of the interventional study was to evaluate the ability of exoskeleton applied resistance to knee extension (i.e., a flexion torque) during walking to improve gait function. Briefly, the exoskeleton tracks the user's limbs as they walk and applies a resistive (flexor) torque during periods of knee extension in weight bearing (Mst) and/or swing (Lsw). These resistive torques have been previously shown to increase knee extensor muscle activity during walking [25]. The objective is to deliver this gait training at high dosages, with the hypothesis that doing so will increase knee extensor muscle strength and activation during walking, which can ultimately improve crouch gait.

After setup, participants completed 12 weeks of gait training using the exoskeleton at home or in the community. Participants were instructed to walk for 5 days/week for 1 hour/day using the exoskeleton. Participants were also provided a laptop to connect wirelessly to the exoskeleton through the app. Participants were requested to complete weekly telehealth visits (Microsoft Teams) with the study team during the 12-week intervention period (Fig. 2). During these visits researchers could view live video of the participant walking with the exoskeleton while its sensor data were streamed and recorded via the laptop app. Researchers also verbally reviewed the user's experiences during the past week's gait training sessions. Based on this information, researchers made changes to controller thresholds as necessary to ensure the exoskeleton was accurately tracking the user's gait phases and applying correct torques. Adjustment to torque magnitudes were also be made to progress (or dial back) the intervention intensity as needed. These changes were logged in text-based format (JSON file).

TABLE I

PARTICIPANT INFORMATION

Participant	Diagnosis	Gender	Age (yrs)	Height (cm)	Weight (kg)	GMFCS
P1	cerebral palsy	male	15	150	46.4	III
P2	cerebral palsy	male	14	162	41.2	II
P3	muscular dystrophy	female	10	143	41.3	-
P4	cerebral palsy	female	6	110	17.9	III
P5	spina bifida	male	11	146	38.6	-

B. Study Participants

Data were collected as part of an ongoing clinical trial [26]. The study was approved by the Institutional Review Board of the National Institutes of Health (protocol #001180) and is registered on clinicaltrials.gov (NCT05726591). Five participants (Table 1) who completed the 12 week home-based exoskeleton gait training intervention were included in this analysis. All participants and their parents/guardians completed informed assent and consent, respectively.

C. Objectives, Data Collection, and Outcomes

The primary objectives of this manuscript were to evaluate the initial feasibility and patient satisfaction with the resistance-based exoskeleton therapy delivered in the home environment over 12 weeks. Two aspects of feasibility were assessed. First, robustness of the exoskeleton during home use was quantified for hardware by the number of required maintenance events, and for the software/control system by the number of required adjustments to controller parameters during the intervention period. Second, participant adherence to the prescribed training protocol was assessed using patient self-reported exoskeleton use (dates and durations) as well as the occurrence of adverse events and side effects.

To assess participant satisfaction with the exoskeleton, we administered the QUEST 2.0 [27] which asks participants to rank their satisfaction with the exoskeleton in 8 categories (dimensions, size, adjustability, safety, durability, ease of use, comfort and effectiveness) and services related to the device in four categories (service delivery, repairs and servicing, professional services, and follow-up services).

III. RESULTS

A. Feasibility of Exoskeleton Gait Training in the Real-World

We completed regular, weekly telehealth visits with research participants during the 12-week intervention period. These visits typically lasted 20-40 minutes and included at least 1 clinical member (physical therapist) and one technical member (engineer) from the research team. During each visit, the participant walked with their exoskeleton while it was wirelessly connected to the app to stream, save and display data in real-time (Fig. 2, Fig. 3). Based on these data, the ability of the exoskeleton to track the 5 states of the gait cycle was assessed, and if necessary, thresholds that governed the transitions between states were adjusted to improve state machine tracking.

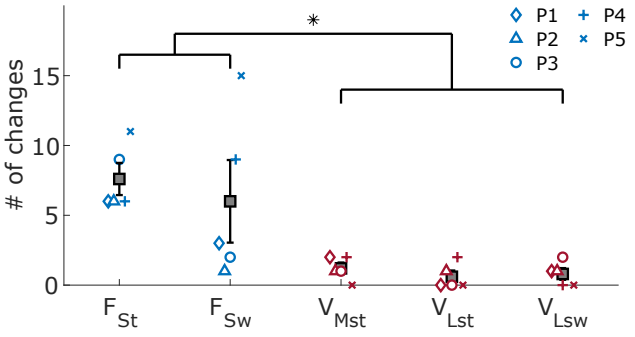

Fig. 4. The total number of changes of exoskeleton controller thresholds over the 12-week intervention period. Mean values for each threshold are shown as squares with error bars indicating 1 standard deviation. Individual data points show adjustments for each participant. Blue indicates FSR thresholds and red indicate angular velocity thresholds. * indicates significant difference between FSR and velocity thresholds.

We found that the 5-state finite state machine could robustly track user walking across the 12-week intervention period (Fig. 4). The majority of control parameters were stable with fewer than 3 adjustments during the entire intervention. The most frequent parameters requiring adjustment were the FSR based measures (F_{St} and F_{Sw}). In the majority of instances in which FSR thresholds were adjusted, the state transitions were still present but delayed. However, this was not the case in the two instances of FSR failure as described below. The knee angular velocity-based thresholds (V_{Mst}, V_{Lst}, and V_{Lsw}) had comparatively fewer adjustments than FSR-based thresholds. This result was statistically significant (paired t-test) with $p < 0.001$ (Fig. 4). We observed a correlation trend with participant age, wherein the younger participants (P3, P4, and P5) tended to require more adjustments than the older ones.

From a hardware perspective, the exoskeleton was robust across the intervention period. One actuator in one participant required repair due to a failure in the power supply circuitry. Three underfoot FSR sensors required replacement; one due to a loss of sensitivity and two due to complete failure. Mechanically, the KAFO design was robust with two participants reporting slight loosening of single fasteners that required manual tightening.

B. Participant Adherence to the Intervention

The exoskeleton delivered therapy applies resistance to knee extension during multiple points of the gait cycle, which is intended to make walking more difficult as an exercise. Although the trial is ongoing, our initial findings support the feasibility of our high dosage intervention design. Three of five participants have returned the self-reported usage log to date, reporting 44, 56, and 57 total walking sessions over the 12 weeks. Two of three completed at least 80% of the 60 session target and the one who did not experienced a medical event of a family member which disrupted therapy delivery. Within each day of training, participants reported 41.4 ± 3 mins (mean ± standard deviation) of walking. These initial findings indicate a high dosage of gait training

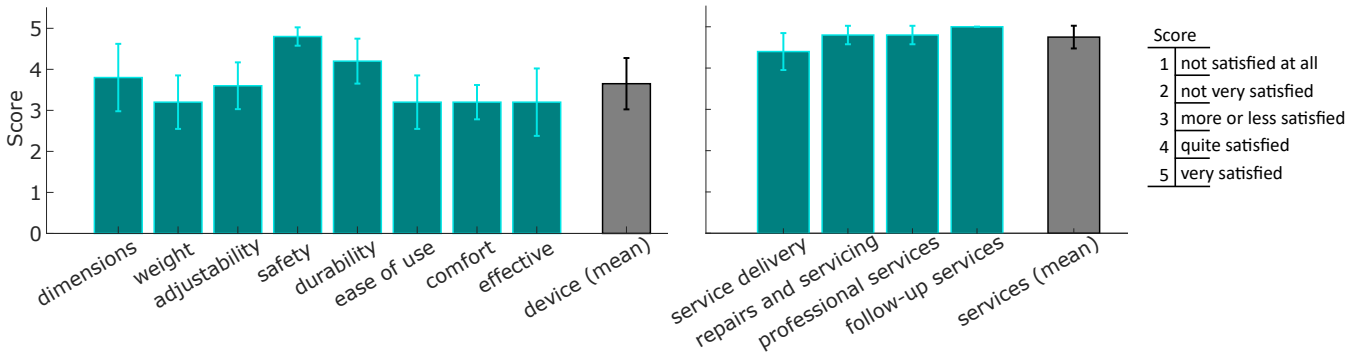

Fig. 5. Results of the QUEST 2.0 survey (n=5) to assess satisfaction with the exoskeleton device (left) and services (right). Green bars indicate mean for each item; gray bars indicate mean across the items for the device (left) and services (right). Error bars indicate 1 standard deviation.

is attainable, but the desired 60 minutes of walking was not fully achieved. Participants reported exoskeleton use across diverse settings including at home (overground and treadmill), in the community (sidewalks, streets and places of business), at public gyms, (overground and treadmill), physical therapy, school, and on an outdoor track.

To date, there have been no serious adverse events and no unanticipated problems with the exoskeleton intervention in participants who have completed the 12-weeks of therapy. One participant reported soreness of the knee extensor muscles and knee joint, which was an expected side-effect. This was addressed by providing several days of rest and a reduction in the resistance torque during walking for 1 week, after which the participant was able to return to their previous resistance level.

The goal of the intervention is to increase the delivered resistance torque over time if tolerated by the participant. We were able to achieve this goal in all 5 participants, with total increases in torque ranging from 0.5 to 2.5 Nm, constituting increases of 20-50% from their initial resistance levels.

C. Participant Satisfaction

Overall, participant satisfaction (n=5) with the exoskeleton device (QUEST 2.0) was good (Fig. 5), with a mean score of 3.65 and greater than half of responses to the 8-item device survey being either "quite satisfied" (4) or "very satisfied" (5). Importantly, safety was the most highly rated aspect of the exoskeleton with 4/5 scoring this aspect as "very satisfied" while 1 was "quite satisfied", thus indicating that participants felt secure using the exoskeleton delivered gait training in the home and community environments. Four areas received mean scores of "more or less satisfied": weight, ease of use, comfort and effectiveness. The first 3 categories suggest that design improvements which make the physical device as well as the user interface less cumbersome would be beneficial. Effectiveness was the only category in which a participant reported a score of 1 ("not satisfied at all"). It is possible scoring in this category was affected by the intended application: the purpose of the exoskeleton was for exercise, which makes walking more difficult. Multiple users reported disliking this effect, compared to walking without the exoskeleton. Given that the QUEST 2.0 asks "how effective your assistive device is", it is possible this incompatibility was driving the lower scores.

Compared with the physical device, participants were overall more satisfied with the services they received from the study team (Fig. 5). The mean score across the 4 categories was 4.7/5, with only 1 response scored as "more or less satisfied" (3), while all others were either "quite satisfied" (3/25 responses) or "very satisfied" (21/25).

IV. Discussion

There is emerging evidence to support feasibility of exoskeleton use in the real-world including multiple recent examples of assistive devices demonstrating mobility and energetic benefits in naturalistic settings in healthy individuals as well as aging and pediatric populations [19-22]. Yet, these studies have been done under researcher supervision and have focused, to our knowledge, on assisting mobility. Thus, the ability to deliver gait training that applies resistive torques to the limbs using a wearable exoskeleton in multiple settings remains unknown. Here we show the first evidence that this is feasible with a single joint knee exoskeleton in a diverse pediatric cohort.

Although the overall clinical trial is ongoing so we cannot yet assess the functional or biomechanical efficacy of the intervention, our preliminary findings show feasibility, safety and tolerability to support continued investigation of this approach. Importantly, in three participants, the exoskeleton intervention delivered assistance during midstance and resistance during late swing while the other two received resistance to knee extension during both phases. Further, all participants utilized assistive devices (such as trekking poles, lofstrand crutches or walkers) when walking overground. Thus, our findings indicate that our resistance and combined assistance and resistance approaches are well tolerated in a broad clinical population with neuromuscular disorders.

Many control strategies exist for delivery of exoskeleton torques during walking. Our findings indicate that the finite state machine approach is relatively stable across a 12-week intervention period in children with neuromotor disorders using assistive devices (i.e., walkers or crutches) in multiple environments. Notably, the thresholds related

to underfoot sensing were the most sensitive week-to-week (Fig. 4), whereas those for angular velocity were more stable. Taken together with the finding that the FSR was the most often replaced component, these results suggest removal of the FSR underfoot would enhance robustness. Potential alternatives include the use of IMUs to track foot ground contact, or alternately a continuous phase control approach [20] rather than a finite state machine.

Overall, protocol adherence was as forecasted in the initial study design [26]. Although some participants reported less satisfaction with certain aspects of the device, it was generally well tolerated. These high ratings are likely due to the interdisciplinary nature of the study team performing the clinical trial, which included physicians, physical therapists, recreation therapists, orthotists, and engineers. It is important to note this large of a team is not likely to be feasible for delivery of the intervention in typical clinical settings, so future studies are warranted to examine how to optimize intervention delivery. It will also be important to compare user perceptions of the device with the functional outcomes from the study. Other factors affecting home use not directly captured by the QUEST 2.0, such as ability to don/doff the device, operate the exoskeleton independently, and battery life should also be evaluated. Additional limitations include the relatively small size of the cohort to date, especially given the range in ages and statures, and the lack of a control condition, such as the home use of a wearable exoskeleton for assistance versus gait training. Importantly there were no serious adverse events or other safety concerns and no issues with major noncompliance. Thus, our findings provide initial evidence that gait training with a resistive exoskeleton paradigm in the real-world is safe and tolerable in a pediatric cohort, and should continue to be pursued in the future.

ACKNOWLEDGMENT

The authors thank Jesse Matsubara and Jordan Dembsky for their contributions to data collection and analysis, Brent Sperry for his pedorthotic services, and Robin Greenfield and Karen Perkins for providing recreation therapy services.

Demographic-Driven Electromyography Analysis: Advancing Personalized Biosignal Interpretation

Maedeh Mohammadiazni, Yue Zhou, and Ana Luisa Trejos, *Senior Member, IEEE*

***Abstract*— The integration of rehabilitation robotics and surface electromyography (sEMG) offers a powerful approach for monitoring and enhancing recovery in patients with neuromuscular disorders. However, variability in baseline sEMG readings across individuals can limit its effectiveness. Factors such as age, height, and weight influence these baselines, and there is a lack of personalized baselines that account for demographic differences. This study proposes a novel model to estimate individualized baselines for one important sEMG parameter, Root Mean Square (RMS). Demographics and physiological data were collected from 30 healthy participants, and sEMG signals were recorded using four electrodes on the forearm muscles during a pushing task at two wrist positions. A Decision Tree Regression model was developed for each combination of the two wrist postures and four electrode locations, resulting in eight combinations, with optimal features identified using the Recursive Feature Elimination method. The regression models achieved accuracies ranging from 88.81% to 95.6%. A global sensitivity analysis using the Sobol method evaluated the importance of each input feature. Results indicate that gathering more comprehensive sEMG data for the most influential factors could improve model generalizability. The findings of this study offer a promising approach for individualized sEMG baselines, with potential applications in rehabilitation robotics to enable personalized recovery strategies for neuromuscular disorders.**

I. INTRODUCTION

Neuromuscular disorders include a range of conditions that impact the muscles and nervous system [1], [2]. Accurate diagnosis of these conditions is critical for effective management and treatment [3]. Surface Electromyography (sEMG) is a valuable tool in the diagnostic process, providing detailed insights into muscle and nerve function by analyzing the electrical signals generated during muscle activity [4]. Distinguishing between normal sEMG patterns and deviations is crucial for identifying changes associated with neuromuscular disorders, where normal sEMG refers to the expected sEMG value in the absence of neuromuscular impairments. This capability extends to applications in rehabilitation robotics, particularly in biofeedback systems that assist in neuromuscular recovery. By leveraging sEMG to detect and interpret abnormal muscle activation patterns, biofeedback devices can provide real-time feedback to patients, enabling them to adjust their movements to achieve more normative muscle activation.

As a standard practice, identifying abnormal sEMG signals has relied on visual inspection and comparison with normative values or baseline measurements from a population [5], [6]. However, a significant limitation of this approach is its failure to account for inter-individual variability, which can affect the accuracy of assessing neuromuscular disorders. Specifically, the features of the sEMG signal are influenced by individual factors such as age [7], [8], gender, and muscle mass—underscoring the limitations of using a single standard for normal sEMG features across all individuals. To address these challenges, such studies have attempted to use machine learning techniques [9]–[11]. By leveraging large datasets, these techniques aim to model the variability in sEMG signal features across different populations, enabling more personalized and precise analyses of sEMG signals. However, gathering large labeled datasets is often a major challenge, as it demands a considerable amount of annotated data for model training, which can be both time-consuming and expensive to acquire.

To overcome these challenges, this study proposes a novel method for developing models that estimate the normal sEMG characteristic of forearm muscles, personalized for each individual. By integrating individual demographic factors, including age, forearm length, forearm circumference, wrist circumference, height, and weight, along with physiological factors such as wrist sensory threshold and wrist motor threshold, the models aim to estimate personalized baselines for a key sEMG parameter, Root Mean Square (RMS), a measure of sEMG signal strength. RMS was selected as it reliably measures sEMG signal amplitude, directly associated with muscle activation, making it useful for assessing muscle function and detecting abnormalities in neuromuscular health [12], [13]. The objective of the proposed method is to address a critical limitation in the standard practice of using generalized normative values for sEMG analysis by accounting for variability in individual factors. This approach has the potential to enhance the accuracy of neuromuscular disorder assessments by estimating normal sEMG features in patients, providing a baseline for comparison after the onset of a neuromuscular disorder. Additionally, it can support applications in rehabilitation and biofeedback systems by enabling individualized assessments of muscle function.

II. METHODOLOGY

Surface EMG signals are influenced by multiple factors, necessitating a comprehensive approach to accurately model and interpret them [14]. In addition to individual differences, factors such as electrode placement and arm posture can significantly impact the quality and interpretation of sEMG signals [15]. The position of the electrodes can influence the recorded signal due to variations in the alignment of muscle fibers relative to the electrode. Similarly, arm posture can affect muscle activation patterns, altering their electrical activity. These factors contribute to additional variability, emphasizing the importance of considering electrode placement and arm posture when interpreting sEMG data. Accordingly, to achieve the objective, this study investigated two wrist postures and considered four electrode placements on the arm to account for these factors. For each combination of the two wrist postures and four electrode locations (corresponding to four channels, as shown in Fig. 2), one model has been developed, resulting in eight models. These models, which predict the RMS of the sEMG signal based solely on individual features, are built using the Decision Tree Regression (DTR) approach, with all models having the same architecture and parameters. The DTR approach was chosen due to its ability to capture complex relationships in the data and its robustness to outliers, making it well-suited for various regression tasks [16].

To develop the models and explore the relationship between the RMS of the sEMG signal and individual features, it was essential to identify which features were most relevant. Since it was uncertain whether the relationship involved all features, just one, or a combination of several, the Recursive Feature Elimination (RFE) technique [17] was employed. This method iteratively removes less important features, helping to identify the optimal set of predictors. By using RFE, the most influential features were selected, resulting in the best models for predicting RMS. For evaluation, the trained model predicts the RMS of the sEMG signal for individuals in the test group without accessing their actual RMS values. The predicted values are then compared to the actual values to calculate the accuracy. The global Sobol sensitivity analysis [18] was then conducted to assess the impact of each of the most influential features identified through RFE on the models' predictions, aiming to determine the extent to which each factor contributed to the variability in the predicted RMS. Fig. 1 provides a summary of the entire process of model development and sensitivity analysis.

A. Data Collection

To investigate the proposed approach, this study recruited thirty healthy participants (ethics approval was obtained from the Human Research Ethics Board at Western University, Project ID: 117923). Prior to participation, all individuals provided informed consent and were briefed on the study's procedures and goals. The demographics and physiological features of the participants (as listed in Table I) were collected and used as input parameters for the model. To measure wrist sensory and motor thresholds, participants were seated on a chair, with their arm resting on the armrest, as shown in Fig. 2. A pair of commercially available wet electrodes (KendallTM H590P, Fig. 2, #2) were used and placed on the muscle responsible for wrist flexion, identified through the palpation technique. One electrode was positioned approximately 5 cm distal to the medial epicondyle, and the second electrode was placed 1 cm distal to the first one along the longitudinal direction of the flexor carpi radialis. These two electrodes were connected to a transcutaneous electrical stimulator (TENS 210, Fig. 2, #1). A consistent series of electrical pulses were delivered to the electrodes. The pulse width was set to 200 μs and the pulse frequency to 50 Hz, following the parameters commonly reported in the literature (e.g., [19]). The stimulation current increased from 0 mA to the participant's sensory threshold and motor threshold, and the corresponding values were recorded.

For sEMG data collection, four pairs of sEMG electrodes were placed on the forearm muscles of the participants (as shown in Fig. 2, #3). Velcro straps securely positioned the electrodes, ensuring stable skin contact and minimizing movement interference. Participants were instructed to exert their maximum voluntary pushing force against a block that was securely held by the experimenter for a duration of 3 seconds. The block was adjustable, allowing for the achievement of various wrist flexion angles during the task. Data were collected in two wrist postures: one at 30 degrees and the other at maximum flexion.

B. Processing of sEMG Signal

Processing sEMG signals serves several purposes, including reducing noise from various sources such as electrical interference and movement artifacts. It also enhances the Signal-to-Noise Ratio (SNR) and enables the detection of muscle activity onset.

Initially, the raw sEMG signals were downsampled from 4 kHz into 1 kHz and then filtered using a bandpass filter to remove low and high frequencies. Specifically, a high-pass filter with a cutoff frequency of 10 Hz and a low-pass filter with a cutoff frequency of 400 Hz were employed. These cutoff frequencies are commonly used in sEMG signal processing [20]. To prevent the filtered sEMG signals from averaging to zero, rectification was applied, converting negative oscillations into positive values. To detect onsets, or sudden increases in muscle activation levels, the rectified sEMG signals were smoothed by applying a moving average filter. The onset point in the energy signal obtained with Teager-Kaiser energy operator (TKEO) [21] was identified as the point where the most significant increase in the RMS of the signal occurred. To detect offsets, the rectified sEMG signals were similarly analyzed; however, with a focus on the point where the RMS of the energy signal, calculated using the TKEO, dropped significantly after the onset. The TKEO equation is given as follows [22]:

$$\psi[e_n] = e_n^2 - (e_{n+1} \times e_{n\infty 1}) \,, \tag{1}$$

TABLE I

OVERVIEW OF PARTICIPANT DEMOGRAPHICS AND PHYSIOLOGICAL FEATURES

Age (years)	Forearm Length (cm)	Forearm Circumference (cm)	Wrist Circumference (cm)	Height (cm)	Weight (kg)	Wrist-Sensory Threshold (mA)	Wrist-Motor Threshold (mA)
27.56± 7.18	25.4± 2.06	24.78± 1.91	15.93± 1.28	171.25± 8.4	68.94± 10.29	11.5± 2.28	20.76± 8.12

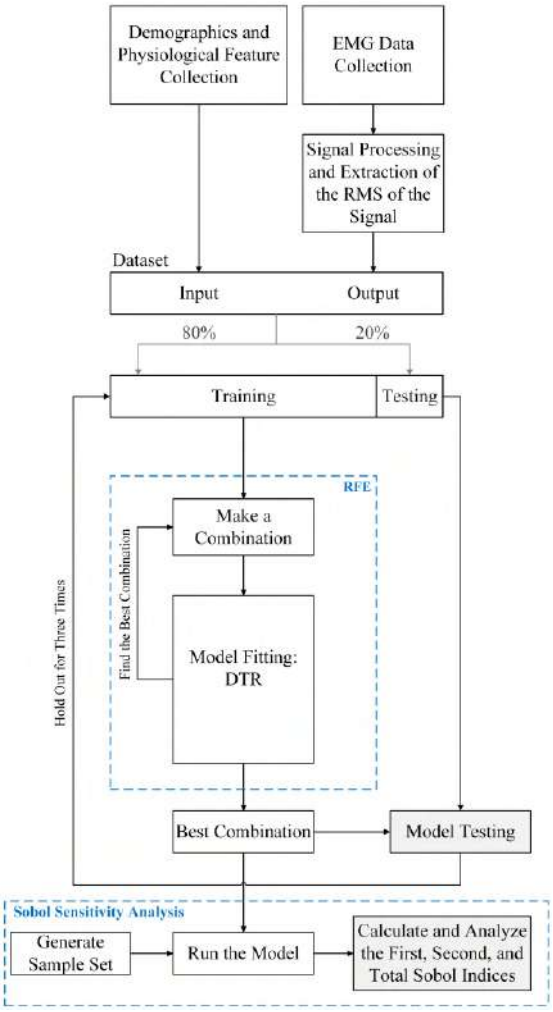

Fig. 1. The workflow of model development and Sobol sensitivity analysis involved the collection of demographics and physiological factors of individuals, which were considered as inputs for training. The sEMG signal was processed to compute its RMS, which was used as the output. The dataset was divided into training (80%) and testing (20%) subsets. RFE was applied to the DTR model to identify the optimal combination of input parameters for maximum accuracy. During testing, the model predicted the RMS of the sEMG signal without referencing the actual RMS value, and the predicted RMS was compared with the real RMS to evaluate model performance. The training and testing process was repeated three times using the holdout method with predefined, non-overlapping 20% test sets. The Sobol sensitivity analysis was then conducted, where samples were generated, the model was applied, and Sobol indices were calculated to assess the influence of input parameters. This entire process was repeated for each of the eight models, created from the combinations of two wrist postures and four electrode locations.

(c) Front view of the hand during sEMG measurements. (1) Transcutaneous electrical stimulator (TENS 210). (2) Stimulation electrodes (KendallTM H590P). (3) sEMG electrodes. Each channel consists of two electrodes, with a 2 cm distance between adjacent channels. (4) sEMG data acquisition device (Intronix 2024F Isolated Amplifier). (5) The block was used in the experiment to create different wrist flexion angles.

where e represents the sEMG measurement and n denotes the data point number. Following the detection of onset and offset, the sEMG signal starting from the onset and ending at the offset was selected, and the RMS of this window was calculated for each individual.

C. Model Development

The aim of developing a DTR model is to predict the RMS of sEMG signals for individuals in the test group based on their unique features, without requiring actual sEMG data. To achieve this, the model was trained on a training group using normalized individual features, including age, forearm length, forearm circumference, wrist circumference, height, weight, and wrist sensory threshold as inputs, with the normalized RMS of sEMG signals as the output. The trained model was then tested on the test group to predict the RMS values of sEMG signals. To achieve this, the dataset was divided into two subsets using a hold-out validation approach: 80% for training and 20% for testing. To ensure robustness and minimize the impact of any specific data split, this process was repeated three times.

The optimal combination of individual features was selected

using the RFE technique. In DTR, data were split into smaller subsets based on feature values, creating a tree-like structure where each node represents a decision rule [16]. The DTR algorithm seeks to reduce variance to identify optimal splits, with the leaf nodes representing the predicted target values [16].

The combinations of input features that maximized the predictive accuracy of the DTR model were identified using RFE, and the model was subsequently evaluated using the Mean Absolute Percentage Error (MAPE) as the performance metric. MAPE measures the average percentage difference between the predicted and actual values, and is calculated as follows:

$$\text{MAPE} = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{y_i - \hat{y}_i}{y_i}\right| \times 100 \ , \tag{2}$$

where y_i is the actual RMS value, $\hat{y}_i$ is the predicted RMS value, and n is the total number of observations. Eight regression models were developed using two wrist postures (30 degree flexion and maximum flexion) and four electrode placements on the forearm, resulting in 8 distinct models.

D. Sobol Sensitivity Analysis

A global sensitivity analysis was conducted to assess the influence of individual demographics and physiological factors used to develop the DTR model on its behavior. This analysis enables the exploration of the impact of both individual and combined changes in these parameters on variations in the RMS of sEMG signals. In this study, the Sobol sensitivity analysis method was applied, a widely used technique in uncertainty quantification and global sensitivity analysis [18], [24]. Considering the RMS of the sEMG signal (Y) as a function of the individual features, the relationship can be expressed as follows:

$$Y = f(\mathbf{Z}) \ , \tag{3}$$

where Z represents the set of model parameters, which correspond to the individual features in this study. The Sobol method determines the importance of each parameter by decomposing the variance of Y into components attributable to each input parameter. For a square-integrable function, this decomposition is given by the following [18]:

$$f(\mathbf{Z}) = f_0(\mathbf{Z}) + \sum_{s=1}^{n}\sum_{i_1<\cdots<i_S} f_{i_1\ldots i_S}(\mathbf{Z}_{i_1},\ldots,\mathbf{Z}_{i_S}) \ , \tag{4}$$

where f_0 is the expected value of f. It has been shown that the summands in the equation above can be recursively calculated using integrals. Further details on how these parameters can be computed are provided in [18], [24]. After performing the substitutions, the total variance is computed as follows:

$$D = \int f^2(\mathbf{Z})\, d\mathbf{Z} - f_0^2 \ . \tag{5}$$

Moreover, the partial variances are defined as follows:

$$D_{i_1,\ldots,i_S} = \int f^2_{i_1\ldots i_S}(\mathbf{Z}_{i_1},\ldots,\mathbf{Z}_{i_S})\, d\mathbf{Z} \ . \tag{6}$$

TABLE II

AVERAGE MAPE ACCURACY OF THE EIGHT MODELS FOR CHANNELS 1 TO 4 AT DIFFERENT WRIST ANGLES OVER THREE TEST SETS

Channel	Accuracy at 30° Flexion	Accuracy at Maximum Flexion
1	93.20 ± 3.75	91.05 ± 6.14
2	94.76 ± 0.77	95.41 ± 0.85
3	91.07 ± 2.49	94.01 ± 2.41
4	88.81 ± 1.26	95.60 ± 1.10

The Sobol indices are defined as follows [18]:

$$S_{i_1,\ldots,i_S} = \frac{D_{i_1,\ldots,i_S}}{D} \ . \tag{7}$$

The first-order Sobol index, which considers only a single input parameter, quantifies its individual effect, while higher-order Sobol indices capture interactions between multiple parameters. The total-order Sobol index for a given parameter i is the sum of all Sobol indices involving that parameter and is defined as follows:

$$S_i^T = 1 - S_{\sim i} \ . \tag{8}$$

The symbol $\sim i$ indicates that the variable i is excluded. The total-order Sobol index represents the overall contribution of a parameter to the output, including its interactions with other parameters. The Sobol sensitivity analysis was performed using the SALib library in Python [25], [26]. A normal distribution was assumed for all parameters in the Sobol sensitivity analysis procedure.

III. RESULTS

A. Model Development Results

The optimal feature combination that yields the best DTR learner was determined using the RFE method. The findings revealed that the optimal combination varies depending on wrist position and electrode location. Fig. 3 provides an example of the variability in results across different electrode locations (channel numbers shown in Fig. 2). As shown in Fig. 3, the highest accuracy for the best-performing combinations was achieved with five features for Channel 1, four features for Channel 2, five features for Channel 3, and three features for Channel 4. Fig. 4 illustrates the prediction MAPE accuracy of the optimal models (selected using RFE) for estimating the RMS of the sEMG signal across three test sets, with a total of eight models (2 wrist postures×4 sEMG channels). The average MAPE accuracy of the models for Channels 1 to 4 at two wrist postures is illustrated in Table II.

B. Sobol Sensitivity Analysis Results

After finding the optimal feature combination using RFE that results in the most accurate DTR model, those features underwent Sobol sensitivity analysis. The first-order, second-order, and total-order Sobol indices are shown in Fig. 5 for the wrist at 30 degree flexion and at maximum flexion. The first-order indices illustrate the effects of each input parameter on the output variations, the second-order indices

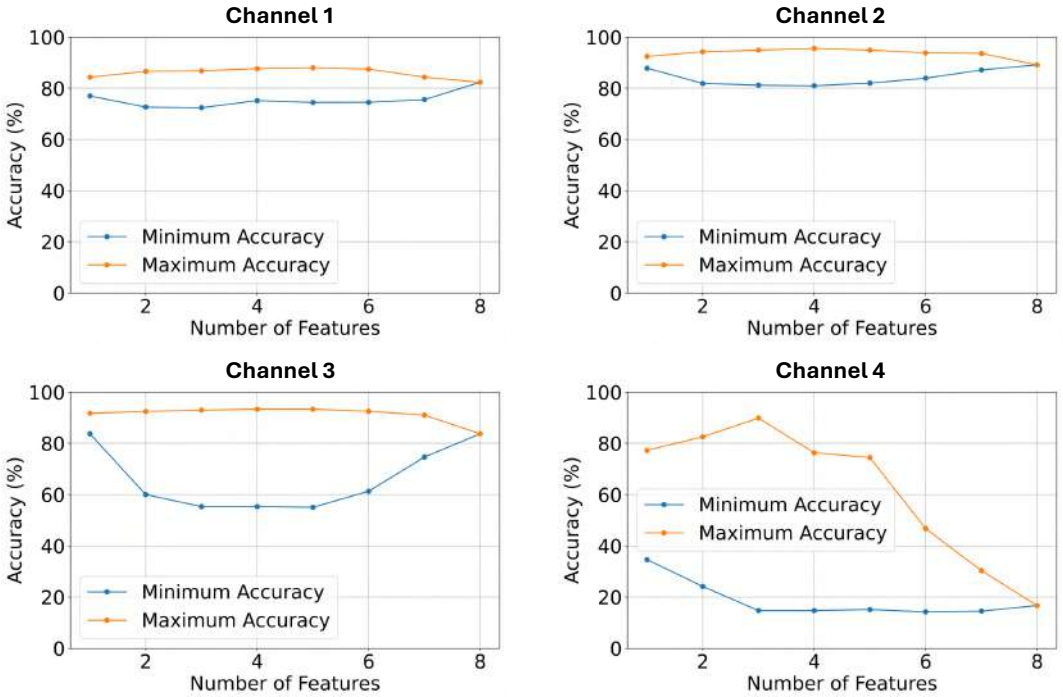

Fig. 3. The maximum and minimum MAPE accuracies among all possible feature combinations, where a separate model was developed for each combination, are shown in this figure for predicting the RMS values based solely on individual features for Channels 1 to 4 during 30-degree wrist flexion. The eight features are age, height, weight, arm length, arm circumference, wrist circumference, and sensory and motor thresholds. These accuracies are presented as a function of the number of input features, without access to the actual sEMG signal during estimation. The results indicate that increasing the number of input features does not necessarily improve accuracy.

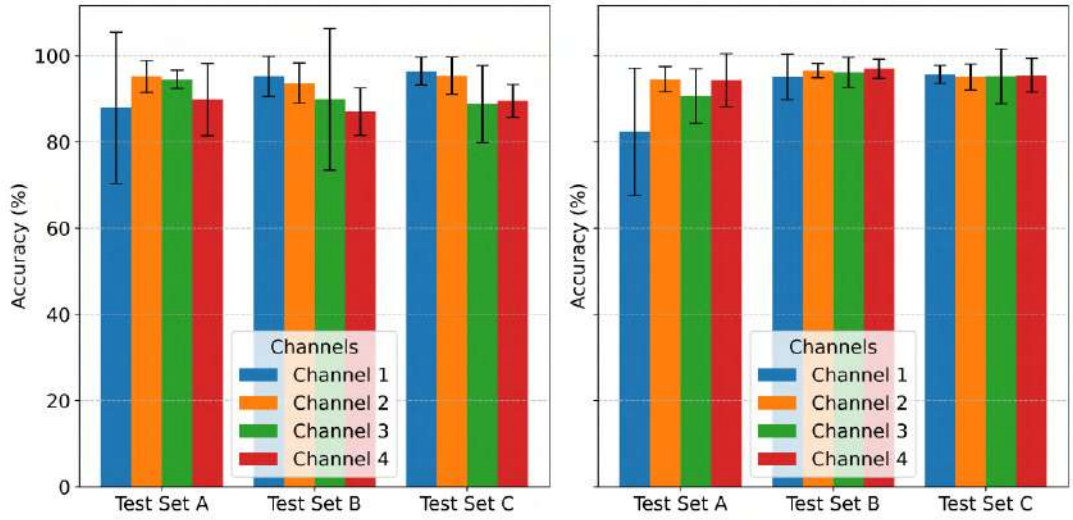

Fig. 4. The MAPE accuracy of the top-performing models (identified through RFE) reflects their ability to predict the expected RMS values based solely on individual features, evaluated across three separate test sets (each obtained through hold-out validation), without access to the actual sEMG signal during estimation. The left figure shows results for 30 degree wrist flexion, and the right figure depicts results for maximum wrist flexion. The channel numbers correspond to the electrode locations depicted in Fig. 2. With three test sets, four channels, and two wrist postures, a total of 24 results ($3 \times 4 \times 2$) are presented. The standard deviation reflects the variation in accuracy across the corresponding test set.

capture the interactions between pairs of input parameters and their joint contribution to the output variance, and the total-order indices capture both the direct effect of an input parameter and its interactions with other parameters.

The analysis of the total-order Sobol indices for wrist at 30 degree flexion, as shown in Fig. 5, revealed that age has the most significant direct effect on the RMS of the sEMG signal for Channels 1 to 4. The second-order Sobol indices for wrist at 30 degree flexion, shown in Fig. 5, highlight significant interactions between age and other demographic variables, including height for Channel 1, motor threshold for Channel 2, wrist circumference for Channel 3, and forearm circumference for Channel 4. The analysis of the RMS of the sEMG signal across four channels during maximum wrist flexion, as shown in Fig. 5 reveals that the total-order Sobol indices identify age, wrist circumference, height, and motor threshold as the most influential parameters for Channels 1 to 4, respectively. The second-order Sobol indices during maximum wrist flexion in Fig. 5 highlight significant interactions: for Channel 1, age and forearm length; for Channel 2, wrist circumference and forearm length; for Channel 3, height and age; and for Channel 4, motor threshold and height.

IV. DISCUSSION

This study introduced a method for predicting the RMS value of a normal sEMG signal in a personalized manner, assuming that the normal sEMG signal is not available due to factors such as a neuromuscular disorder. The purpose of this approach is to allow for better individualized comparisons between baseline and post-onset sEMG signals in neuromuscular disorders, improving the detection and monitoring of these conditions. This section discusses the importance of the findings of this study and identifies key areas for improvement to enhance the proposed approach.

The use of RFE to identify optimal individual features revealed that including more features does not necessarily lead to improved model accuracy. A meaningful relationship exists only between certain individual features and the sEMG signals. As shown in Fig. 3, for the best-performing combinations, the highest accuracy was achieved with different numbers of features for different channels. Additionally, the results highlight that both the number and type of features are critical for developing an optimal model. For example, while combinations with five, four, five, and three features for channels 1, 2, 3, and 4, respectively, yielded the highest accuracy, other combinations with the same number of features resulted in significantly lower accuracy: approximately 74% for Channel 1, 82% for Channel 2, 60% for Channel 3, and 12% for Channel 4.

In addition, the application of the Sobol method for global sensitivity analysis revealed that some features have a greater impact on the variability of the RMS values of the sEMG signal, offering a valuable tool for refining study designs and informing participant recruitment strategies. Researchers can broaden their recruitment to include a more diverse or targeted population that represents these key factors better. This makes it possible for the collected sEMG data to be more generalizable and relevant to a wider range of individuals, increasing the external validity of the study and improving the robustness of the findings.

Despite the promising results, several limitations must be acknowledged. One limitation is the relatively small sample size, which may restrict the generalizability of the findings. A larger sample would provide more robust data and increase confidence in the predictive capabilities of the model. Furthermore, the demographic variables included in this study were limited, focusing on eight factors. Other factors, such as sex, dominant hand, physical activity levels, or underlying medical conditions, could also influence baseline sEMG patterns and were not accounted for in this model. Although this study included 15 men and 15 women, sex was not considered as an influencing factor in the Sobol analysis due to limitations of the SALib library, which does not support categorical variables in its sensitivity analysis. As a result, the impact of sex could not be directly assessed or quantified using the Sobol analysis.

In addition, sEMG signals are influenced not only by muscle activity but also by the electrical properties of the skin between the electrodes and the muscles. For instance, changes in sweat levels, skin temperature, and ambient humidity can impact these properties, leading to variations in sEMG recordings [27], [28]. Future research should explore these factors to refine the model and enhance its applicability to diverse populations and conditions. Furthermore, while wrist posture was varied in this study, the analysis did not account for more complex movements or additional joint positions that could affect sEMG variability. The inclusion of other joint angles may provide a more comprehensive understanding of how these factors influence muscle activation across different functional tasks. Incorporating these variables in future studies could potentially refine the ability of the model to predict sEMG signal variations under real-world conditions. Future work should explore machine learning models beyond the DTR used in this study, assessing how different model structures and parameters influence the results. Additionally, a deeper investigation into the anatomical and biomechanical factors affecting EMG variability due to electrode placement is needed. Given the limitations of static models in capturing temporal dependencies, future research will also explore dynamic modeling approaches, such as recurrent neural networks, to improve predictive accuracy.

Nevertheless, this study demonstrates that it is possible to obtain an individualized prediction model for analyzing sEMG signals, offering valuable insights into personalized neuromuscular assessments. Furthermore, this approach has the potential to be applied in rehabilitation robotics, such as biofeedback systems, by leveraging individualized baseline sEMG predictions to adapt therapy to patients' specific needs. In individuals with neuromuscular disorders, the normal sEMG signal is often unavailable due to muscle damage. By using the predicted baseline RMS values, rehabilitation robots can tailor the intensity and type of feedback provided during physical therapy sessions, optimizing recovery strategies. However, limitations should be addressed in future

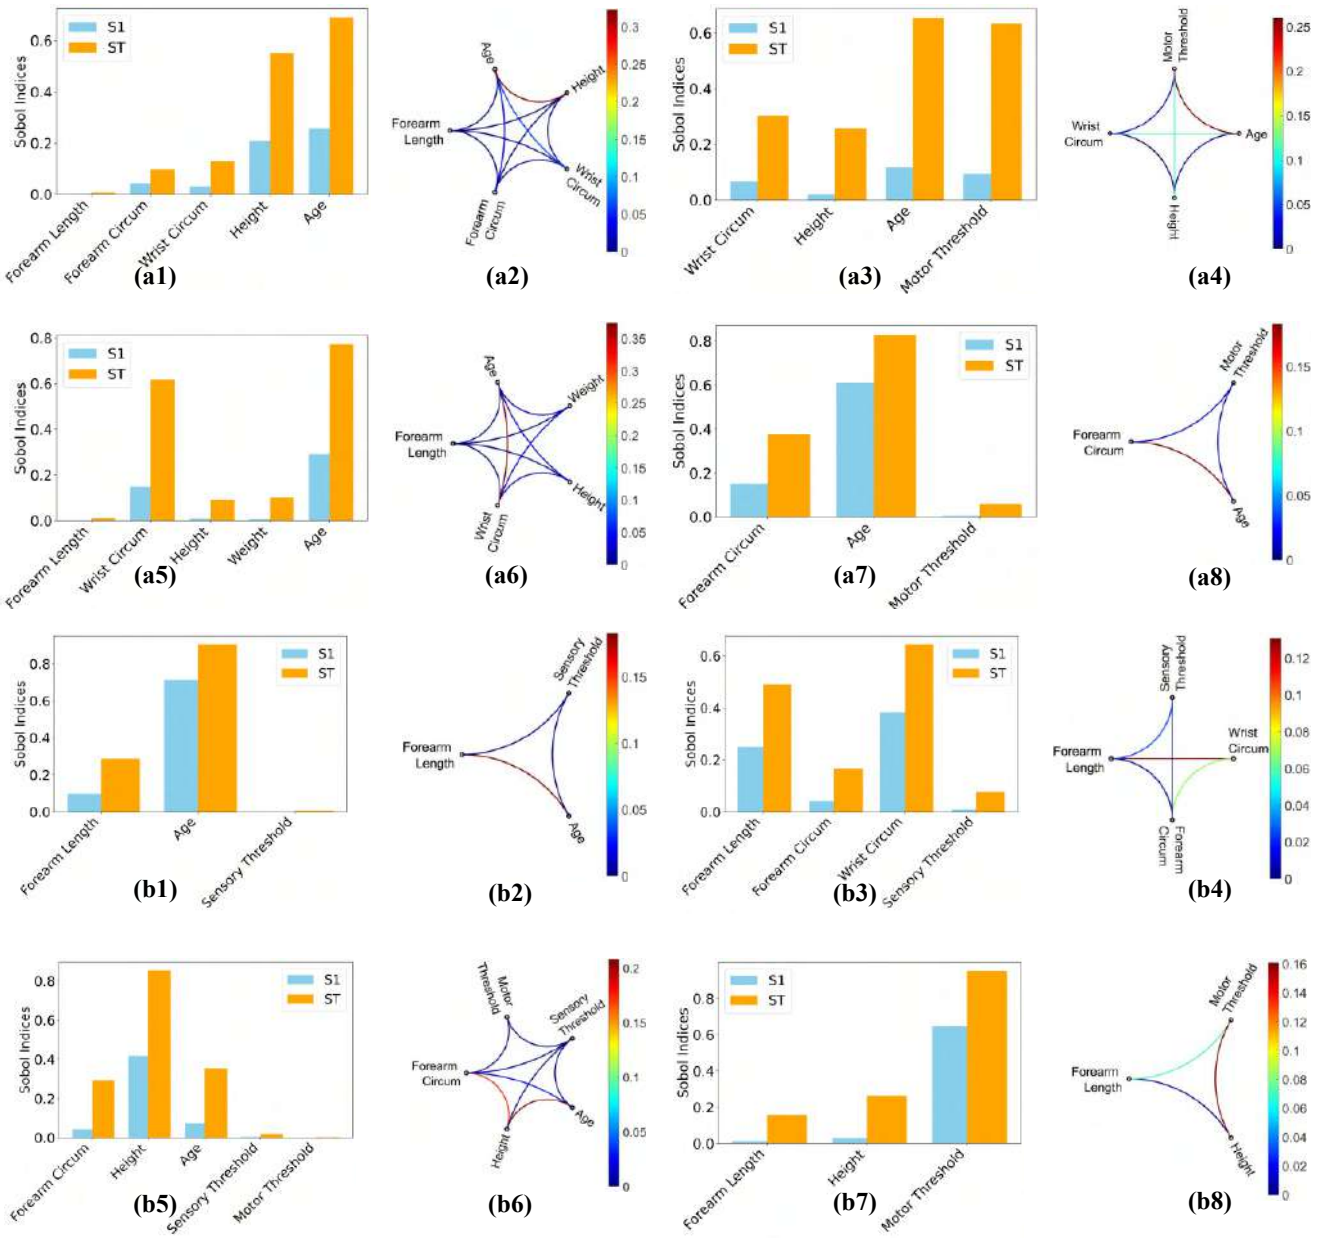

Fig. 5. The bar plots display the first-order (S1) and total-order (ST) Sobol indices for the RMS of the sEMG signal at 30 degree wrist flexion for (a1) Channel 1, (a3) Channel 2, (a5) Channel 3, and (a7) Channel 4, and at maximum wrist flexion for (b1) Channel 1, (b3) Channel 2, (b5) Channel 3, and (b7) Channel 4. The circular plots show the second-order Sobol indices for the RMS of the sEMG signal at 30 degree wrist flexion across (a2) Channel 1, (a4) Channel 2, (a6) Channel 3, and (a8) Channel 4, and at maximum wrist flexion across (b2) Channel 1, (b4) Channel 2, (b6) Channel 3, and (b8) Channel 4. The color bar indicates the magnitude of the interactions between pairs of input parameters, with red representing higher values (stronger interactions), blue representing lower values (weaker interactions), and intermediate colors representing values in between these extremes.

research to enhance the model's robustness and applicability. By doing so, the model could become more reliable and applicable across a wider range of patient populations, ultimately providing valuable tools for improving neuromuscular diagnoses and assessments in both clinical and research settings.

V. CONCLUSIONS

In conclusion, this study highlights the potential to develop a model capable of predicting individualized baseline features of sEMG signals. The model presented in this study combines individual demographic factors such as age, height, weight, arm length, arm circumference, and wrist circumference, along with physiological features including sensory and motor thresholds, to predict personalized baseline values of a key sEMG parameter, the RMS of the signal. Considering that sEMG patterns vary with arm posture and electrode placement, this study analyzed two wrist postures and four electrode positions on the arm to account for these factors. Eight DTR models were developed using various combi-

nations of two wrist postures and four electrode locations. For each model, the optimal configuration was obtained by applying the RFE technique, and the accuracy of these eight models ranged from 88.81% to 95.6%. A global Sobol sensitivity analysis was then performed to investigate the significance of each input parameter on the variability of the RMS of the sEMG signal. The use of RFE demonstrated that a meaningful relationship exists only between certain individual features and the sEMG signals, which contribute to the development of an accurate model. The results of the Sobol analysis offer valuable insights for future research, indicating that recruiting a more diverse population based on the factors identified in the analysis could lead to a more robust model. Overall, this research represents a significant step forward in the field of neuromuscular diagnostics, offering a promising avenue for the development of more precise and individualized clinical assessments. Future research should aim to incorporate a broader range of demographic factors, explore additional arm postures, and consider other sEMG features. These enhancements could provide deeper insights into neuromuscular assessments and contribute to the refinement of the model, ultimately improving its clinical applicability and accuracy in evaluating neuromuscular disorders. Additionally, by tailoring interventions based on individual features, this model could be effectively integrated into rehabilitation robotics, in the form of biofeedback systems to optimize therapeutic outcomes and support personalized recovery strategies.

ACKNOWLEDGMENT

We would like to express our gratitude to Intronix for providing the Intronix 2024F Isolated Amplifier used in our data collection.

Effects of Hip Adduction-Abduction Exoskeleton-Controlled Step Width on Mediolateral Gait Balance during Walking

Soe Lin Paing[1], Abbas Alili[2], Varun Nalam[3] and He (Helen) Huang[3]

***Abstract*— Mediolateral balance during walking is a critical aspect of functional mobility, particularly in populations with neuromuscular disorders. Step width is one of the key gait parameters influencing balance, and mediolateral hip exoskeletons have emerged as potential tools to modulate step width for improved stability. This study investigated the effects of exoskeleton-controlled step width on mediolateral gait balance represented by various gait balance metrics, including trunk sway, margin of stability (MoS), net external moment, and step width variability, in healthy individuals. Using a reinforcement learning-based control framework, the exoskeleton achieved precise step width control with an average error of 0.46 cm. Results revealed that the step width has a strong positive correlation with trunk sway ($R^2 = 0.9795$), margin of stability ($R^2 = 0.8948$), and net external moment ($R^2 = 0.9188$), reflecting a trade-off between stability and effort. Step width variability was unaffected, suggesting no destabilizing impact from controlled step width adjustments. These findings provide valuable insights into the design and optimization of exoskeletons for enhancing mediolateral stability in clinical and rehabilitation settings.**

I. INTRODUCTION

Maintaining balance is a critical aspect of human mobility, enabling individuals to perform daily activities safely and efficiently [1]. Compromised balance affects a wide range of populations, including older adults, people with amputation, and individuals with neurological disorders, leading to significant health concerns such as an increased risk of falls, reduced mobility, loss of independence, and secondary complications like fractures, head injuries, and chronic pain [2], [3]. Given the wide range of daily tasks and environmental perturbations that can affect balance, humans employ distinct gait balance strategies in two anatomical directions: anteroposterior (AP) and mediolateral (ML). Specifically in the ML direction, humans employ active motor control to maintain gait balance [4]. Any disruption to the components involved in ML control is detrimental to frontal plane stability [5].

Active control of step width has been increasingly validated as a control strategy to maintain balance along ML direction during walking [6], [7]. Simulation studies show that ML balance is maintained by modulating the base of support based on center of mass behavior [8], and is achieved in bipedal locomotion by controlling step width [9], [10]. Reduced ability to control step width and increasing step width variability is observed in older populations and people with chronic neurological disorders, highlighting the role of step width in ensuring mediolateral balance [11], [12]. Hence, solutions must be developed that can effectively restore step width control in affected individuals.

While there is an increasing prevalence of exoskeletons developed for lower limb assistance, most devices primarily target assistance in the anteroposterior (AP) direction [13]–[15]. In order to address the increasingly apparent need for modulating ML balance, we have developed a bilateral mediolaterally active hip exoskeleton [16]. Investigations of the exoskeleton capabilities have shown that the device was able to significantly modulate step width by adjusting the stiffness simulated by the exoskeleton. [17]. Notably, this modulation was achieved without impacting other gait parameters such as step length or gluteus medius EMG activity, confirming that the changes in step width were directly induced by the exoskeleton. Motivated by these results, we have further developed a controller that can accurately control the step width of users during walking and have validated the approach through human subject testing [18]. The study has successfully shown that the developed exoskeleton could control the step width of users through a simple linear controller, paving the way for robot-aided balance assistance focused on ML direction.

Although step width control using a mediolateral hip exoskeleton has been successfully validated, the impact of this control on balance and stability is unclear. Multiple studies investigated and reported how larger step width in populations with neuromuscular deficits affects the gait balance metrics [19]–[21] but the step width changes were volitional and not robot-induced. It is imperative to understand the relationship between exoskeleton-induced step width and balance, as this would have implications for balance assistance. To address this gap, the present study investigated how controlled step width, facilitated by a hip exoskeleton, influences mediolateral gait balance. In this study, we established the relationship between exoskeleton-controlled step width and 4 mediolateral gait balance metrics: trunk sway, margin of stability (MoS), net external moment, and step width variability which could better inform the research on improving the mediolateral gait balance using hip exoskeleton. The research in this paper could provide insights into the feasibility of balance enhancement using exoskeletons and guide controller development.

II. METHODS

The goal of this study is to analyze the impact of exoskeleton-controlled step width on different balance metrics, specifically in the mediolateral direction. To achieve this, we conducted a study involving non-disabled human participants wearing an exoskeleton during walking. The study details are described below:

A. Participants

Three healthy male participants (mean age: 30.3 $\pm$ 1.5 years, mean weight: 82 $\pm$ 9.8 kg, mean height: 1.75 $\pm$ 0.05 m), with no known history of neuromuscular disorders, were recruited for this study. The research protocol was approved by the University of North Carolina at Chapel Hill (# 13-3028), and informed consent was obtained from all participants before the experiment.

B. Experimental Hardware

This study utilized a hip abduction-adduction exoskeleton developed by the Neuromuscular Rehabilitation Engineering Laboratory (NREL) to control participants' step width during walking [16]. The exoskeleton is equipped with two Maxon EC-60 brushless motors paired with 100:1 harmonic gearboxes (CSD-20100-2A-GR-SP674, Harmonic Drive, MA, USA) that generate torque at the hip joints to assist with abduction-adduction movements. Additionally, it includes passive joints to allow unrestricted flexion and extension of the legs. The device is capable of delivering a continuous torque output of 34 Nm and a peak torque of 57 Nm. Interaction torque between the user and the robot is measured using cantilevered load cells connected in parallel with the actuators, enabling precise force control. Figure 1 illustrates the mediolateral hip exoskeleton, highlighting key components such as the actuators, sensors, and other essential elements. The exoskeleton's limbs were securely attached to the participants' thighs using fabric cuffs during use.

C. Control Architecture

The control architecture [22] as illustrated in Figure 2 was implemented to regulate the step width of participants using the hip abduction-adduction exoskeleton.

The admittance controller [23], modeled as a second-order dynamic system characterized by stiffness (K), damping (B), and inertia (I) parameters, was used for the human-robot interaction control. The interaction torque $\tau(t)$ is given by Equation 1.

$$\tau(t) = K(\theta(t) - \theta_{eq}) + B\dot{\theta}(t) + I\ddot{\theta}(t) \tag{1}$$

where $\tau(t)$ is the interaction torque, K is the stiffness, B is the damping, and I is the inertia parameters. $\theta(t)$, $\dot{\theta}(t)$ and $\ddot{\theta}(t)$ are the hip abduction-adduction angle, velocity, and acceleration, respectively, and θ_{eq} is the equilibrium angle. Since the motors are configured to receive velocity commands from the admittance controller, we first compute the acceleration using Equation 2.

$$\ddot{\theta}(t) = \frac{\tau(t) - K(\theta(t) - \theta_{eq}) - B\dot{\theta}(t)}{I} \tag{2}$$

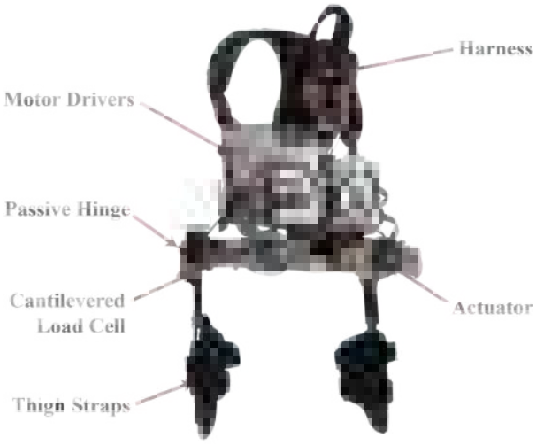

Fig. 1. Back view of the hip adduction-abduction exoskeleton with labeled components.

By integrating this acceleration, we obtain the corresponding velocity command to be sent to the motor in Equation 3.

$$\dot{\theta}(t) = \int_0^t \ddot{\theta}(\lambda)d\lambda \tag{3}$$

Throughout the trials, the equilibrium angle was kept constant at 15-degree abduction angle from the midline for both legs [17]. The admittance controllers were implemented separately for each motor in TwinCAT 3, operating at a frequency of 1 kHz. The admittance controller remains active throughout the entire gait cycle, applying torque to the legs during both the stance and swing phases [17].

Proportional-Integral-Derivative (PID) control was employed to regulate step width by adjusting the stiffness of the admittance controller based on step width error [18] using Equation 4 with the stiffness constrained between -10 Nm/rad and 80 Nm/rad.

$$K(t) = K_p e(t) + K_i \int_0^t e(\lambda)d\lambda + K_d \frac{de(t)}{dt} \tag{4}$$

where $K(t)$ represents the stiffness of the admittance control, $e(t)$ is the difference between the desired step width and the actual step width, and K_p, K_i, and K_d are proportional, integral, and derivative gains, respectively. However, achieving accurate control required manual fine-tuning of PID gains for each participant due to intersubject variability, a process that is both tedious and time-consuming. To overcome this challenge, a Deep Deterministic Policy Gradient (DDPG)-based Reinforcement Learning approach was introduced to dynamically update the PID gains and achieve optimal stiffness for admittance control [17]. The DDPG agent utilized input states including the desired step width, actual step width (measured using heel markers), the error signal (difference between desired and actual step width), and the integrated error signal. Using these inputs, the agent autonomously adjusted the PID gains every 2 seconds. Detailed descriptions of the architecture, training process, and implementation of the DDPG-based step width control

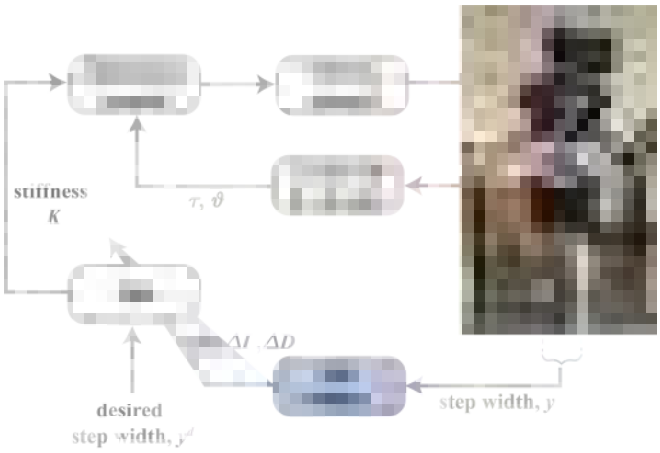

Fig. 2. Control framework for step-width modulation using the hip adduction-abduction exoskeleton. The RL DDPG agent controls step width (y) by adjusting the gains of the PID controller, which in turn regulates the stiffness (K) in the admittance control.

are available in [22]. This adaptive approach enhanced the exoskeleton's ability to achieve precise and efficient step width tracking across participants.

D. Experimental Setup

The setup includes the mediolateral exoskeleton, a motion capture system, and an instrumented split-belt treadmill. Participants began by donning the exoskeleton and having 38 retroreflective markers attached to their lower limbs, pelvis, and trunk. Their preferred walking speed was established by instructing them to walk on the instrumented treadmill while the exoskeleton operated in zero-stiffness mode where no external resistive or assistive torques were applied by the exoskeleton to the user's hip.

Following this, they underwent a 3-minute acclimation period walking with the exoskeleton still in zero stiffness control mode. During the experiment, three-dimensional kinematic data were collected at a sampling rate of 100 Hz using a VICON motion capture system (Oxford, U.K.) equipped with 12 cameras. Simultaneously, three-dimensional ground reaction force (GRF) data were recorded at 1000 Hz using the fully instrumented treadmill (Bertec Corp., Columbus, OH, USA).

E. Experimental Protocol

To establish the desired step widths for each participant, a baseline trial was conducted in which the participant walked on a treadmill at their preferred speed for two minutes with the exoskeleton operating in zero-stiffness mode. The average continuous step width during this trial was calculated and recorded as the baseline step width. Subsequently, the Deep Deterministic Policy Gradient (DDPG)-based controller was tuned to customize its parameters for each participant.

Based on the baseline step width, five desired step widths were defined as baseline step width, decreases of 20% and 10%, and increases of 20%, and 40% relative to the baseline. The selection of imbalanced desired step width levels (i.e., larger increases compared to decreases) was intentionally designed to minimize the risk of force plate crossing during narrower step widths. Force plate crossing can result in inaccurate measurements of ground reaction forces, compromising data reliability. The exoskeleton was then programmed to control the participant's step width to achieve each of these targets. Each trial lasted 2 minutes and was conducted twice for repeated measures, resulting in a total of 10 trials. The data recording was started only after the step width control reached a steady state. The order of the trials was completely randomized for each participant to mitigate potential bias. Sufficient rest was provided between trials to prevent fatigue.

F. Data Analysis

Kinematic data and ground reaction force (GRF) measurements were processed using a 4th-order Butterworth low-pass filter, with cutoff frequencies set at 10 Hz and 25 Hz, respectively. An 8-segment inverse dynamic model was developed in Visual3D software (C-Motion, Germantown, USA) to analyze key parameters, including the center of mass (CoM), the Center of Pressure (CoP), and gait events. To examine the relationship between step width and mediolateral gait balance, four mediolateral balance metrics were analyzed: (1) trunk sway, (2) margin of stability (MoS), (3) net external moment, and (4) step width variability.

In this study, step width was defined as the continuous displacement of heel markers between the left and right legs, rather than step width at heel strike, as the exoskeleton directly controlled this measure. Trunk sway in the frontal plane was quantified as the peak-to-peak displacement of a marker placed on the C7 vertebra, following the method outlined in [24], [25]. The margin of stability (MoS) was calculated using the method described by Hof et al. [26]. Net external moment was computed based on the approach described by Neptune et al. [20]. Step width variability was quantified as the standard deviation of the step width throughout the trial [27].

G. Statistical Analysis

A linear mixed-effects model was employed to assess the effects of step width on each gait balance metric [28]. Step width, treated as a continuous variable, was included as a fixed factor, while participant identity was modeled as a random factor to account for individual variability in the balance metrics. Before fitting the model for each balance metric, key assumptions of the linear mixed-effects model—including linearity, homoscedasticity, normality, and independence of errors—were evaluated to ensure the validity of the analysis.

III. Results

The results presented below illustrate the effects of exoskeleton-controlled step width on four mediolateral gait balance metrics: trunk sway, Margin of Stability (MoS), net external moment, and step width variability. In the accompanying figures, data points are distinguished by symbols representing the three participants: gray squares for Subject 1, green circles for Subject 2, and blue triangles for Subject 3.

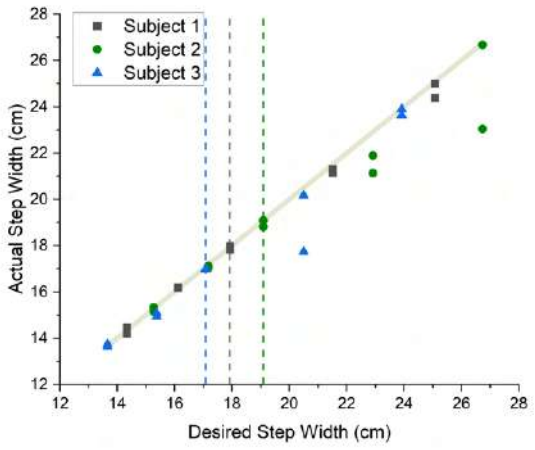

Fig. 3. The performance of step width control. The solid gray line depicts the ideal scenario where the participants' step width track the desired step width accurately. The vertical dashed lines denote each participant's preferred step width, as determined during the baseline trial. Each x-axis position contains two data points, representing the two trials conducted for each condition.

This visualization highlights both individual variability and overarching trends across the metrics.

A. Step Width Control

The exoskeleton effectively controlled participants' step widths in most trials, achieving high accuracy. As illustrated in Figure 3 which showcases the step width across all 10 trials. The average step width error across all trials was 0.46 cm, with a maximum deviation of 3.7 cm. This demonstrates the exoskeleton's ability to maintain step width control within a small margin of error relative to the desired values.

B. Trunk Sway

Trunk sway serves as an indicator of upper body stability and control during walking, providing insights into dynamic balance and postural regulation. As shown in Figure 4(a), trunk sway increased with an increase in step widths. Analysis using a linear mixed-effects model revealed that the effect of step width on trunk sway was statistically significant ($p < 0.0001$), with an R^2 value of 0.97954, indicating a strong relationship. The slope estimates and their corresponding confidence intervals are detailed in Table I.

C. Margin of Stability

The Margin of Stability (MoS) in the mediolateral direction quantifies the distance between the body's extrapolated Center of Mass (xCOM) and Center of Pressure (CoP) in the frontal plane, serving as a measure of the ability to maintain or recover balance during gait [26]. As depicted in Figure 4(b), the MoS also increased with an increase in step widths. Analysis using a linear mixed-effects model confirmed that the relationship between step width and MoS was statistically significant ($p < 0.0001$), with an R^2 value of 0.8948, indicating a strong association.

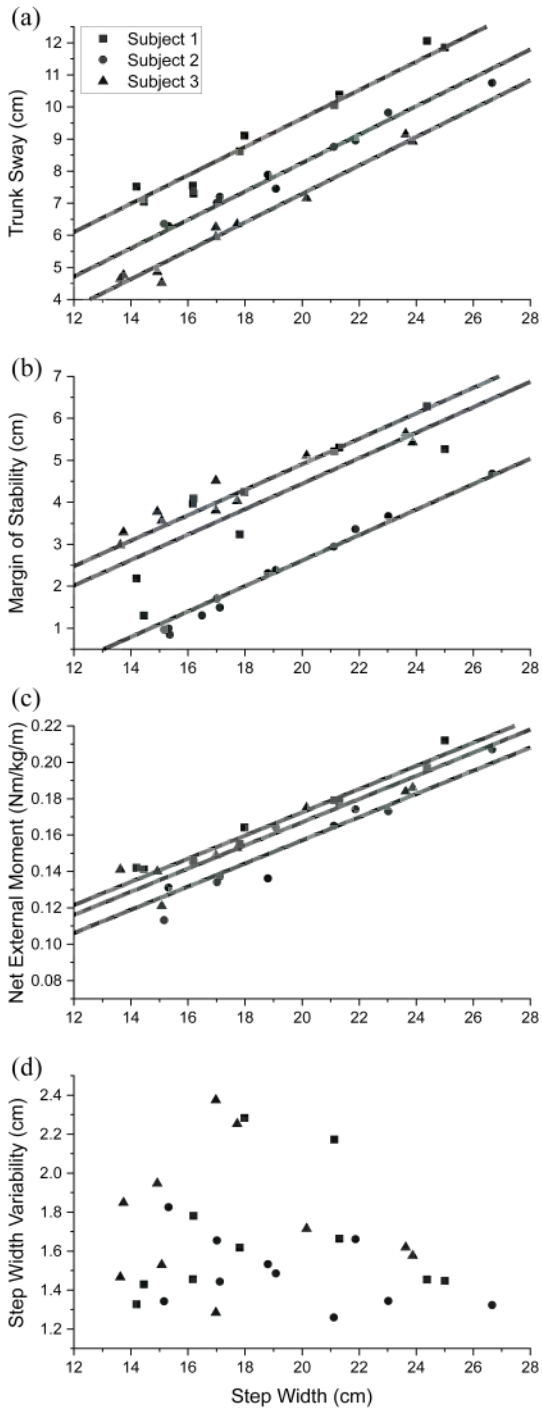

Fig. 4. Relationship between step width and gait balance metrics. (a) Trunk sway. (b) Margin of Stability. (c) Net external moment. (d) Step width variability. Fitted lines account for the random effect specific to each individual.

D. Frontal Plane Net External Moment

The net external moment represents the external forces acting on the body, providing insight into the mechanical effort required to maintain balance during gait. The frontal plane net external moment, normalized by participants' weight and height, is shown in Figure 4(c). Two trials from Subject 2 were excluded due to consistent cross strikes, where the

subject's foot landed across the boundary of two adjacent force plates. This led to inaccurate force measurements, as the data for left and right forces could not be reliably distinguished. The linear mixed-effects model revealed that step width had a statistically significant effect on the net external moment ($p < 0.0001$), with an R^2 value of 0.91884. This indicates a strong relationship between step width and the mechanical demands of maintaining balance.

E. Step Width Variability

Step width variability, which quantifies the consistency of step width during walking, serves as an indicator of stability and control in lateral balance. However, analysis using the linear mixed-effects model did not identify a significant linear relationship between step width variability and step width as shown in the 4(d). This suggests that controlling the step width using the hip exoskeleton does not directly impact the consistency either positively or negatively during gait under the conditions tested.

TABLE I
SUMMARY OF LINEAR MIXED-EFFECTS MODEL RESULTS FOR GAIT BALANCE METRICS

Gait Balance Metrics	***Model Estimate***	***p value***	R^2
Trunk Sway	0.4424	4.91e-21	0.9795
Margin of Stability	0.3034	4.95e-12	0.8948
Net External Moment	0.0064	2.3e-14	0.9188
Step Width Variability	-0.0108	0.4894	0.1160

IV. DISCUSSION

Step width is one of the key strategies for maintaining frontal plane stability during human gait. Populations with neuromuscular disorders often struggle to effectively control their step width, resulting in diminished mediolateral stability. This study shows how a mediolateral hip exoskeleton can influence balance metrics by modulating step width. While previous studies have examined gait balance metrics in individuals with neuromuscular disorders, often noting differences such as larger step widths and altered balance metrics compared to healthy populations [20], [21], no research to date has explored the specific effects of exoskeleton-controlled step width on mediolateral gait balance metrics. Studying whether the exoskeleton-assisted response aligns with or differs from human volitional behavior is crucial, as the findings could have significant implications for control development, rehabilitation strategies, and the understanding of the human neuromuscular system.

The results demonstrated that step width significantly influences mediolateral stability, as reflected by investigating the specified gait balance metrics. Each of these balance metrics focuses on a different aspect of balance. Reduced trunk sway and net external moment could reduce the energy required to stabilize individuals but could make individuals vulnerable to external perturbations. Increased MoS could help in reducing the effects of unexpected perturbations and thereby improving stability.

Trunk sway, Margin of Stability (MoS), and net external moment all increased with larger step widths across participants. While a larger step width enhances frontal plane stability by increasing the MoS, it simultaneously results in greater trunk sway and higher net external moments, indicating increased mechanical effort and upper body movement. This suggests that optimizing mediolateral stability requires a trade-off among MoS, trunk sway, and net external moment to achieve a balanced gait without resulting in high energetic costs. Step width variability, which reflects the consistency of foot placement, showed no apparent linear relationship with step width in this study. This indicates that controlled variations in step width did not negatively impact gait stability, as no destabilizing effects were observed in terms of variability. It could also imply that the torque interactions from the exoskeleton were not perceived as a disturbance by the individuals.

In the observed results, specifically, the net external moment showed similar trends to that observed in [19]. This could imply that the neuromuscular behavior of the individuals in both studies is similar with the exoskeleton contributing to the energy required to increase the step width rather than changing the mechanism by which wider step width is achieved. These results, therefore, imply that we can reduce the additional energetic exertion of ensuring balance through step width modulation implemented through this exoskeleton.

The use of a linear mixed-effects model in this study was motivated by the need to account for both fixed effects such as step width and random effects (individual variability among participants). This modeling approach allows us to capture the linear relationship between step width and gait balance metrics, and our experimental data exhibit a strong and statistically significant linear trend ($p < 0.0001$) across three gait balance metrics: trunk sway, margin of stability, and net external moment. Additionally, the linear mixed-effects model was chosen to analyze the relationship between step width and step width variability to assess whether the exoskeleton's control over step width had any destabilizing effects on gait stability. Although more complex relationships, such as nonlinearity and phase-dependent variations, could provide additional insights, our primary objective was to assess the overall trend in a robust and interpretable manner.

The limited sample size in this study poses challenges in establishing a definitive model that is generalizable to the broader healthy population. Additionally, the observed gait balance metrics results are likely influenced by the behavior of the torque applied to the hip joint by the exoskeleton. It is reasonable to hypothesize that variations in control mechanisms, such as different strategies for torque application or stiffness modulation, could result in differing effects on mediolateral gait balance. Future studies with larger and more diverse participant samples, as well as investigations into alternative control approaches, are essential to better understand these dynamics and enhance the generalizability of the findings. Additionally, further investigations of the

approach on people with balance deficits are essential to validate this approach as healthy individuals may have the ability to mitigate adverse effects of the applied torques, which people with balance deficits could not.

The preliminary results highlight the effects of controlled step width on gait balance in able-bodied individuals. These findings provide valuable insights that could inform the design and control strategies of exoskeletons aimed at enhancing mediolateral gait balance in populations with gait impairments. By understanding how step width modulation impacts balance metrics, future exoskeleton design and control architecture can be tailored to address specific needs, potentially improving stability and mobility for individuals with balance-related gait disabilities.

Analysis of Forces Exerted by Shoulder and Elbow Fabric-based Pneumatic Actuators for Pediatric Exosuits

Mehrnoosh Ayazi,[1] Ipsita Sahin,[2] Caio Mucchiani,[1] Elena Kokkoni,[2] and Konstantinos Karydis[1]

***Abstract*— To enhance pediatric exosuit design, it is crucial to assess the actuator-generated forces. This work evaluates the contact forces exerted by soft fabric-based pneumatic actuators in an upper extremity pediatric exosuit. Two actuators were examined: a single-cell bidirectional actuator for shoulder abduction/adduction and a bellow-type actuator for elbow extension/flexion. Experiments assessed the impact of actuator anchoring points and the adjacent joint's angle on exerted forces and actuated joint range of motion (ROM). These were measured via load cells and encoders integrated into a custom infant-scale engineered apparatus with two degrees of freedom (two revolute joints). For the shoulder actuator, results show that anchoring it further from the shoulder joint center while the elbow is flexed at 90° yields the highest ROM while minimizing the peak force exerted on the body. For the elbow actuator, anchoring it symmetrically while the shoulder joint is at 0° optimizes actuator performance. These findings contribute a key step toward co-optimizing the considered exosuit design for functionality and wearability.**

I. Introduction

Soft exosuits have shown significant promise in assistance, rehabilitation, and human augmentation across diverse applications. Existing efforts have targeted lower limb mobility, such as in walking [1], hip motion [2], knee function [3], [4], and ankle support [5], as well as upper limb mobility, including assistance at the shoulder joint [6], [7], elbow support [8], [9], wrist support [10], and hand function [11]. The vast majority of these efforts consider adult users; limited attention to devices specifically designed for children, particularly those that assist upper extremity (UE) movement in very young children, has been provided so far [12]–[14]. Given the potential of assistive technology to improve motor function [15], more research is needed in pediatric exosuits.

A key measure of exosuit performance is the force generation capability which has been examined mainly on devices aimed at adults [16]–[20]. Both the magnitude and direction of the exerted (contact) forces, as well as their point of application play a role. Excessive or improperly targeted amounts of force (or pressure) can restrict natural movement and cause skin problems, circulation problems, and injuries [16], [21]–[23], ultimately resulting in discomfort and reduced acceptance of the device [24]. As such, detailed profiling of contact forces can provide insight into actuator limitations and dynamic behaviors which in turn can be used to improve the device and its underlying controllers (e.g., [25], [26]). The *desired* force generation capacity of an exosuit is typically determined by the intended task and type of motion assistance (e.g., whole-arm reaching, fine manipulation), thereby guiding component selection and system design. The *achieved* force generation capacity is determined by multiple factors, crucially including among them the anchoring points of the actuators.

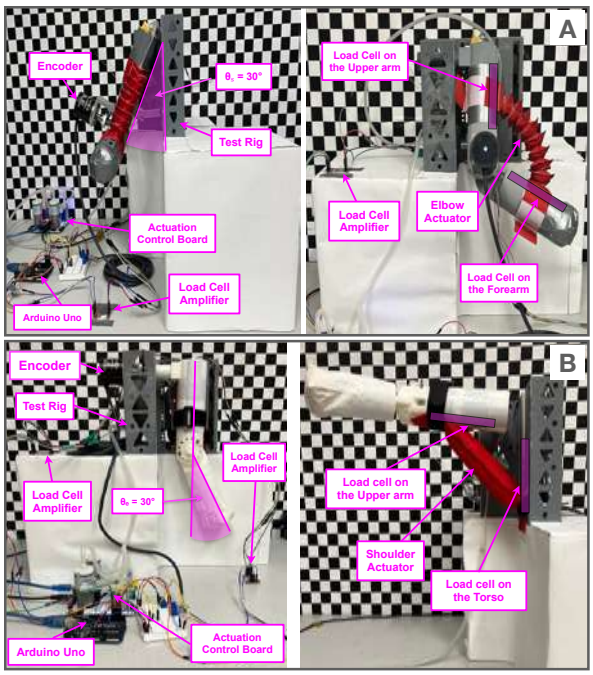

Fig. 1. Experimental setup for force profiling of a fabric-based pneumatic (A) shoulder and (B) elbow actuator. The setup allows various actuator anchoring points and non-actuated joint angle settings (locked in place).

The actuator anchoring points relative to the body can significantly influence joint kinematics and kinetics by facilitating force transfer to the body and stabilizing the body-exosuit interaction [27]–[30]. Our previous work [31] assessed the effect of varying the anchoring points of several different pneumatic actuators on end-effector kinematics, enabling an informed selection of the actuators used herein. A single-cell inflatable actuator [32] for the shoulder led to greater range of motion (ROM) and end-effector path length, while a 10-cell bellow-type actuator [33] with square cells was more appropriate for the elbow in terms of maximizing ROM. In both cases, kinematic performance (i.e. ROM, motion smoothness, etc.) was improved when the anchoring points intersect along the mid-auxiliary line of the body [31]. However, the previous work did not assess joint kinetics and the exerted forces on the body as anchoring points vary.

The goal of this paper was to assess the exerted forces from the aforementioned actuators on the torso, upper arm, and forearm of an engineered apparatus based on 12-month-old infant anthropometrics (Fig. 1). In addition, a preliminary assessment of the underlying relation between input pressure and exerted forces is provided for future automatic controller design. Experiments involved one joint's actuator being active while the other joint remained locked in place at different points. We analyzed the exerted forces and the actuated joint's ROM under varying the active actuator anchoring points and the non-actuated joint's locked angle value. Results reveal optimal actuator anchoring points and the cases where exerted forces are minimized and ROM is maximized for the same actuator input pressure. Taken together with our previous findings [31], this work provides key information about how to place actuators onto a soft pediatric exosuit to improve its function.

II. Materials and Methods

A. Experimental Setup

Two types of soft, fabric-based pneumatic actuators were selected for their range of motion, ease of manufacturing, and durability. A single-cell rectangular actuator [32] was used for shoulder abduction/adduction (achieved through inflation/deflation, respectively, with deflation-driven adduction due to reduced upper arm support). Elbow flexion/extension was facilitated via inflation and deflation, respectively, of a 10-cell bellow-type actuator [33].

Two 3D-printed test rigs (Fig. 1) were designed based on anthropometric data of 12-month-old infants in the 50th percentile [34], [35]. Each rig was configured to support a specific type of actuator (either shoulder or elbow) to study their individual force profiles. Both rigs consist of a base as the torso, an upper arm (UA), a forearm (FA), and a small part weighing 0.06 kg attached at the end of the FA in lieu of the hand. The UA (16.4 cm in length, 14.7 cm in circumference) was connected to the torso via a revolute joint, effectively allowing for shoulder adduction and abduction. The FA (10.85 cm in length and 14.51 cm in circumference) was attached to the UA through another revolute joint, allowing for elbow flexion and extension. Both UA and FA segments were hollow and filled in with sandbags to match a desired UE weight. The combined weight of UA and FA was set at 0.432 kg, based on anthropometrics of an infant of total body mass of 10.8 kg [36].

The primary distinction between the two rigs lies in the positioning of sensors, which are used to measure the normal force generated by the actuator as well as the respective joint angle.[1] Each test rig incorporated two load cells (YZC-133) with a capacity of 5 kg to gauge the contact force exerted by the actuators on the UA, torso, or FA. The placement of these load cells was determined based on the impact area of the actuator during operation. The shoulder actuator exerts forces on the torso and UA. In the rig designed for the shoulder actuator, one load cell was situated within the UA, aligned with the vertical centerline on its inner side. This load cell was coupled with a plate measuring 11.1×1.36 cm to effectively capture the force applied over the area covered by the plate. The second load cell was positioned at the torso of the rig, also aligned with the vertical centerline on the inner side facing the UA, and was attached to a 15.6×1.66 cm plate. Conversely, the elbow actuator exerts forces on the UA and FA. In the respective test rig, the load cells were installed and aligned with the UA and FA vertical centerlines on the front side. The plates connected to these load cells measured 11.6×1.66 cm for the UA and 8.85×1.66 cm for the FA. Each load cell was connected to an amplifier (HX711, Sparkfun) to convert the output data into a readable format at a frequency of 11 Hz, ultimately linked to the ADC pin of a microcontroller board (Arduino UNO). Additionally, a 1024 pulse per revolution rotary encoder (E6B2, Sparkfun) was integrated into the actuated joint to measure the respective joint angle. Encoder data were collected with the use of the microcontroller. The latter transmitted all collected data (amplified load cell and rotary encoder data) to a host computer for data logging and follow-on analysis.

The inflation and deflation of the actuators were managed using an external pneumatic board (Programmable-Air kit). This board features two compressor/vacuum pumps and three pneumatic valves to control the airflow at a rate of 2 L/min. The airflow is adjusted through the pump duty cycle in $[0 - 100]\%$. The pressure can vary between $[-50, 50]$ kPa. The board is equipped with a pressure sensor (SMPP-03) and its own microcontroller (Arduino Nano). The integrated Arduino allows for connectivity to the host computer via a serial-to-USB interface, enabling users to send commands to the pumps and valves and to log sensor data.

B. Experimental Protocol

A series of experiments were conducted to explore how two key elements affect joint ROM and force exertion of each actuator on the test rigs. The first element pertains to variations in the anchoring of the actuators. Two anchoring configurations were tested for the shoulder actuator: one at two-thirds (S1) and the other at one-half (S2) of the UA length, measured from its proximal end (Fig. 2A left panel). The other end of the actuator was attached to the torso. Three anchoring configurations were tested for the elbow actuator based on the distribution of the actuator's cells along the UA and FA: one symmetric (E2) and two asymmetric configurations (E1 and E3). In the E1 configuration, more cells extended on the UA (about 60%) than on the FA, while the opposite was true in E3. In E2, there was a symmetrical distribution of cells on both segments (Fig. 2B left panel). The second element refers to the effect the non-actuated joint being locked in place at different points can have on the active joint's ROM and force exertion of the actuators.

[1] By virtue of this work's actuator mechanical design and placement along the body's mix-auxiliary line, the normal force component is the one primarily contributing to mechanical work associated with the intended motion support as compared to a small but still present shear force component. For this reason, we prioritized the measurement and analysis of normal forces. The inclusion of shear forces is part of future work, as we delve into further motion support (e.g., shoulder flexion/extension).

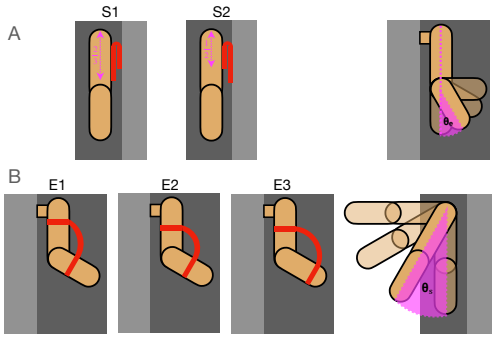

Fig. 2. (A) Schematic diagram of shoulder actuator anchoring: Two anchoring points (S1 at two-thirds and S2 at one-half of the upper arm length from the proximal end) and four fixed elbow angles (0°, 30°, 60°, and 90°). (B) Schematic diagram of elbow actuator anchoring: Twelve configurations with three anchoring points (E1, E2, E3) and four fixed shoulder angles (0°, 30°, 60°, and 90°). E1: Actuator cells distributed 6:4 (UA:FA), with attachment points at two-thirds (UA) and one-half (FA) of their lengths. E2: Cells distributed 1:1, with both attachment points at one-half of their lengths. E3: Cells distributed 4:6, with attachment points at one-half (UA) and four-fifths (FA) of their lengths. Actuators shown in thick (red) curves.

One of the test rigs allowed the elbow joint to be locked at four angles, $\theta_e \in \{0°, 30°, 60°, 90°\}$ (Fig. 2A right panel), while the other featured shoulder joint locking at four angles, $\theta_s \in \{0°, 30°, 60°, 90°\}$ (Fig. 2B right panel).

A total of 30 trials were performed for each configuration. Load cells and encoders integrated into the test rigs measured the exerted force and the angular displacement throughout each trial. Further, input pressure was collected from the pressure sensor on the pneumatic board. Before each trial, the load cell was set to zero with the actuator anchored but not actuated (to ensure that measured forces resulted solely from the actuation during the trials). Each trial for the shoulder actuator lasted 10 sec, consisting of a 5-sec inflation phase followed by a 5-sec deflation phase. The elbow actuator trials also lasted 10 sec each, containing a 5-sec deflation phase followed by 5 sec of inflation. To enable these 5-sec actuation phases, the pumps operated at a 100% duty cycle. [2]

C. Variables of Interest and Statistical Analysis

The computed variables were joint ROM (for both shoulder and elbow joints) and peak force exerted by each actuator on the relevant body segment. To assess how the actuator anchoring configurations and non-actuated locked joint angles affected these two variables, a series of separate non-parametric tests was performed for each factor and actuator (violation of normality was confirmed with the Kolmogorov-Smirnov test). For the shoulder actuator, Mann-Whitney U tests were conducted to identify significant differences in shoulder joint ROM and peak force between the two shoulder actuator anchoring configurations (S1, S2). Kruskal-Wallis H tests were performed to evaluate differences in shoulder joint ROM and peak force across the four non-actuated elbow joint locked angles θ_e. For the elbow actuator, Kruskal-Wallis H tests were conducted to assess significant differences in elbow joint ROM and peak force across the elbow actuator anchoring configurations (E1, E2, E3). Lastly, Kruskal-Wallis H tests were performed to evaluate differences in elbow joint ROM and peak force across the four non-actuated shoulder joint locked angles θ_s. Post-hoc pairwise comparisons were conducted as needed. The significance level at 0.05 was Bonferroni-adjusted to account for multiple comparisons. Statistical analyses were conducted with SPSS v.30.

[2] Achieving rapid actuation is important since infant reaching at this age can be fast, typically lasting about two sec [37]. Here we used 5-sec phases to facilitate analysis. However, as we will show shortly, the actuators can reach maximum ROM within three and two sec for the shoulder and elbow respectively, thus making the exosuit appropriate for our target application.

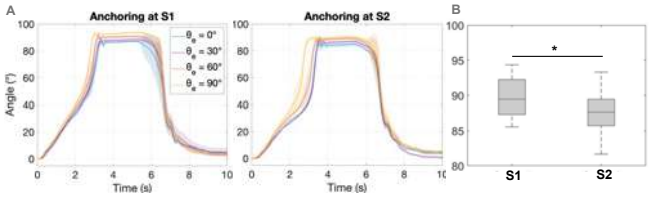

Fig. 3. (A) Changes in shoulder joint angle over time in the two shoulder actuator anchorings for different locked elbow angles. Shaded areas represent one standard deviation. (Best viewed in color.) (B) Boxplot comparing the shoulder joint angle between the S1 and S2 configurations.

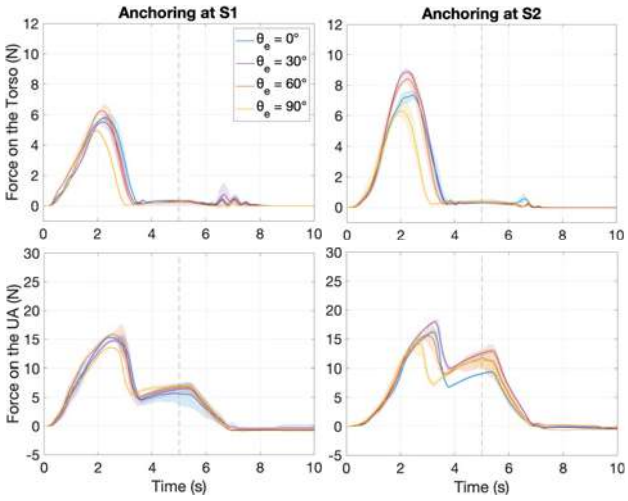

Fig. 4. Temporal evolution of the forces exerted by the shoulder actuator on the torso (Top) and UA (Bottom) for the two shoulder actuator anchorings and different locked elbow angles.

III. Results and Discussion

A. Shoulder Actuator Assessment

The change in shoulder joint angle throughout the trial and across the different non-actuated elbow joint angles for both shoulder actuator anchoring configurations is depicted in Fig. 3A. Overall, shoulder joint ROM was greater in S1 than S2 ($U = 4184$, $p < 0.001$; Fig. 3B). There was an effect of non-actuated elbow joint locked angles on ROM for both S1 ($\chi^2(3) = 102.281$, $p < 0.001$) and S2 ($\chi^2(3) = 83.999$, $p < 0.001$) configurations. Post-hoc tests demonstrated that locking the elbow angle at 60° and 90° leads to a greater shoulder joint ROM than being locked at 0° and 30° for both anchoring configurations ($p < 0.001$ for all comparisons).

The temporal evolution of the forces exerted by the shoulder actuator on the torso and UA across all pertinent configurations is illustrated in Fig. 4. When the actuator was anchored at S1, the peak force was exerted on the torso at 2.19 ± 0.15 sec and on the UA at 2.6 ± 0.18 sec.

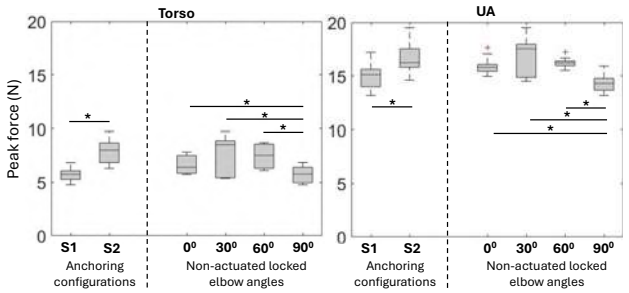

Fig. 5. Boxplots of the exerted peak force for the shoulder actuator on the torso and UA. Results show significant performance differences owing to different actuator configurations and non-actuated locked elbow angles.

When the actuator was anchored at S2, the peak force was exerted on the torso at 2.27 ± 0.15 sec and on the UA at 3.07 ± 0.25 sec. Statistical analysis showed a greater peak force exerted on the torso and UA in the S2 configuration compared to S1, regardless of the non-actuated elbow locked angle ($U_{\text{Torso}} = 13997.500$, $p < 0.001$; $U_{\text{UA}} = 11512.500$, $p < 0.001$); Fig. 5). In addition, the peak force exerted on the torso and UA was significantly different across the non-actuated elbow joint locked angles ($\chi^2{}_{\text{Torso}}(3) = 48.389$, $p < 0.001$; $\chi^2{}_{\text{UA}}(2) = 114.489$, $p < 0.001$). Post-hoc tests showed that locking the elbow at $90°$ leads to a lower peak force both on the torso and UA compared to the other three cases ($p < 0.001$ for all comparisons; Fig. 5). Visual inspection of Fig. 6 suggests that exerted forces appear to vary nonlinearly with the input pressure. When the actuator was anchored at S1, the peak forces on the UA and torso were observed at 16.73 ± 1.54 kPa and 13.45 ± 1.73 kPa, respectively. When the actuator was anchored at S2, the peak forces on the UA and torso were observed at 20 ± 2.44 kPa and 15.1 ± 2.03 kPa, respectively.

The previous results altogether allow for the following observations to be made. In configuration S1, ROM is larger and the peak force is smaller compared to S2. This can be explained by the fact that, when the actuator is placed farther from the shoulder joint center along the UA, the moment arm between its force application point on the UA and the shoulder joint increases. This helps generate more torque for the same actuator pressure. Similarly, when the elbow is mostly flexed (i.e. for $\theta_e = \{60°, 90°\}$) the moment arm between the center of mass of the FA and the shoulder joint's axis of rotation decreases. This reduces the mechanical work required for rotation for the same input pressure thereby increasing shoulder joint ROM. Lastly, it is worth noting that when the single-cell actuator is mounted onto the rig, it is folded into two sections that behave as separate cells initially. During inflation, these sections push outward, increasing force on both the torso and UA. Around mid-inflation, they merge into a single cell causing a discontinuity in the exerted force as well as a reduction in contact with the areas covered by load cells in both the torso (mainly) and UA. This effect may have led to the observed nonlinearities.

B. Elbow Actuator Assessment

The change in elbow joint angle throughout the trial and across the different non-actuated shoulder joint locked angles

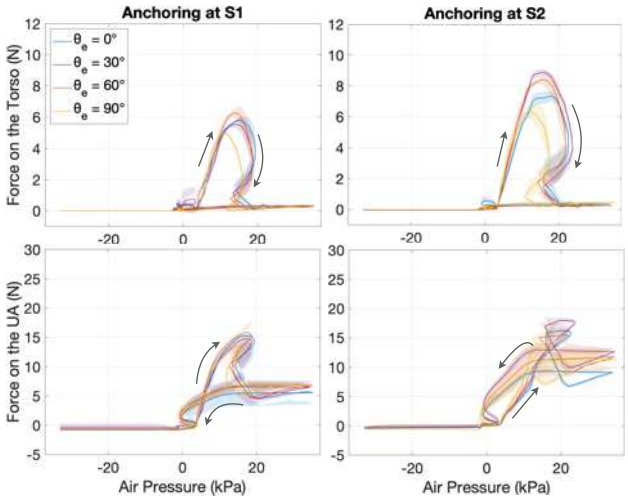

Fig. 6. Evolution of the shoulder actuator forces exerted on the torso (Top) and UA (Bottom) as the internal air pressure of the actuator varies, at different conditions. Arrows demonstrate the inflation-deflation cycle.

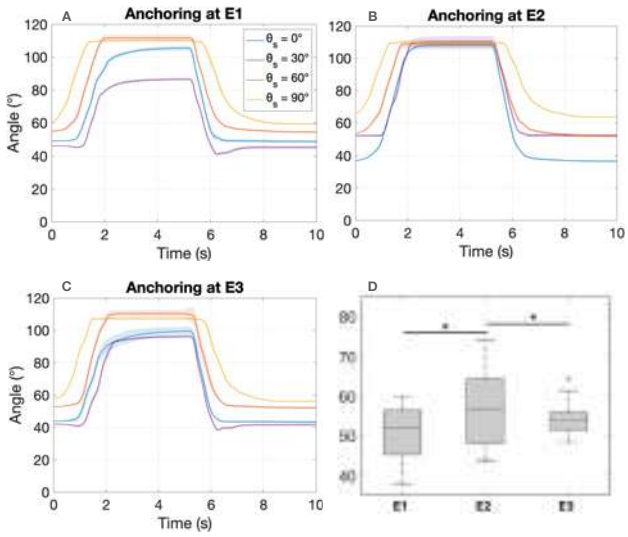

Fig. 7. (A, B, C) Changes in elbow joint angle over time in the three elbow actuator anchorings for different locked shoulder angles. (D) Boxplot showing elbow joint angles across the E1, E2, and E3 configurations.

for all elbow actuator anchoring configurations is depicted in Fig. 7 (A-C). Statistical analysis revealed that the elbow joint ROM was significantly different across the elbow actuator anchoring configurations ($\chi^2(3) = 28.580$, $p < 0.001$; Fig. 7D), with a greater ROM observed for E2 compared to E1 ($p < 0.001$) and E3 ($p = 0.012$). There was a statistically significant effect of non-actuated shoulder joint locked angles on the elbow joint ROM for the three elbow actuator anchoring configurations (E1: $\chi^2(3) = 101.544$, $p < 0.001$; E2: $\chi^2(3) = 102.782$, $p < 0.001$; E3: $\chi^2(3) = 83.809$, $p < 0.001$). Post-hoc tests showed that the smallest elbow joint ROM was observed at a locked shoulder joint angle of $90°$ for the E2 and E3 elbow actuator anchoring configurations, but not for E1 which was at a locked joint angle of $30°$ ($p < 0.001$ for all comparisons).

The temporal evolution of the forces exerted by the elbow actuator on the UA and FA for the three elbow actuator configurations and across the different non-actuated shoulder

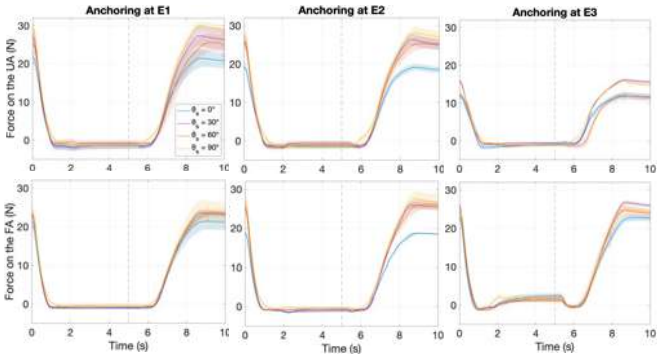

Fig. 8. Temporal evolution of the forces exerted by the elbow actuator on the UA (Top) and FA (Bottom) in all pertinent configurations.

joint locked angles is illustrated in Fig. 8. When the actuator was anchored at E1, the peak forces were exerted on the UA and FA at 8.51 ± 0.29 sec and 8.66 ± 0.34 sec, respectively. When anchored at E2, the peak forces were exerted on the UA and FA at 8.45 ± 0.26 sec and 8.53 ± 0.28 sec, respectively. In the E3 configuration, the peak forces were exerted on the UA and FA at 8.29 ± 0.21 sec and 8.45 ± 0.32 sec, respectively. Statistical analysis revealed that the peak force exerted on the UA and the FA was significantly different across the actuator anchoring configurations ($\chi^2_{\text{UA}}(2) = 243.053$, $p < 0.001$; $\chi^2_{\text{FA}}(2) = 36.783$, $p < 0.001$; Fig. 9). Post-hoc tests showed that the force exerted on the UA was significantly lower in the E3 configuration compared to the E1 ($p < 0.001$) and E2 ($p < 0.001$) ones, whereas, the force exerted on the FA was significantly lower for the E1 compared to the E2 ($p < 0.001$) and E3 ($p < 0.001$) configurations. In addition, the peak force exerted on the UA and FA was significantly different across the non-actuated shoulder joint locked angles ($\chi^2_{\text{UA}}(2) = 71.578$, $p < 0.001$; $\chi^2_{\text{FA}}(2) = 152.088$, $p < 0.001$; Fig. 9). Post-hoc tests showed that locking the shoulder at $\theta_s = 0^\circ$ led to the smallest peak force exerted on both UA and FA, compared to the other three cases ($p < 0.001$ for all comparisons). Visual inspection of Fig. 10 suggests that exerted forces demonstrate hysteresis to input pressure changes. Peak forces were observed at an average of 35.91 ± 0.72 kPa for the UA and 35.72 ± 0.65 kPa for the FA when the actuator was anchored at E1. When anchored at E2, the peak force was observed at 36.16 ± 0.68 kPa for the UA and 35.93 ± 0.65 kPa for the FA. Lastly, peak forces were observed at an average of 36.36 ± 0.7 kPa and 36.19 ± 0.71 kPa for the UA and FA, respectively, when the actuator anchored at E3.

The aforementioned results allow the following observations to be made. The symmetric configuration (E2) is the most efficient in terms of maximizing ROM. This can be explained by the mechanics of this actuator. When it is mounted between the UA and FA and inflated, it bends and attains an arc-like form. The bottom parts of its cells (i.e. the side closer to the body) come closer together while their top sides are being pulled away. Symmetry in the distribution of cells before and after the elbow joint center (i.e. number of cells over the UA and FA, respectively) enable the actuator to attain a more circular arc (compared to a more elliptical one

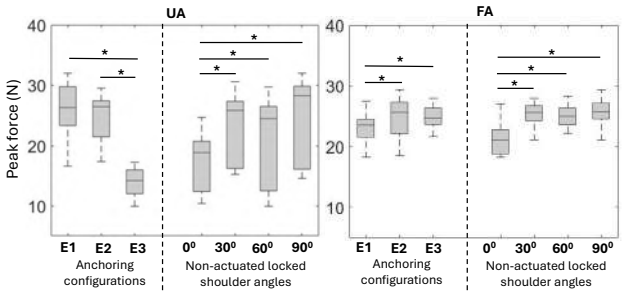

Fig. 9. Boxplots of the exerted peak force for the elbow actuator on the UA and FA. Results show significant performance differences owing to different actuator configurations and non-actuated locked shoulder angles.

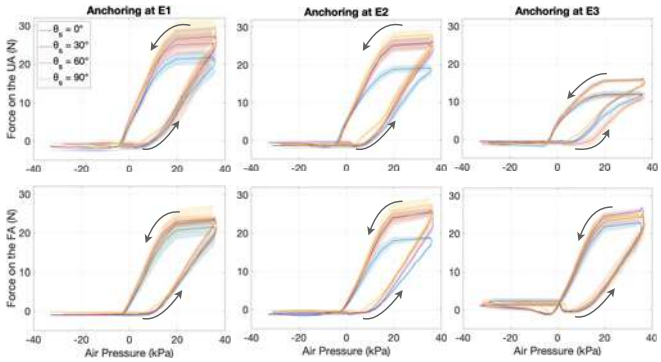

Fig. 10. Evolution of the elbow actuator forces exerted on the UA (Top) and FA (Bottom) as the internal air pressure of the actuator varies. Arrows indicate deflation (flexion) and inflation (extension).

when asymmetry is introduced), generating higher perpendicular force on the FA, increasing moment, and thus resulting in larger ROM. The asymmetric configurations bring some parts of the actuator closer together than others, reducing overall ROM but also reducing the peak force on the UA (E3; fewer cells over the UA) and FA (E1; fewer cells over the FA). The observed hysteresis may be caused by the binary (on/off) valves used in the pneumatic system; continuous flow valve could help remedy this effect. Besides the observed hysteresis, input pressure and exerted forces vary proportionally, while the transition between the deflation and inflation phases is smooth, highlighting the suitability of the elbow actuator in achieving its intended task.

IV. Conclusion

We investigated the contact forces generated by a single-cell actuator for shoulder abduction/adduction and a 10-cell bellow-type actuator for elbow flexion/extension using an infant-scale engineered apparatus. Extensive testing under various conditions revealed key information regarding actuator functionality. For the shoulder actuator: (1a) shifting it closer to the joint center can increase peak force while decreasing ROM, and (1b) increasing the elbow joint angle can help reduce the peak exerted force while improving ROM. For the elbow actuator: (2a) symmetric positioning can maximize ROM and result in equal peak forces exerted on the UA and FA, and (2b) larger shoulder joint angles can cause higher exerted forces and simultaneously reduce ROM.

The actuator anchoring findings (1a, 2a) give insight into how to improve the design for functionality and efficiency.

The findings relating to the effects of the adjacent joint when locked in a particular configuration (1b, 2b) can help create feedforward terms for an exosuit controller. For instance, if the task is to support primarily elbow function in terms of ROM, the underlying (admittance) controller should provide some input to the user to ensure the shoulder remains in a neutral position. A detailed treatise of such control design is part of future work. Further, the observed nonlinearity and hysteresis between actuator input pressure and exerted forces highlight the need for a dynamics-based analysis and modeling which is another direction of future work.

Toward a Customizable Body Weight Support System with Interactive Treadmill for Patients with Diverse Gait Impairments

Yongjin Jo, Youjin Lee and Jonghyun Kim, *Member, IEEE*

***Abstract*— Stroke patients face significant gait rehabilitation challenges, including high physical demands and fall risks. While body weight support (BWS) systems assist recovery, conventional designs remain limited by space, cost, and adaptability. To address these issues, we developed a customizable two-cable driven BWS treadmill system with a movable cable adjustment module for adaptive rehabilitation. Users can configure the harness as a pelvic or overhead support, enabling two training protocols: (1) Performance-Focused Gait Training (PFGT) to enhance gait efficiency and (2) Stability-Focused Gait Training (SFGT) to improve postural control. Clinical testing showed that PFGT increased walking speed by up to 34.7% and step length by 44.7%, while SFGT reduced trunk tilt by 7.3°, promoting gait symmetry and stability. These results highlight the system's capability to provide customized unloading support for individualized gait training, enhancing rehabilitation accessibility and effectiveness.**

Keywords—Gait training, Body weight support, customization

I. Introduction

A significant proportion of stroke patients experience impaired walking ability as a result of residual effects, significantly affecting their activities of daily living [1]. Recovery of lower extremity motor function is crucial for these patients to facilitate a smooth reintegration into daily and social life [2]. However, achieving this recovery is often hindered by several challenges in gait rehabilitation training, including substantial physical and mental demands on both patients and therapists [3]. Furthermore, the risk of falls during training can induce fear in patients [4], which may lead to decreased participation in the rehabilitation process.

Various robotic devices, including wearable exoskeletons and treadmill-based trainers, have been developed to aid gait rehabilitation [5]. Exoskeletons like Ekso [6] and ReWalk [7] assist lower limb movement but face limitations such as poor adaptability to uneven terrains and user discomfort. To address these issues, body weight support (BWS) systems have been developed to enhance safety and reduce the physical burden by unloading body weight during gait training [8]. These systems facilitate natural overground walking [9], promote neuroplastic changes [10], and support the reintegration of walking skills into daily life. BWS systems also reduce fear of falls [11], improving patient engagement, and offer adjustable support levels to balance safety and challenge [12]. Overhead BWS systems, such as Zero-G and Float [13, 14], provide dynamic support via ceiling-mounted rails, enabling overground walking. However, their substantial spatial and financial demands limit their use in smaller clinics, and their lack of customization restricts applicability to patients with diverse gait abilities. To address these limitations of overhead BWS systems, a treadmill has been integrated into a BWS system, allowing patients easier access to training. However, as a trade-off, treadmill-based gait training differs from overground walking due to the treadmill's pre-determined speed, which can be a limitation for regaining independent walking ability in real-world environments [15].

To overcome these challenges, we developed a two-cable driven BWS system integrated with an interactive treadmill [16, 17], which combines the benefits of treadmill-based gait training with overground-like adaptability. Unlike conventional systems, our approach allows users to autonomously regulate walking speed based on real-time position feedback [18], facilitating a more dynamic and interactive training experience. Additionally, the system incorporates a custom harness with pelvic support configuration that enables natural pelvic movement, improving gait biomechanics while maintaining stability. Experimental validation demonstrated that the system effectively controlled unloading forces and provided a feasible training environment [16]. However, its reliance on an interactive treadmill and a wide walking range necessitates adequate trunk control, limiting its suitability to patients with moderate ambulatory abilities, such as those classified within Functional Ambulation Category (FAC) levels 3 to 4 [19]. Like many existing BWS systems, it struggles to accommodate patients with severe gait impairments, underscoring the need for further enhancements to improve clinical applicability and accessibility across a broader patient population.

In this paper, we propose a body weight support system designed to explore tailored gait training strategies for patients with varying levels of walking ability. The system features a movable cable adjustment module, allowing flexible modification of the assistance mechanism to accommodate different levels of trunk control. Using this adjustable assistance mechanism, we implemented two distinct training modes to investigate their effects on patients with different gait impairments. The first mode applies an anterior-posterior cable connection for targeted assistance in mild gait impairments, while the second resembles a

conventional overhead BWS system, enhancing stability for more severe impairments. This study evaluates their feasibility and customized unloading support to inform individualized gait rehabilitation. Experimental evaluations with stroke patients were conducted to assess their clinical applicability.

II. Methods

A. System Hardware

1) *System framework*: The proposed system, which is shown in Fig. 1a, utilizes a two-cable driven body weight support (BWS) mechanism, designed to provide assistance during gait training. The system consists of the following key components:

- Actuation units : Each actuation unit facilitates power transmission through cables and comprises a winch drum, motor (EC-45, Maxon Inc., USA), gearbox (GP 32 HP, 69:1, Maxon Inc., USA), encoder (16 EASY, Maxon Inc., USA) and servo drive (EPOS 70-15, Maxon Inc., USA). These components work in coordination to regulate the force applied to the user, ensuring smooth and adaptive support.
- Tension Sensing Modules : To monitor the real-time tension in the cables, each tension sensing module is equipped with a load cell sensor (LPU-250, Transducer technique, USA). These sensors provide continuous feedback to maintain optimal force control.
- Cable Adjustment Modules : The system incorporates two cable adjustment modules, each featuring an encoder (E40S6, Autonics, Korea) to measure the angle of the cables connected to the user. This ensures accurate tracking of the user's movements and precise force application.

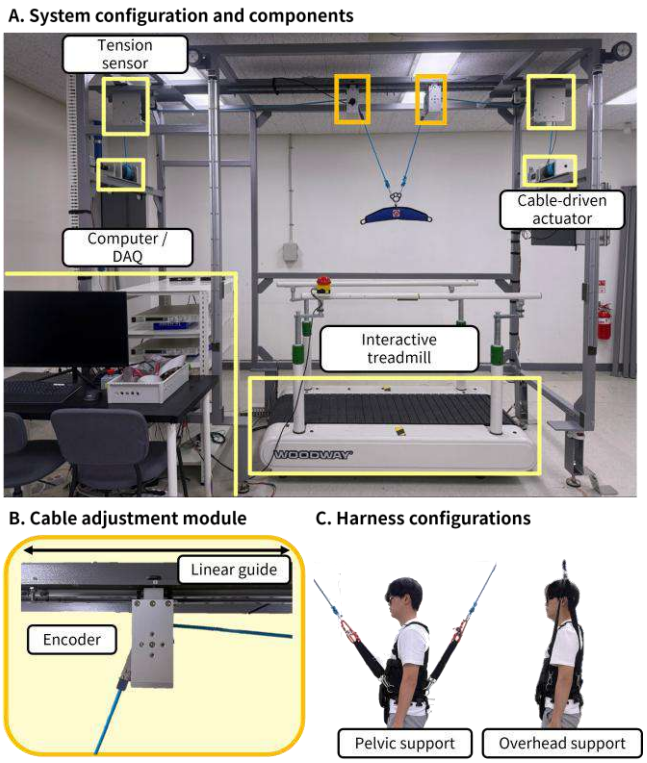

Fig. 1. System configuration and harness attachment types in the body weight support (BWS) system. (a) Overall hardware setup, including the cable-driven actuation system, interactive treadmill, and control units. (b) Detailed view of cable adjustment module with an encoder and linear guide for adaptive force application. (c) Comparison of two harness configurations: pelvic support, where cables are attached in a front-back orientation, and overhead support, where cables provide vertical support.

The two cables are connected in the anterior-posterior direction, delivering tension to the user under the following conditions.

$$\sum F_x = F_1 sin\theta_2 - F_2 \sin\theta_1 = 0 \quad (1)$$

$$\sum F_z = F_1 cos\theta_2 - F_2 \cos\theta_1 = F_r \quad (2)$$

where, F_x and F_z denote A/P and gravitational direction forces and F_1 and F_2 denote cable force connected to user in A/P direction. θ_1 and θ_2 are the angles of each cable. F_r is the reference unloading force. The desired forces of the two cables, denoted as $F_{1,d}$ and $F_{2,d}$, to satisfy Equations (1) and (2) can be calculated as follows:

$$F_{1,d} = \frac{F_r sin\theta_2}{\sin(\theta_1 + \theta_2)}, \quad F_{2,d} = \frac{F_r sin\theta_1}{\sin(\theta_1 + \theta_2)} \quad (3)$$

Feedback control is implemented to provide the desired force. The interactive treadmill adjusts the belt speed in response to changes in walking speed. Details on the system's operation can be found in our previous publication [17].

2) *Cable adjustment module*: The existing system was initially designed to connect cables in the anterior-posterior direction relative to the user, providing body weight support (BWS) while maintaining zero net force in the x-direction (Fig. 2a). To accommodate patients with reduced gait ability or impaired trunk control, we modified the system to also provide overhead BWS capabilities. Overhead BWS connects the cables above the user, increasing the vertical support ratio, which reduces the impact of anterior-posterior forces and enhances stability during walking. However, maintaining the original position of the cable adjustment modules for overhead BWS would lead to an increase of cable angle (θ_1, θ_2), as shown in Fig. 2b. This configuration alters the force distribution, increasing the horizontal force component relative to the vertical force component. Since the primary goal of the BWS is to provide unloading support through vertical forces, a steeper cable angle necessitates a higher overall cable tension to achieve the same vertical force. This, in turn, would require higher-performance actuators. To effectively implement overhead BWS using the current actuators, we installed linear guides on the ceiling, allowing the previously fixed cable adjustment modules to move along with these guides (Fig. 1b). If the module spacing is reduced from the original 1.2m to 0.45m, the required cable tension to provide the same unloading support can be reduced by 43%. This modification enables more efficient overhead support without necessitating enhanced actuators.

During training, the modules can be fixed in place by

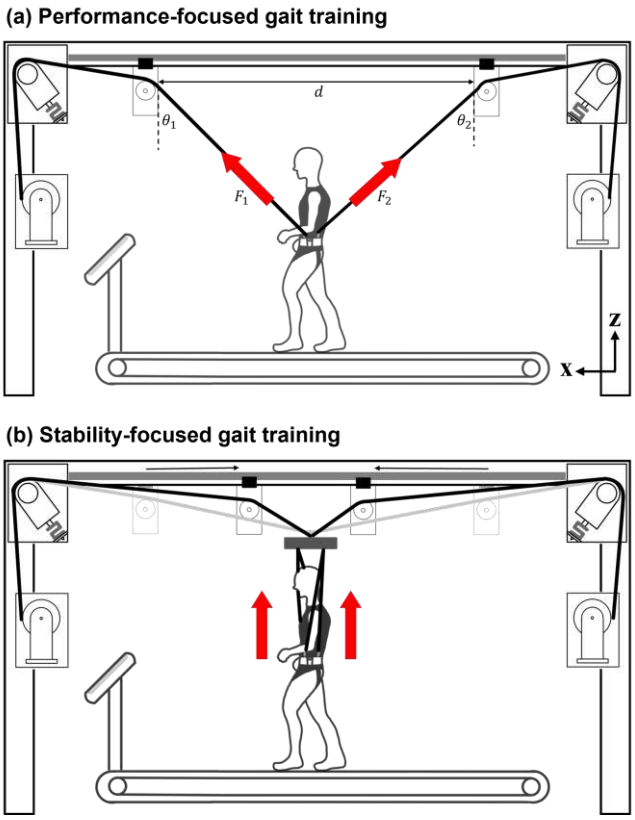

Fig. 2. (a) Wide spacing of cable adjustment module for Performance-focused gait training, (b) Reduced spacing of cable adjustment module for Stability-focused gait training

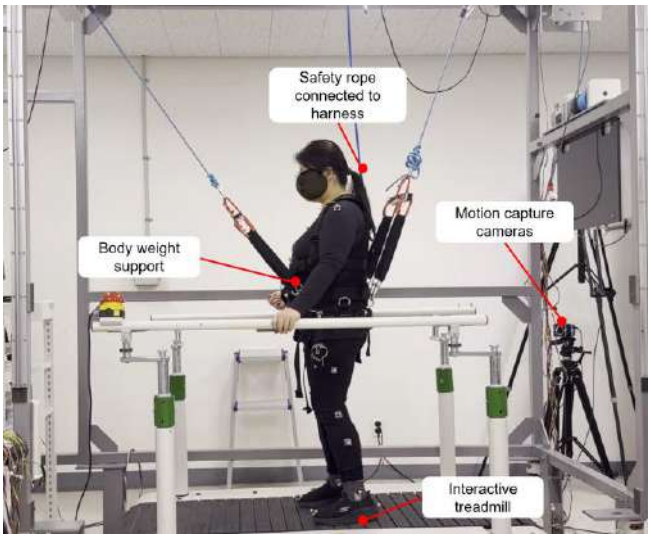

Fig. 3. Experimental setup for system evaluation with patients after stroke

inserting pins into holes arranged at 5 cm intervals, allowing the distance between modules to be freely adjusted. By customizing the assistance mechanism in this way, the pattern of support provided during training can be adjusted to suit individual needs. Adjusting the spacing of the modules also influences the user's walking range. If the user walks beyond the defined module spacing, the pendulum effect may occur, guiding the user back to stay within the designated walking range. Therefore, adjusting the module spacing provides a means of controlling the user's walking range, thereby optimizing the difficulty level of gait training to enhance both training efficiency and user safety.

B. Adaptive Training Modes Design

We designed training modes suitable for patients with varying gait abilities by utilizing the customizable assistance mechanism of the system.

1) Performance-focused gait training (PFGT): performance-focused gait training targets patients with relatively good gait abilities, specifically those at FAC levels 3 to 4. Rather than providing strong unloading support, this training is designed to guide patients to achieve a higher level of walking performance than they could achieve independently. The assistance mechanism of PFGT is shown in Fig. 2a. The cable adjustment module was set to a spacing of 1.2 m to enable gait training over a wide range, with two connection bars attached to cables from the front and rear to support natural movement. A harness with pelvic support configuration was used to avoid applying external force to the user's trunk, enabling natural body movement during walking. Additionally, an interactive treadmill was utilized, which dynamically adjusts to the user's movements, allowing the patient to select their own walking speed, thereby promoting active engagement and natural gait patterns.

2) Stability-focused gait training (SFGT): Stability-focused gait training is intended for patients with limited gait abilities, specifically those at FAC levels 1 to 2. These patients struggle with balance and shifting their center of gravity during walking [17], so the training focuses on maintaining stability while facilitating gait. To provide support in a manner similar to the conventional overhead BWS system, the cable adjustment module was set with a narrow spacing as shown in Fig. 2b. A harness with overhead support configuration was used to provide vertical support, with straps directly connecting the user's trunk to the connection bar. This configuration may restrict some natural trunk movement during walking, but it ensures a stable upward force to assist balance during gait. The module spacing was set to 0.45 m, covering approximately one-third of the total walking range (1.2 m). This setup is intended to support stable walking within a narrow range while reducing the occurrence of the pendulum effect. Although the assistance is provided similarly to a conventional BWS system, the user can still experience a distinct gait pattern. The direction of the assistance force remains upward, however, since the cables are connected to the user through an anterior-posterior arrangement via the connection bar, the benefits of the two-cable driven mechanism are retained. Consequently, as long as the user remains within the defined walking range, they can walk without experiencing the pendulum effect, thereby enhancing stability.

III. EXPERIMENTAL EVALUATION

A. Participants

Three participants with chronic stroke participated in the study. (see Table 1). Prior to the experiment, all participants were provided with a detailed explanation of the study procedures, including visual content describing the

TABLE 1. PARTICIPANTS BASELINE CHARACTERISTICS AND GAIT PERFORMANCE

Participants No.	Sex	Age (y)	Paretic side	Height (cm)	Weight (kg)	Assistive device	FAC level
SN01	Female	41	Right	158	68	None	4
SN02	Male	65	Right	165	60	None	4
SN03	Male	61	Right	172	65	Wheelchair	1

experiment. Medical clearance and written informed consent forms were obtained from all participants, in compliance with the guidelines approved by the Sungkyunkwan University Institutional Review Board (SKKU 2022-06-014).

B. Experimental Design

This study aimed to observe changes in gait patterns when patients with varying walking abilities are provided with different training protocols and levels of body weight support (BWS). Prior to the experiment, participants determined their preferred treadmill walking speed, which was then set as the speed for the interactive treadmill. For SN01 and SN02, gait training was conducted using an interactive treadmill set to their preferred speed under two distinct training modes: Performance-Focused Gait Training (PFGT) and Stability-Focused Gait Training (SFGT). To evaluate the effects of different levels of unloading support, gait patterns were observed under 30% and 50% BWS conditions, which were determined through preliminary experimentation to be the appropriate levels of assistance for effective gait training. Participant movements were recorded and analyzed using a motion capture system (VICON Nexus, UK). The detailed experimental setup can be found in Fig. 3.

The two participants first performed PFGT under 0% BWS (no unloading) for two trials, followed by two trials each under 30% BWS and 50% BWS conditions. Subsequently, they performed SFGT under 0%, 30%, and 50% BWS conditions, with two repetitions for each. Each walking trial lasted one minute, with a one-minute rest interval provided between trials to minimize fatigue. In contrast, SN03, who exhibited significantly lower walking ability compared to the other participants, was provided with different training protocols. Training under 0%, 30%, and 50% BWS conditions was not conducted due to the participant's inability to perform independent walking. Instead, based on preliminary assessments, an unloading support level of 85% BWS was identified as optimal for stable walking. Under this condition, SN03 completed four one-minute walking trials.

IV. RESULTS

In this section, we provide an analysis of the effects of the unloading support level from BWS on joint kinematics, spatiotemporal data, and each subject during assisted gait.

A. Spatiotemporal data

The spatiotemporal data of participants during gait are reported on Fig. 4. This analysis aims to determine whether there were any improvements in gait performance due to BWS assistance.

1) Performance-focused Gait Training: Participants who

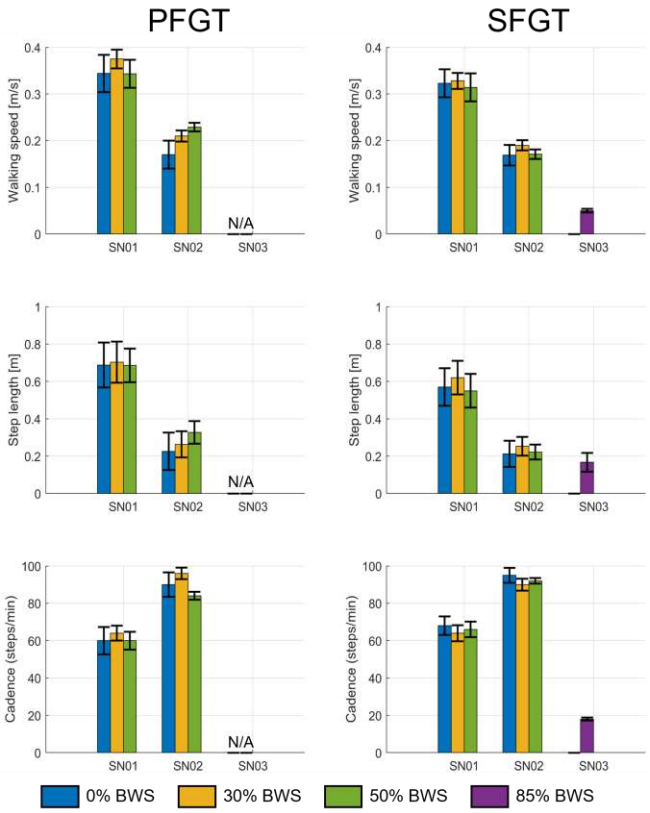

Fig. 4. Spatiotemporal gait parameters averaged across all participants for all the tested condition. (Top) Walking speed, (Middle) Step length, (Bottom) Cadence. SN03 was unable to complete total PFGT training and SFGT with 0% BWS, indicated by "N/A." In SFGT, SN03 achieved walking at 85% BWS. Error bars represent standard deviations.

performed PFGT demonstrated overall improvements in gait performance. Under a 30% BWS condition, compared to the 0% BWS, both participants were able to walk at an increased speed (SN01 - 9%, SN02 - 23.5%). Step length and cadence also increased (compared with 0% BWS) when 30% BWS was provided (SN01 – 2.18% for step length and 6.67% for cadence, SN02 – 16.3% for step length and 6.67% for cadence). Under the 50% BWS condition, SN01 showed a slight reduction in walking speed (-0.3%) and step length (-0.29%). SN02 showed the best walking performance (+34.7% for walking speed, +44.7% for step length and -6.7% for cadence compared to 0% BWS).

2) Stability-focused Gait Training: In PFGT, SN03 was unable to perform gait training even with assistance. However, in SFGT, SN03 successfully achieved independent walking when provided with 85% body weight support (BWS), reaching a walking speed of 0.05 m/s. For SN01 and SN02, no significant improvements in gait performance were observed during SFGT. Notably, under 30% BWS, walking

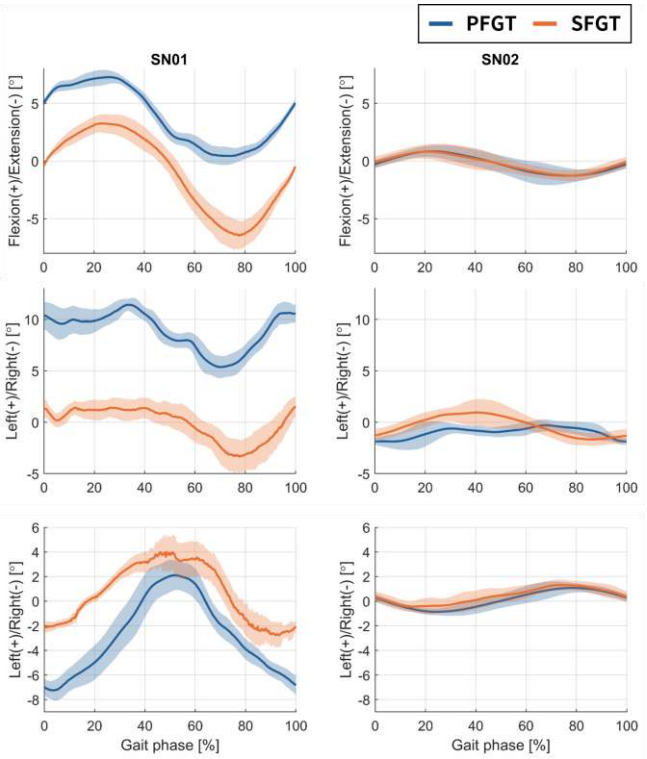

Fig. 5. kinematics during the gait cycle under different training protocols. The graphs compare joint movements for two subjects (SN01, SN02) in performance-focused gait training (PFGT, blue) and stability-focused gait training (SFGT, orange). The plots show variations in joint angles across the gait phase (%) in three planes: (Top) sagittal plane – trunk flexion/extension, (Middle) frontal plane – lateral movement, and (Bottom) transverse plane – rotational movement. Shaded areas represent standard deviations, illustrating variability in movement patterns.

speeds increased for both participants (SN01 by 2.16%, SN02 by 11.7%). Step length increased (SN01 by 8.77%, SN02 by 19.3%), whereas cadence decreased (SN01 by 5.88%, SN02 by 5.26%). Under 50% BWS, SN01 showed a reduction in gait performance (-2.78% for walking speed, -3.5% for step length and -2.94% for cadence). For SN02, there was a negligible difference compared to the 0% BWS condition (+1.18% for walking speed, +4.71% for step length and -2.94% for cadence).

B. Trunk kinematics

The trunk kinematics of the participants during gait are shown in Fig. 5. For SN03, due to environmental constraints that made it challenging to utilize the motion capture camera while ensuring participant safety, trunk kinematics data was only reported for SN01 and SN02. The analysis examines how trunk movement patterns change when two different training sessions are provided. The solid line represents the average trunk angle during gait, while the shaded area indicates the standard deviation. For SN01, when comparing SFGT to PFGT, trunk movement in the sagittal and frontal planes showed an average reduction of 7.3 degrees in both minimum and maximum values. Additionally, the mean position of movement decreased by 6.9 degrees. In the transverse plane, both the min/max values increased by an average of 3.19 degrees, and the mean position of movement increased by 3.5 degrees. In contrast, Participant SN02 exhibited changes of less than 1.3 degrees across all planes.

V. Discussion

In this study, we investigated how a customizable body weight support (BWS) system affects gait stability and performance in two stroke patients. The evaluation focused on trunk kinematics and spatiotemporal data to assess stability and gait performance. The spatiotemporal data indicated that SFGT could even make patients classified as FAC level 1 train using the BWS system. Participant SN03, who could not walk independently and struggled with trunk control, was unable to complete PFGT even with 85% BWS. However, SN03 successfully completed repeated gait training sessions using SFGT. This finding suggests that training can be provided to patients who were previously unable to benefit from the previous system.

For participants with relatively higher gait performance, SFGT did not significantly improve gait function in participants with higher initial performance levels. This might be due to SFGT focusing on stability enhancement, whereas these participants had already surpassed target performance levels. However, significant gains were observed during PFGT. Under the 30% BWS condition, improvements in all spatiotemporal metrics suggested better gait efficiency and safety. At 50% BWS, gait patterns diverged significantly between participants: SN01 experienced a general reduction in gait performance, while SN02 demonstrated the highest performance. These differing outcomes could stem from baseline gait strategies. SN02's improvement suggests that the assistance helped develop a more efficient gait strategy, addressing previously high cadence and short step length often seen as compensatory mechanisms for stability in elderly individuals [20]. The increase in walking speed, along with step length and reduced cadence, indicated enhanced gait efficiency and stability. In contrast, SN01's reduced performance may reflect over-reliance on the provided assistance, which can diminish engagement and overall performance [21]. These findings suggest that the most effective assistance level depends on individual needs.

The results for trunk kinematics also varied between participants. SN01 demonstrated distinct trunk movements between the two training types. When performing SFGT, an offset in trunk angles was observed compared to PFGT across all planes. Specifically, the average trunk angle during the gait phase approached zero in all planes during SFGT, which indicates that SFGT might improve gait symmetry and enhance stability during walking [22]. Even for participants demonstrating good gait capabilities, SFGT can help individuals with gait asymmetry train towards a gait pattern that more closely resembles regular walking. In contrast, SN02 exhibited no significant differences in trunk movement between the two training types. As SN02 had already adopted a stability-focused gait strategy even during PFGT, their trunk moved around a zero-degree position. Therefore, the effect of SFGT on improving trunk stability and symmetry might be diminished. These findings reinforce the importance of postural stability in gait training, further highlighting the potential benefits of tailored assistance for individuals with gait asymmetry.

Overall, our findings demonstrate that the proposed system, which enables customization of assistance

mechanisms based on individual needs, effectively supports diverse gait training strategies. Performance-Focused Gait Training (PFGT) enhances gait performance and efficiency, making it particularly beneficial for patients striving to regain natural walking patterns through increased speed and optimized gait mechanics. In contrast, Stability-Focused Gait Training (SFGT) promotes gait symmetry by reducing trunk tilt and prioritizing stability throughout training. By facilitating trunk control, SFGT extends the benefits of gait training to patients who previously lacked sufficient gait ability to engage in effective rehabilitation.

The findings indicate that different training protocols affect gait performance, highlighting the need for personalized rehabilitation strategies. By evaluating performance-focused and stability-focused gait training, this study provides insights into how adaptive assistance can enhance gait efficiency and postural control. Our system offers adaptable support by dynamically adjusting module distances, ensuring precise assistance tailored to rehabilitation needs. This flexibility improves accessibility in clinical settings, optimizing gait training outcomes.

While our system enables adaptability, this study primarily explores how different training protocols influence patient outcomes rather than implementing a fully individualized model. Instead of directly applying a customization framework, we establish foundational insights by analyzing spatiotemporal data and patient-specific factors. The findings suggest that spatiotemporal data, along with individual characteristics such as height and weight, could help classify patients into appropriate training categories, paving the way for a more adaptive, data-driven approach to personalized gait assistance.

A key limitation is the small and biased sample size (three patients: FAC levels 4, 4, and 1), which may have influenced the results. As the system is expected to benefit FAC levels 2 or 3, future studies should include a more diverse participant pool to validate its effectiveness across different mobility impairments. Additionally, further analysis using joint kinematics and muscle activity assessments is needed to uncover biomechanical changes affecting rehabilitation outcomes.

Despite these limitations, the system demonstrates strong potential for supporting personalized gait rehabilitation through adjustable walking range and assistance mechanisms. As training effects vary by gait pattern, refining adaptive control strategies will be crucial in optimizing assistance levels for individual users. Future advancements integrating real-time gait analysis and automated adaptation could further enhance rehabilitation effectiveness, making gait training more accessible and patient-specific.

Real-time Continuous Calibration of an EMG-Informed Neuromusculoskeletal Model for Assistive Exoskeleton Control

Matthew J. Hambly, Matthew T.O. Worsey, David G. Lloyd, and Claudio Pizzolato

Abstract— **Accurate real-time neuromusculoskeletal (NMS) modeling is crucial for closed-loop neurorehabilitation. This study presents a novel electromyography (EMG)-informed NMS modeling framework with continuous real-time calibration for controlling an upper limb exoskeleton. Using an auto-differentiable NMS model, we implemented a sliding window online calibration to eliminate the need for model calibration prior to use. The framework was validated during a functional reaching task performed with an ArmeoPower exoskeleton. Model accuracy and exoskeleton control performance were compared across uncalibrated, offline calibrated, and continuously calibrated models. The continuously calibrated model achieved comparable accuracy to the offline calibrated model within just 15 movement cycles (110 seconds), eliminating the need for pre-session calibration. Furthermore, the continuous calibration approach provided physiologically plausible predictions of joint moments, enabling exoskeleton control performance comparable to the offline calibrated NMS model. An offline synergy-driven modelling approach was also examined, demonstrating potential to represent unrecorded excitations and improve moment prediction accuracy. By addressing the limitations of prior methods, this framework enhances the usability of EMG-informed NMS models in real-time applications, offering a personalized and adaptive solution for neurorehabilitation, able to dynamically adapt to physiological changes such as fatigue.**

I. Introduction

Motorized exoskeletons provide weight support and actuation to assist movement [1], enabling intensive and frequent rehabilitation for individuals with neurological impairments, such as spinal cord injury or stroke, without the dependence on a large team of therapists [2]. However, to optimize therapeutic outcomes, rehabilitation must effectively engage the user's neurophysiological and musculoskeletal systems [3], which can be achieved by incorporating the user's intent into the exoskeleton's control scheme [4]. Effective feedback mechanisms are therefore necessary to ensure seamless, synergistic interaction between the user and device.

Electromyography (EMG) is one of the most widely used biosignals for exoskeleton control [5, 6], offering insights into user's intent coded in their muscle excitations. Despite its advantages, EMG alone does not fully capture the complex muscle states and non-linear relationships between muscle excitations, muscle forces, joint moments, and movement. This makes EMG alone insufficient for estimating joint moments [7, 8], which can be used for effective exoskeleton control [9, 10]. Data-driven approaches, such as neural networks, have been employed to generate upper-limb exoskeleton control signals from EMG [11, 12] and kinematics [13]. While these methods can model complex relationships, they typically require large training datasets, lack inherent physiological and physical constraints, and do not provide insight into the underlying neuromusculoskeletal (NMS) mechanisms generating movement. Furthermore, coordinated muscle excitation patterns (i.e., EMG) change for the same joint moments and angles across people and even in the same person depending on control tasks, training, and disease state [14-16]. NMS models provide individual-specific representations of the skeletal, joint, muscular, and nervous systems, and predict physiologically plausible muscle forces and joint moments [7]. By incorporating EMG, NMS models can reflect individual-specific motor control [17] making them particularly promising for personalized rehabilitation. The long and continued development of calibrated EMG-informed NMS modelling has produced open-source software, known as CEINMS [18, 19], capable of real-time execution facilitating, for example, lower limb exoskeleton control [10].

To achieve appropriate personalization, the neuromuscular parameters of the model (e.g., optimal fiber length, tendon slack length) must first be calibrated for each individual before executing (i.e., using) the model [19, 20]. Calibration typically involves iteratively adjusting the model parameters to improve tracking of joint moments, while ensuring the model adheres to physiologically plausible solutions, such as maintaining muscle fiber lengths within the functional force-length range and enforcing consistent multi-joint muscle behavior [21]. This calibration process is typically time-intensive, often requiring several hours [22], severely limiting its practicality for real-time applications. Real-time simultaneous calibration and execution of NMS models could bypass the limitations of traditional offline calibration, enabling immediate adaptability and precision. We recently developed a differentiable physics NMS modelling framework that combines neural network optimization techniques with physics-based models [23], and could be extended to deploy real-time continuous calibration without compromising accuracy [24].

In this study, we present a neurally controlled upper limb exoskeleton system, designed for real-time continuous calibration and execution of an EMG-informed NMS model using differentiable physics. We demonstrate the feasibility of real-time continuous calibration and execution for predicting shoulder and elbow joint moments, which directly inform exoskeleton control. Our evaluation compares the prediction

Lloyd, and Claudio Pizzolato are with The Australian Centre for Precision Health and Technology (PRECISE), Queensland, Australia, and the School of Health Sciences and Social Work, Griffith University, Queensland, Australia (correspondence e-mail: matthew.hambly@griffithuni.edu.au).

accuracy and movement precision of the continuously calibrated model with both uncalibrated and offline calibrated models. Additionally, we propose a synergy-informed approach to improve model prediction accuracy.

II. Methods

A. Subjects and apparatus

A single participant (age 23 years, body mass 66 kg, height 1.76 m) with no existing musculoskeletal or neurological injuries took part in this study, providing informed consent. This study was approved by the Griffith University Human Research Ethics Committee (GU ethics no 2022/664).

The sites on the skin for 11 surface EMG recordings were prepared following the SENIAM guidelines [25], with the signals sampled at 2,048 Hz (Quattrocento, OTBioelettronica, Torino, Italy). EMG was recorded from the deltoid (anterior, medial and posterior), pectoralis major (clavicular and sternal), infraspinatus, latissimus dorsi, biceps brachii short head, triceps brachii (lateral and long heads) and brachioradialis. To normalize EMG data, maximum voluntary contractions (MVC) were recorded for each muscle, whereby the participant was instructed to exert maximal effort against a fixed resistance under isometric conditions for three seconds for each muscle group [26]. For this study, we used the ArmeoPower upper limb exoskeleton (Hocoma, Switzerland), equipped with motorized weight support and movement assistance, along with encoders for joint angle measurement. The lengths of the participant's hand, forearm, upper arm, clavicle, and torso were measured to linearly scale a musculoskeletal model.

B. System design

The overall system design (Fig. 1) incorporates the participant using the ArmeoPower exoskeleton (Fig. 1A) and their corresponding models (Fig. 1B-F) modulating the ArmeoPower's assistance (Fig. 1G). The EMG-informed NMS model (Fig. 1E) predicted musculotendon unit (MTU) forces and joint moments from experimentally recorded muscle excitations, MTU lengths and moment arms. The NMS model was based on CEINMS [19], with updated mathematics and code restructuring for faster computation, while still retaining calibration to the individual and execution of the model [24]. EMG-informed execution can be EMG-driven, where the model is directly driven by EMG derived excitations [7], or where excitations of muscles with and without EMGs are adjusted or estimated, respectively, using various methods [19, 27], e.g., synergy-informed (see section IIE).

Muscle excitations were derived from processed EMG recordings (Fig. 1B), following well established procedures [28]. The raw EMG signals were band-pass filtered using a 3rd-order Butterworth filter (30-300 Hz) to reduce noise, then rectified and low-pass filtered at 5 Hz with a 4th-order Butterworth filter to extract the linear envelope. All filters were applied in the forward direction only to enable real-time operation. The processed EMG signals were normalized to the MVC trials to quantify muscle excitations and mapped to their corresponding MTUs in the NMS model [19]. MTU lengths and moment arms were estimated from ArmeoPower and upper limb musculoskeletal models.

ArmeoPower and upper limb musculoskeletal models were driven by the ArmeoPower's real-time angle measurements for the shoulder, elbow, forearm and wrist degrees of freedom (DOFs) via its built-in encoders (Fig 1A). However, these measured joint angles do not directly correspond to the person's anatomical joint angles due to motion between the exoskeleton and human arm. To address this, we developed a custom ArmeoPower model attached to an existing upper limb musculoskeletal model [29] (Fig. 1C) using OpenSim Creator (Version 0.5.16) [30] and OpenSim (Version 4.4) [31]. The musculoskeletal model contained 12 DOFs: three sternoclavicular, three acromioclavicular, three glenohumeral (shoulder plane, shoulder elevation, shoulder rotation), elbow flexion, forearm pronation and wrist flexion. The exoskeleton and musculoskeletal models were connected using slider joints at the humerus, forearm and hand, simulating the physical straps and handle of the exoskeleton. These slider joints allowed small, single-direction movements, preventing the model from being over constrained. So, the measured

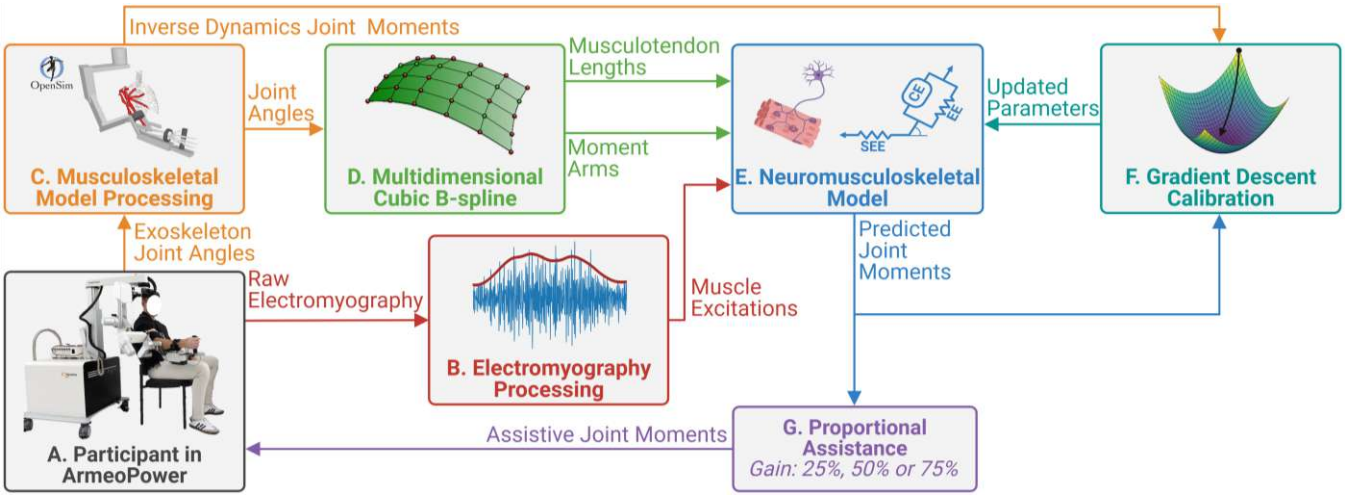

Fig. 1. Overview of the real-time EMG-informed NMS model-based exoskeleton control. (A) The participant is set up in the ArmeoPower exoskeleton, recorded joint angles and providing torque assistance. (B) Raw EMG signals are processed to obtain the muscle excitations. (C) Exoskeleton joint angles are processed through an OpenSim model providing anatomical joint angles and moments. (D) Multidimensional cubic B-splines are used to calculate the MTU lengths and moment arms. (E) The NMS model then predicts joint moments. (F) For continuous calibration, online calibration of model parameters is done using gradient descent. (G) NMS predicted joint moments informed proportional assistance through the exoskeleton motors.

exoskeleton joint angles drove the exoskeleton model kinematics, which in turn drove the musculoskeletal model to obtain the anatomical kinematics necessary to calculate the inputs for the NMS model. The NMS model contained four DOFs: shoulder plane, elevation and rotation, and elbow flexion, actuated by 14 MTUs, each driven by the recorded excitations. These were 3 deltoid, 3 pectoralis major, infraspinatus, latissimus dorsi, biceps brachii long and short heads, triceps brachii medial, lateral and long heads, and brachioradialis. The NMS model required inputs of MTU lengths and moment arms estimated via OpenSim. However, OpenSim cannot estimate these in real-time, so they were computed from MTU-specific multidimensional cubic B-splines (Fig. 1D), generated from the linearly scaled OpenSim model, enabling real-time computation [32].

Calibration requires minimizing the error between the inverse dynamics and NMS predicted joint moments. Real-time inverse dynamics were estimated using the OpenSim C++ API [33] driven by musculoskeletal model kinematics. These moments served as reference for the NMS model calibration (Fig. 1F). Calibration ensures the NMS model accurately represents individual physiology, calibrating model parameters (i.e., optimal fiber length, tendon slack length, strength coefficients and the activation dynamics) initialized from the linearly scaled OpenSim model. At each time step, the NMS model was executed in EMG driven mode (Fig 1E).

The new NMS model can perform separate or simultaneous calibration and execution, due to enhanced computational speed compared to CEINMS. This is possible using our previously validated auto-differentiable NMS modeling framework with efficient gradient-based optimization via backpropagation (Fig. 1F) [24]. To enhance computational efficiency, we adopted a stiff tendon model [34] that eliminated the need for one numerical integration step in the muscle dynamics solution. The NMS model was continuously calibrated using a sliding window approach. The most recent data, capturing approximately one movement cycles (i.e., four seconds) was used for calibration, with a single optimization iteration performed per window to maintain computational efficiency. During calibration, the following loss function was minimized:

$$Loss = \frac{1}{N_i}\sum_{i}^{N_i}\left[\frac{1}{N_d}\sum_{d}^{N_d}\left(\bar{M}_{i,d} - M_{i,d}\right)^2 + \sum_{m}^{N_m} P_{i,m}\left(\tilde{l}_m\right)\right] \quad (1)$$

$$P = \begin{cases} w(x^{min} - x)^2, & x < x^{min} \\ w(x - x^{max})^2, & x > x^{max} \\ 0, & otherwise \end{cases}$$

where N_i, N_d, and N_m are the number of time steps, DOFs and MTUs respectively, $\bar{M}$ and M are the inverse dynamics and NMS predicted joint moments, P is a penalty function for the normalized fiber length ($\tilde{l}_m$), penalizing values (x) outside of the operative range (x^{min}, x^{max}), applying a weighting (w). The loss function minimized joint moment tracking error, while penalizing normalized fiber length values outside of the range 0.5 to 1.5, ensuring physiologically plausible solutions [19]. After each calibration, updated model parameters were applied to the executing NMS model, and calibration restarted on the newest data window. A learning rate decay of 1% per iteration was implemented for gradual parameter adjustments over time.

The NMS predicted joint moments from execution were used in real-time to control the exoskeleton motors for four of its six DOFs, corresponding to the shoulder (plane, elevation and rotation) and elbow (flexion) (Fig. 1G). The predicted moments were scaled by a tunable gain factor (25%, 50% and 75%) and applied as torque outputs from the respective exoskeleton motors, augmenting the user's volitional movements. The remaining two DOFs (forearm supination and wrist flexion) were not actively assisted by the exoskeleton but allowed volitional movement. The ArmeoPower was configured to provide 50% weight support for the arm.

In summary, this computation framework enabled ArmeoPower control using uncalibrated, offline calibrated, and continuously calibrated NMS models. These models were all run using the same experimental protocol.

C. Experimental protocol

The participant performed the *Supermarket* exercise pre-programmed task on the ArmeoPower, selected because it actively engaged all four of the target control DOFs. The exercise required the participant to reach out and grasp a virtual item from a 3D space in front of them, then return the item to a centrally located basket. Upon completing a reaching task, a new target item was randomly selected for the participant to retrieve, ensuring varied and continuous movement. The participant was instructed to complete as many of these reaching tasks as possible within a two-minute period, comprising a single trial. The experiment included trials for each combination of control mode (i.e., uncalibrated model, offline calibrated model, and continuously calibrated model) and control gain (25%, 50%, and 75%), along with an unassisted trial to serve as a baseline. The order of control modes was randomized, and the participant was blinded to the condition sequence to minimize potential bias. A one-minute rest period was provided between trials to minimize fatigue.

During testing, the number of successful reaching cycles, kinematic data, EMG signals and NMS model outputs (i.e., muscle activations and forces, and joint moments) were recorded. For trials involving continuous calibration, the time required to complete each calibration window was also logged. These data were used for the calibration analyses.

D. Calibration analysis

These analyses compared the uncalibrated, offline calibrated, and continuously calibrated NMS models. The uncalibrated model provided a baseline with minimal personalization, while the offline calibrated model represented the conventional approach to obtaining optimal parameters. Offline calibration was performed using the new EMG-driven NMS approach [24], iterating over a recorded movement cycle until convergence, as indicated by no improvement in the loss over several iterations. Offline calibration data was collected from a single movement cycle recorded prior to the main data collection. The total time taken to complete the offline calibration was measured.

The recorded data were segmented into individual reaching tasks using a peak finding method applied to the grip strength data from the ArmeoPower handle, which identified when virtual items were grasped and released. A single movement cycle was defined as the period between two successive grip releases.

To evaluate the accuracy of the NMS models, root mean squared error (RMSE) between inverse dynamics and model predicted joint moments was calculated. The accuracy of the continuously calibrated model was compared against the uncalibrated and offline calibrated models. Additionally, we analyzed how the accuracy of the continuously calibrated model evolved across movement cycles, comparing it to the mean accuracy of the offline calibrated model to determine when their performance converged.

Exoskeleton control performance was assessed by counting the number of successful reaching tasks per trial and measuring the completion time for each task. Additionally, movement smoothness was quantified using the Spectral Arc Length (SPARC) [35] derived from the velocity profile of the hand based on kinematic data. SPARC was chosen in the current study over traditional jerk-based smoothness measures due to its lower sensitivity to measurement noise [35]. The SPARC measurement provides negatives values, with values closer to zero indicating smoother movements.

For analysis of the model calibration effects, data from trials under the different calibration modes were grouped across gain levels. Comparisons were made between the uncalibrated, offline calibrated, and continuously calibrated model-assisted conditions for model accuracy analysis, while the unassisted condition was included in the control analysis. Additionally, for the continuous calibration trials, the metrics from only the movement cycles occurring after the model reached accuracy comparable to offline calibration were analyzed, which was determined to be after the first 15 cycles.

E. Synergy NMS model and analysis

Pre-empting results of the EMG-driven NMS model, this approach did not achieve high joint moment accuracy, primarily due to the inability to record all experimental muscle excitations. To this end, further offline analysis was conducted using muscle synergies to synthesize missing excitations, incorporating additional MTUs that lacked recorded excitations (i.e., supraspinatus, subscapularis, teres minor, teres major, coracobrachialis, anconeus, and brachialis) into the NMS model. Muscle synergy-based NMS modelling approaches offer a promising method to reduce the number of required EMG recordings while maintaining accurate muscle excitation predictions [36].

The model was first calibrated using a synergy-hybrid approach [24], where synergies, comprising primitives and muscle weightings, were extracted using non-negative matrix factorization (NMF) [37] and subsequently optimized to synthesize excitations for MTUs without recorded signals. Calibration was performed on a single movement cycle. Following calibration, the primitives time series data for MTUs with recorded excitations were extracted from the remaining movement cycles using NMF. Excitations for unrecorded MTUs, computed using the calibrated weightings and extracted primitives, were combined with recorded excitations to drive the NMS model.

For this analysis, we used trials from the offline calibrated NMS model control condition. The model was calibrated on the first movement cycle of the trial, then executed on the two subsequent cycles. Only two cycles were used as the primitives and weightings vary over time, limiting the applicability of unrecorded muscle weightings beyond these cycles. This process was repeated for each gain level. For consistency, EMG-driven execution was performed on the same cycles using the synergy-hybrid calibrated model but was driven solely by the recorded excitations. RMSE was calculated between inverse dynamics and NMS model predictions from the EMG-driven and synergy-driven models. For analysis, data across gain levels were grouped together.

F. Statistical analysis

A Shapiro-Wilk test was conducted to assess normality of each dataset. For comparisons of model accuracy and exoskeleton control performance across the three calibration methods (uncalibrated, offline calibrated, and continuously calibrated), one-way ANOVA was applied to normally distributed data, while Kruskal-Wallis ANOVA was applied to non-normally distributed data. For the synergy execution analysis, independent sample t-tests were used for normally distributed data, and Mann-Whitney U tests were applied to non-normally distributed data. Statistical significance was set at $p<0.05$ for all analyses.

III. RESULTS

From the recorded data 20 individual movement cycles were extracted from the unassisted trial, 74 cycles from the uncalibrated trials, 81 from the offline calibrated trials, and 83 from the continuous calibration trials. For the three model control modes the cycles across all control gain level trials were combined.

For the continuous calibration method, RMSE decreased over time, requiring approximately 15 movement cycles to achieve accuracy comparable to offline calibration (Fig. 2 and Fig. 3). On average, a single calibration window took 7.3 seconds to run (110 seconds for 15 cycles), while the offline calibration process required 154 seconds.

The uncalibrated model produced significantly higher RMSE than both calibrated models (Fig. 3). When considering all continuous calibration cycles, the continuously calibrated model had significantly higher RMSE than the offline calibration for shoulder plane and elevation, and elbow flexion, but significantly lower shoulder rotation (Fig. 3). After 15 movement cycles, the continuously

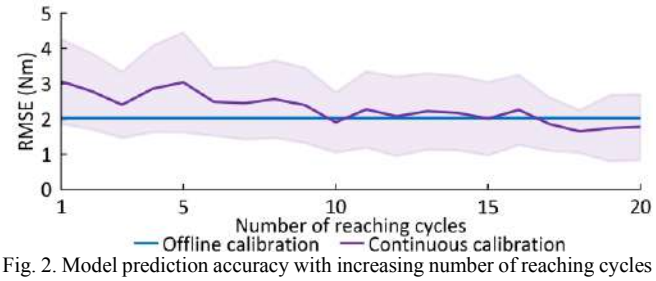

Fig. 2. Model prediction accuracy with increasing number of reaching cycles completed, averaged across all DOFs and control gain configurations.

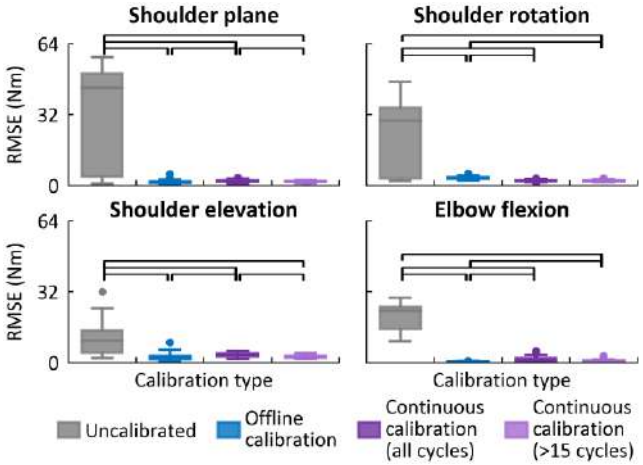

Fig. 3. Moment tracking accuracy using uncalibrated, offline calibrated and continuously calibrated models across all reaching tasks and control gain configurations. Horizontal bars signify a significant difference ($p<0.05$).

calibrated model showed significantly lower RMSE for shoulder plane and elevation compared to all cycles combined, significantly lower shoulder rotation RMSE than the offline calibration, and significantly higher RMSE for elbow flexion than the offline calibration (Fig. 3).

Regarding exoskeleton control performance, the offline calibrated model resulted in significantly higher (i.e., closer to zero) SPARC values compared to both the uncalibrated and continuously calibrated trials (Fig. 4). After 15 cycles, the continuously calibrated model produced significantly higher SPARC values than both the uncalibrated and continuously calibrated models when considering all cycles (Fig. 4). No significant differences were observed for other exoskeleton control performance metrics.

The synergy-driven model approach showed significantly lower shoulder rotation and elbow flexion moment RMSE compared to the EMG-driven method (Fig. 5).

IV. Discussion

Here we implemented a method for continuously calibrating an EMG-informed NMS model without prior calibration, using the predicted joint moments to control an upper limb exoskeleton. The approach was evaluated on a single participant performing functional reaching tasks to assess model prediction accuracy and control performance.

The uncalibrated NMS model consistently produced poor joint moment predictions, while the offline calibrated model provided the best overall moment prediction accuracy (Fig. 3), highlighting the importance of calibration. While the continuous calibration outperformed the uncalibrated model, its significantly higher RMSE compared to offline calibration (Fig. 3) may be due to a learning effect, where the model initially exhibits poor accuracy before improving over time. The continuous calibration method took less time, 15 movement cycles or 110 seconds (Fig. 2), to reach similar accuracy as the offline calibration (154 seconds). Importantly, the offline method also needs recording and processing data before commencing the calibration process, adding to the time required before being able to execute the model. Conversely, the continuous method calibrated the model parameters in a shorter time as the RSME plateaued around cycles 10–15 (Fig. 2), although this plateau had slight RMSE increases and decreases possibly reflecting transient adaptation effects from variability in movement execution, or challenges in navigating the complex solution space of the loss function before stabilizing. These findings underscore the potential of continuous calibration to replace offline calibration in time-sensitive applications. It should be noted that in this study the inverse dynamics moments were calculated without measured external forces, which may introduce ambiguity in the solution and could affect RMSE if unmodeled interaction forces were present.

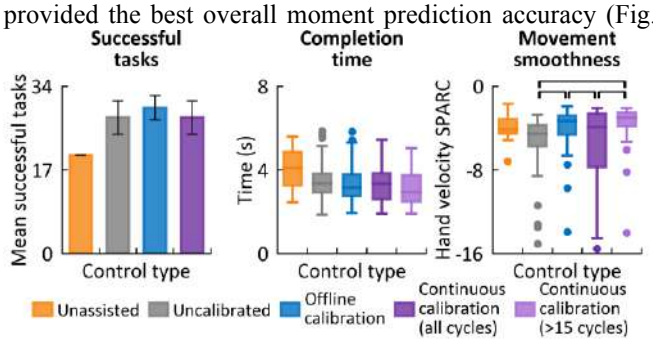

Fig. 4. Exoskeleton control performance using each model calibration type. Data for each control gain level were combined for each calibration type. Horizontal bars signify a significant difference ($p<0.05$).

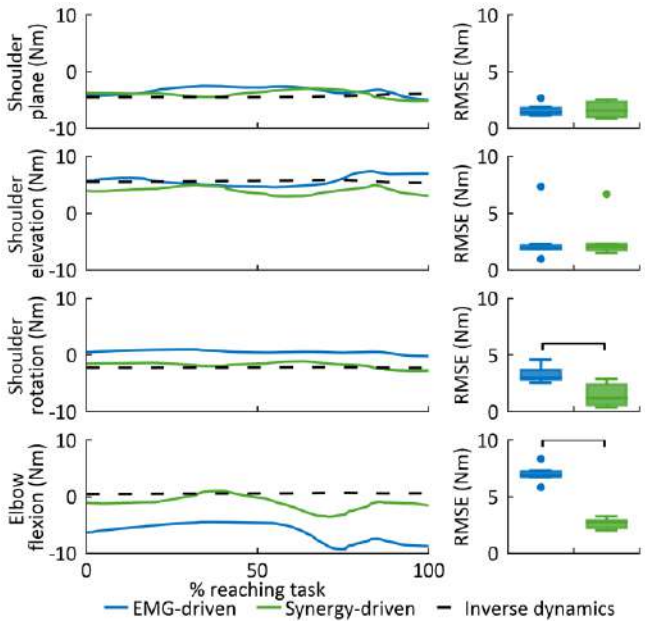

Fig. 5. Moment tracking accuracy with EMG- and synergy-driven approaches. Example time series data from movement cycle from the 25% gain control trial. RMSE was calculated from evaluated cycles across all gain conditions. Horizontal bars signify a significant difference ($p<0.05$).

Poor moment tracking across all methods for some DOFs, particularly shoulder rotation, was likely due to recorded excitations. To address this, we proposed and tested synthesizing physiologically plausible excitations for unrecorded muscles using muscle synergies. This synergy-informed approach improved joint moment predictions, particularly for DOFs with limited excitatory data (i.e., shoulder rotation) (Fig. 5). Future work should focus on adapting this synergy approach for real-time implementation, further enhancing the applicability of EMG-informed NMS modeling in dynamic environments. Continuously updating the weighting for the unrecorded excitations through calibration could also further enhance model prediction

accuracy, allowing the weightings for unrecorded muscles to best align with the time-varying primitives.

Exoskeleton control performance was evaluated across different calibration conditions, revealing that the offline calibrated model consistently delivered the best outcomes across all metrics (Fig. 4), underscoring the critical role of effective calibration in achieving the best control performance. In contrast, the uncalibrated model exhibited higher task completion times and less smooth movements (Fig. 4), likely stemming from poor model accuracy (Fig. 3), as its assistance often misaligned with participants' intentions. The continuous calibration method performed comparably to the offline calibrated model after initial adjustments, despite reduced accuracy at the onset of trials, demonstrated by a significantly higher SPARC value than the uncalibrated model and model continuously calibrated across all cycles (Fig. 4). The limited assistance level (capped at 75% of the user's volitional intent) may have mitigated differences between conditions, demonstrated by no significant differences in completion time between the different models, however, these findings demonstrate the feasibility of NMS model-driven robotic assistance in real-time applications.

Testing on an individual without neurological impairment here was a necessary first step to ensure safety and maintain experimental control. However, broader testing with individuals across a range of motor impairments, including spinal cord injury and stroke, and with a larger population, is essential to evaluate the system's adaptability and effectiveness. While the subject-specific and EMG-driven nature of the model should enable application across a wider population by accounting for neuromuscular differences, current limitations in NMS model accuracy remain a barrier to safe deployment in impaired populations. Additionally, our simple proportional controller may not provide sufficient adaptability and stability, particularly for users with neurological impairment. Since assistive joint moments influence muscle activation, there is a risk that reduced EMG due to assistance could, in turn, decrease assistance, creating a cycle that destabilizes support. These factors underscore the need for more advanced control strategies to be used in combination with NMS modelling, such as PID or adaptive controllers [10], which should be explored in future work.

Several approaches could be investigated to further improve the accuracy of the proposed methods. Firstly, muscle pathways from the underlying OpenSim musculoskeletal model are often simplified functions or geometries. These pathways can be highly sensitive to model scaling, potentially causing discontinuities in the MTU lengths used as input to the NMS model, leading to erroneous model predictions, particularly for the complex shoulder joint. The development of better representations of muscle pathways [38] may lead to improved NMS model predictions. Additionally, neural network surrogate models could improve setup and computational efficiency for calculating MTU lengths and moment arms compared to the multidimensional cubic B-spline method used in this study [39]. Another potential source of error lies in the recorded EMG signals, which can contain noise and crosstalk, particularly for muscles in close proximity of each other. While processing removes a large portion of the noise and the activation dynamics helps smooth the signal further, oscillations in the recorded signals will likely be present in the extracted primitive signals, and therefore in the synthesized excitations. To partially overcome these issues, the recorded muscle excitations could also be replaced with synergy reconstructed signals, similar to the commonly used EMG-assisted NMS model execution [19, 27]. While a stiff tendon model was used here for computational efficiency, incorporating an elastic tendon model could yield a more accurate representation of musculotendon behavior. Our previous work demonstrated the accuracy of an elastic tendon within a differentiable framework [24], although further optimization may be required for efficient real-time applications.

The ability to perform neural and muscle-level analyses through EMG-informed NMS modeling offers meaningful opportunities to understand and improve movement control. This approach enables detailed evaluation of individual muscle contributions during various motor tasks, which could inform personalized rehabilitation and training strategies. Real-time continuous calibration of NMS models, as demonstrated in this study, represents a step forward in adapting NMS models to dynamic physiological conditions, such as fatigue or recovery from injury [22], enhancing their clinical and real-world applicability. Integrating this technology with other assistive strategies, such as functional electrical stimulation (FES), could create hybrid rehabilitation systems, combining the benefits of each approach. While the exoskeleton provides mechanical assistance, FES can stimulate weakened muscles, promoting neuroplasticity and functional recovery. Subject-specific NMS models have shown potential in quantifying volitional contributions during FES [28], suggesting this integration could lead to improved monitoring and potentially even therapeutic outcomes. Beyond clinical applications, the insights provided by real-time NMS modeling could be applied to optimizing athletic performance and reducing injury risk.

V. Conclusion

In this study, we introduced a real-time continuous calibration and execution process for an EMG-informed NMS model to control an upper limb exoskeleton. The continuously calibrated model achieved comparable accuracy to an offline calibrated model after approximately 15 movement cycles, taking just 110 seconds. Offline analysis leveraging synthesized excitations from synergies for muscles with unrecorded EMG enhanced model accuracy. The proposed method delivered exoskeleton control performance comparable to the offline calibrated model, outperforming the uncalibrated model. By removing the initial calibration process, this approach enhances the practicality of EMG-informed NMS models for real-time applications, enabling personalized and physiologically valid predictions of muscle forces, and joint moments, making it a valuable tool for closed-loop neurorehabilitation systems.

Somnomat Care: A Novel Robotic Bed for Vestibular Stimulation in Nursing Homes

Ricardo Manríquez-Cisterna[1], Oriella Gnarra[2,4], Ankit A. Ravankar[1†], Alexander Breuss[2], Tatsuya Yoshimi[3], Jose Victorio Salazar Luces[1], Diego Paez-Granados[2,4], Kenji Kato[3], Robert Riener[2,5], Yasuhisa Hirata[1]

***Abstract*—Sleep disorders affect one-third of the general population, with prevalence significantly increasing among the elderly. Rocking beds utilizing vestibular stimulation have shown promise as non-pharmaceutical interventions for improving sleep quality. However, existing designs lack the necessary features for retirement facilities, such as protective handles and reclining backrests, limiting their accessibility for elderly individuals who often experience markedly reduced sleep quality. In this work, we introduce Somnomat Care, an evolution of the long-running Somnomat sleep intervention project. While Somnomat Casa was designed for home use, Somnomat Care extends this concept to nursing homes and clinical environments, offering hospital-style functionality. Key enhancements include adjustable headrests, leg rests, and safety side rails, ensuring usability and safety for elderly residents. Preliminary feasibility testing with Somnomat Care demonstrated its viability and ease of integration into elderly care facilities or nursing homes. Combining innovative sleep robotics with tailored design for vulnerable populations, the newly designed robotic bed aims to enhance sleep quality, improving overall health and well-being in institutionalized elderly individuals. Future studies will validate its efficacy and assess long-term benefits, positioning Somnomat Care as a practical tool for improving sleep in geriatric care environments.**

I. Introduction

Sleep is critical in maintaining overall health and well-being, particularly in vulnerable populations undergoing rehabilitation. During sleep, vital physiological processes, including memory consolidation, metabolic regulation, and tissue repair happen, which are essential for recovery and rehabilitation. Inadequate or poor-quality sleep is associated with various adverse health outcomes, such as cognitive decline, cardiovascular diseases, and reduced physical function, making it a crucial factor in rehabilitation programs [1].

Fig. 1. Overview of the Somnomat Care. Our contribution allows the introduction of a reclining frame and safety rails, taking into account safety and usability.

The global population is aging rapidly [2], resulting in a significant increase in the number of elderly individuals requiring rehabilitation care. This trend has placed considerable strain on the healthcare systems of many countries, which are already facing a shortage of healthcare professionals. In response, numerous countries are investing efforts to address this issue by introducing robotics and technology to assist with the decreasing workforce [3]–[6]. Among the many challenges with the aging, sleep disorders are particularly prevalent in older adults, with common issues including insomnia, sleep apnea, restless legs syndrome, and circadian rhythm disturbances [7]. These disorders not only impair sleep quality but also exacerbate comorbidities, reduce the effectiveness of rehabilitation programs, and diminish quality of life. Current pharmacological treatments for sleep disorders, while effective in some cases, often have undesirable side effects, particularly when used long-term. Such side effects include dependency, cognitive impairment, and residual daytime sleepiness, necessitating the exploration of alternative therapeutic approaches [8].

Vestibular Stimulation (VS), a non-pharmaceutical intervention, has emerged as a promising technique for improving sleep quality. It leverages the vestibular system, critical in regulating balance and spatial orientation, to promote relaxation and enhance sleep architecture [9]. Among the various applications of VS, rocking beds have shown particular promise in

inducing and sustaining sleep [10]. These systems gently rock the user, mimicking the natural motion experienced during infancy, which has been shown to enhance slow-wave sleep and improve sleep continuity [11]. Unlike other methods, these beds work overnight without requiring active participation.

Historically, rocking beds were designed primarily for short-term studies on the sleep-enhancing effects of VS in healthy individuals. Early examples include Woodward et al.'s 1990 parallel swing bed, suspended from the ceiling and powered by a motor [9], and Bayer et al.'s design, which used metal bars and an electric engine to generate horizontal oscillations [11]. Later, Morita et al. introduced a rocking chair replicating the soothing motions of a caregiver [12].

More recently, the Sensory-Motor Systems Lab at ETH Zurich developed advanced rocking beds, known as "Somnomat" to study the effects of VS on sleep under various conditions. These beds, capable of multidirectional movements, were used in studies showing significant benefits: enhanced sleep spindles in young adults, faster deep sleep transitions in older adults, and positive impacts on nap sleep architecture [13]–[15]. The first iteration of the Somnomat used a rope robot to move a bed with six Degrees of Freedom (DOF), demonstrating the concept's potential but facing challenges in practicality and scalability [16]. Subsequent iterations isolated individual DOF, but still, their large size and specialized requirements limited their use to controlled laboratory settings, preventing broader application in home environments or long-term studies [13]–[15]. The newest Somnomat, the Somnomat Casa, simplifies the system to a single DOF while ensuring safety and usability [17]. This bed also has a torque-limiting motor, pressure-sensing strips, and hinging panels to enhance safety and comfort in a system resembling a conventional bed [18].

Despite these advancements, the transition of the Somnomat system into healthcare environments, particularly nursing homes, required further adaptations. Nursing homes impose unique requirements, including enhanced safety mechanisms, adjustable components such as reclinable backrests and leg rests, and a compact design suitable for healthcare facilities. The design should also include safety provisions and quick intervention with the components in emergencies to isolate the user from the bed quickly and put them into critical care. This paper introduces the latest iteration, "Somnomat Care", which incorporates these adaptations to address the specific needs of nursing home residents while maintaining the core principles of vestibular stimulation (Figure 1). We detail key design features and technical modifications implemented in the Somnomat Care that further enhance its applicability compared to the previous iterations, highlighting its potential to improve sleep quality in elderly populations undergoing rehabilitation.

The rest of the paper is structured as follows: Section I gives a brief overview of Somnomat Casa, which forms the backbone for our new design, Somnomat Care. Section II describes the new structural design features, technical details and modifications, software architecture, ROS middleware integration, and safety features of Somnomat Care. Finally, Section III provides a brief discussion and conclusion for the article.

II. Somnomat Casa

In this section, we first give a brief overview of Somnomat Casa, which was designed at the Sensory-Motor Systems Lab at ETH Zurich, Switzerland. This design forms the inner core of our new robot bed, Somnomat Care. The following paragraphs provide a formal introduction to the key components of Somnnomat Casa.

The Somnomat Casa is a robotic bed that provides vestibular stimulation on the longitudinal axis and is intended for use in the home environment. It has a frequency range from $0.04\,\mathrm{Hz}$ to $0.4\,\mathrm{Hz}$ in a constant $10\,\mathrm{cm}$ amplitude. Previous literature shows that accelerations ranging from $0.2\,\mathrm{m\,s^{-2}}$ to $0.3\,\mathrm{m\,s^{-2}}$ show effectiveness at improving sleep, which falls in line with the accelerations attainable with Somnomat Casa, which are between $0.006\,\mathrm{m\,s^{-2}}$ to $0.63\,\mathrm{m\,s^{-2}}$ [19]. This motion is achieved by suspending the full top frame of the bed on 4 Roberts linkages [20, p. 11], special four-bar linkages that attain an approximate straight-linear motion in a small range. This top frame is connected to the bottom frame of the bed by a crank-slider mechanism, allowing for periodic motion. The crank is connected to a $400\,\mathrm{W}$ servo motor (EC60) produced by Maxon Switzerland AG motor and coupled to a 14:1 gearbox produced by IMS Gear SE Co. KGaA, Germany.

The designed bed measures $90\,\mathrm{cm} \times 200\,\mathrm{cm} \times 60\,\mathrm{cm}$, which is comparable to a regular single-size bed. The user interface is a simple two-button design meant for ease of use without any training required. One button toggles the rocking motion, and the second button turns on the handle light. This handle also incorporates two sensors: an ambient light sensor and an accelerometer.

The Somnomat Casa uses the handle-mounted light to communicate error states to the user. In the error state, the handle will turn red, indicating a problem with the bed. Similarly, for safety triggers, the robot incorporates 6 pressure-sensitive strips and two magnetic reed sensors; when triggered, the bed will stop the motion and signal red. The strips are placed on the ends of the bed and the top of the headboard and footboard; the reed sensors are placed near the pivot point of the head and footboard because they are hinged to prevent entrapment. as seen in Figure 2.

III. Somnomat Care: Design and Development

This section outlines the modifications implemented on the Somnomat Casa, forming the foundation of the proposed robotic bed. The following subsections detail the enhanced features and software upgrades significantly improving the system's capabilities.

A. Design Considerations

The development of the Somnomat Care system began with extensive consultations with nursing home staff and residents to ensure the design aligns with their needs. Key insights

were drawn from discussions with facilities accommodating individuals who, despite requiring assistance, retain partial independence. The inclusion criteria for potential users focused on adults with self-reported initial insomnia, characterized by prolonged sleep-onset latency exceeding 20–30 minutes. Additional requirements included the willingness to adhere to the study protocol and an absence of participation in concurrent sleep intervention studies. These insights informed the following technical specifications:

- **Reclinable Backrest and Leg Rest:** To enhance comfort and adaptability for diverse user needs.
- **Safety Restraints Compatibility:** Essential for ensuring the security of individuals with limited mobility or high fall risk.

Safety is a primary concern, particularly the need to rapidly convert the bed into a flat surface to facilitate emergency access. This requirement underscores the importance of designing a system that integrates seamlessly with existing caregiving protocols while maintaining ease of use for caregivers.

B. Safety Features

Implementing Somnomat Care prioritized safety, particularly given its intended use in environments with frail or disabled individuals. Building on the safety mechanisms of its predecessor, Somnomat Casa, which design incorporated multiple features to mitigate risks. Hinging panels with reed sensors were installed to halt the rocking motion upon collision detection. To further enhance safety, pressure sensors were positioned along the bed edges to prevent accidents involving the corners, and torque-limiting was employed in the main motor to reduce risks of entrapment. In the case of Somnomat Care, recognizing the importance of emergency response, the design ensures that all components above the mattress line can be quickly removed. This adjustment allows caregivers unobstructed access to users during critical situations, aligning the system with the requirements of healthcare environments. Although mandatory for emergency response, this feature also allows unobstructed caregiving day to day, for example to exchange bed sheets, change the users' clothes or to transfer the user.

C. Design Process

By evaluating the users' requirements, a plan was developed for modifying the existing Somnomat Casa and creating a new version suited for nursing care, subsequently named *Somnomat Care*. To comply with hospital and caregiving facilities standards, all accessories and parts have to be approved for medical use, and the bed should avoid having fixed components above the mattress line. Two options were considered: reclining frame conversion kits for home beds or dedicated care beds. However, conversion kits typically lack the ability to mount side rails, requiring an accessory rail installed under the mattress. This limitation makes them unsuitable for individuals who may face emergencies. Consequently, the second option was chosen: the Rento bed from Paramount Bed, Japan. Among its various sizes, the Mini 180 model was selected as it fits within the Somnomat Casa frame. After procurement, all measurements and geometries were verified, and installation confirmed no interferences between the components.

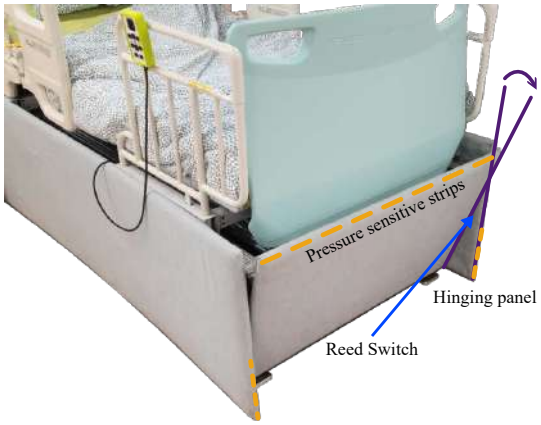

Fig. 2. Somnomat Casa safety sensors. Pressure-sensitive strips located around the hinging end panel provide safe operation in case of any possible collisions.

During the assembly of the new bed, concerns arose regarding cognitive load and ease of use. To address this, the control systems were integrated, enabling the entire robotic system to be operated from a single interface.

The original handle of the Somnomat Casa was removed to accommodate the new Paramount bed structure. This handle not only controlled functions such as activating the rocking mechanism and toggling the night light but also housed two important sensors: an illuminance sensor and an accelerometer. These sensors are valuable for sleep studies as they provide insights into the sleeping environment and detect movements on the bed. This required the design of a new remote control for the robotic system, allowing these sensors to be effectively incorporated.

D. Usability

When designing the system, consideration was taken of the target users, and it was defined that the system needs to be simple for elderly users regardless of their aging process. To achieve the goal, all systems were fused into a simple-to-use remote control that can be hung around the bed, replacing the Paramount bed remote and the Somnomat Casa handle because of the previously mentioned requirement of not having anything fixed above the mattress line (for safety and convenience reasons), both controllers needed to be merged into a single handheld operation interface. Another usability feature is the addition of folding casters, these allow the bed to be transported between rooms, this is necessary in the nursing care environment, and also allows studies to be conducted in the users' room, which should be less stressful for the person.

E. Remote Control Design

The proposed remote control was designed for reliability and ease of use, featuring a screen and 8 buttons to manage all connected systems (Figure 3). A handheld case, fitted

Fig. 3. New remote control for Somnomat Care, this control is designed to be simple to use and give adequate feedback to the user regardless of their impairments.

with a silicone cover, was sourced and machined to house the components: a piezo transducer for auditory feedback, an illuminance sensor replacing the one from the original handle, a screen to display system status for users or caregivers, button backlighting for nighttime use, and an ATSAMD51G19A microcontroller enabling double-buffered screen functionality. Icons were selected instead of text to support multilingual users, while auditory feedback was carefully designed with distinct tones—such as rising or falling pitches—to clearly convey actions like starting or adjusting bed positions.

A 3D-printed resin handle is mounted on the back of the remote. This handle serves two key functions: it allows the remote to be hung in convenient positions and acts as a light pipe to direct ambient light to the sensor below. This design prevents the sensor from being obstructed, whether the remote is hung or resting on a surface.

To overcome the limitations of the Somnomat Casa's error notification system—which signals issues only by changing the night light to red without offering guidance—the redesigned remote provides error messages and clear, actionable instructions. For instance, the interface guides users step-by-step to resolve the most common issue: realigning a triggered hinging panel.

A custom bus architecture and communication protocol were developed to ensure seamless interaction between system components. The remote communicates with the low-level controller via RS-232, enabling efficient data exchange and synchronized operation across the system.

F. System Architecture

Somnomat Care intends to integrate Somnomat Casa with a new reclinable hospital frame and a new set of sensors and controls. Somnomat Casa was designed as a main board where the main motor driver, a low-level controller, power supplies, and two Raspberry Pis connect together; the purpose of the Raspberry Pis is to do data logging and to host a Robot Operating System (ROS) subsystem to distribute the Somnomat's sensory information as standardized messages, as well as enabling its operation via ROS, making it readily available for integration with different robotic and/or IoT

TABLE I
COMMUNICATION PROTOCOL

Idx	**1**	**2**	**3**	**4**	**...**	**5+Len**	**6+Len**
Field	Header (S, M)		Command	Length	Data	CRC	Footer (T)
Example	S	M	0x10	0x00	0x00	0x22	T

systems. In the case of Somnomat Care, a low-level central controller was added, which we named the bottom controller; it communicates all the different systems, based on an ATSAMD21G18A, Microchip, USA; this micro-controller was selected because it includes many serial ports, making it ideal for our application. One of the serial ports is connected using I^2C to the Somnomat Casa Controller, another is connected using RS-485 to the Paramount Bed Controller, and a third one, using RS-232, is connected to the remote control that will command the full system. Additionally, another embedded Linux system was added, running on a Raspberry Pi, where an accelerometer connects to replace the one contained in the Somnomat Casa handle. This can be seen in Figure 4, where the protocols or methods are described in more detail. To replace the light, a new light bar was added that attaches using hangers to the headrest of the Paramount bed frame. This is also connected via USB to the embedded system. The main reason for adding new systems to the existing ones is to containerize responsibilities. As stated before, all the devices communicate via a common protocol defined for this system. The protocol is a simple message specification whose details can be seen in table Table I. From the protocol design, the use of error detection increases the reliability of the system, and it is flexible enough to add new commands in the future for more sensors or functionalities. On Table II, the different functions are listed, divided by their domain, and allow other parts of the system to instruct functions on the main bus. For example, the remote controller sends the ambient light value constantly and also listens for angle notifications to show on the screen; on an error from any system, the remote control can show it in a simple way to the user, providing pictorial information on how to solve the issue if it can be fixed by the user. It is this system that ties every component together and allows the robotic bed to work as a single unit.

G. ROS2

ROS2 is an open-source software development kit and a middleware for robotics. It builds on a set of industry-standard tools for communication, Data Distribution Service (DDS), a publisher-subscriber framework. For interface description, the Interface Description Language (IDL) is a programming language-independent description tool for interfaces between different software packages. Somnomat Care is built with ROS2 compatibility to enable deployment in different scenarios, such as integration with several sensors, robotic systems or triggers from different systems for more complex automation. The currently implemented topics are:

- Backrest and Leg Rest position
- Light color and status

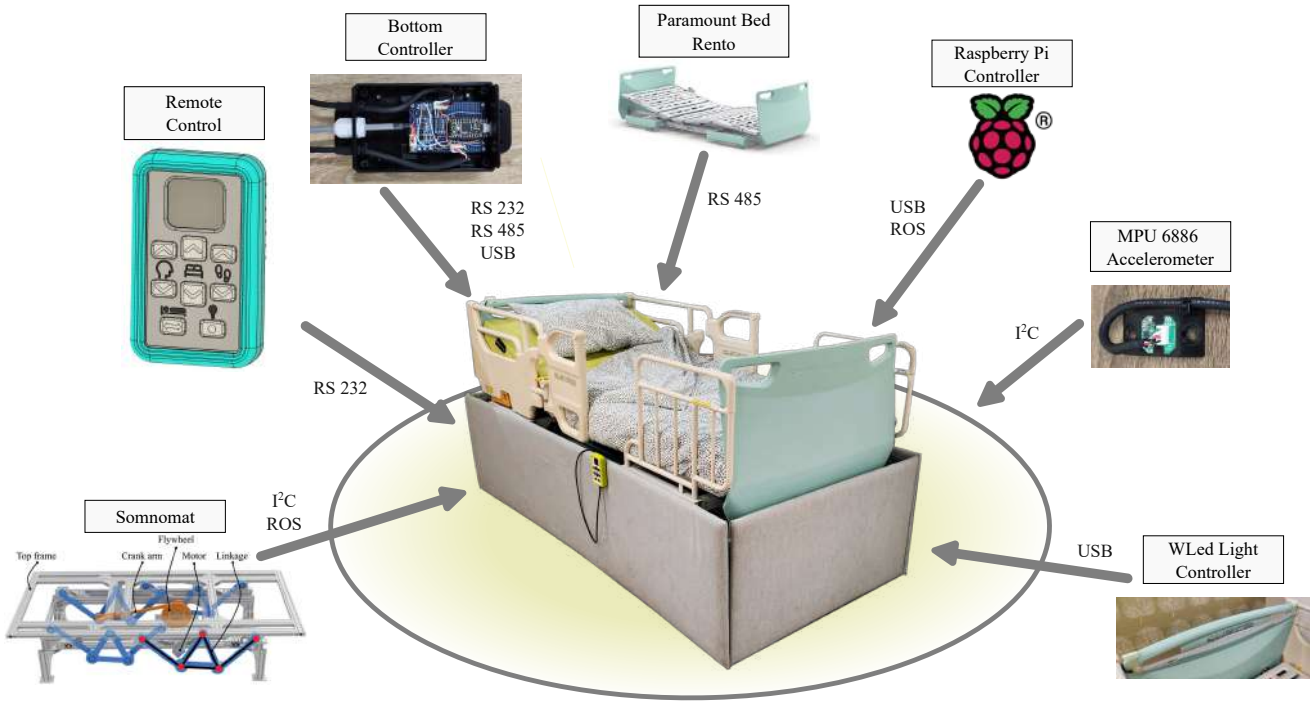

Fig. 4. System diagram: This figure shows the different interconnected parts that compose Somnomat Care. The objective is to allow Somnomat to be used safely in Healthcare environments.

TABLE II
PROTOCOL COMMANDS

Common	Ping	0x10
	Send datetime	0x11
	Send error	0x12
Paramount bed	Lift head	0x20
	Lower head	0x21
	Lift legs	0x22
	Lower legs	0x23
	Lift all	0x24
	Lower all	0x25
	Head angle notify	0x26
	Leg angle notify	0x27
	Set head position	0x28
	Set legs position	0x29
	Get head angle	0x2A
	Get legs angle	0x2B
Somnomat	Toggle rocking	0x30
	Toggle light	0x31
	Set speed	0x32

Remote	Set remote brightness	0x50
	Activate alarm	0x51
	Toggle buzzer	0x52

- Ambient light measurement
- Acceleration measurement
- Toggle rocking
- Rocking speed
- Current error

With these topics, it is possible to integrate the robotic system with many different systems straightforwardly, thanks to the ROS standards, interconnection with disparate systems can be achieved with ease.

H. Future Enhancements

During the final phase of the system's design, additional functionalities were identified for potential integration. In particular, we propose the integration of a millimeter-wave (mmWave) sensor that enables non-invasive monitoring of bed occupancy, body poses, cardiovascular activity, and respiratory rate. This allows for a better understanding of the user's sleep patterns, and when vestibular stimulation is required, it also allows the user to toggle the lights or perform other interventions. A mmWave sensor shows a great fit for this application because of unobtrusiveness, ease of use, and the measured parameters fall within the range of commercial sensors during sleep, where, for example, the implemented sensor does not record heart rates above $100\,\mathrm{bpm}$.

An additional sensor under consideration is an ultrasound sensor for measuring bladder fullness. This sensor enables monitoring of the user's need to visit the toilet, potentially preventing unintended urination. It could be integrated into the system to trigger interventions, such as activating lights or more vigorous rocking, to awaken the user while simultaneously sending notifications to nursing staff. These functionalities aim to enhance the user's quality of life. However, a significant limitation of such sensors is the requirement for direct attachment to the user's body, which may lead to discomfort or rejection by some patients.

IV. Conclusion and Outlook

The Somnomat Care is the first robotic bed worldwide designed for elderly care facilities that allows for safe investigation of VS in the elderly. In this work, we presented a user-

centric design with advanced safety and usability features that address the unique challenges of nursing home environments.

We presented a new design update from the previous version that emphasizes user safety. This update includes new sensor integrations for improved and reliable data capture, user-friendly controls with ergonomic features, and advanced control through the Robot Operating System (ROS). These enhancements improve the overall design for conducting long-term vestibular studies in nursing care homes and expedite research on interventions for sleep disorders. Additionally, the new design supports modular plug-and-play sensor integration for future upgrades and facilitates ROS-based communication with other robotic systems, thereby bridging the gap for robot-based interventions.

Reliability testing revealed areas for improvement. After identifying potential failure points, some components were redesigned. Thanks to the modular architecture, these changes were easy to implement. Our goal is to develop a highly reliable system capable of operating in care environments for extended periods, even in the absence of specialized personnel.

Currently, efforts are ongoing to implement the first Somnomat Care in a Japanese nursing care facility. Japan represents an ideal environment for the implementation of Somnomat Care, given its demographic shift toward an aging population and the associated rise in age-related health challenges, particularly insomnia, which impacts more than 30% of the elderly.

We will first implement Somnomat Care in a study addressing sleep-onset insomnia. In a five-week study, residents of the elderly care facility will evaluate a combined approach of sleep hygiene recommendations and vestibular stimulation through Somnomat Care. The protocol includes a baseline week for monitoring natural sleep behaviors and EEG recordings, followed by an intervention phase where personalized sleep recommendations are implemented alongside vestibular stimuli. A two-week washout period will assess adherence to recommendations without interventions, concluding with follow-up EEGs to evaluate changes in sleep architecture. The study will then not only allow us to assess the feasibility and acceptance of the Somnomat Care as an interventional device in residents of elderly care facilities but also serve as a pilot for a future large-scale study to investigate the effects of VS on sleep quality, sleep onset latency, and daytime performance.

The initial deployment of Somnomat Care in Japanese nursing facilities will provide critical insights into its real-world efficacy. Data from these trials will inform iterative improvements and pave the way for broader adoption in healthcare settings globally. Future studies will explore the long-term impacts of vestibular stimulation on sleep architecture, comorbidities, and patient well-being, focusing on scalability and adaptability to diverse populations.

***Abstract*—This work presents a multimodal bidirectional armband that innovatively integrates sensing and feedback modules in an ergonomic, non-invasive design to enhance prosthetic functionalities. The armband is capable to deliver modality-matched force feedback while ensuring optimal skin adherence for electromyographic sensors, without interference. We performed a device characterization and evaluated its efficacy in improving users' ability to perceive object grasp while using the Hannes prosthetic hand. Moreover, we conducted an assessment to ensure the absence of interference between the feedback mechanism and the electromyographic acquisition system. Positive preliminary results demonstrate the armband's versatile design potential to fit into volume-adjustable sockets or in osteointegrated limb different subjects, enhancing prosthetic control and user experience, therefore providing a promising step toward advanced human-machine interaction.**

Keywords— prosthetic fitting, non-invasive feedback, EMG sensing, custom socket, upper limb prostheses.

I. INTRODUCTION

People with upper limb impairments often encounter significant obstacles when attempting routine activities. Prosthetics can help in restoring functional abilities and improve quality of life for individuals with limb absence. Despite potential advantages, many upper limb different subjects still choose not to use a prosthesis, due to issues with the socket or with the prosthetic end effector [1]. Although this latter can restore a significant portion of the missing hand functions, the absence of effective sensory feedback restoration greatly affects the user's ability to close the sensorimotor loop. Both invasive and non-invasive interfaces have been explored to convey proprioceptive [2], tactile [3] or thermal [4] information thereby improving control, increasing embodiment and reducing phantom limb pain [5]. Non-invasive methods rely on wearable haptic feedback devices, through skin-stretch [6], pressure [7], vibration [8] or electrical stimulation [9]. Force feedback is crucial for daily activities that require fine force modulation and precise pressure adjustments [10]. Feedback on grip force enables users to adjust the strength of their grasp in real-time, without relying on visual guidance only, which can require mental effort, especially in dynamic situations or when handling fragile objects [11]. Thus, developing a system integrating real-time force feedback could enhance both functional outcomes and the user's quality of life. Regarding the socket's issues, traditional solutions lack conformability, and may lead to electrode displacement, range of motion reduction, sweating, and skin irritation. These concerns limit user comfort, wear time, and complicate donning and doffing [12]. To this end, there is a clear need for advancements in materials and socket designs that prioritize stability, comfort [13], and functionality, ultimately improving the overall prosthetic experience [14]. Adjustable-volume prosthetic sockets, as the Socketless Socket from Martin Bionics, have been recently developed. These solutions simplify the fitting manufacturing [15], and overcome many of the previously mentioned limitations of traditional sockets, as sweating and skin irritation. While several research groups have distinctly explored upper limb signal extraction and haptic feedback [16], our work introduces a single armband that combines functionality with ergonomic design, simultaneously allowing non-invasive integration of myosensors with haptic feedback. In the field of upper limb prosthetics, surface electromyography (sEMG) is the main source of input for the device control. Many sEMG bracelets have been developed. One key distinction is the number of sensors: for instance, the MyoArm (Thalmic Labs) features eight sensors [17], while higher-density alternatives like EMaGer offer increased resolution [18]. Additionally, these devices vary in their construction materials, which may include rigid components, flexible elements, or a combination of both. Furthermore, some designs incorporate additional sensors, such as Inertial Measurement Units [19] or Force Myography sensors [20],

This work was supported by INAIL (Istituto Nazionale per l'Assicurazione contro gli Infortuni sul Lavoro) under Grant Agreement PR23-PAS-P1, Dexter Hand. * These authors equally contributed to this work.

to enhance functionality. Haptic feedback bracelet-like solutions are used to provide proprioception [2], contact pressure on fingers [7], or grip strength [21], mainly using vibromotors or squeezing cuff. Vibrotactile bracelets usually deliver information in a nonhomologous fashion. Squeezer bracelets, in contrast, can enhance feedback strategies by conveying grip strength as proportional compressive force to the upper limb. They generally differ in positioning (wrist, forearm, or bicep) and type of compression element (belts, Shape Memory Alloys materials, or pneumatic systems), typically controlled both in position/velocity or force/torque, employing various mechanisms [16]. While some devices integrate both sensing and feedback [22], they often lack customization, compactness and wearability. To address these gaps, we designed an innovative, customizable bidirectional armband, the Multimodal Bidirectional Armband for Sensing and Feedback (MBASF), that people with limb difference can wear comfortably, which provide both sensing and feedback. The armband could be integrated in an adjustable prosthetic socket, or it could totally replace it in case of osteointegration. Moreover, it has the potential to integrate multiple different feedback actuators. To this end, the proposed armband has been tested with the Hannes hand prosthesis for a preliminary validation in upper limb prosthetics field. The paper is organized as follows: Section II describes the MBASF system, while Section III explains the Experimental setup and Section IV the Validation methodology. Results are presented in Section V. Section VI and VII draw discussion and conclusions.

II. THE MBASF SYSTEM

MBASF integrates EMG sensing and haptic feedback into a single, wearable armband to enhance functionality and the user experience. It incorporates sEMG sensors, allowing proportional myocontrol of the prosthetic hand opening and closing based on muscle activity. Additionally, it features a custom-made squeezer for a real-time modality-matched feedback restitution of the prosthesis' grip force.

A. Design Requirements

A careful analysis of the challenges and user requirements led to the identification of several core objectives that guided the design evolution. The goal was to create a device not only functional, but also practical and comfortable. Specifically, the design aimed to achieve precise positioning, by ensuring optimal placement of the EMG sensors on the acquisition surface [23], and sufficient elasticity, allowing users to wear and remove it independently without assistance. At the same time, it was crucial to maintain an adequate rigidity to ensure that the sensors and the motorized constrictor remain stable and properly fixed during use.

B. Mechanics

The armband (Fig. 1.A) combines a rigid material (SLS-printed PA12) to provide structural support for the components, and a flexible material (SLS-printed TPU) to enable radial elasticity. This design allows for a comfortable adherence to any residual limb facilitating independent donning and doffing without assistance and ensures to hold both sensors and actuators in place. Ottobock's MyoBock sensors (13E200=50 AC) were chosen for reliable EMG signal acquisition. Five rigid housings were designed for hosting up to four EMG sensors, and the electronic board (data acquisition and processing unit). By design, it is possible to insert pairs of EMG sensors, typically used for dual-site control, into four housings. This, combined with the option to rotate the armband around the arm, provides flexible positioning to target the areas with the highest muscle activity, thereby enhancing signal quality. Moreover, thanks to the custom electronics receiving up to four EMG sensors, a machine learning-based control could be supported. The five housings are connected by two accordion-shaped stripes made with flexible material at high elastic recovery, assuring a firm EMG sensors-skin adherence. Additionally, the constrictive feedback component was designed around a motorized winch (Fig. 1.B). The winch-based system provides a proportional grip force sensation by tightening around the forearm, enabling a feedback loop that mimics natural grip pressure. The motorized constrictor stabilizes the position of the sEMG sensors on the user's arm by applying an initial preload force, selected by the experimenter. The mechanism employs a flat DC motor

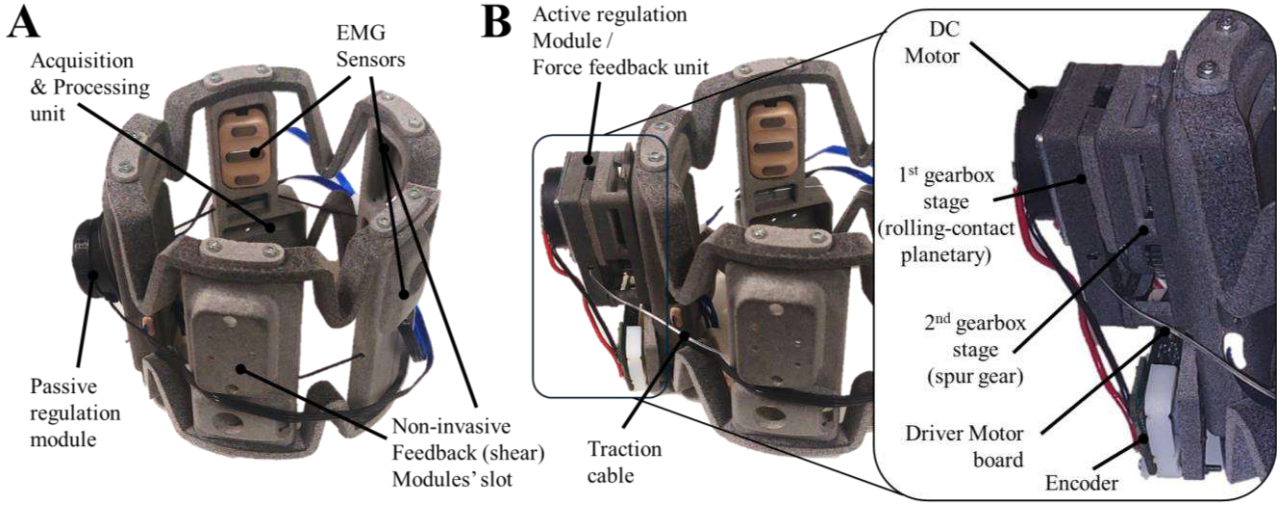

Fig. 1. MBASF mechanical architecture A) passive constrictor for regulation, B) active constrictor for non-invasive force feedback.

(Faulhaber DC motor 2607 6V) coupled with a two stages reductor (the first stage is based on a rolling-contact planetary 12.6:1, whilst the second one is based on spur gears 4:1). The entire mechanism exerts up to 315 mNm with an overall efficiency of around 0.5, therefore resulting in around 50 N winding force. The winding drum (11 mm diameter) hosts an on-axis magnet to provide absolute angle measurement via a magnetic digital encoder (AMS AS5045B). The drum has been engineered to perform one single rotation thus allowing the magnetic encoder to be reset during the bracelet's initial calibration phase hence resulting in an absolute measurement. Through this design it is possible to guarantee scalability and adaptability to any forearm sizes.

C. *Electronics and Control*

The proposed bracelet integrates two electronic modules, connected via CAN Bus, respectively responsible to acquire the sEMG sensors and to control the motorized constrictor (Fig. 2.A). From the control perspective, a proportional dual-site direct control mode is implemented for hand aperture and closure. Once the force feedback module is active, the current from the hand's motor directly correlates with the grip force exerted on the grasped object, allowing the system to restore a grip sensation on the residual limb as described in *(1),* where u_k denotes the position control command for the squeezer motor, I_k represents the motor current measured from the hand, I_{max} is the maximum current the motor can deliver, $\dot{x}$ indicates the velocity of the hand motor, and $\dot{x}_{th}$ is the threshold defined to activate the squeezer motor. The hand velocity ($\dot{x}_k$) calculated as difference between two consecutive position measurements over time, which are filtered using a low-pass filter with a cutoff frequency of 5 Hz. Muscle contraction regulates the closure speed of the prosthetic hand; upon encountering an object, sustained contraction leads to an increase in the motor's supply current (I_k) above a predefined threshold while the closing speed approaches zero. At this stage, electronic board detects that an object has been grasped and actuates the constrictor motor accordingly. As a consequence, the feedback module provides an intuitive, force-based response aligned with a modality-matching approach. In particular, the constriction force is proportional to the current delivered to the hand (I_k), reflecting the grasp force: higher currents indicate a stronger grip, prompting greater constriction, while lower currents signal a lighter grip and gentler constriction.

$$u_k = \begin{cases} \dfrac{I_k}{I_{max}} \cdot 100, & \dot{x}_k > \dot{x}_{th} \\ 0, & \dot{x}_k \leq \dot{x}_{th} \end{cases} \qquad (1)$$

III. EXPERIMENTAL SETUP

The testing setup (Fig. 2.B) consisted of three main components: a multimodal armband for sensing and feedback, the Hannes hand prosthesis, and a custom-designed sensorized object for measuring grip strength. The Hannes hand is an advanced biomimetic prosthetic hand developed by the Istituto Italiano di Tecnologia (IIT) and Centro Protesi INAIL. It combines myoelectric control with a unique mechanical differential system, allowing for versatile and adaptive grasping like a human hand. The prosthesis features a fast response time (full closure in less than 1 sec) and a maximum grasp force of 150 N. It is designed to perform a wide range of grips, from fine to power grips, enabling users to execute daily activities with ease [24]. Inspired by [25], we developed a standalone, sensorized 3D-printed object to characterize our squeezer. The object features a cylindrical shape designed for a comfortable grasp with the hand. It includes an on/off button, a LiPo battery pack (12V, 1500 mAh), an acquisition electronic board with embedded Bluetooth module, and five radially distributed compression load cells (FX293X-100A-0010-L with operative range 0÷5000 mV and 0÷45 N) strategically positioned to ensure that at least one cell is activated regardless of the grasping point. This custom-designed sensorized object measures and real-time streams via Bluetooth to a custom Unity-based Graphical User Interface (GUI) the exerted grip force (Unity GUI).

IV. VALIDATION METHODOLOGY

To evaluate the efficacy of the armband, we first conducted a device characterization followed by a twofold exploratory study using the Hannes hand prosthesis. This study involved ten healthy participants (five males and five females, aged between 26 and 35) and one trans-radial limb different subject (female, 29), for a preliminary feasibility study. Each participant provided written informed consent

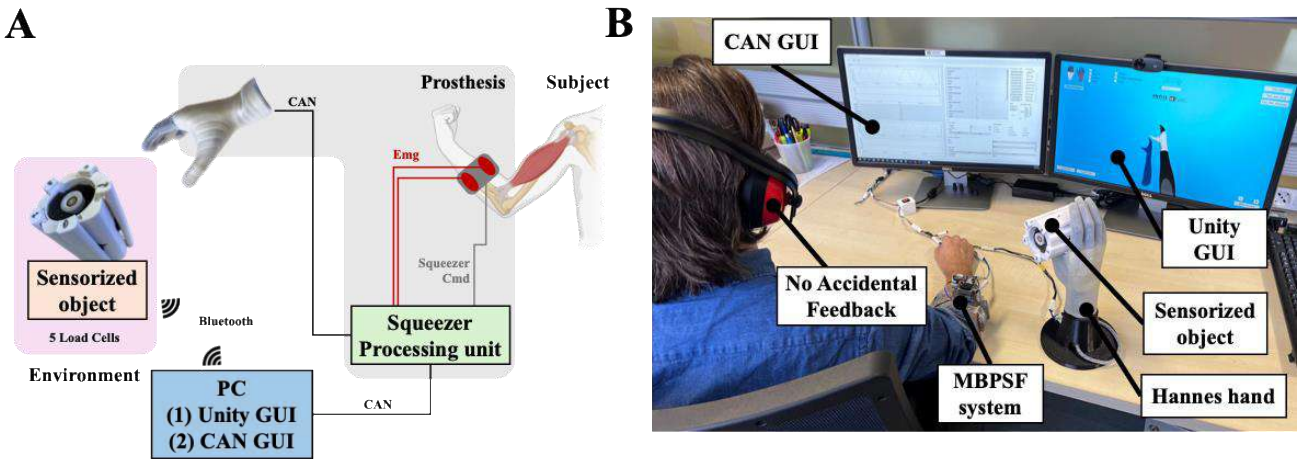

Fig. 2. Overall system and testing architecture A) MBPSF electrical architecture, B) Experimental setup with related testing architecture.

prior to the study, which followed the principles of the Declaration of Helsinki and received approval from the Territorial Ethics Committee of the Liguria Region (Protocol code: IIT_REHAB_HT01). Participants were seated in front of a table, blindfolded, and sound-isolated to eliminate sensory cues other than those provided by the armband. The right-handed Hannes prosthesis was fixed on the table, and the MBASF armband was positioned on each participant's right forearm, with EMG sensors aligned with wrist flexor and extensor muscles, to enable closing and opening of the prosthesis, respectively. Before starting the experimental session, the experimenter adjusts the tightness of the armband according to the forearm dimensions, hence ensuring a secure fit and consistent contact with the skin. Additionally, the EMG sensor thresholds were adjusted for each participant to ensure optimal controllability of the Hannes hand. Participants were then given five minutes of training with the constrictor in place to familiarize themselves with the feedback mechanism.

A. *MBASF System Characterization*

To validate the system, we started by characterizing the squeezer bracelet. To this aim, a sinusoidal reference signal (0.5 Hz, 10 repetitions) was imposed to the squeezer's DC motor (CAN GUI) while simultaneously recording the force exerted on a sensorized object placed inside the armband (Unity GUI). We then correlated the armband's constriction force with the squeezer motor current, as detailed in Subsection V.A. Notably, in real-life scenarios, the squeezer's DC motor is current-controlled using a remapped value proportional to the hand's DC motor absorbed current while grasping an object (Subsection II.C).

B. *Feedback efficacy test*

This test aimed at evaluating the efficacy of strength feedback. We expected that, during a blindfolded grasping task with the feedback device active, participants would achieve a high success rate in discerning whether an object is grasped. In this test, one experimenter controlled the Hannes closure trough the sliders on a custom made GUI (Fig. 2 - Unity GUI) to grasp the sensorized object, which may or may not have been placed in the prosthetic hand by a second experimenter. Participants were instructed to report, after each closure, whether they identified the grasped object, or a void closure based on the feedback information provided by the MBASF device. The test consisted of 10 trials per participant, with the presence or absence of the object randomly determined. The number of void closures was fixed for each participant (5) to minimize variability between subjects. The success rate was evaluated. Moreover, after completing the test, System Usability Scale (SUS) [26] was administered to the limb different participant to evaluate the system's usability.

TABLE I. Results for both healthy and limb different subjects.

Test	Healthy subjects	Trans-radial limb different subject	
	Success rate	*Success rate*	*SUS score*
Feedback efficacy	95%	90%	87.5
Sensing efficacy	100%	100%	-

C. *Sensing efficacy test*

To evaluate the accuracy of armband EMG sensing during active force feedback, a sensing efficacy test was also performed. The squeezer bracelet was controlled by sinusoidal reference (f = 0.4 Hz), inducing alternating squeezing-relaxing movements to simulate dynamic "real-world-like" conditions. Participants performed 10 voluntary closures and openings of the Hannes prosthesis via sEMG sensors, verbally stating 'open' or 'close' after each movement. This allowed the experimenter to verify sensors' functionality by ensuring the prosthesis responded correctly to the commands thus assessing any artifact generated by the skin-electrode interface. Performance was assessed by counting EMG sensor alterations, defined as instances where no signal or corresponding hand movement was detected, and calculating the success rate.

V. RESULTS

A. *MBASF System Characterization*

Fig. 3.A illustrates the system characterization. The curves should be interpreted in a counterclockwise direction. The constriction force of the armband exhibits an exponential relationship with the supply current, operating within a range of 0 to 900 mA for current and 0 to 32 N for force. Once the maximum constriction force of 32 N is generated (between 800 and 900 mA), the supply current drops immediately to zero.

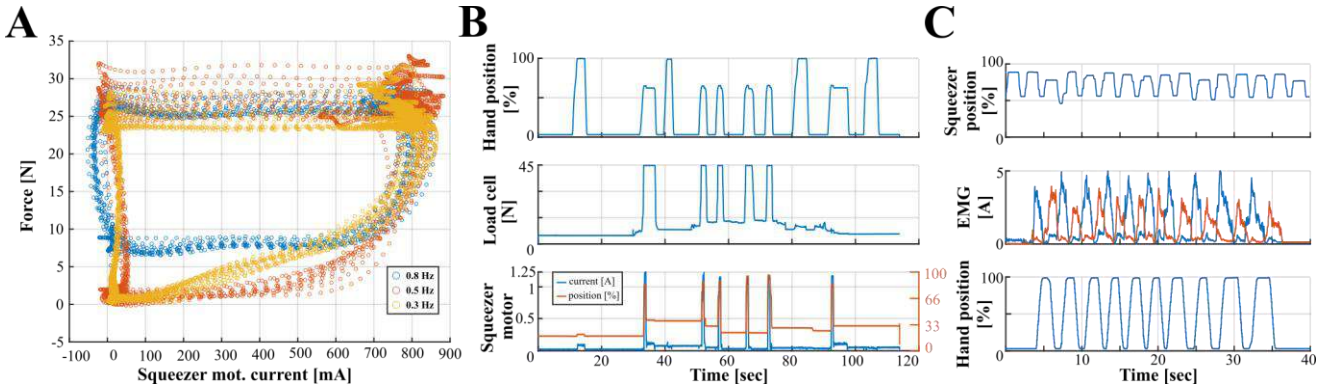

Fig. 3. Validation results A) MBAFS characterization; Single person example for B) Feedback efficacy test and C) Sensing efficacy test.

B. *Feedback efficacy test*

The healthy subjects performed a total of 100 trials. Five participants each made one error in recognizing a void grasp, giving an average success rate of 95% (TABLE I). The trans-radial limb different participant failed 1 time only on a total of 10 trials, again during a void grasp, resulting in a success rate of 90% (TABLE I). In Fig. 3.B, an example for a single participant illustrates the setup's measurements acquired during the test, such as the hand's encoder position, the load cell readings, and the squeezer motor current and position. The load cell subplot presents the value of the most activated load cell among the five available at every moment. Overall, this figure highlights the correlation between the exerted grip force by the hand (through the load cell) and the squeezer's DC motor current absorption. Moreover, regarding the SUS questionnaire, the trans-radial subject scored 87.5/100 points.

C. *Sensing efficacy test*

During the sensing efficacy test, no EMG sensor alterations were detected, either with healthy participants or limb different participant, achieving both a 100% success rate (TABLE I). In Fig. 3.C, as in Fig. 3.B it is possible to appreciate an example of results for a single participant. In this figure, during the sinusoidal operation of the squeezer, ten signals can be clearly identified for both the closure and aperture EMG sensors. These activations correspond to the hand closures and apertures, i.e., 100% and 0% of Hand position, respectively, as reported in Fig. 3.C.

VI. Discussion

The armband is designed to generate a squeezing force proportional to the hand's current *(1)*, starting from zero, when the hand is open, and gradually increasing during the object grasping. In Fig. 3A the blue curve does not return to zero because the system dynamics prevent full release at frequencies above 0.5 Hz. This occurs because constriction responds faster, while release relies on the passive elasticity of the armband, resulting in a noticeably slower response. From the feedback efficacy test (Fig. 3 B), the reaction time of the armband can be determined as the time difference between the initial increase in force, measured by the load cell in the sensorized object, and the moment the constrictor begins to close (approximately 10 ms). Meanwhile, 30 ms delay is measured in the release phase of the armband, which maintains the constriction force even in the absence of current. After this delay, the constrictor fully releases the wire, hence returning to a state of 0 N and 0 mA. These behaviours confirm the mechanical release dynamics of the actuation unit, which exhibit a slower response compared to the electrical constriction dynamics. Linking Fig. 3.A with Fig. 3.B, through the common variable squeezer motor current, it is possible to correlate the constriction force on the forearm with the hand grasping force. Moreover, the high success rate for both healthy (95%) and limb different subjects (90%) (TABLE I), demonstrates that the feedback offers an intuitive, force-based experience, hence allowing the user to easily understand when the object is grasped. As consequence, it is reasonable to suppose that this device could enhance the user's ability to proportionally modulate grip strength, improving both control and precision. The five errors in recognizing a void grasp may be caused by the armband, which must have tightened even though no object was grasped. This could be caused by two factors: the polyarticulated nature of the hand, which, may sometimes cause the fingers to touch each other, therefore increasing the motor current absorption and triggering the squeezer; or the armband's preset at zero value. For this latter, if any increase in arm volume occurs, the armband tries to return to its initial zero position, creating a tightening sensation even when the hand is not grasping an object. The SUS score of 87.5 (TABLE I), above average as greater than 68, indicates a satisfying level of usability. Moreover, according to the user's comment, MBASF is capable to evoke a grasping sensation like those of a natural limb. Indeed, the user stated that the constriction of the residual limb somehow evoked the perception of a strong contraction of both major muscle groups, like what occurs when gripping an object. Finally, in the sensing efficacy test, no alteration of the EMG sensors was registered, resulting in a success rate of 100% (TABLE I) for both healthy and limb different subjects. We can affirm that our armband successfully integrates sensing and feedback in a single wearable device as no interferences are generated by the constrictor while measuring sEMG signals.

VII. Conclusion

In this work, we explored the potential of a non-invasive human-machine interface, a multimodal armband, which combines sEMG sensing and feedback capabilities into a single wearable device. The development and design process of the armband is outlined, and we validated its efficacy through a device characterization and experimental tests with 10 healthy subjects and 1 limb different participant. Testing the armband with a final user provided first evidence of its usability. Considering the promising preliminary results, it is possible to hypothesize that the system should be able to allow users to sense grip force, offering an experience closer to the one perceived by the intact counterpart. Of course, we acknowledge that this assumption requires further analysis with the prosthesis worn by the user and tested in scenarios inspired by activities of daily living, also examining potential improvements in task performance. It will be interesting to explore if the user reduces reliance on visual feedback or improves fine force regulation. Overall, the multimodal bidirectional armband (MBASF) is easily customizable and can also be exploited as a platform for research development in both sensing and feedback strategies. The number of EMGs can be increased for machine learning-based control techniques [27] (Fig. 4.A), or direct control of hand and elbow for trans-humeral subjects with Targeted Muscle Reinnervation. Hence, the proposed armband could be easily deployed to people with limb difference at the trans-humeral level (Fig. 4.B). Furthermore, various feedback actuators can be added within the armband's housings to restore simultaneously

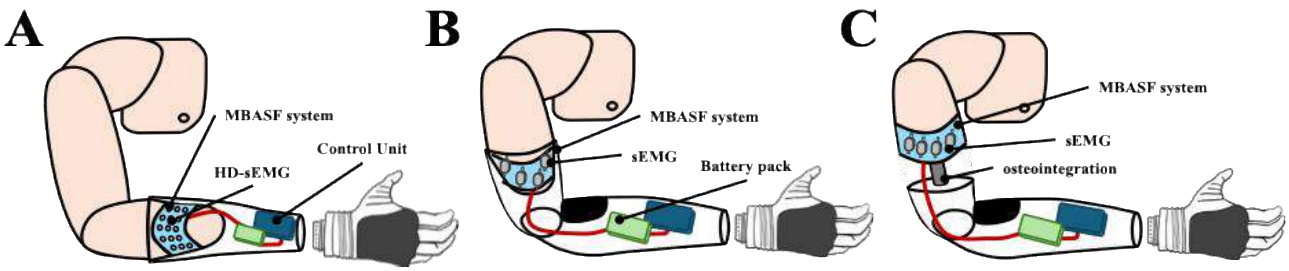

Fig. 4. Target scenarios of the MBASF armband integrated in standard sockets for A) trans-radial and B) trans-humeral, with C) osteointegration.

multiple sensations, such as touch [28], to decrease mental workload and improving human-machine interaction [29]. Finally, the armband could fit into the recently developed volume-adjustable prosthetic interfaces [15] for an everyday use or could substitute the socket in patients with osteointegration, to facilitate independent donning and doffing (Fig. 4.C). Although the small sample size of users in the experimental test, both in terms of number and types of limb difference, MBASF delivers modality-matched force feedback while ensuring optimal skin adherence for electromyographic sensors. This is a promising step toward advanced human-machine interaction, whose effectiveness could be in deep validated along with an extended clinical trial to quantitatively verify these preliminary results.

Automated Selectivity-Driven Algorithm for transcutaneous Spinal Cord Stimulation

Mouhamed Zorkot*[1] , Riccardo Carpineto[1], Solaiman Shokur[1,2], Silvestro Micera[1,2] and Mohamed Bouri [1]

***Abstract*—Spinal cord injury (SCI) impairs motor function and quality of life. Transcutaneous Spinal Cord Stimulation (tSCS) is a non-invasive method to restore motor function by activating spinal circuits below the lesion. However, its effectiveness is limited by individual variability, reliance on manual electrode placement, and offline muscle analysis. To address these challenges, we developed an online method for detecting spinal reflexes and muscle responses using two automated algorithms: the Ranking-Based Approach (binary method) and the Automated Selectivity-Driven Approach (leveraging a selectivity index), both designed to optimize electrode placement and stimulation amplitude for precise activation of proximal or distal muscles. In a study with six healthy participants in the supine position, the posterior root muscle test was performed automatically using tSCS across three rostrocaudal spinal electrodes. Our findings reinforce the evidence of the rostrocaudal tSCS selectivity, with rostral electrodes activating proximal muscles and caudal ones targeting distal muscles. Both algorithms identified optimal electrode positions and stimulation amplitudes, enhancing tSCS selectivity for lower-limb muscles. Our results suggest that the Automated Selectivity-Driven Approach is more appropriate for increasing selectivity for targeted muscle recruitment. These results highlight the potential of automated methods to improve tSCS selectivity for SCI rehabilitation and other conditions.**

I. INTRODUCTION

Each year, over 500,000 people sustain spinal cord injuries (SCI), often resulting in significant mobility impairments and a lifelong need for rehabilitation [1]. Although existing therapies, such as traditional physical rehabilitation and technologies such as exoskeleton and functional electrical stimulation, offer some support [2], they often have limitations to restore natural movement and muscle coordination [2], [3]. An emerging technique for gait rehabilitation is Spinal Cord Stimulation (SCS), encompassing both invasive epidural (eSCS) and non-invasive transcutaneous (tSCS) methods, and has shown potential to enhance motor and neurorehabilitation by restoring voluntary movement, enhance sensory-motor recovery and promote supraspinal-spinal connectivity [3].

eSCS has been extensively studied over recent decades for its role in restoring voluntary movement after SCI [3] . Targeted activity programs combined with precise electrode placements have enabled patients with sensory-motor deficits to regain natural control over their legs, facilitating standing, walking, and stair climbing [3] . These advancements represent a breakthrough in neurorehabilitation; however, the clinical application of eSCS is limited by its invasive nature, which requires surgical intervention. In contrast, the non-invasive tSCS method offers broader clinical applicability. It probably activates similar neural structures in the spinal cord as eSCS[4] and, when combined with locomotor training, has shown promising functional improvements in SCI cases, improving locomotor activity, limb mobility, and walking function restoration [5], [6].

Standard tSCS clinical protocols typically use single-site, tonic stimulation with a surface electrode placed between T11-T12, delivering stimulation at 30 Hz frequency, 1 ms pulse width, and an amplitude set at 10% below the motor threshold as determined by the Posterior Root Muscle (PRM) reflex test [5], [6]. Conducted in a supine position, the PRM test evaluates short-latency spinal reflexes triggered by proprioceptive fibers in the posterior roots, activating motor neurons and producing muscle responses detectable via electromyography (EMG). This test is essential for understanding spinal cord responses to tSCS, guiding both electrode placement and stimulation amplitude selection [5].

Emerging research has explored enhancing tSCS selectivity through rostrocaudal electrode positioning along the spinal cord [7]. Studies with healthy participants in the supine position have demonstrated that this configuration can selectively recruit proximal and distal muscles [7], [8]. These findings suggest that optimizing electrode placement and stimulation parameters may enable precise motor neuron activation, supporting neurorehabilitation protocols aimed at improving joint-specific movements more effectively.

Identifying optimal electrode placement is often time-consuming and prone to suboptimal results due to individual variability across subjects and sessions. Moreover, conventional tSCS approaches rely on manual electrode positioning and offline muscle activity analysis, limiting their potential for precise and targeted selective activation [9]. Salchow-Hömmen et al. [9] proposed a binary algorithm for automated calibration using a multi-electrode spinal approach to determine the best-positioned electrode and stimulation amplitude that activates the largest number of lower-limb muscles. However, this method does not focus on optimizing tSCS selectivity.

To accelerate the process and enhance the precision of target muscle recruitment, an automated online protocol for spinal reflex detection and muscle responses induced by tSCS using electromyography (EMG). Furthermore, Two algorithms were developed and validated: a binary approach (Ranking-Based Approach), inspired and adapted from Salchow-Hömmen et al. [9]. and a novel selectivity-

[2]Biorobotics Institute Scuola Superior Sant'anna, Pisa, Italy

driven approach (Selectivity-Driven Approach). These algorithms were developed to identify the optimal spinal electrode position and stimulation amplitude for effectively recruiting target muscles. The objective is to enable precise targeting of specific proximal or distal muscles by leveraging the rostrocaudal selectivity potential of tSCS and determine optimal parameters for single-site clinical applications.

II. Methods

A. Participants and experimental setup

We recruited 6 neurologically intact participants (5 male and female, age: 25.0 ± 3 years, height: 176.5 ± 13 cm, body mass: 69.0 ± 11.0 kg) who gave their consent to take part in this study that was reviewed and approved by EPFL Human Research Ethics Committee (HREC000477). tSCS was assessed using the PRM test [10] with three 2.5 cm electrodes placed centrally on the spinal cord between T10 - T11, T11-T12 and T12- L1 vertebrae. Stimulation was applied via a custom-made electrical stimulator (NeuroPulse), to deliver charge-balanced biphasic double pulses with a pulse width of 1ms, an interpulse interval of 50 ms. With respect to the abdominal electrodes, the selected stimulating electrode served as anode for the first phase and the cathode for the second phase of the biphasic pulses.

Muscle activity was recorded via EMG from four proximal muscles (Rectus Femoris [RF], Semitendinosus [ST], Vastus Lateralis [VL], and Vastus Medialis [VM]) and three distal muscles (Gastrocnemius [GASTRO], Tibialis Anterior [TA], and Soleus [SOL]) on both legs, using the Trigno Research+ system (Delsys, USA). The protocol was executed using a customized algorithm implemented in Python and integrated with the Delsys API.

Experimental Protocol: The PRM test was performed with an automated online protocol for spinal reflex detection developed (Section II.C). The algorithm continuously monitored muscle activity during stimulation (Sample Rate: 2148 Hz). Researchers set minimum and maximum amplitude thresholds, with each stimulation repeated three times at 5-second intervals. Amplitude increments began at 5 mA, and upon detecting a spinal reflex based on pre-established motor evoked potential (MEP) criteria, the increment was reduced to 2 mA for finer control. After detecting the first reflex for each electrode, fifteen additional stimulation amplitudes were applied, covering a range of up to 30 mA above the first reflex or the maximum amplitude tolerated by the participant. This protocol enabled detailed analysis of muscle recruitment categorized into proximal, distal, and optimal stimulation to recruit all muscles for conventional single-site tSCS approaches. Selectivity analysis focused on rostrocaudal selectivity based on spinal electrode placement, with recordings performed for each of the three electrodes (E1 to E3).

B. EMG Pre-Processing for online protocol

Pre-Processing: Online synchronization of stimulation and recording used 5-second EMG windows per repetition, relying on stimulation artifacts for precision. EMG signals

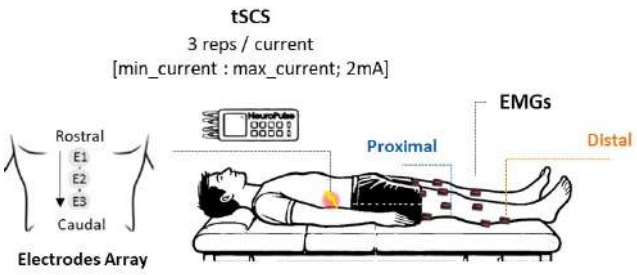

Fig. 1: **Experimental Setup:** Three electrodes (E1–E3) were placed rostrocaudally at T10-T11, T11-T12, and T12-L1. EMG data were recorded from proximal and distal muscles during automated tSCS with double-pulse stimulations every 5 seconds, repeated three times per amplitude.

were pre-processed by removing the median and detected artifacts to correct offsets and interference. Artifacts were blanked at -4 ms to 4 ms and 46 ms to 54 ms. A second-order notch filter (Butterworth, 43-47 Hz) and a first-order low-pass filter (Butterworth, 300 Hz) were applied. Noise levels for each muscle (i), amplitude (j), repetition (r), and electrode (n) were computed as the standard deviation of the signal during rest ($2.5\,\text{s} < t < 5\,\text{s}$), serving as a baseline threshold.

Artifact Detection: Stimulation artifacts were identified using a non-causal double differentiation method based on a discrete approximation of the Laplace operator. Artifacts from the first stimulus were flagged if: (1) peaks exceeded three times the noise standard deviation, (2) peaks at the interpulse interval (50 samples later) also surpassed this threshold, and (3) peak amplitudes were similar (ratio 0.8). Identified artifacts were used to synchronize EMG signals.

C. Automated tSCS Stimulation Protocol

1) ***Automatic Evaluation of Spinal Reflex****:* In MEP detection, peaks exceeding the noise threshold ($3SD \cdot emg_{\text{i,noise}}$) are identified within the time window $t_0 < t < t_0 + 40$. Upon detecting a peak, it is marked as t_{max}, and peak-to-peak amplitudes are calculated for the intervals $t_{max} - 8 < t < t_{max} + 15$ and $t_{max} + 42 < t < t_{max} + 65$, denoted as $amp_{1,i}(n, I)$ and $amp_{2,i}(n, I)$, respectively. The suppression level of the second response relative to the first is computed, and responses are classified as MEPs if the suppression level exceeds 70%, the amplitude $amp_{1,i}(n, I)$ is greater than 50μV, and it surpasses the threshold of $3SD \cdot emg_{\text{i,noise}}$.

2) ***tSCS Selectivity Analysis****:* For the selectivity analysis, recruitment curves were generated for each muscle across the three electrode configurations, using 2 mA increments in stimulation amplitude starting from the first detected reflex. At each amplitude level, three double-pulse stimulation repetitions were performed, and the average peak-to-peak value of the first pulse was calculated for repetitions exhibiting a spinal reflex. Evoked responses for each muscle were normalized to the average maximum evoked response across all three electrodes. If no response was observed at a specific amplitude but present at the previous one, the recruitment

value was maintained at the last detected level to ensure consistency in the area under the curve (AUC) calculations and minimize false negatives.

Muscle recruitment was quantified as the AUC of its recruitment curve, normalized to the maximum possible recruitment value. The selectivity index (SI) [8] was calculated to evaluate the normalized recruitment of a specific muscle relative to the average activation of all other muscles, expressed as:

$$SI_m = REC_m - \frac{\sum_{n \neq m}^{M} REC_n}{M-1}, \tag{1}$$

where REC_m is the normalized recruitment of the specific muscle, and the second term is the average normalized recruitment of the remaining $M-1$ muscles, excluding muscle m.

For this study, selectivity was analyzed based on target muscle groups (SI_T), categorized into proximal and distal muscles. The SI formula was adapted to account for these groups by averaging REC_m (REC_T)values across the target muscles (M_T) and comparing them to the average recruitment of non-target muscles. The selectivity index for the target muscle groups (SI_T) is then calculated as:

$$SI_T = REC_T - \frac{\sum_{n \in M_T}^{M} REC_n}{M - M_T}. \tag{2}$$

where M_T represents the set of all target muscles.

This index ranges from -1 to 1, providing clear interpretations:

- $SI_T = -1$: Target muscle group M_T is minimally recruited compared to non-target muscles.
- $SI_T = 0$: Target muscle group M_T is equally recruited as non-target muscles.
- $SI_T = 1$: Target muscle group M_T is maximally recruited compared to non-target muscles.

*3) **Automated Determination of Optimal Stimulation Position and Amplitude for tSCS**:* Two independent methods were developed to identify the optimal electrode position and stimulation amplitude. The first method, inspired by Salchow-Hömmen et al., [9], employs a Ranking-Based Approach using binary classification (presence or absence of reflex responses). The second method, known as the Selectivity-Driven Algorithm, enhances precision by targeting specific muscle groups through the application of the SI_T equation.

a) Ranking-Based Approach: This approach utilizes a hierarchical set of prioritized rules to determine the optimal electrode (n) and stimulation amplitude (I), based on the classification of reflex responses. The selection process follows these rules:

1) Only electrodes where at least 50% of target muscles exhibit reflex responses are considered (minimum criterion);
2) Among these, electrodes activating the highest number of target muscles are prioritized;
3) If multiple electrodes meet the above criteria, the one with the smallest difference between maximal (I) and first response (I') amplitudes is selected;
4) If still tied, the electrode requiring the lowest stimulation amplitude (I) is chosen.

The algorithm identifies the electrode (or electrodes, in case of a tie) and corresponding stimulation amplitude that best satisfy these conditions. For selectivity evaluation, the algorithm first determines the amplitude range where fewer than half of the non-target muscles are activated. Within this selective amplitude range, the same criteria (1–4) are applied exclusively to the target muscles. This process ensures that the algorithm selects the electrode that most effectively stimulates the target muscles while minimizing activation of non-target muscles. If no reflex responses are detected in the target muscles within the maximum selective amplitude, the electrode is classified as non-selective.

b) Automated Selectivity-Driven Approach :

This algorithm was developed to optimize tSCS selectivity for the targeted recruitment of proximal or distal muscle groups. The process leverages recruitment curves, AUC, and quantitative values of SI_T to determine the optimal spinal electrode position and stimulation amplitude required to achieve the desired muscle group activation.

The algorithm begins with the initial step of the Ranking-Based Approach, selecting electrodes that meet the minimum criterion of activating at least half of the target muscles before half of the non-target muscles are activated. It then calculates the mean selectivity for target muscle groups at each electrode using the SI_T formula to evaluate performance. Additionally, the stimulation amplitude is conditioned to ensure a minimum activation of at least 5% of the target muscles.

D. Statistical Analysis

Statistical analyses compared selectivity indices (SI_T) for proximal and distal muscle groups across spinal electrodes. As described by Bryson et al. [8], each participant provided one SI_T per electrode per condition, adhering to a *within-subject repeated-measures design*. Although SI_T is a single value per condition, it is derived from the mean peak-to-peak (P2P) amplitude of each target muscle across the full stimulation current range.

Data normality was first assessed with the *Kolmogorov-Smirnov test*. We applied the *Kruskal-Wallis test* ($\alpha = 0.05$) to evaluate differences in SI_T across electrodes. *Post-hoc Wilcoxon signed-rank tests* with *Benjamini-Hochberg correction*($\alpha = 0.05$) were used for pairwise comparisons, ensuring statistical rigor while accounting for repeated measures.

III. Results and Discussion

A. Online detection of spinal reflexes

The stimulation and recording setups were successfully implemented in all six participants without adverse events. To confirm a reflex, at least two out of three pulses must be identified as spinal reflexes. Online spinal reflex detection was compared with offline analysis, demonstrating consistent

recruitment curves. The online system provided effective feedback, reliably identifying spinal reflexes and ensuring robust synchronization during EMG recordings.

Spieker et al. [11] introduced a machine learning and mechanomyography-based method for automated spinal reflex detection using PRM, aiming to streamline setup and reduce time compared to EMG-based approaches, such as this study and that of Salchow-Hömmen et al. [9]. Although the EMG setup may take longer, it ensures greater reliability in muscle selectivity analysis, providing a more precise assessment of muscle responses than the acceleration data from mechanomyography.

Designed to streamline clinical applications, it supports automated stimulation protocols and enhances tSCS selectivity analysis, showing potential for optimizing therapy by targeting specific muscle groups.

B. Algorithm Prediction

After the online detection of spinal reflexes and the near-instantaneous creation of recruitment curves and normalized AUCs for all muscles for each electrode, two automated algorithms were developed: the **Ranking Approach**, inspired from Salchow-Hömmen et al. [9] and modified to assess rostrocaudal selectivity, is a binary method primarily aimed at maximizing the number of target muscles (proximal or distal). In contrast, the **Automated Selectivity-Driven Approach**, a novel method proposed in this study, utilizes quantitative values derived from SI_T (Eq. 9) while incorporating the conditions of the Ranking Approach sequentially (Section II.C3). Table (I) presents the results of both algorithms in determining the stimulation amplitude and the optimal spinal electrode positioned along the rostrocaudal axis to optimize selectivity for recruiting the target proximal or distal muscles.

		Target: Proximal			
		Ranking Based		Selectivity Driven	
		Electrode	Amp (mA)	Electrode	Amp (mA)
Subjects	S1	E3	30	E2	54
	S2	E3	44	E2	68
	S3	E3	30	E2	48
	S4	E2	60	E2	68
	S5	E2	58	E2	74
	S6	E2	58	E2	68

		Target: Distal			
		Ranking Based		Selectivity Driven	
		Electrode	Amp (mA)	Electrode	Amp (mA)
Subjects	S1	E3	30	E3	34
	S2	E2	44	E1	82
	S3	E3	44	E3	32
	S4	E3	38	E3	44
	S5	E1	66	-	-
	S6	E3	44	E3	48

TABLE I: Electrode and stimulation amplitude selected by ranking- and selectivity-based algorithms for optimal proximal or distal muscle activation..

Both approaches successfully identified the optimal electrode and stimulation amplitude to maximize recruitment of the target proximal or distal muscles. For participant S5, the **Automated Selectivity-Driven Approach** failed to identify an electrode that increased selectivity for the distal target muscle. This result is consistent, as SI_T for this participant only presented negative values for distal muscle recruitment (Table II). Although the two algorithms produced identical results for some participants (Proximal: S6; Distal: S3, S4, S6), divergences were observed in determining the optimal electrode and stimulation amplitude for the proximal and distal target muscles.

Our novel proposed approach, based on quantitative results SI_T, appears to be more robust in determining the optimal electrode and stimulation amplitude for the selective recruitment of the proximal target muscles. This robustness stems from the algorithm's ability to compare quantitative activation values across all muscles and stimulation amplitudes. The automated approach demonstrates potential for translational applications, particularly in the rehabilitation of specific lower-limb joints, reducing the time required for electrode placement, and minimizing errors associated with the identification of manual vertebrae and spinal variability. The comparison will be further analyzed and detailed in Section III.C, compared to the offline analysis of SI.

For single-site tSCS, the primary approach in clinical studies, the objective is the recruitment of all lower-limb muscles without selectivity. In this context, only the **Ranking Approach** was applied to identify the optimal electrode and stimulation amplitude, adhering to its criteria while targeting overall muscle activation. Although not shown in the table, results indicate a preference for caudal electrodes: E3 was selected for participants S1 (AMP = 29 mA), S3 (AMP = 27 mA), S5 (AMP = 45 mA), and S6 (AMP = 41 mA), while E2 was chosen for S2 (AMP = 65 mA) and S4 (AMP = 56 mA). This preference aligns with the anatomical enlargement of the lumbosacral region along the rostrocaudal axis [7], [8], [12].

C. RostroCaudal Selectivity

We investigated the rostrocaudal selectivity potential of tSCS using a multi-site automated stimulation protocol. Recruitment curves were generated, areas under the curves (AUC) calculated, and selectivity indices (SI) computed for individual muscles and proximal/distal muscle groups. Figure 2.a shows recruitment curves for subject S1, illustrating electrode placement along the rostrocaudal axis of the spinal cord. Electrode E1 (T10-T11) primarily recruited proximal muscles with higher AUC values, while electrode E3 (T12-L1) showed stronger recruitment and AUCs for distal muscles, consistent with prior studies [7], [8], [12] highlighting the effects of tSCS along the rostrocaudal axis, particularly in lumbosacral enlargement.

Normalized AUCs were used to compute the SI. Figure 2.b demonstrates that tSCS at T10-T11 selectively activates proximal muscles, while stimulation at T12-L1 targets distal muscles. While these findings align with recent studies, such as Bryson et al. [8], subject S1 exhibited a higher SI for proximal muscles when stimulated at E2 (T11-T12). This

discrepancy can be attributed to individual anatomical variations in the spinal cord [13], [10] or potential inaccuracies in electrode placement. Such inaccuracies may arise due to subject-specific variability and the limitations of manual vertebral identification and electrode positioning on the spinal cord [9].

As shown in Figure 2 .a, the selectivity of tSCS remains limited for recruiting single target muscles due to the manual application protocol and the inherent constraints of the non-invasive approach [4]. To address this limitation, we adapted the selectivity equation to group target muscles into distal or proximal categories (SI_T), as explained in Section II.C and defined in (2). Table (II) present the selectivity of target muscle groups (SI_T) for all subjects (S1 to S6) across each electrode.

		Spinal Electrodes		
		E1	E2	E3
Subjects	S1	0.351	0.585	0.554
	S2	0.103	0.235	0.153
	S3	0.198	0.553	0.204
	S4	0.230	0.386	0.251
	S5	0.008	0.289	0.103
	S6	0.076	0.482	0.362

Distal	< 0.250	0.250 - 0.500	> 0.500
Proximal	< 0.250	0.250 - 0.500	> 0.500

TABLE II: SI per subject and electrode,with positive values indicating greater selectivity for the target muscle group)

As expected, grouping the AUCs of distal and proximal muscle groups reveals a clear trend: SI_T increases for proximal muscles with stimulation at electrodes E1 or E2 and for distal muscles at electrode E3 (Table II). This confirms that tSCS at rostral positions selectively activates proximal muscles, while caudal positions, such as T12-L1, exhibit greater selectivity for distal muscles [7], [8], [12]. However, some variability was observed. Subject S2 showed greater selectivity for distal muscles at E1, while subject S5 exhibited no significant selectivity between muscle groups. These deviations may stem from limitations in manual electrode placement [9] or biophysical factors influencing tSCS conductivity, such as vertebral bones, skin, and adipose tissue tissue [13].

For the entire group ($S = 6$), SI_T analysis (Figure 3) using the Kruskal-Wallis test revealed significant differences in median SI_T values among electrodes for distal muscle groups. Since only two muscle groups were analyzed, the SI_T values and statistical results were identical for both proximal and distal groups; therefore, we present results for only one target muscle group. Post-hoc Wilcoxon pairwise comparisons with Benjamini-Hochberg correction identified significant differences between E1 vs. E2 ($p = 0.0312$) and E2 vs. E3 ($p = 0.0312$), while E1 vs. E3 showed no significant difference ($p = 0.1562$).

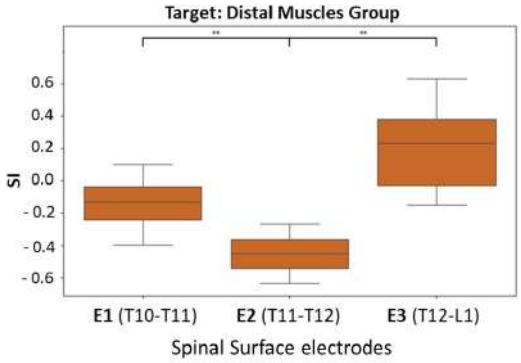

Fig. 3: Rostrocaudal Selectivity for Distal Muscles Group (S=6)

In the group analysis ($S = 6$), a rostrocaudal selectivity trend was observed: rostral electrodes showed greater selectivity for proximal muscles (E1 and E2), while the caudal electrode (E3) favored distal muscle recruitment [7], [8], [12]. However, both individual and group analyses of the selectivity index (SI) revealed that electrode E2 (T11-T12) exhibited higher proximal muscle selectivity than electrode E1 (T10-T11).

This partially contrasts with findings by Bryson et al. [8], likely due to several factors, including anatomical variations in the spinal cord, biophysical influences, and the limited sample size of our study. Additionally, our recruitment curves suggest that selectivity, whether proximal or distal, improves at lower stimulation amplitudes.

Ranking-Based vs. Selectivity-Driven Approach: A Comparative Analysis Based on Selectivity Results

When comparing the analyzed algorithms (Table I) and individual SI_T outcomes (Table II), differences between the **Selectivity-Driven Approach** and the **Ranking-Based Approach** become more evident. The Selectivity-Driven Approach consistently selects the electrode with the highest selectivity, while the Ranking-Based Approach, being binary, often chooses a suboptimal electrode for proximal (S1, S2, S3) or distal (S2, S5) muscle groups. Still, the Ranking-Based Approach remains useful for single-site tSCS, optimizing lower-limb recruitment while reducing setup time.

Additional sessions per subject and a larger sample are needed to fully assess robustness. However, based on muscle activity analysis and the direct SI equation, we suggest that the **Selectivity-Driven Approach** tends to better identify the electrode and stimulation current for optimal selectivity. Given that selective recruitment depends on electrode position and lower stimulation amplitudes, alternative methods beyond the AUC approach [13] and the binary algorithm [9] are essential for improving tSCS selectivity. The Selectivity-Driven Approach shows potential for clinical application, enhancing targeted muscle recruitment and rehabilitation outcomes.

Further validation is needed, but this approach can be translated into protocols using different stimulators, provided an EMG setup is available. Additionally, the algorithm features a user-friendly Graphic User Interface, facilitating

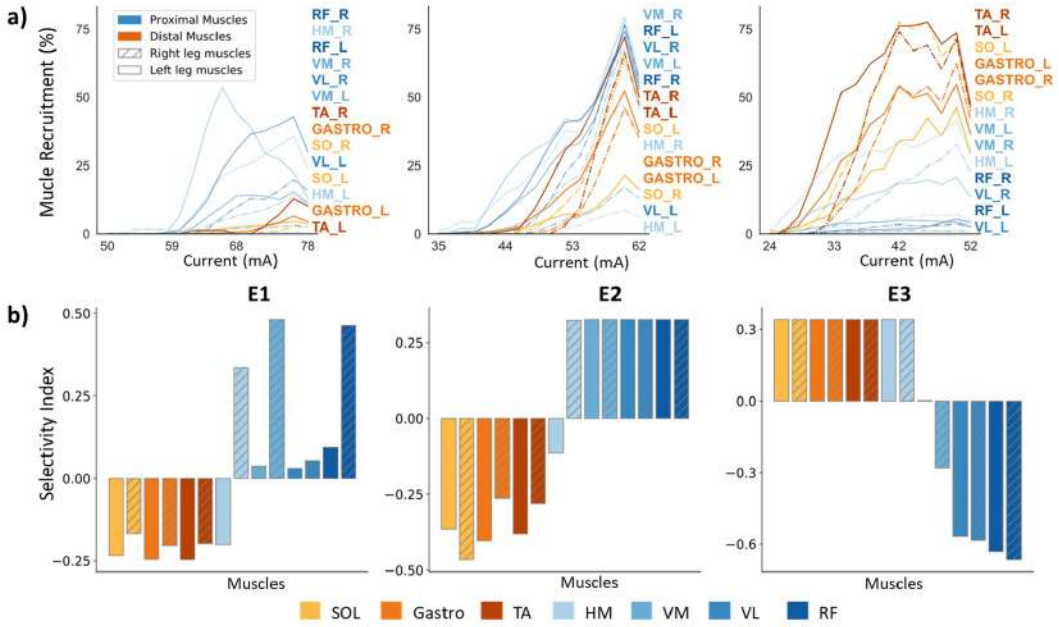

Fig. 2: a) Recruitment Curve and B) Rostro-Caudal Selectivity of S1 for Proximal and Distal Muscles.

clinician-driven parameter selection for targeted muscle recruitment via tSCS.

IV. MAIN FINDINGS

The observed rostrocaudal selectivity trend highlights the potential of multi-site tSCS for targeted muscle recruitment through precise electrode positioning. Rostral electrodes primarily activated proximal muscles, while caudal electrodes favored distal muscles. However, this trend varied in some cases, likely due to intersession variability and anatomical differences in spinal structures, underscoring the challenge of consistent electrode placement.

Both algorithms identified electrodes and stimulation currents for optimal selectivity, producing similar overall results but differing in specific choices. While additional sessions and participants are needed to assess algorithm robustness, we suggest the **Selectivity-Driven Approach** as the preferred method. By directly analyzing muscle activity rather than relying on binary classification and incorporating the SI equation, it offers greater precision in electrode selection, making it a promising tool for selective rehabilitation of specific joints and locomotor tasks.

Abstract— This work seeks to answer the question of whether adding swing phase dorsiflexion assistance further improves performance when walking with ankle exoskeletons providing standard powered stance phase plantar flexion assistance. The purpose of this study was to evaluate how novice exoskeleton users respond to stance phase plantar flexor assistance alone vs stance phase plantar flexor assistance combined with swing phase dorsiflexion assistance. We hypothesized that combining these assistance modalities would result in decreased metabolic power, reduced muscle activity, and improved gait mechanics. Participants performed walking trials with an untethered ankle exoskeleton under various conditions: plantar flexion assistance only or combined plantar flexion and dorsiflexion assistance. A baseline condition, where the exoskeleton was mechanically disconnected but with the same added mass, was also collected. While no significant differences were observed in steady-state metabolic power, muscle activity or toe clearance, there was a strong positive correlation (0.913) between the improvements in metabolic power across different assistance conditions. This suggests that individuals who benefited from one type of assistance also tended to benefit from the other, highlighting the potential for personalized exoskeleton design and control strategies.

Keywords— Exoskeleton, Powered Exoskeleton, Gait Mechanics

I. Introduction

Powered exoskeletons are often created with the intent to enhance human physical performance, but little research has been done on how motor patterns change when the exoskeleton is introduced [1], [2], [3]. Enhancing the efficiency of individual locomotion has been a challenging task, with only recent advancements allowing untethered exoskeletons to demonstrate a net metabolic benefit over not wearing the exoskeleton at all [4], [5], [6], [7], [8]. Many researchers have stated that a better understanding of the person wearing the exoskeleton is necessary to develop more comprehensive and impactful control strategies [9], [10].

Many of the most capable exoskeletons are currently tethered and are targeted to static research and rehabilitative settings [11], [12]. Untethered devices that have shown an ability to reduce metabolic power are rare and fewer than five are currently in the literature [1], [13]. It has been shown that merely copying the biological joint mechanics may be detrimental to metabolic power and that factors like optimal assistance onset timing and amplitude vary between individuals [12].

Extensive efforts have been dedicated to optimizing exoskeletons for walking in recent years; however, further research is warranted to assess the physiological response to fundamental modes of locomotion and assistance [14]. As exoskeletons improve metrics such as tracking error and bandwidth, we are now able to evaluate more nuanced control schemes [15]. The primary function of ankle exoskeletons is to assist in stance phase support and during push-off, providing positive ankle power to facilitate forward propulsion. For individuals with neuromuscular conditions, such as drop foot, swing phase dorsiflexion assistance from ankle exoskeletons can facilitate efficient walking. However, we are not aware of any research comparing individual responses to stance phase plantar flexor assistance with vs without swing phase dorsiflexion assistance in any study population. Our hope was that by providing the community with information on how novice users react to these two ankle assistance modes, the field can leverage this information to improve the effectiveness of new exoskeleton designs and controllers.

We sought to understand the effects of adding swing phase dorsiflexion assistance during walking with standard stance phase plantar flexion assistance, including the potential influence on motor learning [16], [17], in unimpaired adults to use a reference for future explorations in individuals with drop foot. We compared metabolic power, muscle activity, and joint kinetics during walking with (1) only stance phase plantarflexor assistance and (2) combined stance phase plantar flexion assistance with swing phase dorsiflexion assistance. The effects of acclimation and condition testing order were minimized using a repeated-reversal study design. We hypothesized that adding swing phase dorsiflexion assistance would result in decreased metabolic power and swing phase dorsiflexion muscle activity, as well as increased minimum toe clearance compared to only stance phase plantar flexion assistance [18]. The contribution of this work is the first exploration of swing phase dorsiflexion assistance

II. Methods

A. The Exoskeleton

The exoskeleton was a lightweight bilateral, bidirectional battery-powered system that could assist the ankle joint in both plantar and dorsiflexion. Device characterization and sensor validation was reported previously [19], [20]. The mass of the device was approximately 2.6kg, the majority of which was housed on a waist assembly that transmitted force to a pulley that was co-located with the ankle joint. The device was powered by a 910 mAh LiPo battery housed in the waist assembly, and mechanical work done by two 24V Maxon (USA) brushless DC motors was transferred to the ankle assembly (Fig. 1 A) by steel cables housed in Bowden tubes. These cables rotated a pulley at the ankle, which drove a carbon fiber footplate. While in assistance modes, torque tracking error was 0.37-0.70 Nm [21]. Low level control was done onboard the device using an Arduino NanoBLE microcontroller connected to a custom printed circuit board. High level remote control of the device was done over Bluetooth Low Energy using a custom iOS application running on a tablet which also recorded the state data from the device in real-time.

B. Controller Description

The exoskeleton controller relied on two primary measurements: the force-sensitive resistor (FSR) values, which dictated the assistive torque assigned by a low-level controller. This torque was directly proportional to the FSR readings, with higher force levels corresponding to greater target torques. To validate these assigned torques, a custom aluminum sensor was integrated to enable real-time planar torque measurements. This sensor facilitated closed-loop proportional-derivative control, ensuring the safe operation of the system.

Furthermore, the controller for plantar and dorsiflexion assistance was synchronized with the FSR to identify each leg's stance phase. During this phase, the device provided plantar flexion assistance, while in the absence of stance phase detection, dorsiflexion assistance was activated (Fig. 1 B,C). Notably, dorsiflexion assistance was divided into two distinct

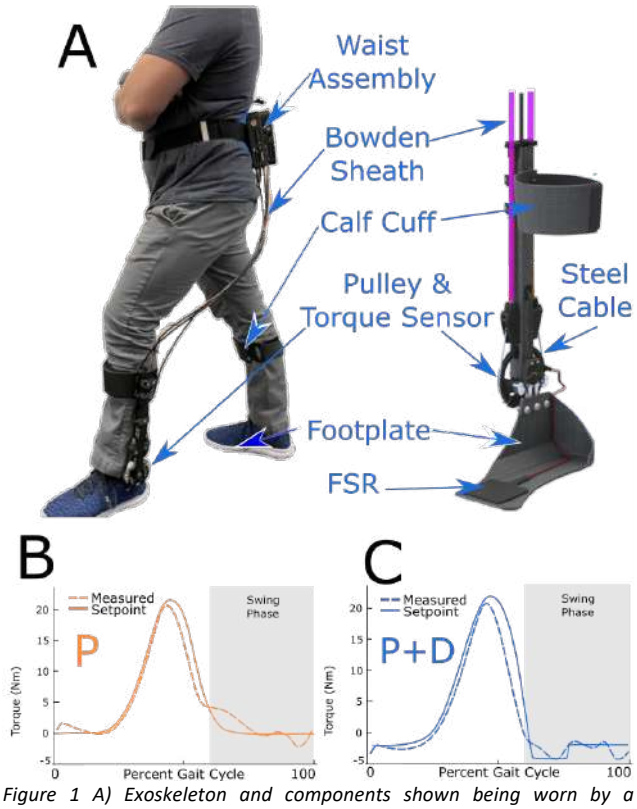

Figure 1 A) Exoskeleton and components shown being worn by a participant, B) Plantar-only torque profile for assistance, C) Plantar and Dorsiflexion torque assistance. Torque setpoints with values below zero indicate dorsiflexion assistance, while values above zero indicate plantarflexion assistance

target torques: one for early-swing phase and another for late-swing phase. The exoskeleton device defined early swing as the first 300ms after the foot left the ground, and the remainder of swing was considered late-swing. Enhancing the absolute assistance prescribed during early swing improved the overall quality of torque tracking for the device. This targeted assistance was subsequently applied from mid-swing through the initiation of stance.

C. Measurement Methods

Surface Electromyography (EMG) data was collected using lightweight Trigno Avanti sensors (Delsys Natick, MA USA). Eight such sensors were attached directly to the skin of each participant and assessed the lateral gastrocnemius, tibialis anterior, vastus lateralis and lateral biceps femoris on each leg. EMG data was synchronized with motion capture data. The final minute of each condition was selected so that the data most likely to be in steady-state conditions would be evaluated. Both peak and integrated EMG activity were evaluated during swing phase to identify changes in muscular activity while dorsiflexion assistance was in effect. Participants received no prompting or time calls.

Each subject was outfitted with 38 markers for 3-D motion capture calibration using an eight-camera Vicon system that had been previously validated [22]. Four calibration markers were removed for walking trials, but were located initially on the medial malleolus and medial condyles of each leg. Markers for motion tracking included four on the upper torso,

for on the hip, and each leg had two clusters as well as five joint markers. The four torso markers were located on the cervical spine C5, the xiphoid process of the sternum and on each of the acromioclavicular joints. The hip markers were located on each of the anterior superior iliac spines, and on the exoskeleton waist assembly in line with each posterior superior iliac spine. Each leg had two clusters of four markers located on the links of the leg. The upper cluster was placed in line with the lower 1/3 of the femur, while the lower cluster was centrally located on the tibia. Both clusters were oriented to face anteriorly with a slight external lateral bias. In addition to the clusters, each leg also had a marker on the lateral condyle and the lateral malleolus. Each foot was marked on the first and fifth toes and a posterior oriented marker was located on the calcaneus.

Gas exchange calorimetry using a Cosmed (Concord, CA USA) K5 was used to assess total energy expenditure. The device was a low-weight untethered system, and was calibrated each day within an hour of being donned. Primary analysis for this study was metabolic power, which was calculated according to a modified Brockway equation (1), normalized to body mass (M) [23]. The modified Brockway equation used values of the volumetric flow rate of expired oxygen $\dot{V}O^2$ and carbon dioxide $\dot{V}CO^2$ to estimate metabolic power.

$$MeT = \left(16.58 * \dot{V}O^2 + 4.51 * \dot{V}CO^2\right)/M \quad (1)$$

The participant's leg length was used to determine nondimensional walking speed for both visits [24]. We set a target nondimensional walking speed of 0.5, based off of a desire to see strenuous walking without approaching the walk-run threshold (0.72) [25]. The equation for nondimensional walking speed (2) normalized based on each participant's leg length (L) and accounted for stride-length being highly correlated with efficient walking speed [26], [27].

$$\text{Walking speed} = 0.50 * \sqrt{(9.81 * L)} \quad (2)$$

In an attempt to account for learning effects, each participant underwent an acclimation visit less than 36 hours before data collection was done. Order effects were mitigated through the double reversal condition ordering (Fig. 2). The level of assistance (torque) was based on the mass of the participant, and dorsiflexion was 10 percent of plantar flexion assistance [22].

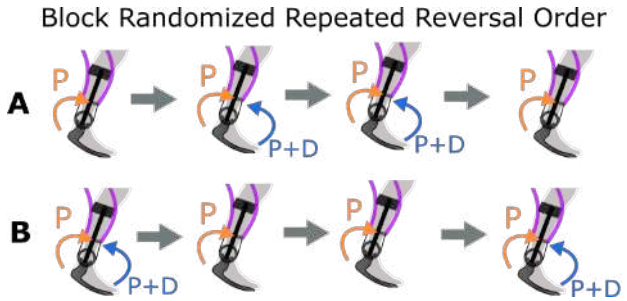

Figure 2 Participants were assigned to one of two study order groups A or B. Testing order went from left to right and only altered the mode of assistance that was delivered. This order of exposure was present in both the acclimation visit and the testing visit. "P" indicates plantar flexion assistance only, while "P+D" indicates both plantar and dorsiflexion assistance.

D. Protocol

Initially participants underwent a 30-45 minute acclimation visit in which they walked on the treadmill, donned the exoskeleton, walked for five minutes in each of the tested conditions, leg length was measured according to Carty and Bennett and were fitted for the calorimetry mask. This process allowed them to establish a comfort level with the laboratory environment and ask questions freely.

Prior to data collection, the participants underwent a 20-minute re-acclimation period where they walked in the exoskeleton a second time. The experimental protocol consisted of six bouts of walking with the exoskeleton, each lasting eight minutes with eight minutes of rest in between. Between conditions, there were eight-minute seated resting periods where conversation was kept to a minimum. Meyers et al. showed that 100 steps gave participants enough time to make biomechanical adjustments to steady-state walking [28], as a result we felt confident that prior conditions were not impacting subsequent tests. Each walking trial was monitored throughout by real time calorimetry, surface EMG and the first thirty seconds of the sixth minute was motion tracked.

Immediately prior to the first walking trial, a standing baseline was collected for no less than three minutes. Estimates of metabolic power during steady-state for each condition were calculated by taking the mean of all values of the final two minutes of the condition and comparison of conditions was done using the mean of similar conditions for each participant. Each trial was recorded in its entirety for both the EMG and calorimetry, however only the first half of the sixth minute of each trial was recorded with motion capture due to hardware limitations. This timing of motion capture was selected for its representative nature. Every participant initially experienced a mechanically disconnected scenario known as zero-torque where the ability of the device to impart torque to the ankle was removed.

The participants were split into two groups and experienced either the ``A" or the ``B" protocol (Fig. 2). Testing order ``A" corresponded to stance-phase plantar flexion only assistance followed by two plantar and dorsiflexion assistance conditions, with a stance-phase plantar flexion only condition to conclude assisted walking. Testing order ``B" was the inverse, with plantar only assistance making up the middle conditions. In both testing orders there was a zero-torque trial that preceded the testing and one that followed the testing.

E. Data Analysis

The measured metrics in this study were normalized metabolic power, EMG signals for the eight muscles observed, and the dynamics and kinematics of walking. Significance for all metrics was set at alpha = 0.05. We calculated the averages for each metric across different conditions and analyzed differences using repeated measures

t-tests, due to the exploratory nature of this research we chose not to adjust significance values for repeated measures. For each metric, the value associated with each condition was the average of the two trials conducted under that condition.

Metabolic power data and muscular activity were calculated based on the final minute of walking in each condition. EMG data were scaled relative to the average maximum peak in the initial zero-torque condition and metabolic data were scaled to the mean metabolic power of the initial zero-torque condition. Calculated metrics such as joint moments and powers were calculated using OpenSim [29]. To complete the analysis a previously validated custom model was employed, and data were not manipulated (scaled or filtered) prior to this analysis [30]. Exoskeleton data were recorded but were not used in the analysis of this study except to verify that tracking errors remained in the reported ranges. Due to the number of conditions that our participants underwent, ANOVA analysis was not done; the associated power of any test we could have run would have been under 0.10 and the results would have been uninformative [31].

III. Results

A. Metabolic Power

The zero torque conditions were not significantly different from one another and indicated that no group level fatigue occurred. There was an average decrease in metabolic power of 10.66% ($p = 0.003$) for plantar flexion-only assistance; combined plantar and dorsiflexion assistance resulted in a 12.51% improvement ($p < 0.001$) compared to the zero-torque condition. The cohort saw no significant change in metabolic power when comparing plantar flexion only assistance to combined plantar and dorsiflexion assistance ($p = 0.051$). Individual responses to additional assistance varied and a variety of positive and negative responses were observed (Fig. 3).

B. Joint Powers and Ranges

OpenSim was used to reconstruct joint mechanics. Step data were analyzed, and any outlying steps greater than two standard deviations from the median step curve were identified and removed using root-mean-square error. The mean step for the cohort in each condition was examined for differences in power. Fig.4 displays the powers for each joint (hip, knee and ankle) averaged over the observed steps and averaged across participants. This showed insignificant changes to hip ($p = 0.248$), knee ($p = 0.285$) and ankle ($p = 0.148$) excursion between the plantar and plantar with dorsiflexion assistance conditions.

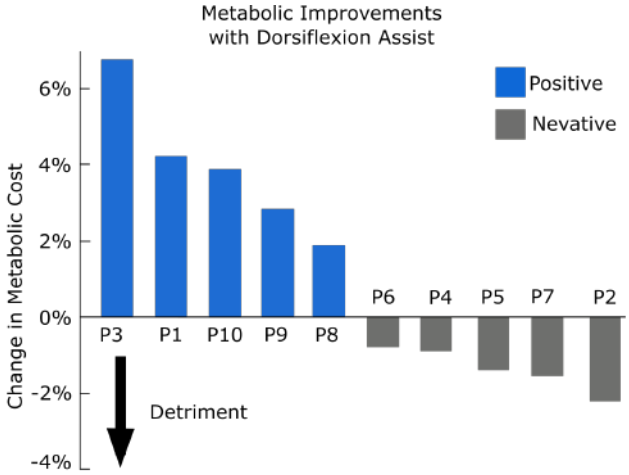

Figure 3 Relative change from in metabolic power for each participant.

C. Muscle Activity and Toe Clearance

The mean tibialis anterior activation for both legs was compared and we found that plantar and dorsiflexion assistance resulted in insignificant changes to both integrated ($p = 0.291$) and peak ($p = 0.085$) activation relative to plantarflexion only assistance. The lateral gastrocnemius, vastus lateralis and lateral biceps femoris also showed insignificant changes for both peak and integrated measures ($p > 0.05$). Minimum toe clearance did not differ significantly between the two conditions ($p = 0.311$).

IV. Discussion

This study compared metabolic power, muscle activity, and minimum toe-ground clearance when walking with stance phase plantar flexor assistance with and without swing phase dorsiflexion assistance. Despite no statistically significant

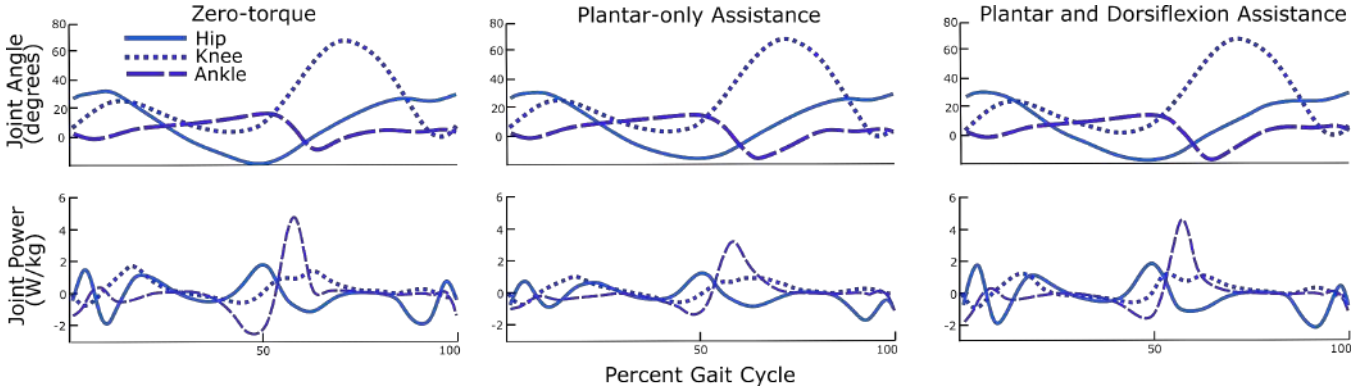

Figure 4 Joint kinematics and dynamics averaged across participants and conditions. No statistically significant differences were identified between these conditions at $p < 0.05$.

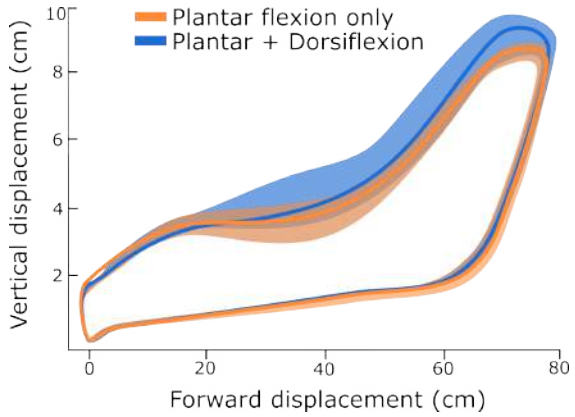

Figure 6 All participant toe paths (left and right) were averaged for each condition. Ground clearance decreased by at most 4.4% and increased by at most 23.9% for individuals.

changes in group-level metrics, individual-level analysis provided valuable insights. While the mean toe clearance was not significantly different between the assistance conditions, there was an increase in the mean value for 8 of the 10 participants; the high variability among participants, reflected in a standard deviation of 10.5%, overshadowed the small change in the mean (Fig. 5). This gives hope to future investigations for similar devices reducing trip risk.

When the tibialis anterior EMG was separated based on the metabolic responses seen in Fig. 6, it appeared that heightened levels of tibialis anterior activity near toe-off may have been beneficial, as those with the greatest positive response to the addition of dorsiflexion exhibited this muscular pattern. We examined this disparity using statistical parametric mapping, but due to the small sample size we did not find a statistical difference ($p = 0.116$). The results also suggest that the metabolic benefits observed in some participants may stem from the adoption of new movement strategies enabled by the exoskeleton. Training protocols that encourage exploration of optimized movement patterns could amplify the benefits of exoskeleton use. Furthermore, identifying and reinforcing key gait phases, such as pre-swing

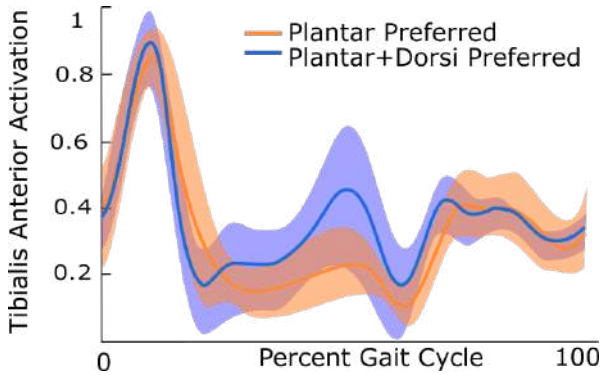

Figure 7 Plantar preferred individuals had lower metabolic power when only receiving plantarflexion assistance, while the Plantar +Dorsi preferred participants had lower metabolic power with assistance in both directions.

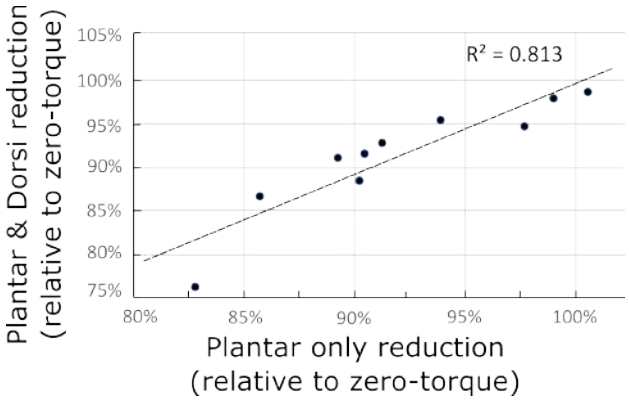

Figure 5 The impact of one mode of assistance from the exoskeleton was highly correlated with the impact of the other.

dorsiflexion, where assistance is most effective, could enhance the device's impact.

Finally, participants appeared to have related responses to the two different kinds of exoskeleton assistance. As Fig. 7 shows, the greater the improvement in metabolic power a participant had with plantar only assistance, the higher their improvement was likely to be when dorsiflexion assistance was included, the correlation coefficient of this relationship was 0.913 and a linear fit had an R^2 value of 0.834.

The variability in individual responses highlights the need for personalized assistance strategies in powered exoskeletons. While some participants demonstrated positive metabolic and muscle activity changes, others did not. This suggests that a one-size-fits-all approach may not be optimal for diverse users with varying neuromuscular and biomechanical profiles. Customizing the magnitude and timing of assistance based on individual gait mechanics, strength, and adaptability could enhance the exoskeleton's effectiveness. Adaptive control systems that dynamically adjust to the user's needs in real time may lead to more consistent benefits across users.

Future research into the effectiveness of dorsiflexion should incorporate the knowledge that novice users of powered exoskeletons have highly disparate responses and that large sample sizes would be needed to establish meaningful impacts. Additionally, we saw that individuals who were positively impacted by one control strategy may be more likely to respond positively to additional assistance. Validation of this observation would allow researchers to optimize different fundamental control strategies given a person's initial reaction to an exoskeleton. Such research could open the door for improving peak performance as well as creating controllers that may help even those who are initially less accepting of external assistance from a worn robotic system.

V. Conclusion

While no significant group-level differences were observed, individual responses revealed promising avenues

for future development. Personalized assistance, trust-building measures, and training protocols aimed at promoting beneficial movement strategies could significantly improve outcomes in powered exoskeleton use. These findings underscore the importance of tailoring exoskeleton systems to the unique needs and characteristics of users to maximize their potential for enhancing mobility and reducing metabolic cost.

Conflict of Interest

Z.F.L. is a co-founder with shareholder interest in a start-up company that is seeking to commercialize wearable exoskeleton technology related to this work.

Effects of Deep Core Activation Method Using Wearable Cyborg HAL in a Supine Position for Ameliorating Defecatory Function: A Pilot Study

Hayato Tamai, Akira Uehara, Yoshiyuki Sankai, and Hiroaki Kawamoto, *Member, IEEE*

***Abstract*— Fecal evacuation disorder and incontinence are prevalent problems among patients with spinal cord injury (SCI) which greatly affect their quality of life. A major cause of these issues is well associated with weakness in their deep core muscular activity. Current programs for amelioration in their deep core muscles are either difficult to apply to patients with SCI or highly invasive. We have previously proposed a minimally invasive method using the wearable cyborg Hybrid Assistive Limb (HAL) for use by patients with SCI. In our proposed method, long-term repetition of supine HAL-assisted hip flexion is thought to activate deep core muscles potentially ameliorating deep core muscular activity. Here, we conducted a pilot study to validate that our methodology is applicable to a patient with SCI. A 24-year-old SCI patient with motor paralysis in his deep core muscles underwent four weeks of supine HAL-assisted hip flexion for thirty minutes, four times per week. To evaluate the effect of the intervention on the muscular activity, IAP measurement and sphincter electromyography were performed for seven days pre- / post-intervention. These assessments were repeated at a two-month follow-up after the intervention to verify the persistence of the effects. The increasing trends were observed in all periods of both IAP and in sphincter electromyogram. There was a significant increase in IAP and sphincter electromyogram between the pre-intervention and two-month follow-up ($p < 0.001$). These results demonstrate not only the applicability of our methodology to a patient with SCI but also the potential for ameliorating deep core muscular activity.**

I. Introduction

Neurogenic bowel dysfunction (NBD) is a major problem in patients with spinal cord injury (SCI) [1, 2]. The National Spinal Cord Injury Statistical Center Database [3] indicates that over 60% of patients with SCI currently experience bowel problems. Among various symptoms in NBD, fecal evacuation disorder and incontinence especially cause psychological stress for patients with SCI. Some literature suggests that the patients with NBD feel depression due to necessity of manual evacuation or incontinence concerns [4, 5]. Thus, an effective treatment program for NBD is urgently needed so that patients can live comfortably.

To address the dysfunctions in patients with SCI, it is essential to ameliorate deep core muscular function. Vallès et al. identified the pathophysiological mechanisms underlying NBD in patients with SCI [2]. Patients experiencing significant evacuation difficulties were found to have an inability to increase intra-abdominal pressure (IAP) and a lack of voluntary anal relaxation during defecation. Those with severe incontinence lacked anal contraction in response to rectal distension. The IAP increase and anus contraction rely on the deep core muscles, which is the box-structured muscle group including the internal oblique (IO), transversus abdominis (TrA), and pelvic floor muscles (PFM) (Fig. 1). However, in patients with SCI, particularly those with a neurological level of injury at or above the lumbar level, have weakness in the deep core muscles contributing to these symptoms [6]. Therefore, the recovery of deep core muscular function is critical for the elimination of NBD.

Although previous studies have explored methods for restoring deep core muscle function, existing treatments are either difficult to apply to patients with SCI or highly invasive. One promising approach is PFM training, which involves techniques such as imagining moving the penis up and down for men or feeling the vagina pull upward and inward for women. However, because the PFM is not directly involved in joint motion, it is challenging to consciously contract these muscles. This often results in incorrect maneuvers, such as compensatory movements using other muscles—i.e., abdominal or gluteus [7]. While exercises combined with joint movement, such as Kegel exercises, are another option, these are impractical for most SCI patients as many of them have lower limb paralysis. Alternative includes electrical stimulation or biofeedback therapy. However, these options are highly invasive or requiring surgical intervention [8, 9]. Thus, to effectively treat NBD in patients with SCI, less invasive

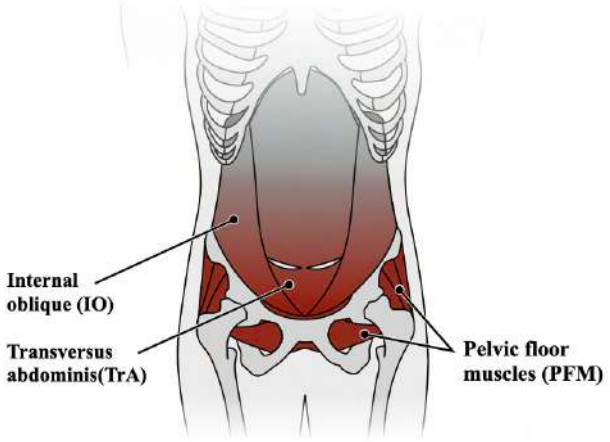

Figure 1. The specific segment of deep core which plays a crucial role for defecation.

therapies are needed that can also be applied to the physically impaired patients.

Cybernics treatment, on the other hand, can potentially ameliorate muscular functions with lower invasion in patients with SCI. Cybernics treatment is known as treatment strategy using wearable cyborg Hybrid Assistive Limbs® (HAL; CYBERDYNE Inc.) improving/regenerating motor functions in patients with various neurogenic dysmotility. The HAL detects wearer's motor intention by measuring bio-electrical signals (BES) from the electrodes attached on their skin surface. These signals control actuators in the HAL joints assisting exercise in unison with the wearer's intention. HAL-assisted motion generates sensory inputs from muscle spindles, ears, eyes, and other sensory receptors back to the wearer's brain. This intention-based sensory feedback loop activates the nervous system which in turn alters the patient's brain, nerves, and muscle function. Repeating this HAL-assisted motion has been considered to promote neural plasticity and sustain the effects of recovery on muscular function. Obviously, this technique is minimally invasive and can be applied to any individual, as long as their BES can be observed, even if the signals are weak. [10-12]

We have previously proposed a treatment methodology using wearable cyborg for deep core dysfunction based on the principle of cybernics treatment [13]. This method aims to activate the neural pathways controlling the deep core muscles by establishing a sensorimotor loop between brain and deep core muscles as the cybernics treatment. In this method, the wearable cyborg detects wearer's motor intention toward the deep core from the electrodes attached on their lower abdomen and lift their legs in a supine position (Fig. 2) [13]. In our hypothesis, the deep core muscles contract with fascial connected hip flexor during this process, and sensory feedback can be transmitted to the brain from deep core, thereby establishing the sensorimotor loop. Unlike conventional exercise therapy, this approach allows patients to recognize whether they are correctly contracting their deep core muscles during exercise. This is believed to prevent compensatory movements and facilitate the selective activation only of the deep core muscles. Furthermore, as the movement is assisted by the wearable cyborg, it can be performed even by patients with lower limb paralysis. After a long-term repetition of this robot-assisted supine hip flexion, it is thought that the neural pathways controlling the deep core muscles will undergo plasticity, enabling patients to regain deep core muscular function.

We have previously demonstrated the safety and applicability of this methodology in healthy individuals [13]. In this study, we conducted a one-month pilot trial for a patient with chronic SCI to confirm its applicability to the patient and the effect of amelioration in deep core muscle activity after a long-term intervention.

II. Materials and Methods

A. System Configuration

The system used for our method consisted of the HAL, a polypropylene sheet, and a urethane molded bed. The wearer attached electrodes to their fusion site of IO and TrA (IO-TrA) and connected them to the HAL (Fig. 2).

The surface electrodes on the IO-TrA can transmit the wearer's motor intention sent toward the deep core muscles to the HAL. As the deep core muscles move in coordination with each other [14] and some of their motor unit potentials leak from the IO-TrA [15, 16], the BES on the wearer's IO-TrA can be regarded as the motion intention toward the entire deep core muscles.

HAL has the actuators at both the hip and knee joints. Details of the HAL control algorithm is described in other literature [17]. Briefly, we used two control modes of HAL: Cybernic Voluntary Control (CVC) and Cybernic Impedance Control (CIC). The CVC mode determines the actuator torque based on the intensity of the wearer's BES. In contrast, the CIC mode determines the torque according to the angular velocity of joint motion. In our method, the hip joint was operated in CVC mode to reflect the BES from the IO-TrA into the hip flexion torque. The knee joint was controlled in CIC mode and to make it behave as a free axis.

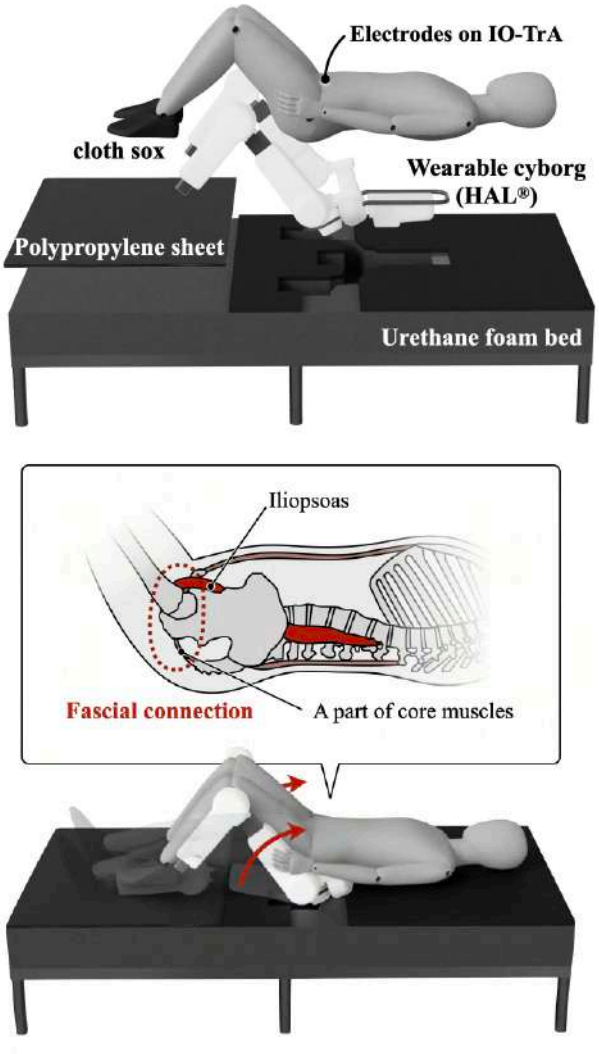

Figure 2. Overview of our method. HAL-assisted supine hip flexion establishes the sensorimotor loop between brain and deep core muscles. Repeating this exercise induces neural plasticity in their deep core, resulting in regaining muscular function.

A polypropylene sheet was placed under the wearer's feet to reduces friction with the ground. This prevents the wearer from stepping on the ground with the lower limbs during hip flexion. The sheet enables the wearer to perform hip flexion by selectively contracting the core muscles without relying solely on the compensatory movement of the lower extremity muscles.

B. Study Design

A case study was conducted involving a pre-clinical test and a four-weeks of HAL intervention. A preclinical test was performed to validate our methodology is applicable to a patient with SCI. Clinical assessments were carried out before, im-mediately after, and two months following the HAL intervention, each for one week, to verify the amelioration in deep core muscular activity (Fig. 3).

C. Participant

This case focused on a 24-year-old male patient (height, 178 cm; weight, 60 kg) who had injured his spinal cord due to a lumbar burst fracture at L1 four years before this study. The neurological level of injury (NLI), ASIA impairment scale (AIS), sensory zone of partial preservation (sensory ZPP), motor zone of partial preservation (motor ZPP) of the patient are presented in the following table (Table 1). Voluntary anal contraction was not preserved. The participant was not taking any medications or treatments for bowel control. The participant had undergone physical therapy for six months immediately following hospital discharge but had not received HAL training prior to this study.

Regarding his defecatory function, the participant exhibited a slight perception of the urge to defecate. However, due to paralysis of the deep core muscles especially in PFM, the participant was required to strain excessively in order to evacuate the stools. Frequently, even with straining, it was challenging to adequately expel the stool (Cleveland Clinic Constipation Score = 10). Although his voluntary anal contraction was not preserved, he had managed to control defecation by adhering to a scheduled toilet routine, resulting in the absence of incontinence episodes for three years (Wexner score = 0). The participant provided written informed consent before this study according to the Declaration of Helsinki.

D. Preclinical Test

A preclinical test was conducted to validate that our method was applicable to the participant by validating that HAL could achieve supine hip flexion based on his intention, engage all of the deep core muscles, and ensure that hip flexion is driven by the deep core muscles rather than by compensatory movements of the hip flexors.

Fig. 4 illustrates the experimental setup. The participant performed hip flexions with and without the HAL while measuring BES from IO-TrA, PFM, and rectus femoris (RF). Initially, surface electrodes (Vitrode; Nihon Koden) were attached to the IO-TrA and RF, and an intra-anal electrode (Anuform®; Neen) was inserted into the anal canal, where the PFM are concentrated. At first, in the configuration without the HAL, the participant lay supine. A speaker placed beside the participant played beeps every 5 s. The participant was instructed to engage his deep core muscles and perform hip flexion in order to achieve a hip angle of over 60 degrees only while the beep was sounding. This exercise was repeated three times. Subsequently, the participant donned the HAL and repeated the same test with HAL's assistance in the supine position. During both experimental sessions with and without the HAL, the electrodes on the IO-TrA were connected to the HAL and BES were recorded using its associated software (HAL Monitor; CYBERDYNE Inc.) at a sampling frequency of 1 kHz. The electrodes on the RF and PFM were connected to a recording computer, and BES was logged at a sampling rate of 500 Hz using a microcomputer (ESP32; Espressif Systems).

To determine that the HAL could achieve hip flexion based on the participant's motor intention, we verified the

synchronization between the hip joint angle and the BES from the participant's IO-TrA during HAL-assisted hip flexion. Additionally, to ascertain whether all of the deep core muscles were engaged during the hip flexion, we confirmed the increase in the amplitude of BES in both IO-TrA and PFM during the beep playback. The BES was rectified by applying a low-pass filter with a cutoff frequency of 10 Hz and the root mean square over a time window of 10 ms. The mean amplitude was calculated from the signals during the middle 3 s of the 5 s hip flexion period, with the initial and concluding seconds excluded to minimize the impact of variability at the onset and offset of the signal. The mean values derived from three measurements were employed as representative values. The BES when the beep was not played was recorded as the baseline value with the same calculation procedure. Furthermore, to ensure that hip flexion is driven by the deep core muscles rather than by compensatory movements of the hip flexors, we measured the BES of one of the hip flexors, RF, and the deep core muscles (IO-TrA and PFM). The activity ratios of these muscles were compared between protocols with and without HAL. The muscle activity ratio was calculated by dividing the amplitude of IO-TrA, PFM, and RF with HAL assistance by their respective amplitudes without the HAL.

E. Intervention

The participant performed HAL-assisted supine hip flexions four times a week for a total of four weeks (Fig. 5). In the intervention program, the participant first attached electrodes to the IO-TrA and connected these electrodes to the HAL's hip actuator with cables. Subsequently, the participant engaged in approximately twenty to thirty repetitions of hip flexion while wearing the HAL, to familiarize himself with the wearable cyborg. The instruction for engaging the deep core muscles was as follows: "Please flex the hip over approximately 60 degrees while contracting the pelvic floor as if closing the anus." Subsequently, five sets of ten HAL-assisted hip flexions were carried out per session. The duration of each session with the HAL was approximately 30 mins.

The gain of the assistive torque for the HAL's hip actuator was set using the controller to enable the deep core to exert approximately 60–70% of the maximum force produced by the participant. This setting was informed by the literature which introduced pelvic floor muscle training [18, 19]. As the sessions progressed, the gain of the assistive torque gradually decreased as the participant became accustomed to the training.

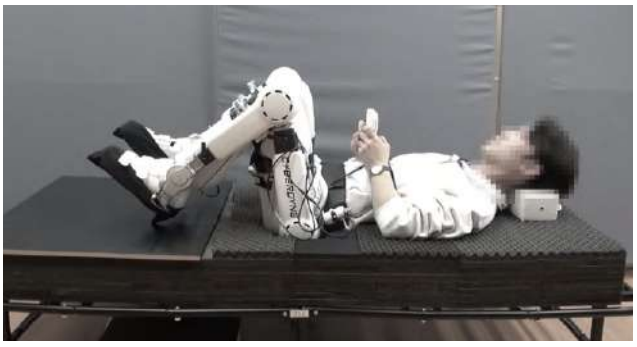

Figure 5. HAL-assisted hip flexion was performed by the participant for sixty minutes per a time, four times a week for a total of four weeks.

E. Outcome Measures

To determine the impact of the intervention on deep core muscular activity, two assessment indices were employed: IAP measurement and sphincter electromyography. These assessments were carried out at pre-, post-, and two-month follow-up of the HAL intervention for a week respectively to determine the persistence of the intervention effects.

F. IAP Measurement

One of the muscular activities that contributes to stool evacuation was evaluated by measuring the IAP increase during straining. The change in IAP is accurately reflected by the change in rectal pressure measured at a 10 cm depth of the anal canal [20]; thus, changes in rectal pressure at this depth were recorded and assessed as changes in IAP in this study. Rectal pressure measurement was carried out by inserting an air-filled balloon catheter into the participant's anal canal as previously described by Miller et al. [21]. The balloon catheter (Safired® Balloon Catheter; Terumo) was equipped with a transducer (2SMPP-02; Omron) connected to its balloon tube. The pressure change inside the balloon caused by the patient's straining was converted into discretized values by the transducer. The values were amplified by a differential amplifier circuit with a gain of 21x and recorded by a microcomputer (ESP32; Espressif Systems) at a sampling rate of 500 Hz. Prior to use, the measuring equipment was calibrated in a glass container connected to a gauge pressure sensor (MPS-C35R-NCA; CONVUM), which exhibited a linear response per unit rise in actual pressure.

In the left lateral position with the hip and knee flexed at 90 degrees, a catheter was placed 10 cm proximal from the participant's anal orifice, and 10 ml of air was injected into the balloon. Once the pressure within the balloon had reached equilibrium with the rectal pressure, the participant was instructed to strain for 5 s at a time, for a total of five repetitions, with a 5 s interval between each strain. To eliminate variations in amplitude during the onset and offset, the average pressure during the middle 3 s of each straining period was calculated, excluding the first and last 1 s. The median of the five measurements was used as the representative value. IAP measurements were conducted over seven days during each of the pre-, post-intervention, and two-month follow-up periods.

G. Sphincter Electromyography

The muscular function for maintaining fecal continence was assessed by using sphincter electromyography. Sphincter electromyography allows for the evaluation of motor unit potential recruitment during voluntary sphincter contraction, including denervation-reinnervation potentials [22, 23]. Therefore, in this study, sphincter electromyography via a transanal electrode was used to assess changes in neural activity in the sphincter. The change in potential while the participant was squeezing was obtained from the transanal electrode (Anuform®; Neen). These signals were amplified using a differential amplifier circuit with a gain of 220x and recorded by a microcomputer (ESP32; Espressif Systems) at a sampling rate of 500 Hz.

In the left lateral position with the hip and knee flexed at 90 degrees, a transanal electrode was inserted into the participant's anal canal. The participant was instructed to

perform a squeezing action for 5 s for a total of five repetitions with 5 s intervals between each. The acquired signals were processed by the BES and rectified by applying a low-pass filter with a cutoff frequency of 10 Hz and the root mean square over a time window of 10 ms. To eliminate variations in amplitude at the onset and offset of the signal, the average amplitude during the middle 3 s of each squeezing period was calculated. The median of the five measurements was used as the representative value. Sphincter electromyography was conducted over seven days during each of the pre-, post-intervention, and two-month follow-up periods.

H. Statistical Analysis

To assess the plausibility of the intervention effects on muscular activity, IAP measurement and sphincter electromyography data were statistically analyzed. The Dunn-Bonferroni multiple comparison test followed by the Kruskal-Wallis test were used to compare between pre- and post-intervention measurements, as well as pre-intervention and two-month follow-up measurements. Statistical significance for all measures was set at $p < 0.05$ after the Bonferroni adjustment. Given the small sample size, the effect size r was calculated as a standardized measure to assess the magnitude of the observed effects. Effect sizes were calculated by dividing the test statistic Z by the square root of the sample size n. Standardized effect sizes were categorized as small (r = 0.10), medium (r = 0.30), and large (r = 0.50) [24]. All statistical analyses were performed using SPSS software version 29.0 (SPSS Inc., Chicago, IL, USA).

III. Results

The participant completed preclinical test and all six-teen HAL-sessions. No intervention-related adverse events were observed.

A. Preclinical Test

Fig. 6 presents the representative time series data of hip joint angles and BES in IO-TrA during HAL-assisted hip flexion. The upper panel represents the hip joint angle, while the lower panel represents BES in IO-TrA. As the participant performed symmetrical movements for both legs, only the data for the right leg are shown as a representative result. The shaded area in the graph indicates the duration of the beep sound playing, signaling the participant to flex his hip joint. Fig. 7 shows the time series data of BES in IO-TrA, PFM, and RF during hip flexion both with and without HAL assistance. The red and blue lines represent the data obtained during hip flexion with- and without HAL assistance, respectively. Table 2 shows the average amplitude of BES in IO-TrA, PFM, and RF at the baseline and during hip flexion, both with- and without HAL assistance. Fig. 8 shows the ratio of muscle activity in IO-TrA, PFM, and RF with the HAL compared to without the HAL.

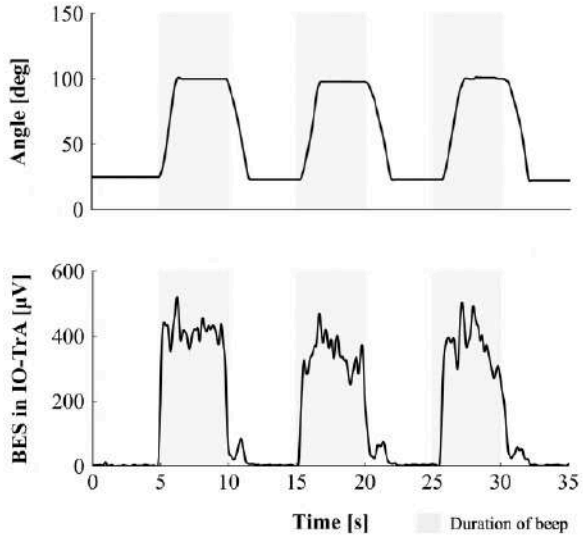

Figure 6. Time series data of the hip joint angle and BES in IO-TrA during HAL-assisted hip flexion. The shaded area indicates the duration of beep playing.

With HAL assistance, the hip joint angle and BES in the

TABLE II. BES DURING BASELINE V.S HIP FLEXION

Measured area	***Baseline* [μV] (±SD)**	***Hip flexion* [μV] (±SD)**
IO-TrA (with-HAL)	13.49 (± 10.22)	385.1 (± 26.75)
IO-TrA (without-HAL)	10.37 (± 10.50)	147.7 (± 24.72)
PFM (with-HAL)	6.848 (± 1.918)	14.99 (± 0.543)
PFM (without-HAL)	6.661 (± 0.247)	8.309 (± 0.130)
RF (with-HAL)	9.268 (± 7.088)	185.0 (± 5.971)
RF (without-HAL)	1.750 (± 0.247)	309.8 (± 59.08)

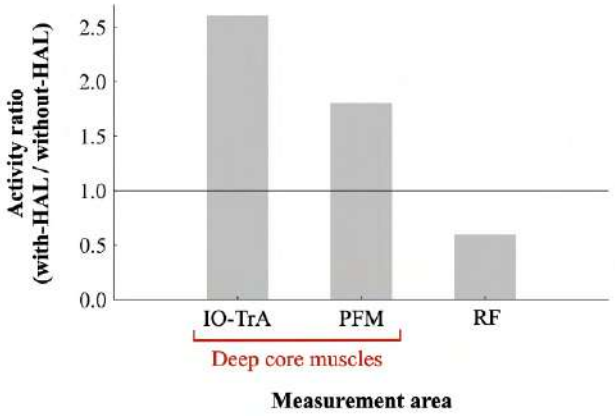

Figure 8. Activity ratio in IO-TrA, PFM, and RF with vs without HAL assistance during hip flexion.

IO-TrA were synchronized (Fig. 6). The BES increased in all measured areas at the onset of the beep. Thereafter, BES levels remained above baseline and then decreased to baseline levels after the beep stopped. Similarly, without HAL assistance, the BES showed comparable changes (Fig. 7, Table 2). The ratios of muscle activity in both IO-TrA and PFM were > 1.0. Conversely, the ratio in RF was < 1.0 (Fig. 8).

B. Pre / Post and Follow-up Comparison

Fig. 9 presents the median of the IAP measurements during the pre-intervention, post-intervention, and two-month follow-up periods. Error bars represent the 95% confidence intervals (95%CI) calculated using the bootstrap method. Increasing trends were observed in IAP (pre: Mdn = 2.96 kPa, 95%CI = [2.44, 3.43], post: Mdn = 4.55 kPa, 95%CI = [4.13, 5.65], follow-up: Mdn = 5.02 kPa, 95%CI = [4.83, 5.51]). Statistically significant increases and large effect sizes in IAP were observed both from pre- to post-intervention ($p = 0.0133$, $r = 0.72$) and from pre- to two-month follow-up ($p = 0.0006$, $r = 0.97$).

Fig. 10 illustrates the median of the sphincter electromyography values for the same periods along with their 95%CI. Increasing trends were observed (pre: Mdn = 0.05 μV, 95%CI = [0.09, 0.27], post: Mdn = 0.79 μV, 95%CI = [0.22, 1.42], follow-up: Mdn = 9.75 μV, 95%CI = [7.13, 11.9]). There were no significant differences between pre- and post-intervention ($p = 0.1548$). A significant increase and large effect size from pre-intervention to two-month follow-up was confirmed ($p = 0.0001$, $r = 1.08$).

Although a subjective outcome, the participant reported an improvement in ease of evacuation after the procedure. The Wexner Score remained unchanged at 0, while the Cleveland Clinic Constipation Score decreased from 10 to 8.

IV. Discussion

In the preclinical testing, we confirmed that HAL could realize hip flexion based on the wearer's motor intentions, resulting in all the deep core muscles working. The synchronized change in the hip joint angle and BES in IO-TrA during HAL-assisted hip flexion suggests that HAL successfully achieved hip flexion based on the participant's intention. The increase of the BES in all measured segments of the deep core at the onset of the beep sound indicates that the entire deep core musculature was engaged during HAL-assisted hip flexion.

Although the participant could perform hip flexion in a supine position without HAL, the increased activation ratio of IO-TrA and PFM, coupled with the decrease in that of RF, indicates that hip flexion without HAL predominantly involved compensatory actions using the hip flexors rather than the deep core, in contrast to HAL-assisted hip flexion. This demonstrates that HAL could selectively detected motion intentions directed towards the deep core and facilitate hip flexion accordingly. The finding suggests that the proposed methodology enabled the participant to consciously engage paralyzed muscles which were difficult for him to contract voluntarily. In other words, it can be assumed that the participant became able to relearn how to voluntarily contract the deep core muscles that he had previously forgotten the way to contract, through HAL-assisted hip flexion.

The significant increase in IAP with a large effect size from pre- to post-intervention suggests the participant seemingly relearned the correct way to strain. The significant difference in comparison between pre-intervention and two-month follow-up measurement allows us to assume that the proposed method enabled to repeat selective activation on the nerves related with deep core, which enhances its synaptic connections, resulting in the sustained effect on the participant's muscular activity under the principles of cybernics treatment [10-12]. Although there were no significant differences between pre- and post-intervention sphincter electromyography measurements,

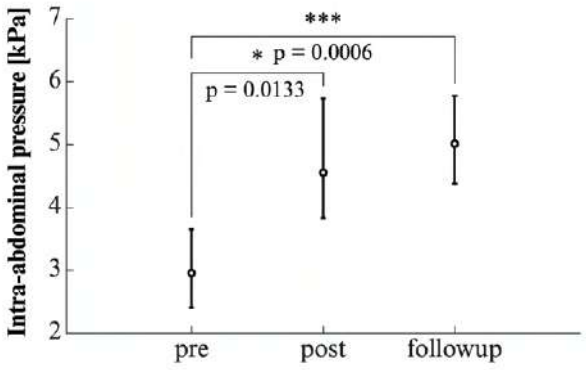

Figure 9. Pre/post and follow-up comparison in IAP measurements.

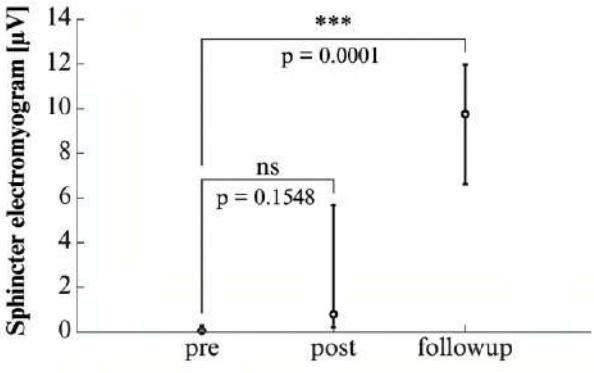

Figure 10. Pre/post and follow-up comparison in electromyography.

the post-intervention values showed non-zero values compared to the near-zero values observed pre-intervention. This implies that the intervention may have facilitated increased motor unit potential recruitment around the PFM. Moreover, even though the participant had not demonstrated voluntary anal contraction for over four years, the significant increase in sphincter electromyography observed at follow-up, compared to pre-intervention suggests that the intervention may have served as a catalyst for enhancing the neural pathways. We hypothesized that this neural enhancement provided the opportunity to move the deep core musculature in daily life after intervention and that the repetition of the voluntary muscular movement would have further enhanced the neural connections. This is reflected by the positive changes in IAP and sphincter electromyography values at follow-up vs. pre-intervention.

These findings confirm that the proposed deep core activation method is applicable for the participant with SCI and provides a sustained effect on ameriolation for deep core muscular activity. However, one limitation of this study is that the participant had relatively mild NBD, which makes the specific effects on improving bowel habits unclear. Furthermore, as this is a case study, it is unknown whether similar intervention effects can be achieved in patients with different types of SCI, such as supraconal or conal/infraconal injuries, or at different stages of injury, such as acute, subacute, or chronic.

Despite these limitations, HAL-assisted hip flexion has the potential to ameliorate not only deep core muscular activity but also the bowel habits at the same time. Several studies demonstrated that voluntary mild exercise in a supine position coordinate autonomic nervous system activity, such as in the vagus nerves [25, 26] which innervate the intestine, potentially improving colonic motility. Other studies proved that aerobic exercises seemingly regulate the autonomic nervous activity associated with colonic propulsion as well [27-29]. This suggests the possibility of improving the entire intestinal tract by performing the supine HAL-assisted exercise combined with proper breathing, which uses more oxygen. In terms of patients with SCI of different severities, our previous studies on cybernics treatment have demonstrated its application to SCI patients with different injury locations and stages [30], [31]. For patients whose BES cannot be appropriately measured from the skin surface, a pre-programmed control method called Cybernic Autonomous Control (CAC), which has been developed to automatically control the patient's lower limb and is now an alternative for them [17].

This pilot study does not allow for an assessment of the long-term sustainability of the clinical effects. Further studies with larger sample sizes and various injury types combined with the long-term assessment of bowel habit change are needed to confirm these assumptions. We intend to apply the proposed method to several patients with spinal cord injuries who also suffer from severe NBD. This will confirm the impact on the anorectum and gastrointestinal tract, which are innervated by both autonomic and somatic nerves. The results could eventually lead to the establishment of a completely new treatment for NBD.

V. Conclusion

We conducted a pilot trial to confirm that our proposed methodology is applicable to a patient with chronic SCI. A 24-year-old person with SCI accompanied by anorectal dysmotility underwent a four-week period of the supine HAL-assisted hip flexion for thirty minutes four times per week. Clinical assessments of its effect on deep core muscles were performed using IAP measurement and sphincter electromyography at pre-, post-intervention, and two-month follow-up periods. The results of the preclinical test confirmed that the proposed method enabled hip flexion based on the participant's motor intention and facilitated the engagement of the entire deep core musculature. Comparison of pre- / post-intervention measurements showed the increasing trends both in IAP and in sphincter electromyography. There were significant increases in IAP and sphincter electromyography between pre-intervention and two-month follow-up measurements. These results demonstrate not only the applicability of the proposed methodology, but also its potential for the amelioration on the deep core muscular activity in patients with chronic SCI.

Ethical declaration

This study was fully conducted in accordance with IEEE AUTHOR ETHICS GUIDELINES. In accordance with IEEE policy and my ethical obligations as a researcher, I disclose that all authors and one subject who participated in the experiments are past or present employees of CYBERDYNE Inc. and that I have fully disclosed these interests to IEEE.

***Abstract*—Assistive robots have tremendous potential to support older adults in their homes. The design of robots for home use is in its nascence, but broad commercial success will depend on the robot design and the older adults' willingness to adopt this technology in their homes. We aimed to understand older adults' perceptions about the potential for use of assistive robots in their homes. We grounded this exploration by understanding their views about aging independently. Using a mixed-methods approach, we interviewed 27 older adults (aged 60-79) about aging and assistive robots and assessed their technology and robot experience. Their views about aging independently revolved around living where they considered home and being able to do their activities on their own. They were open to a robot supporting them in their homes and shared activities the robot could support. We identified factors that should be considered when designing and deploying robots to support the autonomy of older adults.**

Keywords—Successful aging, human-robot interaction, acceptance

I. Introduction

In the United States, approximately 18 million adults over age 65 have difficulty or receive help with self-care, mobility, or household activities [1]. Technologies such as assistive robots have tremendous potential to support these individuals [2, 3, 4]. Robots might augment the person's capabilities, support their independence, enable functional activities, and ultimately lower healthcare costs associated with logistics for health screening, healthcare consultations, and monitoring [5, 6]. However, only a few robots with such capacity are commercially available and can be reliably operated remotely to support older adults in their homes [7].

Given that the design of robots for home use is in its early stages, it is important to understand older adults' openness to having them in their homes. Broad commercial success will depend on the robot design and the older adults' willingness to adopt this technology in their homes. Assistive robots, by definition, are meant to assist with everyday activities. As such, we first explored how older adults think about their independence. This approach primed them to think about what might be needed to support that independence and set the context for the discussion of their views about having an assistive robot in their own home. The research questions that guided the research were as follows:

1. What are the general perceptions of older adults about aging independently?
2. What are their views about using a robot in general to support aging independently?
3. How might older adults use an assistive robot to support their everyday home activities?
4. What are the facilitators and barriers to older adults' acceptance and use of an assistive robot in their homes?

II. Method

A. Participants

Participants were recruited from the TechSAge Participant Registry (TechSAgeRERC.org) and through word of mouth. Inclusion criteria were aged 60-79; access to internet and a video camera; and a score above 37 on the Modified Telephone Interview for Cognitive Status (TICS-M, [8]). Table 1 provides the socio-demographic characteristics for the 27 participants. Given that an estimated 25% of people over age 65 have a mobility disability [9], we oversampled this population as they might be more likely to benefit from having an assistive robot in their home. Reported mobility impairments were due to a range of conditions, including Parkinson's disease, multiple sclerosis, spina bifida, post-polio syndrome, and spinal cord injury.

B. Materials and Measures

Fig. 1. Stretch Research Edition robot (RE1) by Hello Robot (Hello Robot, 2020; https://hello-robot.com/product)

Robot Videos - We selected one assistive robot to use for the study to enable the participants to become familiar with its capabilities and to think deeply about the pros and cons of this type of assistive robot. The Stretch robot (Fig. 1, developed by Hello Robot Inc.) is a mobile manipulator robot designed to support everyday activities using a lightweight telescoping arm mounted on a mobile base [10]. We prepared a series of short video clips showing the Stretch robot's capabilities in home settings. The first video depicted Stretch completing various tasks in the home, such as vacuuming a couch, wiping a kitchen countertop, watering plants, or getting clothes from a dryer during laundry. The next set of video clips depicted Stretch completing tasks with the addition of a mounted tablet computer, such as medication reminding, delivery of a pillbox, or a cooking task. The last series of video clips showed Stretch supporting the activities of daily living (ADLs) of an individual with quadriplegia (e.g., Stretch supporting with self-feeding).

TechSAge Background Questionnaire - Participants were asked general demographic questions using the TechSAge Background Questionnaire (TSBQ, [11]) administered at the start of the interview. The TSBQ covers general demographics and health information, including current conditions, vision, hearing, and mobility capabilities.

Robot Trust Questionnaire - Participants were asked a series of questions to determine their trust in using robots, which was an adapted measure [12]. Participants responded to statements regarding trust in robots on a five-point Likert scale ranging from strongly disagree (1) to strongly agree (5).

Robot Familiarity and Use Questionnaire - Participants were asked about their familiarity with various types of robots [13]. For each robot listed, the participants responded on a five-point scale ranging from having no familiarity at all (1) with the robot to having used and operated the type of robot frequently (5).

Semi-Structured Interview - The interview questions explored understanding of aging independently and the implications of using robots at home. After each set of videos participants were queried about their impressions and opinions of the Stretch robot.

TABLE I. CHARACTERISTICS OF PARTICIPANTS (N=27)

Variables	Total	
	*n**	*%*
Gender		
Female	18	67
Male	9	33
Age		
60-65	9	33
66-72	14	52
73-79	4	15
Racial Group		
White/Caucasian	25	92
Black/African American	1	4
More than one race	1	4
Marital Status		
Single	2	7
Married	15	6
Separated	2	7
Divorced	3	11
Widowed	2	7
Do not wish to answer	3	11
Highest level of Education		
High school/GED	1	4
Vocational Training	2	8
In progress college / Associate's Degree	2	8
Bachelor's Degree (BA, BS)	9	38
Master's Degree (or other post-graduate training)	9	38
Doctoral Degree (PhD, MD, EdD. DDS, JD, etc.)	1	4
Income (US$)		
Less than 25,000	1	4
25,000-49,999	3	11
50,000-74,999	3	11
75,000 or more	14	52
Do not know for sure	1	11
Do not wish to answer	5	19
"With whom do you live?"		
Live alone	8	32
Roommate or Friend	1	4
Spouse or Partner	17	65
General Health (self-reported)		
Poor	0	0
Fair	4	15
Good	9	35
Very Good	8	31
Excellent	5	19
Mobility Impairment		
Yes	8	30
No	19	70

* Numbers do not always add to 27 due to missing data.

The questions also explored their perceptions about using the robot to support daily living activities. The study flow is presented in Fig. 2. The interview was conducted over Zoom. This was to make it easier for participants to participate in the study from the place that was convenient for them. It also provided participation opportunity for those who had more severe forms of mobility impairment who may not be able to travel to a specific study location.

C. Data Preparation and Analysis

Transcribing and Segmenting - After the interviews were completed, the research team edited the transcripts to ensure they matched the audio verbatim with personal information

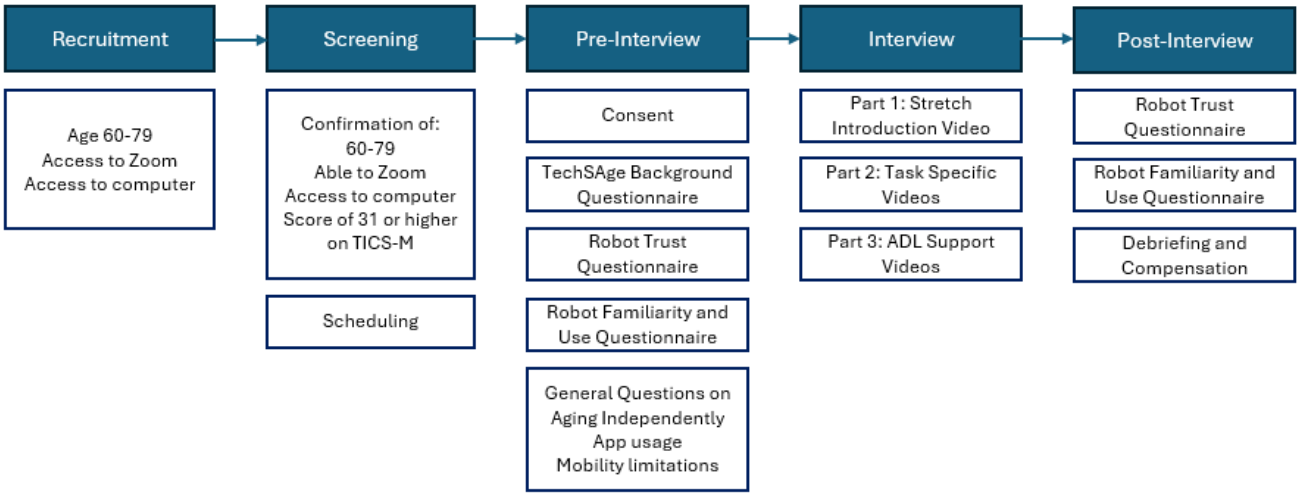

Fig. 2. Study flow diagram

omitted. Transcripts were segmented into analysis units, which were statements about participants' perceptions regarding using robots in their homes.

Coding Scheme Development - We used thematic coding to identify key topics and themes relevant to the research questions. We developed the coding scheme by reviewing a random sample of the transcripts and extracting key topics and common themes based on literature related to human-robot interaction (HRI) and the themes that emerged from the participants' comments [14]. This was an iterative strategy whereby categories were assigned using existing themes from the HRI literature and new categories were added based on the emerging themes. The authors reviewed the themes together.

III. Results

A. *What were the general perceptions of older adults about aging independently?*

Participants were asked, "What does aging independently mean to you?". We added this question after the first 10 participants to understand the common attitudes of older adults towards aging independently in general that had emerged spontaneously in the initial interviews. Thus 17 participants were asked this question directly and we observed three emergent themes (see Fig. 3). The theme "Person" referred to any discussion that revolved around being independent as a person, and not relying on another human for assistance as they age ("That means you can… You don't need anybody's help. That you can take care of yourself."). The theme "Place" was coded when the participant mentioned that staying in their preferred place was important to aging independently ("I guess it means living in one's own home with any necessary adaptive devices."). The "Tasks" theme referred to any comments that included being able to complete one's responsibilities ("…be able to do your day-to-day tasks. So daily activities would be very important"). As is evident in Fig. 3, participants often used a combination of themes ("That I'm able to live in a place by myself and do almost everything myself without having to depend on somebody else to come and do it for me").

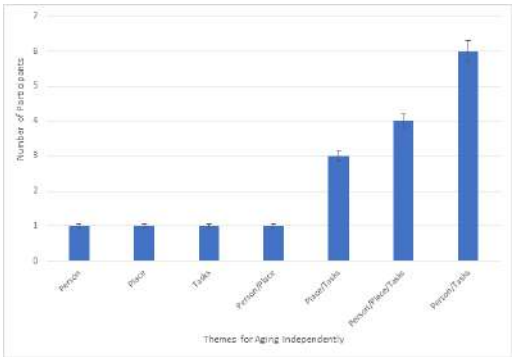

Fig. 3 Themes from "What does aging independently mean to you?" (n=17)

B. *What were older adults' views about using a robot, in general, to support aging independently?*

With respect to robot experience most participants answered, "Have only heard about or seen this robot" (M=2.74, SD=0.68) for the familiarity portion of the questionnaire, except for the remote presence robot, which had a majority answer of "Not sure what this is" (M=2.00, SD=0.90). With respect to robot trust the answers clustered around "Neither agree nor disagree" (M=3.36, SD=0.88). However, more than

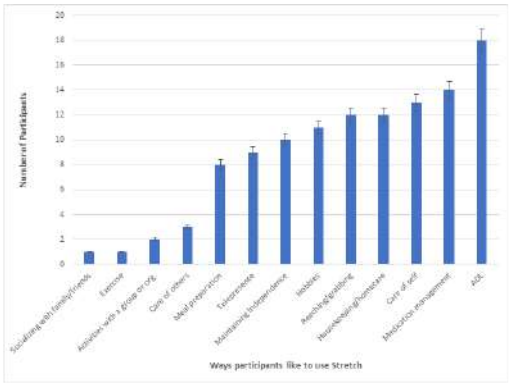

Fig. 4. Ways the older adult would like to use Stretch in their homes

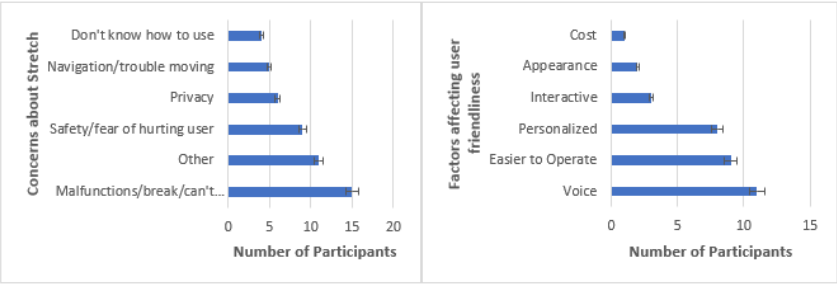

Fig. 5. (a) Concerns about Stretch (b) Ways to increase user friendliness.

half of the participants (19/27) agreed they would depend on a robot to support them. The majority of the participants expressed a willingness to have a robot to support aging independently: "*Oh yeah, I would, I would definitely, I would enjoy the cleaning up aspect. I hate to clean up, and I would employ a robot in a minute if it could clean things up like that. I have no problems with robots in general. I, I'm waiting, waiting for them*". After watching videos of Stretch assisting a man with quadriplegia with activities, participants were asked if they thought this robot could enhance independence for someone with a disability. All 27 participants answered with "yes". They were also asked, in the context of a robot working with somebody who has a disability, if they would trust this robot (Stretch) to help them. 26 participants answered "yes," with 1 answering "not sure" because they felt they did not have enough information to answer.

C. Initial Thoughts and Impressions of Stretch Robot

1) First Impressions

After watching the video demonstrations, participants were asked, "What is your first impression of Stretch?" and 25/27 had a positive first impression. They described Stretch as helpful, useful, and versatile. Other commonly shared first impressions include amusement from watching Stretch perform various tasks, being pleasantly surprised by Stretch's ability to complete many different tasks, and uncertainty about how Stretch was completing these actions, whether by automation or remote control. Furthermore, 4 participants stated explicitly that they wanted Stretch in their home or asked where to purchase it.

2) Appearance

With respect to appearance, 13/27 participants mentioned feeling neutral, neither positive nor negative: "*To me it [Stretch] just looked like a regular robot kind of thing*". Others (12/27) commented that the Stretch robot appeared very functional and mechanical and 7/27 mentioned that it had a very sleek, thin, or streamlined look that would have a "*small footprint... which you would need if you were going to use it in a house*". Some comments pointed to the fact that if the robot could successfully complete the tasks it was designed to do, that would be a higher priority for them than the robot's appearance.

3) How might older adults use Stretch robot to support their everyday home activities?

When asked if they could see themselves using this type of robot in their home, all 27 participants responded yes. Six participants elaborated on that, saying that they could see themselves using this robot in their homes, but only with the onset of mobility issues, disability, or greater need later in life. Fig. 4 shows participants' preferences about activities they felt Stretch could be used for in their homes. Participants without mobility impairments mentioned uses such as medication management and ADLs (dressing, bathing, toileting, grooming, etc...) whereas participants with mobility impairments focused on reaching/grabbing, meal preparation, and homecare. Participants who were wheelchair users commented about already having made adjustments so they could do things we showed Stretch doing, but that Stretch could be very helpful for levels of reach that they could not achieve. One noted, "*And myself who have had surgery or something of that sort and during recuperation the sort of go fetch function would be particularly useful if someone has either permanently or temporarily limited mobility.*"

D. What are the facilitators and barriers to acceptance and use of Stretch robot by older adults in their homes?

1) Ease of use

Over half of the participants (17/27) considered Stretch to likely be easy to use from the videos, but some participants (9/27) whose responses were coded as "other" or "not sure" noted that they could not be sure of Stretch's ease of use based solely on the videos alone. Only one participant responded with "no". They said they would need to try Stretch out themselves or they felt it could be easy to use with some practice.

2) Concerns

Concerns were related to functionality (see Fig. 5a), such as the robot breaking, and consequently not knowing how to fix it or not having an easy avenue to have robot fixed (n=15), a malfunction hurting the user (n=9), or generally not knowing how to use Stretch (n=4). Concerns related to privacy such as hacking and data storage were mentioned but less frequently (n=6).

3) User friendliness

The helpful additions mentioned most were about functionality, with 11/27 mentioning that adding voice communication (both to and from) and making Stretch easier to operate would increase its user-friendliness. However, this does not imply that they stated Stretch was not easy to use; rather, it simply suggests ways to make Stretch even easier to use (see Fig. 5b).

4) Adaptability through attachments

Participants (10/25) asked questions about items that were added onto Stretch to fulfill certain tasks (e.g., vacuum, washcloth, etc...) as well as how Stretch was controlled (e.g., remotely, autonomously, etc...). For example, "*Do those*

attachments come with Stretch?"; "*Do I need to know how to attach them myself?*"; "*How would I learn to operate Stretch?*". We posit that questions like these could be a barrier to the acceptance and adoption of Stretch but could be understood as facilitators to the adoption of Stretch for use in homes. The addition of the tablet received the most positive responses, with 16/25 participants expressing positive comments.

IV. Discussion

A. Perceptions about aging independently

Our goal was to understand older adults' perceptions about accepting assistive robots in their homes and to explore their views about such robot supporting their autonomy. We first explored their perceptions of aging independently to provide a foundation for them to consider how a robot could provide support. Similar to the pattern observed by [15] about definitions of aging in place, participants described common concepts of space, person, time, and their combinations. These concepts are consistent with the definition of aging in place as "One's journey to maintain independence in one's place of residence as well as to participate in one's community" [15].

The concepts of aging independently related to prioritizing tasks critical for an assistive robot to support. The older adults were open to the concept of using an assistive robot in their home and expressed positive expectations for the impact it could make. This supports the narrative in the literature about older adults desiring a robot that can help them do the things they want, in the way they want, when they want, with whom they want, where they want, and how they want it [16]. This perceptions they shared on aging independently grounded the discussion and set the context for understanding their views on the role robots could play in supporting independent aging.

B. Acceptance of robots for personal use in homes

All the participants affirmed that they would like to use the robot in their own homes irrespective of the differences in their background, socio-demographic status, initial perception of the robot, and health status. This is a testament to their willingness to accept the robot for personal use at home. The tasks they mentioned aligned with the existing literature about robotic support for older adults [17, 18]. The tasks we demonstrated to them through videos in the study were carefully selected and informed by literature [2, 3, 13, 18]. We showed the participants tasks supported by previous studies' findings and considered relevant to the target population. The participants related to these tasks, and provided more in-depth insights on how they would want the robot to support them.

We saw a positive response from the participants for various tasks that they would like the robot to support them with. In general, the need for assistance with ADLs is the most common among older adults who require a higher level of care [19]. This kind of support from robots will require more complex functions, sensing, and processing, such as identifying objects accurately and deciding on the most appropriate way to pick up these objects. This points to the delicateness of the support required in home environments, and how user satisfaction with these tasks impacts acceptance [3]. With the emergence of more advanced robots for domestic uses and home healthcare [20, 21], we foresee more applications of robots to support older adults with ADLs in their homes. These results point researchers, developers, and home healthcare teams to the openness of older adults regarding the idea of robot assistance as identified in the literature [22] and the use of the robot supporting them in their homes. When expressing their thoughts about acceptance, the older adults focused more on the functional ability of the robot as a priority rather than appearance, which is consistent with the findings from [23].

This was a major contribution that differentiated the study from previous work. Prior studies focused on what the robot could do to support older adults; the current study revealed how older adults would want the robot to support them through these tasks. We used data from the literature to inform the design and choice of the tasks that would be demonstrated to the participants in order to spur more ideas from the participants. The participants were able to relate to the tasks shown to them in the videos and then shared more insights on how they wanted these tasks executed and the impact this would have. This approach provided the opportunity for a more comprehensive discussion on how to make the robot's support in the home successful. We recommend this approach for further studies and for designers considering a starting point for the tasks to demonstrate the robot's capabilities and potential. Studies such as [2, 3, 13, 16, 18] have presented a collection of potential tasks that could demonstrate the robot's potential to support older adults in various contexts.

C. Understand the facilitators and barriers to acceptance.

Perception of the robot's usefulness in the homes stands out as a facilitator to the acceptance of an assistive robot. Most of the older adults mentioned that their ease of using the robot, including the ease of communicating with the robot will impact their willingness to use the robot in their own homes. This connects with technology acceptance model [24], wherein perceived usefulness and ease of use have been validated to impact the intention and actual use of a technology. Increasing user-friendliness is a facilitator that has been proven to support people's interaction with robots and to potentially influence acceptance of these robots [25, 26]. The most prominent element mentioned by the older adults that could contribute to user-friendliness was voice communication, which aligns with earlier propositions of voice communication to improve interpersonal communication and natural human-robot interactions [28, 29, 30]. It is critical to consider these facilitators alongside the concerns that the older adults expressed, such as ease of fixing malfunctions, safety, and privacy management.

V. Conclusion

In sum, our findings unveiled factors that could impact the adoption of robots by older adults in their homes. The older adults had an overall positive perception of a robot assisting them with a range of tasks. The insights they shared should be considered for future developments of robot design to facilitate more widespread adoption and use of these robots in homes. We provide these details to support designers, practitioners, and other researchers conducting similar forms of testing, participatory design, or deployment. Future research and development efforts should carefully consider how robots' actions can be adapted to meet the changing needs of individuals as they age to support their autonomy.

ACKNOWLEDGMENTS

This research was funded in part by the National Institute on Aging (National Institutes of Health) Small Business Innovation Research Grants, Phase I (R43AG072982) and Phase II (R44AG072982). Human-Centered Geodesics for Motion Planning

Francesco Bianchin[1], Davide Astarita[2], Lorenzo Amato[2], Emilio Trigili[2], Satoshi Endo[1], Sandra Hirche[1]

***Abstract*—This paper addresses the challenge of designing human-like reference trajectories for exoskeleton-aided rehabilitation, with a focus on mimicking human joint coordination while addressing clinical requirements. Redundant kinematic chains in human biomechanics pose challenges to trajectory planning: state-of-the-art algorithms often do not explicitly address the problem of replicating natural movements nor do they provide a suitable performance over a wide range of human motions. To address this challenge, this paper proposes a geodesics-based computational method that incorporates joint-level constraints, in addition to energy and level of comfort criteria to solve the problem of redundancy and better emulate human movements. Using upper-limb data retrieved with an exoskeleton platform, the advanced method demonstrated significant performance gains over standard approaches like the minimum-jerk model and cubic polynomial planning, and leads to human-like trajectories, while closely aligning with human demonstrations, both at the configuration (joints) and task-space (hand) level. In particular, we provide detailed comparisons across various motion types and subjects, demonstrating the versatility of the proposed method and its strong potential for application in clinical and assisted living settings.**

***Index Terms*—Trajectory planning, Exoskeleton rehabilitation, Human motion, Geodesics**

I. Introduction

An ongoing challenge in exoskeleton research is developing reference trajectories that recreate human-like motions in terms of joint coordination and velocity profiles, while also meeting the joint specific constraints required for rehabilitation tasks [1]. Achieving this is complex, as human motion often results from redundant kinematic chains [2]. When it comes to motion planning, kinematic redundancy is often exploited to address secondary objectives, but also introduces challenges in trajectory planning by increasing the solution space and complicating the selection of optimal joint configurations. This issue is particularly pronounced in inverse kinematics-based methods, which focus on inverting task-space trajectories but frequently overlook the intricate joint coordination required for human-like movement. This presents an opportunity to advance motion planning techniques by leveraging redundancy, not just for optimization, but to better replicate natural, human-like motion [1].

To address these limitations, researchers have explored different approaches that leverage kinematic redundancy to recreate natural human coordination [3]. These approaches generally fall into two main categories [4], namely analytical and computational methods on the one hand [5], [6], and data-driven methods, mainly traceable to the learning by demonstration subfield, on the other [7], [8].

In this work, we take a data-informed computational view on the problem, as we postulate a comprehensive set of criteria that capture the human optimization processes underlying motion generation and validate them with data. A commonly used computational approach involves the minimization of kinetic energy, as described in [9]. This method interprets human motion generation as the solution to an underlying geometric optimization problem, resulting in a geodesic path in the configuration space. It was originally proposed to model 3D pointing motions, where the kinetic energy criterion enhances performance compared to alternative methods, including Euclidean configuration-level planning [10] and the minimum torque-change model [11]. Geodesic-based trajectories have already been applied in exoskeleton-related research, as in [12], [13], where kinetic energy minimization is combined with considerations of scapulo-humeral rhythm to address limitations associated with assuming a fixed position of the shoulder's center of rotation. However, a thorough investigation of how to adapt the geodesics approach to a broader set of motions is still missing, as well as an exploration of how the underlying metric can be exploited for application-specific objectives.

In this work, we reformulate the trajectory generation approach by introducing novel optimization criteria—specifically, an anthropomorphism measure and potential energy minimization [14]—to enhance the human-like quality of the synthesized motion. Additionally, we extend the framework to accommodate constraints relevant to assistance and rehabilitation robotics. In particular, geodesic-based methods allow for modifications to the underlying Riemannian metric, enabling joint-level constraint satisfaction through the incorporation of barrier-function metric terms. We thus achieve the stated objective of generating human-compliant trajectories and exploit redundancy to reproduce key characteristics of natural human motion. To evaluate the effectiveness of our approach, we conducted an extensive validation using a dataset of real-world demonstrations from seven healthy subjects performing free-arm motion experiments. Joint trajectories

This study was part of the Innovation Network eXprt of the Technical University of Munich, funded by the Federal Ministry of Education and Research and the Free State of Bavaria under the Excellence Strategy of the Federal Government and the States. This work was supported by the EU Commission through the H2020 ReHyb project (Rehabilitation based on hybrid neuroprosthesis, Grant Agreement: 871767) and partially supported by the RIG – Robotics Institute of Germany, supported by the BMBF – Federal Ministry of Education and Research of Germany.

were recorded using the NESM-γ exoskeleton system [15], [16]. The experimental trials focused on two main objectives: optimizing the parameters of our method to balance different optimization criteria effectively and performing a comparative evaluation against existing approaches. Specifically, we analyzed the performance of our geodesics-based method (GEO-HL) relative to minimum jerk (MJ), inverse kinematics (IK), and standard kinetic energy geodesics (GEO), assessing human-likeness based on configuration and end-effector error indicators. Empirical results demonstrate that our revised geodesic method outperforms conventional approaches, such as the minimum jerk model and cubic polynomial trajectory planning, in capturing human-like motion characteristics. The remainder of the paper is structured as follows. The motion planning problem is formulated in Section II. In Section III, we propose a novel geodesic-based approach to address typical rehabilitation-oriented requirements. The experimental trial setup is described in Section IV, while the data analysis is detailed in Section V. Section VI provides extensive comparisons between the proposed method and other approaches popular in the literature, and final remarks are presented in Section VII.

II. Problem Statement

In the context of our work, we define a motion planning task as follows. Given a known initial configuration $\mathbf{q}_0 \in Q$, where $Q \subseteq \mathbb{R}^n$ is the joint configuration space, and an end-effector target $\mathbf{x}_f \in \mathbb{R}^3$, we optimize over trajectories $\gamma : \lambda \in [0,1] \rightarrow \mathbf{q}(\lambda) \in Q$, where $\lambda \in \mathbb{R}$ is an affine parameter defining the level of trajectory completion. The basic requirement for a trajectory planning algorithm is that $\mathbf{q}(0) = \mathbf{q}_0$ and $\mathbf{x}_f = \mathbf{x}(\mathbf{q}_f) = \mathbf{x}(\mathbf{q}(1))$, i.e. the final joint configuration in the planned trajectory realizes the workspace target. In order to deal with the redundancy of the kinematic chains of interest, we perform a bi-level optimization procedure, i.e.:

1) Generate candidate trajectories $\gamma_{\boldsymbol{\alpha}}$ joining $\mathbf{q}_0$ and $\mathbf{q}_f(\boldsymbol{\alpha})$, where $\boldsymbol{\alpha} \in \mathbb{R}^p$ parameterizes the set of valid end-configurations, in accordance with the kinematic chain under analysis, having p redundancies.
2) Select $\gamma_{\boldsymbol{\alpha}^*}$ among candidate trajectories optimizing over a given cost J, i.e. $\gamma_{\boldsymbol{\alpha}^*} = \arg\min_{\boldsymbol{\alpha}} J(\gamma_{\boldsymbol{\alpha}})$

This work addresses the challenge of generating human-like trajectories by approximating typical human joint coordination. To achieve this, the cost function $J(\cdot)$ is designed to reflect human optimization principles, ensuring the synthesis of trajectories that are both natural and compliant with rehabilitation-related requirements, such as the satisfaction of prescribed joint limit constraints.

III. Geodesic-based Trajectory Generation

In this section, we briefly outline the basics of geodesics-based trajectory generation, as a means to attain phase 1 of the bi-level optimization. We then focus on metric augmentation strategies for application-oriented objectives and we address the issue of redundancy, to address phase 2 of the bi-level optimization.

When looking for geodesics, we formulate the problem of generating trajectories as an optimization problem on a suitably defined Riemannian space, as detailed in [9]. Given the configuration space Q and the configuration tuples $\mathbf{q} = [q_1, ..., q_n]^T \in Q$, which represent the joint variables and degrees of freedom (DoFs) involved, we note that a Riemannian manifold on Q is defined by means of a metric tensor $\mathbf{M}(\mathbf{q}) \in \mathbb{S}_n^+$, where S_n^+ is the set of symmetric positive definite matrices of size n, with components M_{ij}, such that the infinitesimal squared distance is given by

$$d\sigma^2 = \sum_{i=1}^{n}\sum_{j=1}^{n} M_{ij}(\mathbf{q}) dq_i dq_j \in \mathbb{R}^+ \tag{1}$$

where $d\sigma$ is the infinitesimal distance in the Riemannian manifold [17].

In [9] the metric is given by kinetic energy, which is a criterion often used in the human motion analysis field in order to interpret human planning strategy. It is given by

$$M_{ij}(\mathbf{q}) = \frac{\partial K(q, \dot{q})}{\partial \dot{q}_i \dot{q}_j} \tag{2}$$

where $K(\mathbf{q}, \dot{\mathbf{q}})$ represents the kinetic energy function associated to the kinematic chain under analysis, $\mathbf{q}$ represents the joint configuration and $\dot{\mathbf{q}}$ the joint velocity. One can see that the metric is configuration-dependent and relates to the inertial properties of the kinematic chain for the selection of desired configurations. Finding a geodesic path between two points in the configuration space using such metric means finding the shortest path according to the associated kinetic energy. Minimizing the distance between $\mathbf{q}_0$ and $\mathbf{q}_f(\boldsymbol{\alpha})$ with metric (2) inherently minimizes the kinetic energy expended along the path. As shown in [9], trajectories generated according to (2) are endowed with efficiency. When moving along kinetic energy geodesics, all accelerations act in direction tangential to the joint path, meaning that they minimize the torque required with respect to non-geodesic paths.

The use of exoskeletons for rehabilitation/assistance poses additional challenges beside efficiency, starting from joint constraints introduced by the mechanical structure of the robotic system, in terms of limited joint ranges of motion, due to mechanical stops [15], and the reduced range of motion of rehabilitation patients. We address this challenge by exploiting the Riemannian formulation, introducing a suitable change in the underlying metric $\mathbf{M}(\mathbf{q})$. In particular, if we take the joint limits to be of the type $[\mathbf{q}_m, \mathbf{q}_M]$, where $\mathbf{q}_m$, $\mathbf{q}_M$ are the minimum and the maximum attainable values for the joints as dictated by mechanical and patient-related constraints, one can modify the kinetic energy metric $\mathbf{M}(\mathbf{q})$ by adding a diagonal matrix term of the type

$$\begin{aligned} \mathbf{M}_1(\mathbf{q}) &= [\mathbf{M}_1(\mathbf{q})]_{ii} \\ &= -\frac{1}{t} log\left((q_i - q_{m,i})(q_{M,i} - q_i)\right) \\ &- \frac{2}{t} log\left(\frac{q_{M,i} - q_{m,i}}{2}\right) \end{aligned} \tag{3}$$

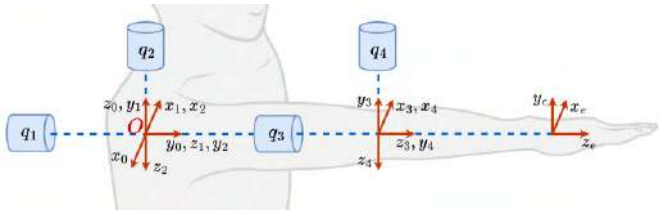

Fig. 1. Kinematic chain model for the 4DoF human arm and exoskeleton supporting system [15], with joint variables q_1, q_2, q_3 representing the shoulder's adduction/abduction, flexion/extension and internal/external rotation DoFs respectively, and q_4 representing the elbow's flexion/extension DoF.

where parameter $t \in \mathbb{R}_+$ can be used to modulate the barrier function terms $[\mathbf{M}_1(\mathbf{q})]_{ii}$, which are joint-specific and go to infinity for joint angles that are close to the limits. Considering that $\mathbf{M}_1(\mathbf{q}) \in S_n^+$, $\tilde{\mathbf{M}}(\mathbf{q}) = \mathbf{M}(\mathbf{q}) + \mathbf{M}_1(\mathbf{q}) \in S_n^+$ is still a valid metric tensor that combines the kinetic energy metric with a joint constraint term. Note that the efficiency inherent to $\mathbf{M}(\mathbf{q})$ is preserved, as the effect of term $\mathbf{M}_1(\mathbf{q})$ is significant only for areas of the manifold close to the joint limits.

The effect of $\mathbf{M}_1(\mathbf{q})$ can be easily exemplified by generating trajectories for the system considered for the experimental study, i.e. the 4-degree-of-freedom (4-DoF) arm model shown in Fig. 1. Trajectory generation between joint configurations is performed by solving the Euler-Lagrange equations derived from the metric, formulating it as a boundary value problem with the two configurations specified as the initial and final boundary conditions, as detailed in [9], [18]. In particular, consider trajectory generation between configuration $\mathbf{q}_0 = [50\ 50\ 15\ -20]^\circ$ and configuration $\mathbf{q}_f = [40\ 2\ -20\ -48]^\circ$, with joint constraints encoded by $\mathbf{q}_m = [0\ 0\ -50\ -50]^\circ$ and $\mathbf{q}_M = [50\ 50\ 20\ 0]^\circ$, which exemplify a reduced range of motion. Using metrics $\mathbf{M}(\mathbf{q})$ (pure kinetic energy) and $\tilde{\mathbf{M}}(\mathbf{q})$ (kinetic energy metric corrected by means of the joint limit metric), one obtains the trajectories shown in Fig. 2. One can see that the simple kinetic-energy metric leads to trajectories violating the imposed range of motion for the elbow (q_4), while the same does not happen when applying the modified metric.

In order to address phase 2 of the bi-level optimization procedure, one needs to select a suitable final configuration, in order to address the redundancy problem. After computing the geodesic path joining $\mathbf{q}_0$ and $\mathbf{q}_f(\boldsymbol{\alpha}) = \mathbf{q}(\boldsymbol{\alpha}; \mathbf{x}_f)$ for each candidate configuration $\mathbf{q}_f$ encoded by parameter $\boldsymbol{\alpha} \in \mathbb{R}^p$, one obtains the family of geodesics $\gamma_{\boldsymbol{\alpha}} : [0, 1] \to Q$. In order to select the optimal candidate among the ones codified by parameter α, we propose a multi-criteria cost with the purpose of achieving a human-like behaviour. To formulate the optimization problem, we first establish the key assumptions and postulates that motivate the structure of the cost function. The first assumption is kinetic energy expenditure minimization, according to an efficiency principle, as also argued in [9]. This is characterized by the term

$$E(\gamma_{\boldsymbol{\alpha}}) = \frac{1}{2}\int_0^1 \mathbf{q}'(\lambda,\boldsymbol{\alpha})^T \tilde{\mathbf{M}}(\lambda,\boldsymbol{\alpha})\mathbf{q}'(\lambda,\boldsymbol{\alpha})d\lambda \tag{4}$$

$$= \frac{1}{2}\Sigma^2(\boldsymbol{\alpha}) \tag{5}$$

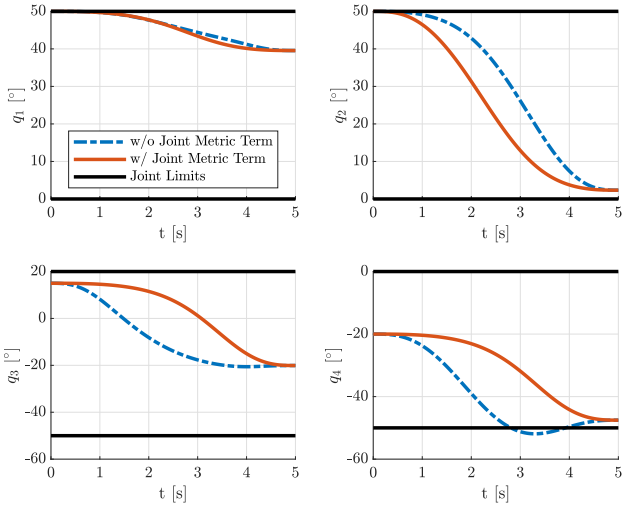

Fig. 2. A trajectory generation example where imposed constraints (black limits) would be violated without the joint constraint metric. Geodesics using $\mathbf{M}(\mathbf{q})$ are dashed blue, and those using $\tilde{\mathbf{M}}(\mathbf{q})$ are orange, shown for joint variables $q_1, \ldots, q_4$.

where $\tilde{\mathbf{M}}(\lambda, \boldsymbol{\alpha})$ is the metric tensor dependent on configuration and redundancy parameters. Along the same lines, we postulate potential energy to influence human motion preferences due to the additional metabolic cost associated with high-energy configurations. The corresponding term in the cost function is

$$U(\gamma_{\boldsymbol{\alpha}}) = U(\mathbf{q}_f(\boldsymbol{\alpha})) \tag{6}$$

where $U(\mathbf{q}_f)$ represents the potential energy of the final joint configuration. The third assumption is the preference for anthropomorphism in human movements, which translates into the tendency to avoid extreme joint angles to maintain comfort and residual mobility, in accordance with the end-state comfort hypothesis [19]. This concept is encapsulated in

$$\mathcal{A}(\gamma_{\boldsymbol{\alpha}}) = \mathcal{A}(\mathbf{q}_f(\boldsymbol{\alpha})) = \left\| \frac{2(\mathbf{q}_f(\boldsymbol{\alpha}) - \bar{\mathbf{q}})}{\mathbf{q}_M - \mathbf{q}_m} \right\| \tag{7}$$

where $\bar{\mathbf{q}} = \frac{\mathbf{q}_M + \mathbf{q}_m}{2}$ is the joint range mean value. Lower values of $\mathcal{A}(\cdot)$ indicate a configuration farther from joint limits, promoting mid-range postures. With these principles in place, the optimization problem is formulated as follows

$$\gamma_{\boldsymbol{\alpha}^*, GEO\text{-}HL} = \arg\min_{\boldsymbol{\alpha}} J_{GEO\text{-}HL}(\gamma_{\boldsymbol{\alpha}}) \tag{8}$$

where the composite cost function $J_{GEO\text{-}HL}$, emphasizing human-like geodesics, integrates the criteria

$$J_{GEO\text{-}HL}(\gamma_{\boldsymbol{\alpha}}) = E(\gamma_{\boldsymbol{\alpha}}) + w_u U(\gamma_{\boldsymbol{\alpha}}) + w_a \mathcal{A}(\gamma_{\boldsymbol{\alpha}}) \tag{9}$$

where w_u and w_a are weight parameters reflecting the relative importance of potential energy and anthropomorphism. These weights need to be tuned based on the kinematic chain under study, and we employ a data-driven approach for calibration, as exemplified for the 4-DoF arm model in experimental trials.

Computational Aspects

Generating trajectories via configuration-based geodesics involves solving a boundary value problem between $\mathbf{q}_0$ and $\mathbf{q}_f(\boldsymbol{\alpha})$ with a numerical solver, alongside optimizing valid final configurations $\mathbf{q}_f(\boldsymbol{\alpha})$. This high computational cost can limit real-time implementation. However, since most robot-assisted rehabilitation tasks require pre-designed trajectories for safety, this cost is usually not a bottleneck. The optimization process can also be made more efficient by seeking suboptimal solutions or reversing the approach—first identifying quasi-optimal end configurations in $\boldsymbol{\alpha}$, then generating fewer geodesics for these configurations.

IV. Experimental Trials: Objectives and Setup

The analysis based on experimental trials has two main objectives: (1) tuning the parameters w_u, w_a in the selection cost from Eq. (9) and (2) comparing existing methods (MJ, IK, GEO) with the proposed GEO-HL approach in terms of human-likeness. This is achieved through error measures evaluated against true recorded trajectories. Trajectory data collection was conducted using the NESM-γ exoskeleton platform [15], [16] in transparent mode, ensuring no external forces acted on subjects. NESM-γ is a powered upper-limb exoskeleton for motor rehabilitation, featuring four active revolute joints driven by series elastic actuators (SEAs) with compact custom-designed hollow springs. Transparent mode operation was maintained through low-level torque controllers applying zero reference torque while compensating for gravity and friction. The passive joints of the exoskeleton were fixed to ensure consistent results across subjects and to focus on the active joints' motions. A board with twelve targets was placed at a fixed distance from the subjects to allow unhindered arm movements. Target (3) was aligned with the robotic shoulder's center of rotation. The experiment was conducted using the right arm, as it was the dominant side for all subjects. Given the mirrored kinematic structure of the upper limbs, data collected from either side is applicable for the study's objectives. The selected tasks consist of predefined motion sequences that explore different joint coordination patterns within the 3D workspace. A distinction is made between tasks, which are considered as structured sets of movements, and individual motions, which correspond to specific trajectory segments between two postures (i.e. a task is generally made up of a sequence of multiple motions). Task subdivision was implemented to facilitate repetition. The evaluation focuses on individual motions (Motions 1-30), as they exhibit distinct acceleration and deceleration phases while targeting specific 3D workspace objectives. We study such motions, as we aim to provide a planning algorithm able to generate human-like trajectories starting from a known joint configuration and ending in a given 3D workspace objective. This can, in turn, be extended to planning composite tasks composed of multiple simple motions by concatenating the planned paths.

The following notation describes the movement postures: R: rest position on the side; K: rest position on the knee; M: mouth; S: contralateral shoulder; (1)-(12): numbered board targets. Fig. 3 illustrates the experimental setup, while Fig. 4 shows the target placements. The selected tasks are:

Participant Information

Seven healthy subjects (4 male, 3 female) with normal limb function participated in the study. Their ages ranged from 25 to 31 years. Two participants had extensive experience with robotics, two had basic knowledge, and the remaining three had little to no prior exposure. All subjects completed the experimental protocol using their dominant right arm.[1]

Experimental Routine

A fixed target board ensured consistency across trials. Each subject repeated all six tasks 10 times, resulting in a total of

[1]The study was approved by the Ethics Committee of Scuola Superiore Sant'Anna (approval n. 18/2024), and experiments were conducted at Schön Klinik (Bad Aibling, Germany), following the principles stated in the Declaration of Helsinki. All participants signed informed consent.

420 task trajectory samples and 2100 motion trajectories[2]. The duration of each experimental session ranged from 30 to 45 minutes, depending on the participant.

V. Data Analysis Setup

For the analysis and comparison of trajectory generation methods, recorded experimental data serves as the ground truth for human likeness levels. Before detailing the analysis and results, we briefly introduce the methods being compared to our proposed approach, along with specifications for the human arm case. We use the swivel angle parametrization to characterize the redundant DoF of the 4DoF arm model [20]. This allows to represent valid joint configurations at a given 3D workspace position as:

$$\mathbf{q}_f(\alpha) = \mathbf{q}(\alpha; \mathbf{x}_f), \alpha \in I(\mathbf{x}_f) \tag{10}$$

where α is the swivel angle, and $I(\mathbf{x}_f) \subseteq \mathbb{R}$ represents the valid swivel angle range for a given 3D end-effector pose, defined by the joint limits. α is a free parameter representing the redundant DoF of the kinematic chain, with the choice of the most suitable final configuration $\mathbf{q}_f(\alpha)$ being part of the optimization process.

We now introduce the methods for comparison. Note that the temporal aspect of planning is excluded from this evaluation, as all trajectories were generated on a normalized time interval.

A. Human-like Geodesics (GEO-HL)

To validate the additional selection criteria in the composite index (9) and compare the proposed method to others, a tuning procedure is performed to find optimal parameters for weighing the components (i.e., w_u, w_a). A grid search is applied, evaluating joint trajectory fit over 66% of the dataset. The training set consists of 20 randomly selected motions from the 30 recorded (see Sec. IV), with the remaining 10 motions used for evaluation. This should provide evidence that the selected model configuration generalizes to motion categories not belonging to the ones covered by the training set.

In particular, as part of the grid search, we tested $w_u \in [0, 0.15]$ and $w_a \in [0, 1.2]$, in order to find the configuration of parameters to be used in the trajectory selection performed with Eq. 9, that guarantees a minimum of the joint fit index under evaluation, i.e.

$$RMSE_{joints} = \sum_{l=1}^{L} \sqrt{\frac{1}{4K} \sum_{j=1}^{K} \sum_{i=1}^{4} (q_i(j) - \hat{q}_i(j))^2} \tag{11}$$

where index $i = 1, ..., 4$ refers to the different joints and index j to the sample. Such index represents the root mean square error over the L tuning trajectories, to be computed as the deviation of the generated trajectory q with respect to the ground truth demonstration $\hat{q}$. We found a minimum to exist for $[\hat{w}_u, \hat{w}_a] \approxeq [0.08, 0.4]$ for the full "training" set, as shown in Fig. 5. The same figure highlights the importance of including additional selection criteria w.r.t. kinetic energy, as the value of total error across the training set significantly

[2]The dataset can be found at https://github.com/TUM-ITR/HuG-MP.git

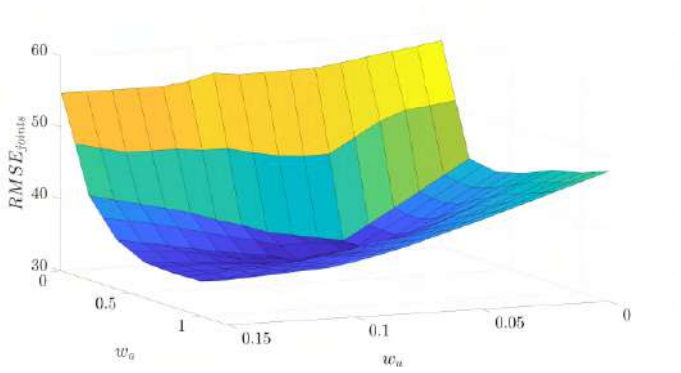

Fig. 5. $RMSE_{joints}$ behaviour as we vary selection parameters w_u, w_a.

decreases as we include both the potential energy and the anthropomorphism criteria. In particular, the anthropomorphism criterion is relevant for reducing the fit error, while the potential energy principle has an effect on the quality of fit, but only when used in combination with the anthropomorphism criterion.

B. Kinetic energy Geodesics (GEO)

We then take the base geodesics method into consideration. In particular, in the case of the human arm model, one has

$$\gamma_{\alpha^*, GEO} = \underset{\alpha \in I(\mathbf{x}_f)}{\arg\min}\, E(\gamma_\alpha) \tag{12}$$

Note that basic kinematic and dynamic parameters are technically required to compute the path kinetic energy $E(\gamma_\alpha)$. We omit a complete sensitivity analysis, but we note that the generated trajectories are mostly sensitive to kinematic parameters (i.e. upper arm and forearm lengths), which were accurately measured, with respect to dynamic parameters (i.e. inertias and masses), which were approximated.

C. Minimum Jerk Trajectories (MJ)

A prime candidate for trajectory generation is represented by the Minimum Jerk (MJ) model. It is one of the leading models in terms of representing the kinematics of human trajectories, originally introduced in [10], and then often exploited for trajectory planning for upper-limb exoskeletons [5], [21]. In particular, it is possible to compute the family of MJ trajectories ($\gamma_{\alpha,MJ} : [0, T] \rightarrow Q$) joining $\mathbf{q}_0$ and $\mathbf{q}_f(\alpha) = \mathbf{q}(\alpha; \mathbf{x}_f)$, $\alpha \in I(\mathbf{x}_f)$ (i.e. for each admissable final configuration). It is then straightforward to choose the global MJ solution as:

$$\gamma_{\alpha^*, MJ} = \underset{\alpha \in I(\mathbf{x}_f)}{\arg\min}\, J_{MJ}(\gamma_{\alpha,MJ})$$

where the cost function is the integral of the squared jerk across each candidate trajectory:

$$J_{MJ}(\gamma_{\alpha,MJ}) = \sum_{i=1}^{4} \int_{t_0}^{t_f} \left(\frac{d^3 q_i(\lambda)}{d\lambda^3}(\alpha) \right)^2$$

D. Inverse Kinematics-based Trajectories (IK)

We then considered trajectory generation based on the direct solution of the inverse kinematics problem. Advantages of the method are often related to the computational efficiency, as it does not consider the full spectrum of valid final configurations. Hence, the method remains a popular choice for trajectory generation in the context of upper-limb exoskeletons [22]. In our implementation, we first solve a generalized Inverse Kinematics problem for the final 3D objective, including the joint limits as constraints and the initial configuration $\mathbf{q}_0$ as an initial guess for the solver:

$$\mathbf{q}_f = gik(\mathbf{x}_f, \mathbf{q}_0, \mathbf{q}_m, \mathbf{q}_M) \tag{13}$$

The problem is solved by means of the MATLAB Robotic System Toolbox, exploiting the Broyden-Fletcher-Goldfarb-Shanno (BFGS) gradient projection algorithm. This is a basic approach to select the final configuration, as it just finds an objective-compliant configuration $\mathbf{q}_f(\alpha)$ that is close to the initial configuration $\mathbf{q}_0$, without additional criteria that relate to motion analysis. We then generate the full joint trajectories as cubic polynomial interpolants between configurations $\mathbf{q}_0$ and $\mathbf{q}_f$, similarly to what is done in [22], as to guarantee null initial and final velocities, in addition to a smooth behavior. This approach can be seen as providing a base performance for the task, since it achieves the desired objective with minimal joint variation and a reasonable velocity profile, but without exploiting any human-related optimization criteria.

E. Evaluation Setup and KPIs

We next proceed with a thorough evaluation of the postulated model on the motions not yet taken into consideration for tuning. We then compare its results with respect to those provided by competing methods. This evaluation data comprises 34% of the dataset, i.e. 700 trajectory samples across 7 subjects and 10 motion types[3]. This evaluation guarantees a fair comparison between the methods, and shows that the selected parameters in the tuning step generalize to motions not yet evaluated. The performance metrics used for comparison are summarized as follows:

1) Error at the Joint Level ($RMSE_{joints}$): The first and most relevant criterion is related to the accuracy attained by the methods at the joint level. This is because it best represents the human likeness of the generated trajectories, as they encode the coordination dynamics, which are not visible at the end-effector (hand) level. The evaluation criterion is mathematically defined as in Eq. 11.

2) Error of Final Configuration ($RMSE_{\mathbf{q}_f}$): Another relevant index is given by the root mean square error on the final configurations $\mathbf{q}_f$ attained for each motion, i.e. when subjects pause in order to perform the subsequent motion in the task sequence. The metric is expressed by:

$$RMSE_{\mathbf{q}_f} = \sqrt{\frac{1}{4}\sum_{i=1}^{4}(q_{f,i} - \hat{q}_{f,i})^2} \tag{14}$$

[3]Motions 2, 12, 14, 16, 21, 22, 24, 25, 26, 30 from Sec. IV

where i refers to the joint indexes 1 to 4.
This index is a direct measure of whether the generated trajectory mirrors the intention of the subject, as it approaches the workspace objective with a comparable configuration.

3) End-Effector Error (e_h): We finally consider the average end-effector error. The index is formulated as:

$$e_h = \frac{1}{K}\sum_{j=1}^{K}||x_h(j) - \hat{x}_h(j)||^2 \tag{15}$$

namely as the average euclidean distance between the predicted and true hand position across the whole trajectory.

VI. Results and Discussion

The presented approaches are copared by evaluating the accuracy they provide with respect to the ground truth trajectories (i.e. the experimental trials) in terms of a set of metrics. To test statistical significance, paired Wilcoxon signed-rank tests were employed, contrasting our proposed method GEO-HL against each one of the comparison approaches. The attained p-value is specified for each test.

Table I includes the $RMSE_{joints}$ values attained by the proposed methods (GEO-HL, GEO, MJ, IK) over the evaluation dataset, categorized by motion type. For each motion, we present the average performance and standard deviation of the $RMSE_{joints}$ index, in addition to the percentage improvement (or degradation) of the proposed approach GEO-HL with respect to the competing ones. One observes that our proposed method generally outperforms all other approaches, underperforming only for Motion 14 (bottom-up motion on the board). It should be noted that the standard deviation of the performance index for this motion is generally high across all methods under analysis, suggesting that Motion 14 is poorly repeatable and exhibits joint coordination dynamics that are difficult to model. This indicates the general validity of the method when it comes to reproducing human-like motions (which can be analysed at the joint level) and highlights how the GEO-HL provides a satisfactory performance on human motions not pertaining to the pointing class. Regarding this point, one can see that the GEO method performs adequately when it comes to motions belonging to the pointing class (i.e. 16, 21, 25), with a comparable performance to GEO-HL, which confirms the findings of [9]. Conversely, performance of base GEO downgrades for motions belonging to other classes, proving that the augmentation of the selection criteria done for GEO-HL was necessary in order to extend the applicability of the geodesics method in the context of human-like motion generation. Table II includes the $RMSE_{joints}$ index results in terms of subjects (1-7). One can observe how GEO-HL improves on the other methods for each of the subjects under consideration. When it comes to the full dataset, without any motion or subject distinction, GEO-HL attains an average value of $RMSE_{joints} = 0.123$ rad, which is a significant improvement over the base GEO method (-55.4%), but also with respect to both the MJ method (-23.03%) and the IK one (-26.25%). We provide a comprehensive performance overview of the methods on the evaluation dataset through

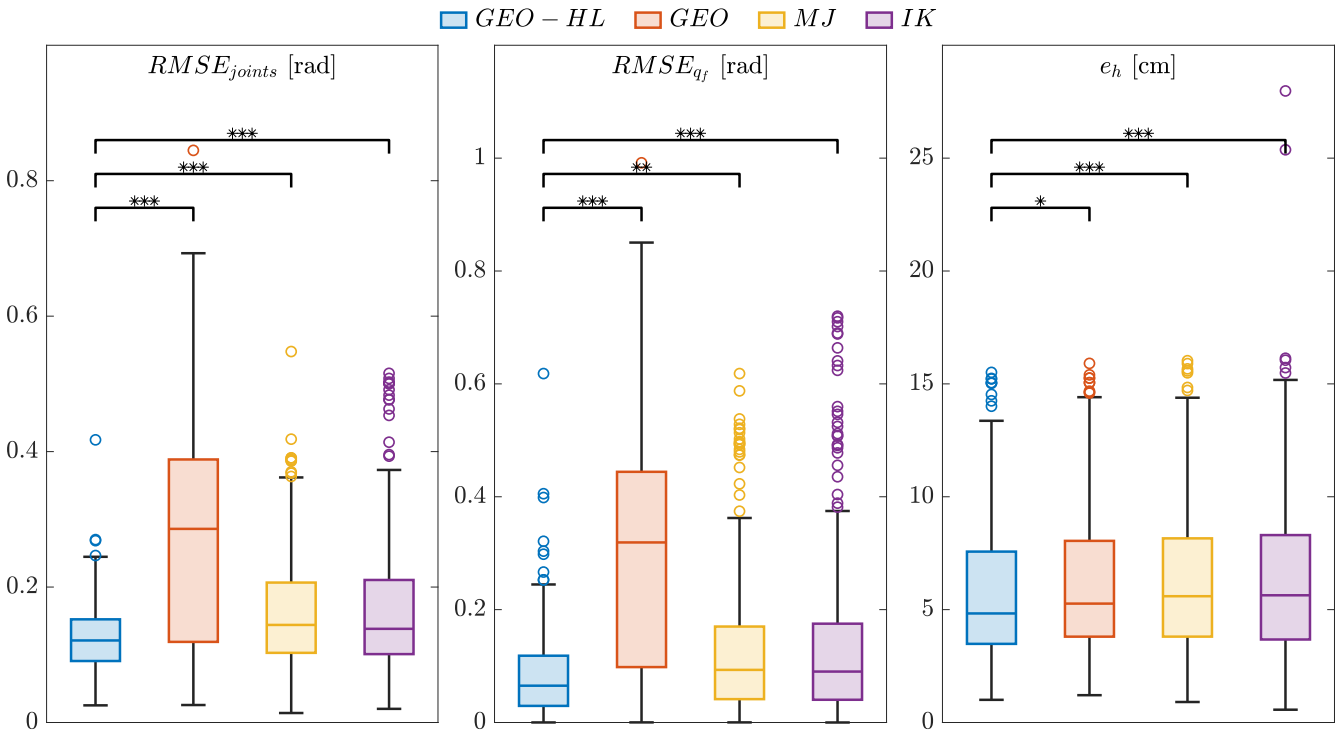

Fig. 6. Boxplots of the performance indexes attained by the GEO-HL (blue), GEO (orange), MJ (yellow), IK (purple) approaches across the whole evaluation dataset. On the left we present the boxplots for the $RMSE_{joints}$ index, representative of the error at the joint level; in the central panel we show the $RMSE_{q_f}$ results, indicating the final configuration error; the right panel includes the results for e_h, i.e. the end-effector error index. The p-value attained in the pair-wise Wilcoxon tests is shown according to the asterisk notation: * for $p < 0.05$, ** for $p < 0.01$, *** for $p < 0.001$.

the summary in Table III and the boxplots in Fig. 6 (left panel). They highlight the superior performance of GEO-HL across the entire dataset. The pairwise tests confirmed the statistical significance of the increase in performance of GEO-HL, with p-values of $p < 0.001$ in the comparisons against GEO, MJ and IK. Notably, GEO-HL exhibits a generally lower number of outlier trajectories that the method fails to represent accurately—compared to the other methods under consideration. This observation underscores the robustness and consistency of GEO-HL in capturing the underlying patterns of different motion types and subjects at the joint level.

When it comes to the end-configuration error ($RMSE_{\mathbf{q}_f}$, Fig. 6, central panel), our method GEO-HL showed significant improvement with respect to the other methods, improving on average on the base GEO method by -72.7% , and by -33.3%, and -39.0% over the competing approaches MJ and IK, respectively (see Table III). The improvement in performance is attested by the pairwise tests, with p-values of $p < 0.001$, $p < 0.01$, $p < 0.001$ against GEO, MJ and IK respectively.

Fig. 6 (right panel) reports the end-effector error distributions (e_h) achieved by the different methods, shown in the form of the associated boxplots, while Table III shows the average values obtained. Our method GEO-HL showed significant improvements with respect to the competing methods. In particular, GEO-HL achieved an average workspace error of 5.76 cm, which is a -6.9% improvement over GEO ($p < 0.05$), and a -7.0% ($p < 0.001$) and a -8.7% ($p < 0.001$) improvement against MJ and IK respectively. This metric is relevant for assessing the accuracy of motion in the workspace and the successful completion of tasks, as some studies suggest that movement is initially planned in the hand space (end-effector space) [23]. While it offers valuable insights into the overall correctness of the trajectory and is a common criterion for evaluating trajectory generation methods, end-effector error alone does not capture joint coordination, which is essential for achieving human-like motion, especially in rehabilitation

		-6.9%	-7.0%	-8.7%

contexts [24]. In summary, results show that our method generally achieves lower end-effector errors than the other methods, and does so while better encoding joint coordination, as demonstrated by its low $RMSE_{joints}$ and low $RMSE_{\mathbf{q}_f}$ values.

VII. CONCLUSIONS AND FUTURE WORK

In this study, we addressed the challenge of generating target-oriented human-like trajectories proposing a modified geodesics-based motion planning method. Our method was shown to excel at replicating the natural characteristics of human motion while combining motor efficiency with flexibility. The method is particularly well-suited for scenarios requiring constraints such as rehabilitation-oriented restrictions or adaptations to pathological conditions, ensuring that the generated trajectories remain both functional and human-like. Moreover, this method further improves the ability to capture the coordination typical of human movement. To validate its capabilities, we compared our method's performance against other popular methods and the standard implementation of geodesic trajectories using real-life human arm motion data. Our results showed that the proposed method not only achieved superior accuracy but also demonstrated an enhanced ability to replicate human-like motion patterns. Future research will explore higher-DoF models, advanced metric learning, and real-time exoskeleton testing for assistance.

Design of an Active Sling-Suspension Robot for Adaptive Gravity Compensation of the Upper Limbs

Rodrigo Mendez[1], Aine Grady[1], Peter Snow[1], Rui Loureiro[1]

***Abstract*— This paper presents the design, prototyping, and preliminary evaluation of a novel active sling-suspension robot for gravity compensation of the upper limbs, developed for rehabilitation and assistive applications. The robot features a modular, scalable design with low inertia, achieved through a compact structure and optimized weight distribution. An admittance controller and a proportional controller were implemented to ensure effective gravity compensation and precise arm movement tracking, providing an always normal pulling force.**

Preliminary experimental results performing pick-and-place tasks demonstrated effective winch cable tension tracking while maintaining accurate position tracking with minimal error.

I. INTRODUCTION

Upper limb motor rehabilitation and assistance are critical for individuals with motor impairments, such as those resulting from stroke, spinal cord injuries (SCI), or neuromuscular diseases. These conditions can lead to significant functional limitations, including muscle weakness, impaired coordination, and reduced range of motion, which hinder the performance of everyday tasks [1]. For individuals affected by such impairments, regaining the ability to move and control their arms is essential for restoring independence in Activities of Daily Living (ADLs), such as eating, dressing, and personal hygiene [2]. Without effective rehabilitation, these motor deficits can result in long-term disability, decreased quality of life, and increased dependence on caregivers. Therefore, targeted interventions are vital not only for promoting physical recovery but also for enhancing patients' psychological well-being and overall quality of life [3].

Rehabilitation robotics has emerged as a promising approach to support upper limb motor recovery in patients with impaired mobility. By integrating robotics with therapeutic exercises, these systems can deliver consistent, intensive, and personalized rehabilitation sessions [4]. Unlike traditional manual therapy, robotic devices provide precise control over movement patterns, adjustable levels of assistance, and real-time feedback, enabling more engaging and interactive therapies [1].

During the delivery of robot-assisted rehabilitation for the upper limbs, gravity compensation, also referred to as weight support or antigravity assistance, is a common yet essential feature. Its primary purpose is to offset the torque generated by the weight of the impaired arm without interfering with the participant's natural movement patterns [5]. By reducing the muscular effort required to lift the limb, gravity compensation allows patients to focus on functional movement, thereby increasing the number of repetitions and enhancing Range of Motion (ROM) during therapy, which aids in the recovery of motor control [6].

Currently, there are various types of devices capable of providing gravity compensation, ranging from simple passive end-effector systems to sophisticated active exoskeletons. Passive devices primarily consist of mechanical systems that provide static balance through counterweights, springs, cams, or rubber bands [7]. Their main advantages include being lightweight, having low inertia, and utilizing low-cost materials, as these systems do not require actuators. However, most passive systems have a limited workspace, and the level of support they provide can only be adjusted manually, if at all [8].

In contrast, active devices are typically electromechanically actuated systems. Although these devices are more expensive, complex, and bulkier than passive ones, their advantages are considerable. For instance, active systems can automatically estimate the required level of support and adjust it in real-time. This capability is essential because the torque generated by the weight of the arm changes depending on its position. Without this adaptability, there is a risk of providing either excessive or insufficient support to the limb [9], [10].

In addition, sling-suspension devices are commonly designed specifically to provide gravity compensation and can be used either on their own or in combination with end-effector robots to offer an additional point of support for the arm's weight [11]. These systems are generally simpler than conventional end-effector robots and exoskeletons, as they primarily provide pulling forces. Despite this limitation, their simplicity makes them a more accessible and cost-effective alternative. However, most sling systems offer a fixed level of support that must be calibrated in advance, as seen in devices like the Dynamic Arm Support Sling FOCAL and the Helparm. This fixed support can lead to over- or under-compensation when the arm moves. Additionally, because the suspension cable is anchored to a fixed point, it may generate unwanted horizontal forces during arm movements [12].

The aim of this study is to present the design and proof-of-concept of a novel active sling-suspension robot for gravity compensation of the upper limbs. This device is designed to

follow the movement of the arm, continuously providing a normal pulling force and automatically adjusting the level of support as needed, all while minimizing inertia and complexity to preserve the key advantages of sling-suspension systems. The electromechanical and control system design of the first prototype will be detailed. Finally, a preliminary evaluation with a user performing pick-and-place tasks will be analyzed and discussed, providing insights for potential future work.

II. DESIGN CRITERIA AND CONCEPTUAL MODEL

The design of the active sling-suspension robot was driven by the goal of developing an engaging and interactive rehabilitation device that overcomes the main drawbacks of traditional sling-suspension systems, while minimizing the additional inertia and complexity typically associated with the integration of actuators. The following design criteria were established to achieve this goal and to ensure that the device meets functional and practical requirements of both clinicians and users,

- Adaptive Gravity Compensation: To avoid over- or under-compensation and provide interactive therapy, the system must deliver real-time adaptive support that adjusts based on the user's arm position, movement, or other desired rules.
- Minimal horizontal pulling force: The system must be able to follow the movement of the arm to continuously provide a normal pulling force.
- Modularity and scalability: The robot's design should be modular and scalable, allowing for easy adjustments, upgrades, and accommodations for diverse usage scenarios.
- Lightweight and low inertia: One of the primary objectives is to minimize the overall weight and inertia of the system for safety and feasibility reasons.
- Simplicity and cost-effectiveness: The design prioritizes simplicity to reduce manufacturing costs and improve accessibility.

Portability and ease of installation are not current priorities but will be considered in future iterations to facilitate use in various clinical environments or even at home.

After iterative design and testing, a novel concept was selected. The proposed design features a two-axis structure: a vertical rotational axis integrated with a horizontal axis, as depicted in Fig. 1. In addition to enabling rotational movement of the horizontal axis, the vertical axis is designed for easy integration into various use-case scenarios, such as use with a wheelchair, in sitting or standing positions, by the bedside, and more. The horizontal axis controls both the rotational and translational movements of a winch housed within it, but without mobile actuators. Instead, the actuators are placed and fixed on the vertical axis to minimize the device's overall inertia.

Thus, by combining the rotational movement of the vertical axis, and the translational and rotational movement of the winch in the horizontal axis, it is possible to provide an adaptive gravity compensation with a normal pulling force.

III. PROTOTYPE DESIGN

The testing and development of the proposed concept is divided into two main stages: the first focuses on the design and prototyping of the horizontal axis, while the second involves the design, prototyping, and integration of the vertical axis. This paper is focused on the first stage.

For the prototyping of the horizontal axis, the following requirements were considered:

- The device must support a load of up to 5 kg, which represents the weight of the arm for over 75% of the world's population following the World Health Organization data, resulting in a final design load of $F_L = 50$ N.
- The device must achieve a vertical (cable movement) and horizontal (winch translation along the horizontal axis) speed of 1 m/s, aligning with the capabilities of commercially available rehabilitation robots, such as the HapticMaster.
- The horizontal axis must have a length of 50 cm to accommodate tracking the arm during various ADLs.
- To facilitate rapid prototyping and cost reduction, commercially available, low-cost components and equipment are considered.

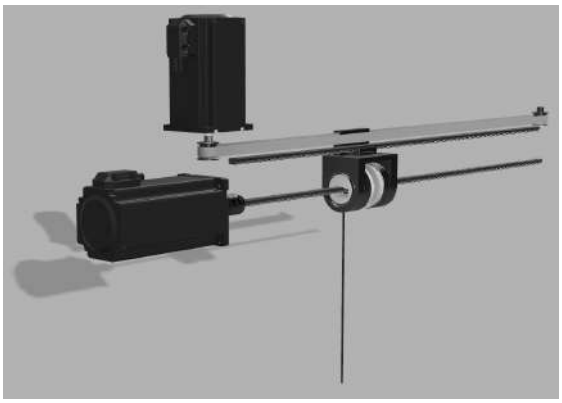

Fig. 2: The horizontal axis concept consists of a horizontally mounted motor with an extended shaft to control the rotational movement of the winch and a vertically mounted motor to drive the linear belt-driven mechanism.

A. Electromechanical Design

After iterative design and testing of the horizontal axis, the chosen mechanism utilizes a linear belt-driven actuator anchored to the winch to control its translational movement along the horizontal axis, and a motor with an extended shaft to control its rotational movement, thereby regulating the cable pulling force. The shaft must permit the translational movement of the winch along it while minimizing clearance between the shaft and the winch to ensure effective control of its rotation. Fig. 2 illustrates this concept.

1) Motor-winch mechanism: To size the motor $M1$ controlling the rotational movement of the winch, it is necessary first to design the diameter of the winch, which must integrate with the extended shaft. For rapid prototyping, a stainless-steel linear rail and carriage are used instead of manufacturing the extended shaft. The linear rail is coupled to the motor shaft, while the carriage is anchored to the 3D-printed winch. Fig. 3 summarize the main characteristics of the linear rail and carriage. The winch is designed with a diameter of 30 *mm*, considering the linear rail, carriage, and standard bearing dimensions, representing the most compact viable option.

Given the diameter of the winch, it is possible to verify that the carriage can support the defined maximum load F_L and appropriately size the motor.

Considering that the suspension robot must move the cable vertically at a speed of 1 *m/s*, this translates to the maximum required rotational speed for the motor,

$$\omega_{M1} = \frac{v_v}{r_w} \approx 640 \ [rpm] \tag{1}$$

where ω_{M1} represents the rotational speed of the motor $M1$ which controls the rotational movement of the winch, v_v represents the maximum vertical speed defined as 1 *m/s*, and r_w the radius of the winch designed as 15 *mm*.

With the winch's diameter, it is now possible to calculate the load torque,

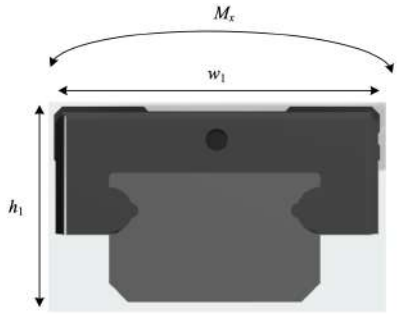

Fig. 3: Linear rail and carriage main characteristics: overall height $h_1 = 10$ *mm*, overall width $w_1 = 20$ *mm*, and maximum torsional torque allowed $M_x = 18.2$ *Nm*.

$$\tau_{M1_L} = r_w \cdot F_{M1_L} = 0.75 \ [Nm] \tag{2}$$

where τ_{M1_L} represents the load torque of $M1$, and F_{M1_L} its maximum load which is equal to F_L.

Considering the calculated speed and load torque, a stepper motor was chosen for this task, as these motors are generally more affordable and compact compared to others that provide the same speed and torque. Consequently, the acceleration torque is the only remaining variable needed to size the stepper motor, which can be approximated as,

$$\tau_{M1_a} = J_{M1_L} \cdot \frac{\pi}{30} \cdot \frac{\Delta\omega_{M1}}{\Delta t} \tag{3}$$

where τ_{M1_a} is the acceleration torque of $M1$, J_{M1_L} is the total inertia, $\Delta\omega_{M1}$ is equal to ω_{M1} in this case, and Δt is defined as 0.5 *s*.

The total inertia is calculated as follow,

$$J_{M1_L} = J_s + J_w \tag{4}$$

where J_s is the extended shaft inertia, approximated as a cuboid, and J_w is the winch inertia, which includes the load mass and is approximated as a hollow disc. The motor shaft and bearings inertia are neglected due to their small values compared to the total inertia.

The required torque, τ_{M1}, is calculated as the sum of the load torque, τ_{M1_L}, and the acceleration torque, τ_{M1_a}. Finally, the stepper motor $M1$ is selected to ensure it can provide the required torque τ_{M1} at the necessary speed, ω_{M1}. A Nema 24 stepper motor was chosen for this task.

2) Linear belt-driven actuator: To size stepper motor $M2$, which controls the translational movement of the winch, a conventional design of a linear belt-driven actuator is used, taking into account the defined load and the 3D-printed

TABLE I: Motor sizing summary. $M1$ controls the rotational movement of the winch, and $M2$ the belt-driven linear actuator.

Motor	Required speed ω (*rpm*)	Required torque τ (*Nm*)
$M1$	640	0.83
$M2$	477	0.11

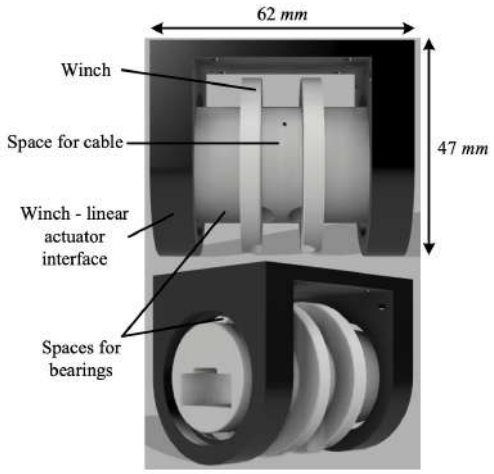

Fig. 4: Illustration of the winch and winch - linear actuator interface. This interface is the mechanism that enables the independent control of both the translational and rotational movements of the winch.

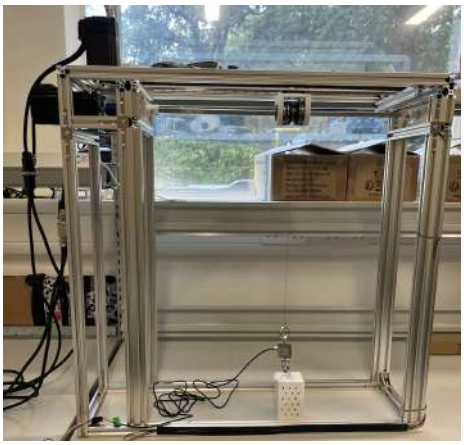

Fig. 5: The horizontal axis prototype is mounted on an aluminum profile frame for testing. It offers an approximate workspace of 500 *mm* horizontally and 590 *mm* vertically. The cable is connected to a weight for initial experiments.

interface depicted in Fig. 4, which anchors the winch to a linear rail and carriage mechanism.

To determine the required speed and torque, the belt and pulleys must be designed first. A GT3 timing belt with matching 20 mm diameter pulleys, one driving and one driven, are selected.

Based on the pulley diameter, the required speed is calculated as follows,

$$\omega_{M2} = \frac{v_h}{r_p} \approx 477 \ [rpm] \tag{5}$$

where ω_{M2} represents the required speed of motor $M2$, Mv_h the maximum horizontal speed defined as 1 m/s, and r_p the radius of the pulley.

The load and acceleration torques are approximated following the same approach presented for $M1$.

Finally, the stepper motor $M2$ is selected to ensure that it can provide the required torque at the necessary speed presented in Table I. A Nema 23 stepper motor was chosen for this task.

For testing purposes, the horizontal axis prototype is mounted on an aluminum profile frame, providing an approximate workspace of 500 mm horizontally and 590 mm vertically. Fig. 5 shows the implementation.

3) Sensors:

- A BNO055 absolute orientation sensor is placed at the end of the winch cable to track cable deviation and, consequently, arm movement.
- An S-beam load cell is integrated into the winch cable to measure tension.
- In addition, an optical encoder is used to monitor the rotational movement of the winch. For safety purposes, an ultrasonic sensor, limit switches, and an emergency stop are also included.

B. Control System Design

Initially, two independent closed-loop control systems were designed: one to track arm movement using the linear belt-driven actuator, and the other to control gravity compensation through the motor-winch mechanism.

1) Horizontal position control: Using the absolute orientation sensor, a conventional proportional control strategy is implemented with a cable deviation reference set to zero, where the control action determines the speed of the motor $M2$ driving the belt-driven mechanism.

2) Gravity compensation control: A conventional admittance controller without virtual stiffness is chosen to control the level of support provided. A gravity compensation estimator calculates the force reference, which can be adjusted based on arm position and other potential parameters, such as joint stiffness or challenge level. The integrated load cell in the cable is used to monitor its tension and close the control loop, while the controller generates a speed reference for the motor $M1$.

Fig. 6 illustrates the closed-loops and architecture of the control system, implemented using a master-slave architecture, with an Arduino Mega 2560 as the master controller and a second Arduino Mega 2560 as the slave to control the motors. The sampling frequency of the system is approximately 90 Hz, limited by the clock speed of the load cell voltage amplifier.

IV. PRELIMINARY EXPERIMENTAL RESULTS

To initially tune the controllers and assess the performance of the prototype, the winch was connected to a known 1 *kg* weight, nonetheless, this experiment is not intended to assess the biomechanical implications of using the device. The admittance and position controllers were empirically tuned based on the design criteria mentioned above, using a fixed gravity compensation reference. The goal was to maximize the speed response without introducing jerkiness, ensuring

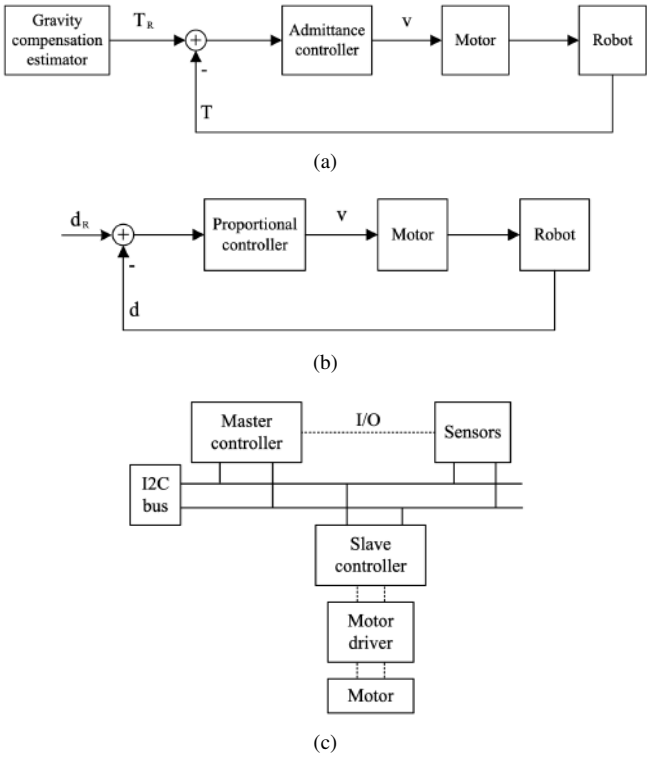

Fig. 6: Control system; gravity compensation (a) and horizontal position (b) control loops, where T represents the winch cable tension, d cable deviation angle, v control action, and the subscript R reference. (c) represents the control architecture.

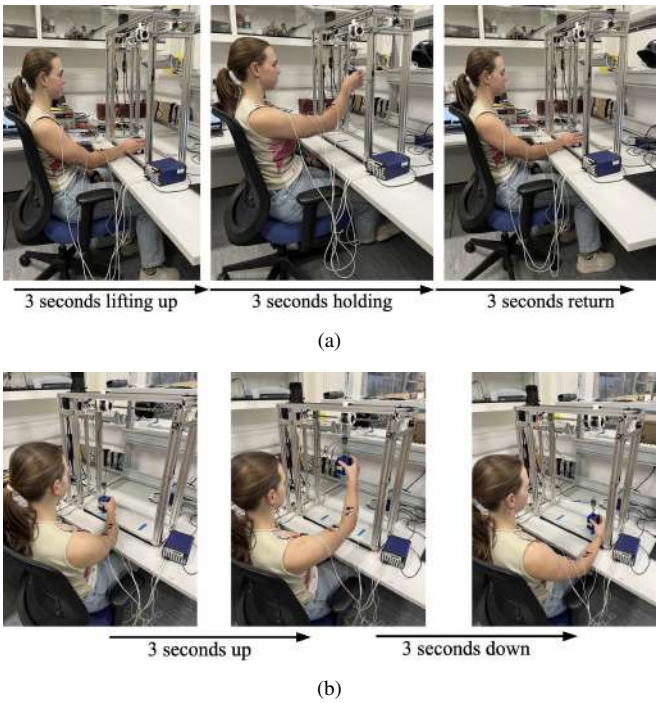

Fig. 7: Experimental setup for tuning and testing the controllers while the user performs pick-and-place tasks: (a) Task 1: describing an only vertical trajectory, and (b) Task 2: describing a parabolic trajectory.

comfort and safety. Subsequently, the device was tested with two different pick-and-place tasks, both with and without gravity compensation, while the user moved the weight at a fixed speed while seated in a fixed natural position, holding the weight with a fixed neutral hand angle. This setup simulated activities of daily living (ADLs) while maintaining consistent biomechanical conditions. One task involved only vertical movement to test the gravity compensation control, while the other followed a parabolic trajectory to test both gravity compensation and position control simultaneously,

- Task 1: the user lifted the weight vertically from the desk to the level of her nose in 3 seconds, held it there for 3 seconds, and returned it to the desk in 3 seconds.
- Task 2: the user lifted the weight from the desk to the level of her nose and returned it to the desk in 6 seconds, describing a parabolic trajectory similar to a pick-and-place task.

In addition to the control variables; cable tension and deviation angle, EMG data from the main muscles involved in the tasks [13]; anterior deltoid, biceps brachii, and brachioradialis, were recorded following SENIAM placement recommendations to provide additional insight about the control performance. Surface bipolar electrodes were used with a sampling rate of 512 Hz, collected using a TMSi Porti7 system. The data were processed as follows: high-pass filtered using a fourth-order 25 Hz Butterworth filter, filtered using a 50 Hz Notch filter, rectified, and low-pass filtered using a fourth-order 2 Hz Butterworth filter. Finally, all EMG data were normalized to maximum voluntary isometric contractions (MVC) [14].

Fig. 7 illustrates the setup of the experimental tests, while Table II and Fig. 8 present the results obtained, from which the following observations can be made,

- The admittance controller follows the reference with a Mean Square Error (MSE) of 0.08% and 0.13% for task 1 and task 2, respectively.
- The position controller tracks the reference with MSE of 0.14% for task 2. The peaks illustrate the effect of implementing a deadband and proportional controller. As expected, position tracking is not required for task 1.
- In both tasks, gravity compensation reduces the activation of all three muscles. Based on RMS values, gravity compensation decreases muscle activation by an average

TABLE II: RMS values of normalized EMG signals from the anterior deltoid (AD), biceps brachii (BB), and brachioradialis (BR) muscles during both tasks.

	Gravity Compensation	RMS Task 1	RMS Task 2
AD	No	16.6%	12.8%
	Yes	8.1%	8.1%
BB	No	4.0%	4.6%
	Yes	2.1%	2.9%
BR	No	6.4%	4.0%
	Yes	1.0%	1.2%

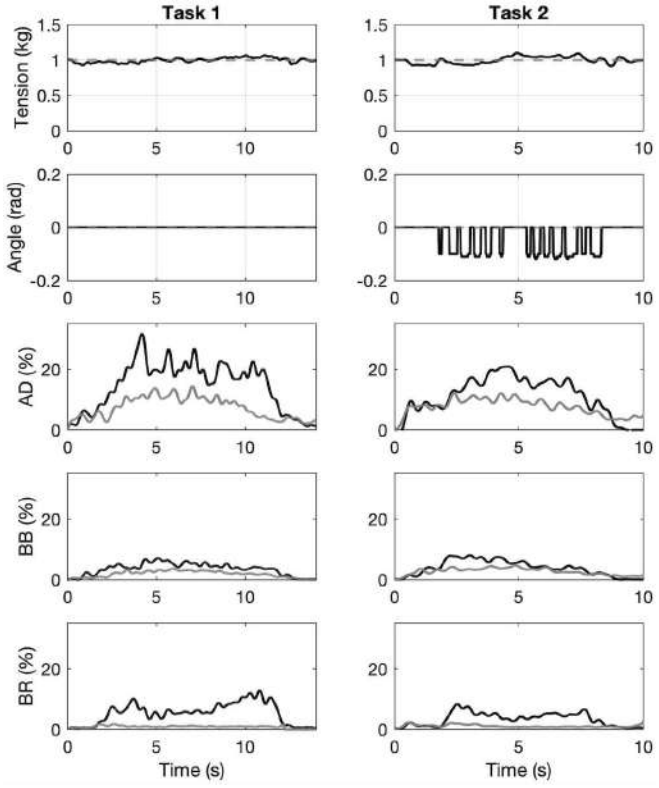

Fig. 8: Experimental results. The first and second rows show the performance of the admittance and position controllers respectively, where the dashed line indicates the reference. The third, fourth, and fifth rows display the normalized EMG data for the anterior deltoid (AD), biceps brachii (BB), and brachioradialis (BR) muscles, respectively. The black line represents the scenario without gravity compensation, while the gray line represents the scenario with gravity compensation..

of 44% for the AD, 42% for the BB, and 77% for the BR across both tasks.

This research was conducted with ethical approval from the UCL Research Ethics Committee (REC) under project ID number 6676/007, and all participants provided informed consent.

V. CONCLUSIONS

The design, prototyping, and initial experimental results of a novel active sling-suspension robot for gravity compensation of the upper limbs have been presented. The proposed concept is modular, scalable, and features low inertia, achieved through its compact design and optimized weight distribution. The flexibility of this concept enables the exploration and implementation of various gravity compensation approaches. For example, it facilitates the evaluation of fixed versus adaptive support and the comparison of providing support from a fixed position versus maintaining an always normal pulling force, unlike conventional sling-suspension devices.

While a comprehensive validation and usability studies are necessary to draw definitive conclusions, the experimental results provide initial insights into the effectiveness of this novel device. The results demonstrate that the robot effectively tracks the desired tension of the winch cable which significantly reduces anterior deltoid, biceps brachii, and brachioradialis muscles activation, while simultaneously providing an always normal pulling force following the arm's movement through monitoring the winch cable's deviation angle.

Future efforts will focus on conducting a validation and usability studies, performing an exhaustive control study, completing the design and integration of the vertical axis, and developing a VR environment to create a more engaging system.

***Abstract*—During physical Human-Robot Interaction (pHRI) for limb mobilization, humans and robots may contribute simultaneously to motion. Some Assist-As-Needed (AAN) strategies rely on models, while others are purely reactive. This paper presents a reactive AAN control for an end-effector robot in upper limb rehabilitation that weights commands dynamically based on local performance. Volunteers in tests followed a planar circular trajectory with visual feedback. Statistical analysis confirms that assistance is provided as needed, balancing performance across users and hands. Additionally, global metrics —including completion time, tracking errors, force, and disagreement— improve compared to standalone trajectories.**

***Index Terms*—Physical Human-Robot Interaction (pHRI), Reactive Shared Control, Adaptive Performance Weighting, Human-in-the-loop, collaborative robotics**

I. Introduction

Assistive robots can aid in the recovery from musculoskeletal and neurological conditions and support early mobilization after injury [1]. By operating more frequently than traditional care and continuously monitoring performance, they can better adapt treatment to patient needs. These robots fall into two main categories: wearables/exoskeletons and end-effector (EE) devices, both widely studied. EE devices assist users in developing motor skills and recovering limb function by constraining trajectory and/or force through repetitive maneuvers. All these systems require physical Human-Robot Interaction (pHRI), demanding careful mechanical design and control strategies since both human and robot contribute to motion. Ignoring human intent may reduce engagement and lead to physical harm. Excessive assistance may also hinder rehabilitation, as minimizing robotic intervention in patients with residual limb control enhances neural plasticity [2].

Shared Control (SC) strategies regulate autonomy levels, adjusting robot and human contributions dynamically [3]. Assist-As-Needed (AAN) controllers minimize assistance to maximize user engagement [4]. In structured tasks with clear targets, state-based models can be used [5], while other approaches assign user skill levels and adjust assistance accordingly [6]. Alternatively, linear blending (LB) of user and robot commands [7] in the absence of user models remains a popular choice. LB arbitration can also adapt reactively based on feedback errors [8].

This work presents an LB-based SC system for a robotic arm with a gripper for human limb mobilization, requiring i) a velocity-controlled manipulator with force sensing and ii) a compliant yet firm gripper. We implement this using a Franka arm equipped with the gripper in [9]. The system assists users in following a predefined path, a task common in Repetitive Task Training (RTT) [10], Mobilization with Movement (MWM) [11], and Occupational Therapy [12]. Human commands, extracted from interaction forces, are blended with robot commands to move toward the goal. Both contributions are continuously weighted by local performance, adapting assistance in real time.

Many AAN controllers focus on minimizing tracking errors [13]. Impedance-based AAN approaches [14], [15] introduce a torque-free region around the reference trajectory and corrective tangential forces [16], [17]. Instead, our AAN controller prioritizes progressive performance improvement over strict error minimization. Though tested only on healthy volunteers, results indicate reduced robot intervention and lower human resistance to assistance.

Section II in this paper presents the framework. Section III details the experiments and results, discussed in Section IV. Conclusions are summarized in Section V.

II. Shared Control Framework

A. Framework Overview

In a SC system, the command signal h is often a linear combination of human (u_h) and robot control (u_a) signals, weighted by α:

$$h(u_h, u_a) = \alpha u_h + (1-\alpha)u_a, \quad 0 \leq \alpha \leq 1. \tag{1}$$

In the proposed framework, h results from a weighted combination of u_h and the robot controller (u_r), further modulated by an overall performance factor η_s (Figure 1). The human and robot contributions are weighted based on their respective performances (η_h, η_r) in the given task.

The system employs a torque-sensitive robotic arm with a full dynamic model to compute external Cartesian forces $\boldsymbol{f}$ at its end-effector (EE). Many modern manipulators

This work has been funded by the "Agencia Estatal de Investigación" under project PID2021–127221OB-I00.

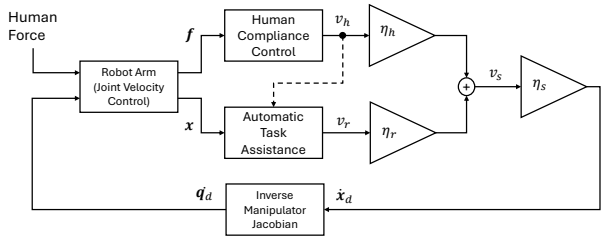

Figure 1: Block diagram of the proposed SC framework.

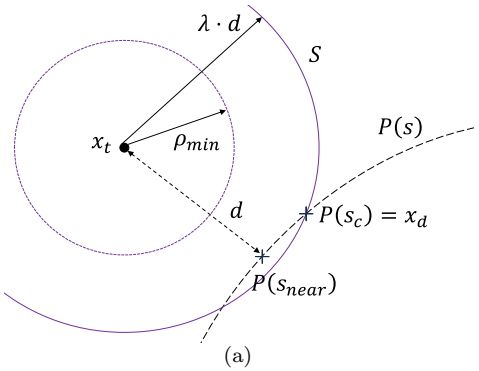
(e.g., Franka Research 3) offer this capability in real-time. Performance values $\eta(t)$ are computed based on how effectively human and robot commands contribute to achieving the goal [18].

B. Human Compliance Control

The estimated human-applied force $\boldsymbol{f}$ at the EE is used in a compliance model to regulate impedance during motion. This is implemented via an admittance model, as in (2), providing specific inertia and viscosity in Cartesian space:



$$\boldsymbol{V}_h(s) = \frac{\boldsymbol{F}(s)}{\boldsymbol{M}s + \boldsymbol{B}} \tag{2}$$

where $\boldsymbol{M}, \boldsymbol{B} \in \mathbb{R}^{3\times3}$ are diagonal positive matrices representing virtual mass and damping, s is the Laplace variable, and $\boldsymbol{F}(s)$, $\boldsymbol{V}_h(s)$ are the Laplace transforms of the human Cartesian force $\boldsymbol{f}$ and velocity $\boldsymbol{v}_h$, respectively.

C. Automatic Task Assistance

The path follower continuously computes the desired Cartesian velocity v_a to reach the next goal from the current EE location.

1) Path Tracking: A spherical look-ahead approach determines the desired goal x_d along the trajectory (Figure 2).

(a)

Figure 2: The path follower selects the new objective point where the virtual sphere $\mathcal{S}$ intersects the path, advancing in the positive direction.

A virtual sphere $\mathcal{S}$ of dynamic radius ρ, centered at $\boldsymbol{x}$, is used to select the next target along a parameterized path $\mathcal{P}(s)$, where $s \in [0, 1]$. The system enlarges ρ (λ) while ensuring a lower bound (ρ_{min}) so that $\mathcal{S}$ intersects $\mathcal{P}(s)$ at least twice. The goal point in the task direction is chosen as $\boldsymbol{x}_d = \mathcal{P}(s_c)$.

2) Desired Automatic Velocity Computation: Let $\boldsymbol{x}$ be the EE position and $\boldsymbol{x}_d$ the goal Cartesian coordinates. The robot's velocity command $\boldsymbol{v}_r$ is given by:

$$\boldsymbol{V}r(s) = \frac{\boldsymbol{K}a}{\tau s + 1}\|\boldsymbol{v}_h\|(\boldsymbol{x}_d - \boldsymbol{x}), \tag{3}$$

where $\boldsymbol{K}_a$ is a diagonal positive matrix representing the attraction constant to the goal, and $\boldsymbol{x}_d - \boldsymbol{x}$ is the position error. A first-order low-pass filter with time constant τ modulates the robot's response.

To achieve AAN, the robot's assistance scales with the human-applied forces ($\|\boldsymbol{v}_h\|$), encouraging active user participation. The low-pass filter smooths noise in external force estimation.

D. Performance Computation

The proposed SC framework relies on local performance assessment, averaging multiple performance targets (e.g., smoothness, safety, precision, comfort). At any time, the performance $\eta_k \in [0, 1]$ of a command k (with $k = h, r, s$) is computed as a weighted combination of m partial performance factors η_{k_i}:

$$\eta_k = \frac{\sum_{i=1}^{m} w_i \eta_i}{\sum_{i=1}^{m} w_i}, \tag{4}$$

where w_i represents the weight of each factor. By default, weights are equal, but can be adjusted for specific task requirements (e.g., prioritizing smoothness or precision).

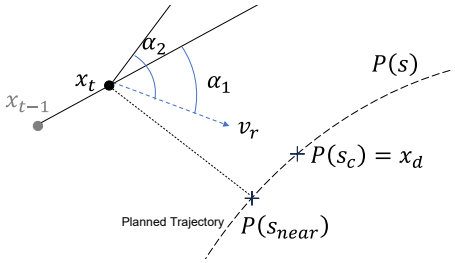


Figure 3: Computation of angles α_{k_1} and α_{k_2} for performance evaluation.

Following [18], we consider smoothness and directness as key performance factors ($m = 2$). The smoothness factor η_{k_1} penalizes abrupt direction changes, while directness η_{k_2} rewards commands that move toward the goal. These factors are computed as:

$$\eta_{k_j} = e^{-C_j|\alpha_{k_j}|}, \quad j = 1, 2 \tag{5}$$

where C_1 and C_2 adjust the sensitivity of each factor. The angle α_{k_1} measures deviation between consecutive commands, while α_{k_2} quantifies deviation from the optimal path (Figure 3). As with w_i, constants C_i can be heuristically tuned or set to 1 by default.

E. Shared Velocity Command (SVC) Computation

Once the human and robot propose commands to reach the target, the controller must combine them to obtain the final Shared Velocity Command (SVC) in two phases:

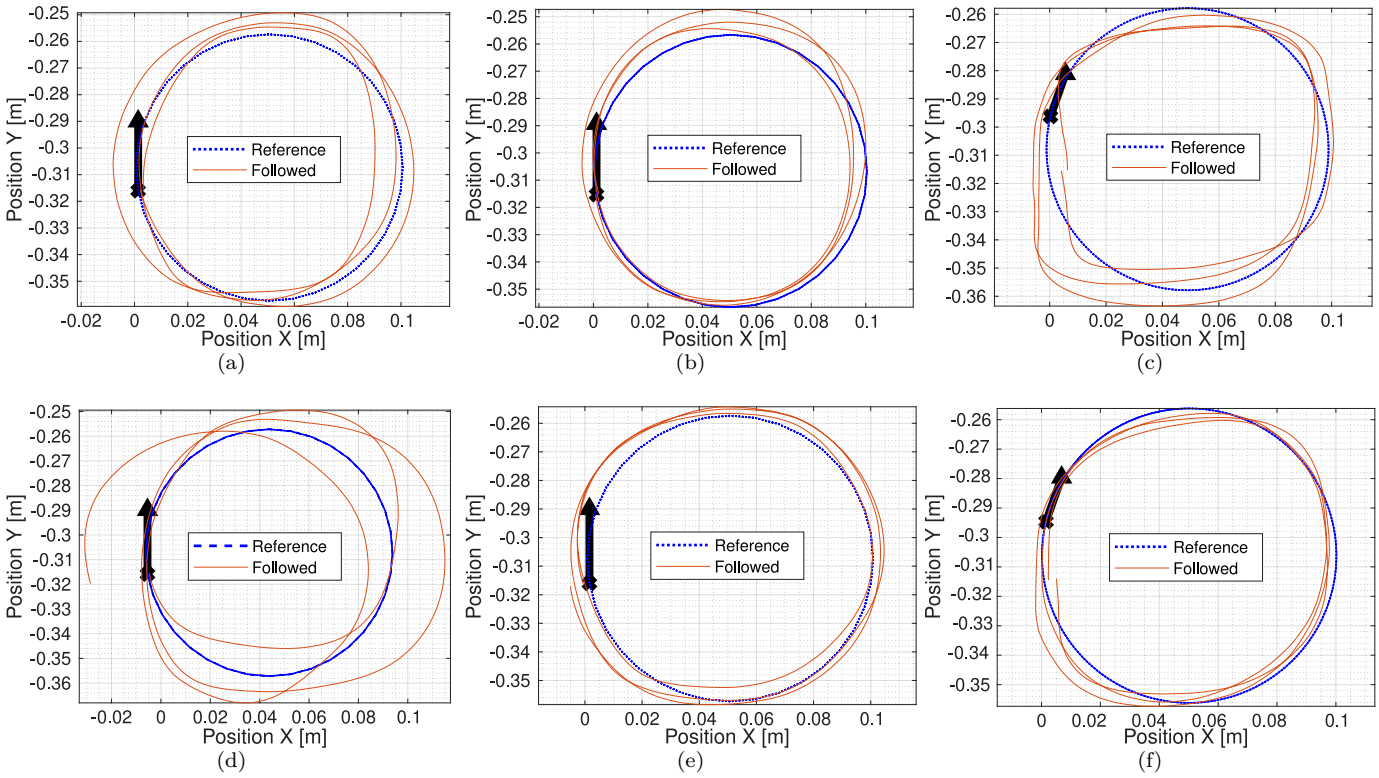

Figure 4: Paths in the XY plane performed by Volunteer 08: (a) DA, (b) DS, (c) DI, (d) NA, (e) NS, (f) NI.

1) Raw SVC Computation: $\hat{\boldsymbol{v}}_s$, is obtained as:

$$\hat{\boldsymbol{v}}_s = \eta_r \boldsymbol{v}_r + \eta_h \boldsymbol{v}_h, \tag{6}$$

where η_r and η_h represent the performance of the robot and human commands, respectively.

2) Performance-Weighted SVC: $\hat{\boldsymbol{v}}_s$ is scaled by its performance η_s, yielding the final command:

$$\dot{\boldsymbol{x}}_{\boldsymbol{d}} = \eta_s \hat{\boldsymbol{v}}_s. \tag{7}$$

Unlike traditional convex blending (1), where inputs are complementary, the weighting in (6) allows η_r and η_h to act independently.

F. Robot Arm Control

To ensure smooth motion, $\dot{\boldsymbol{x}}d$ is saturated if its norm exceeds the maximum Cartesian velocity allowed at the EE, $vmax$. The final velocity command is then transformed into joint velocities using the inverse Jacobian matrix before being sent to the arm's joint controller:

$$\dot{\boldsymbol{q}}_{\boldsymbol{d}} = J(q)^{-1} \dot{\boldsymbol{x}}_{\boldsymbol{d}} \tag{8}$$

This command incorporates admittance to external forces, so motion remains compliant with user interaction.

III. Experiments and Results

A. Experimental Setup

The setup consists of an underactuated gripper [9] attached to a Franka Research 3 robot arm, running a Cartesian velocity controller to assist in tracing a circular path [10]. Since robots typically outperform humans in precision, volunteers were expected to improve their tracing performance collaboratively.

1) Parameters: The admittance parameters $\mathbf{M}$ and $\mathbf{B}$ were set to $\mathrm{diag}(1,1,1)$ kg and $\mathrm{diag}(83.3, 83.3, 83.3)$ Ns/m [19]. $\boldsymbol{K}a$ was set to identity for a good user experience. Since both smoothness and directness are crucial for circular path tracing, performance weights were equal ($w_1 = w_2 = 0.5$), and $C_1 = C_2 = 1$ (Section II-D). The path follower parameters were $\lambda = 1.02$ and $\rho_{min} = 0.015$ m.

2) Participants & Procedure: Ten healthy volunteers (7 male, 3 female) of different ages and backgrounds participated under the Declaration of Helsinki principles[1]. Each completed six tests: standAlone (A), SC mode (S), and Impedance (I) control-based AAN [15], using both dominant (**D**) and non-dominant (**N**) hands. Volunteers, unaware of assistance conditions, traced a 5 cm radius circle clockwise, viewing their trajectory on a screen. Each test consisted of four loops. Figure 4 illustrates typical trajectories, demonstrating that the SC mode resulted in the best curvature outcomes for all loops in both hands.

3) Hypotheses: In order to study the benefits of the system, the following hypotheses were proposed:

- H1: Shared mode improves performance.

[1]CEUMA 7-2023-H

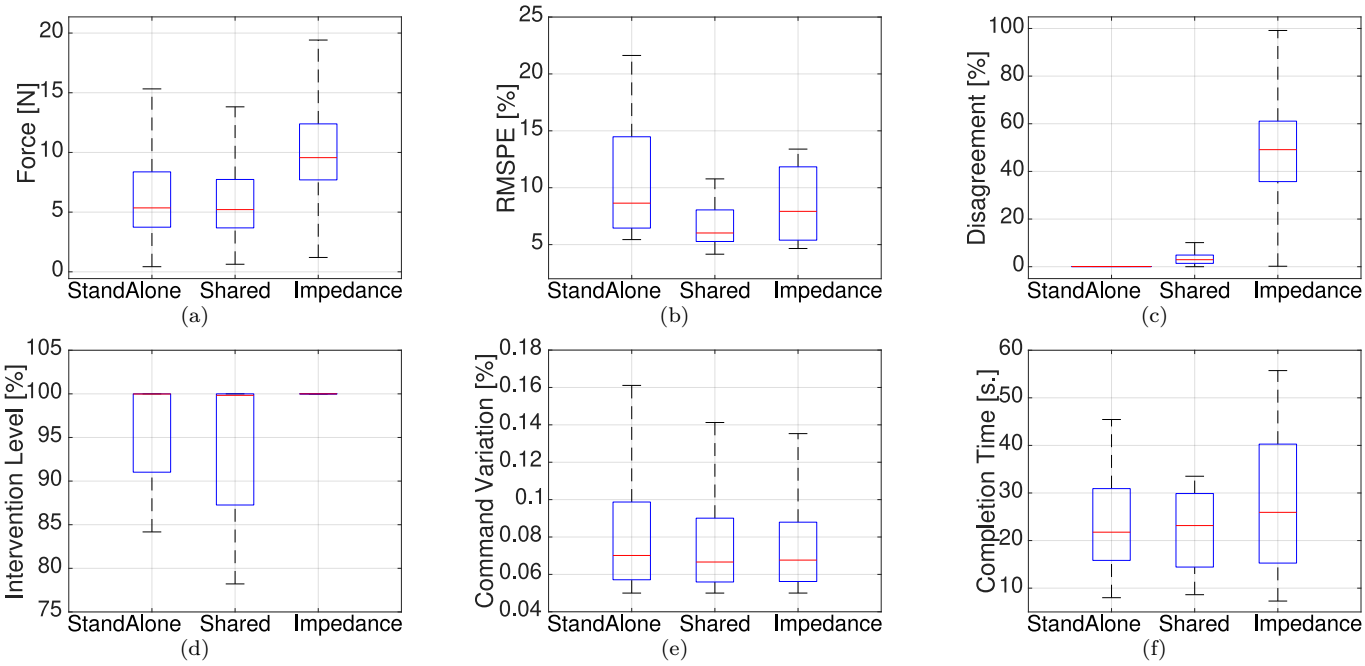

Figure 5: Average tests performance.

- H2: Root Mean Square Percentage Error (RMSPE) decreases in shared mode.
- H3: SC equalizes performance between hands.
- H4: SC reduces RMSPE variance, improving precision.
- H5: Participants feel comfortable with assistance (questionnaire).

B. Result Analysis

Table I presents ANOVA results for the hypotheses in Section III-A. All hypotheses were validated except H3, which aimed to show that SC equalizes performance between dominant and non-dominant hands. This rejection might be due to some users naturally performing equally well with both hands, so we reformulated this hypothesis to consider only users with significant hand performance differences (upper tercile, H_i'). Under these circumstances, ANOVA test confirms that SC significantly reduces performance gaps for "imbalanced" users.

Table I: ANOVA test results.

Hyp.	Data	Factor	ANOVA
H1	user performance	standalone/shared	0.0143
H2	average RMSPE	standalone/shared	0.0423
H3	$\Delta\eta_{hand}$ (per user)	standalone/shared	0.848
H3'	$\Delta\eta_{hand}$ (per user)	standalone/shared	0.0421
H4	RMSPE variance	standalone/shared	0.0347
H5	command variation	standalone/shared	0.0395

Additional statistics of several performance metrics were obtained and are summarized in Figure 5. From these results, the following key findings can be stated:

- SC improves task performance (H1), figure fit (H4), and reduces both RMSPE and cognitive load variance (H2, H5).
- RMSPE decreases in SC mode due to adaptive haptic feedback, though IC introduces higher error variance (see Figure 5b).
- Intervention Level (Figure 5d) is consistently high across modes. In SC, command variation is more controlled, while in IC, users struggle more with the robot, leading to increased force and completion time variability.
- IC mode results in higher forces as users counteract corrections, whereas in SC, disagreement remains low, and performance improves with lower exertion (see Figure 5a).
- SC maintains an effective trade-off between performance and disagreement, keeping force levels moderate. In contrast, IC disrupts these relationships, increasing struggle. This can be observed in the scatter plots in Figure 6, which state dependencies between force, performance, and disagreement across control modes.
- SC provides adaptive assistance, helping users when necessary while maintaining smooth and consistent control. IC, however, alters force-disagreement-performance dynamics, often leading to inefficiency.

IV. Discussion

Our SC law dynamically blends human and robot commands based on local performance, estimated in terms of smoothness and directness. This results in continuous and natural motion, while trajectories remain globally smooth and precise. Moreover, even metrics not explicitly considered in the control function—such as RMSPE, disagreement, cognitive load, and completion time—show

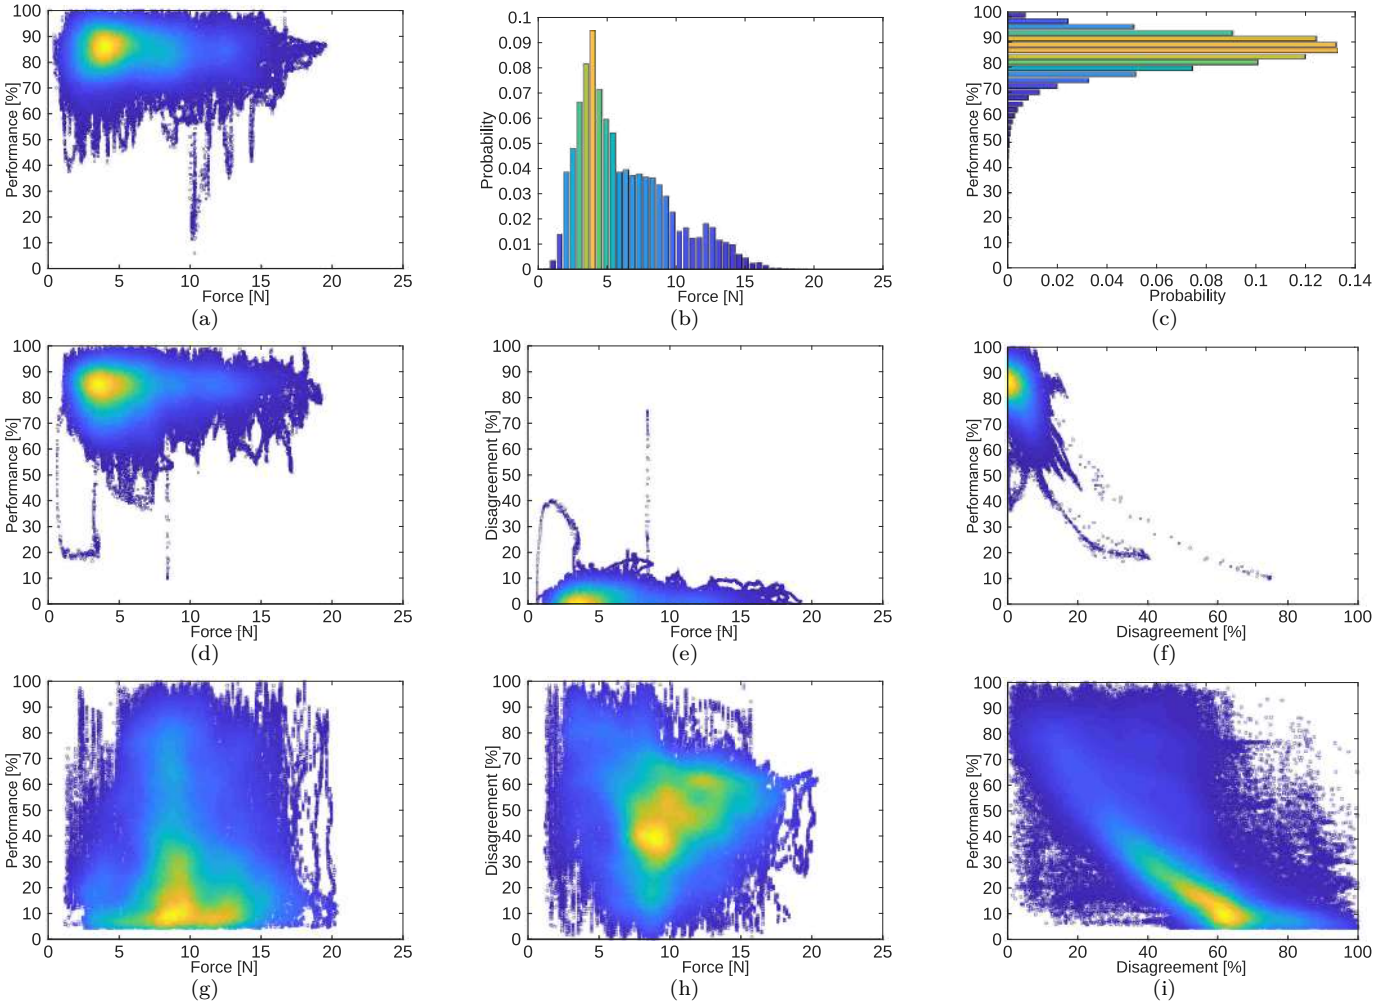

Figure 6: Scatter plots of all Standalone (top row), SC (middle row), and IC (bottom row) tests comparing force vs. performance (left column); force vs. disagreement[1] (mid column); and disagreement vs. performance (right column)[1]. Light-colored areas are more likely to happen.

positive trends in SC mode.

We compared SC against Standalone human control and a classical IC in tests with healthy volunteers. SC improves local performance, reduces RMSPE variance and average error, likely by stabilizing user input and gradually increasing resistance when deviations occur. One of the most notable effects of SC is a significant reduction in performance variance, both across participants and between dominant and non-dominant hands. This indicates that SC adapts to individual needs. Performance homogenization was an intended effect of performance-weighted assistance: rather than elevating performance to robot levels, SC enhances human execution to a consistent and competent standard.

Assistance in SC is well accepted. Lower Disagreement values suggest that human and robot commands align better than in other modes, contributing to improved accuracy and task efficiency. Although users were unaware of the control mode during trials, most reported feeling more comfortable in SC. By contrast, Disagreement was highest in IC mode, where many volunteers described control as jagged. Notably, high Disagreement often occurred when the hand was closer to the body, suggesting difficulties in certain postures.

SC also reduces the number of corrections, as indicated by increased variance in the Intervention Level and lower command variation. Since corrections often correlate with cognitive effort, SC may lower mental workload, though further analysis would be needed to confirm this. Additionally, SC minimizes completion time variation. Observations suggest that some users, especially those less familiar with robots, initially applied insufficient force—perhaps out of concern for damaging the system. In Standalone and IC modes, this sometimes led to intermittent stops, followed by overcompensation, creating oscillatory force patterns. This issue was less pronounced in SC mode.

Regarding system stability, the control loop gains are modulated in real-time based on performance indices

[1]In Standalone control, the user command matches the shared command, resulting in a 1-D histogram instead of a 2-D scatterplot

$\eta_i \in [0, 1]$ which provide direct feedback on task execution. These indices adjust the gains for both robot path-following and human admittance control, reducing them when performance declines (e.g., in terms of smoothness or directness). This approach improves upon conservative passivity-based methods. Additionally, a low-pass filter and saturation on the desired velocity reference enhance stability, considering the limited bandwidth of human arm motion (below 2 Hz) [20].

V. Conclusions

This paper has introduced a novel SC method for pHRI rehabilitation robots, designed to enable continuous human-robot collaboration. SC dynamically blends human and robot commands based on local performance, ensuring smooth motion while allowing users to contribute as much as their abilities permit. By adapting assistance to individual needs, SC effectively homogenizes performance across different users and between dominant and non-dominant hands.

Experimental results demonstrate that SC improves performance while reducing both variance and tracking error. The Intervention Level confirms that users remain actively involved in motion, while low command variation suggests that this occurs without increased cognitive load. Volunteers generally reported higher comfort in SC mode, despite variations in individual preferences. While Disagreement fluctuated with body and arm positioning, it remained lower in SC mode overall. Notably, more skilled users exhibited slightly higher average Disagreement in SC mode, likely due to their tendency to assert greater control. Across all assessed metrics, SC consistently outperformed both Standalone and IC.

Future work will focus on deploying this SC approach in hospitals and nursing homes to evaluate its effectiveness in real-world rehabilitation after ethical approval. Additionally, we aim to incorporate safety constraints for more complex collaborative maneuvers in 3D space and refine robot navigation strategies to better align with human preferences. Beyond rehabilitation, we also envision extending this SC framework to critical pHRI applications, such as rescue, first aid, and nursing robots, where human safety and adaptive assistance are paramount.

Development and Pre-Clinical Validation of Tendon Driven 2 Degree-of-freedom Powered Ankle-Foot Orthosis for Heuristic Algorithm Based on Gait Stability

Kyeongwon Kang[1], Sehee Jung[2], Minseok Lim[2], and Ho Seon Choi[1,*], *Member, IEEE*

Abstract— **In the field of rehabilitation, Powered Ankle-Foot Orthoses (PAFO) are often used, which are wearable robots designed to rehabilitate the mobility of individuals with reduced walking stability, such as the elderly. Previous studies have developed a 2-degree-of-freedom PAFO capable of assisting both the talocrural and subtalar joints of the ankle. However, the use of pneumatic artificial muscles (PAMs) as actuators resulted in low control capacity(low cutoff frequency). To address this limitation, this study developed a tendon-driven device that offers higher cutoff frequencies through a motor system driven by cables. Furthermore, we did pre-clinical experiment, and it showed the possibility of enhancing walking stability with our heuristic-based algorithm for human-in-the-loop optimization. This algorithm was based on the activity of antagonistic muscles to those targeted for assistance at both ankle joints and walking stability was evaluated through Gaussian ellipsoid.**

I. INTRODUCTION

Populations with decreased walking stability, such as the elderly, can enhance their walking function through rehabilitation. Decreased walking stability is usually associated with impaired ankle function [1]. The ankle joint comprises two primary joints: the talocrural joint and the subtalar joint, each with two degrees of freedom [2]. The talocrural joint facilitates plantar flexion and dorsiflexion, while the subtalar joint enables eversion and inversion movements [2]. Among these, eversion movement of subtalar joint plays a crucial role in maintaining walking stability [3]. Therefore, improving eversion movement through training or rehabilitation can potentially enhance overall walking stability.

Various rehabilitation systems are being developed to prevent fall, and powered ankle–foot orthosis (PAFO) is one of them. PAFOs are wearable robots designed to assist the human body by incorporating actuators into exoskeletons worn on the ankle [4]. Most PAFOs are typically designed with one degree-of-freedom (*dof*), primarily assisting the talocrural joint of the ankle [4]. However, the ankle comprises two joints—the talocrural and subtalar joints, and the eversion movement of the subtalar joint plays an important role in walking stability. To address this, in this paper, we selected 2-*dof* PAFO that can assist the two joints of the ankle simultaneously using pneumatic artificial muscles (PAMs) [5]. However, this had the drawback of insufficient transmission efficiency. To address this, we have chosen a tendon-driven mechanism to assist the user's bilateral ankle movements. This method mimics tendons by utilizing cables for actuation.

Despite advancements, current PAFOs often face challenges in effectively assisting users in achieving their intended purpose. A promising approach to address this is human-in-the-loop optimization, which enhances human performance by dynamically adjusting device control based on interactions between the exoskeleton and the user [15]. While numerous studies have explored human-in-the-loop optimization [6], it remains a complex and challenging task due to the intricacy and variability of the human motor control system. Walking strategies while using exoskeletons exhibit unique characteristics and patterns for each individual, making it highly difficult to predict user-specific responses or determine optimal assistive patterns [7].

Therefore, this study aims to develop human-in-the-loop optimization of PAFO to improve walking stability. Previous research has designed such algorithms based on heuristic approaches [8]. This algorithm is also designed based on the muscles to be assisted and the muscles that act collaboratively and antagonistically. For example, during plantar flexion assistance, if the activity of the Soleus (SOL), an agonist muscle, increases, additional torque is applied. Conversely, if the activity of the Tibialis Anterior (TA), an antagonistic muscle, increases, less torque is applied. However, these algorithms are limited to assisting plantar flexion of the talocrural joint and primarily focus on improving walking performance rather than walking stability. In reality, walking stability is closely associated with eversion motion, which also requires assistance for the elderly. The muscles involved in this movement include the Peroneus Longus (PL) as a agonist muscle and the TA as an antagonist. In this study, we utilized a 2-dof PAFO capable of assisting both plantar flexion and eversion movements of the ankle joints. At this time, assisting both ankle joints requires an understanding of their interdependent movements and twisted rotational positions, which must be considered in the design and control of the robot. Therefore, this study developed and simply validated a human-in-the-loop optimization algorithm based on heuristics to enhance gait stability by assisting both ankle movements.

II. 2 Degree-of-Freedom Powered Ankle-Foot Orthosis

A. Description of orthosis

We conducted the study with the 2-*dof* PAFO developed in the previous study [5]. The developed PAFO has two joints of the ankle through anatomical data and uses the two PAMs as actuators to simultaneously assist in plantarflexion and eversion movements. However, we replaced the PAM with a motor drive system connected with cables as shown in Fig. 1(c) for higher cutoff frequencies. In the proposed drive system, one end of the Bowden cable (made of Teflon-coated material) is attached to an ankle-foot orthosis (AFO), emulating the positioning of the tendons of the soleus and peroneus longus (PL) muscles, as shown in Fig. 1. The exoskeleton frame, excluding the knee brace, is fabricated using a 3D printer with polycarbonate (PC) material [16]. The other end of the Bowden cable is connected to an external motor–load cell–spring assembly, in Fig. 2. The rotation of the BLDC motor (DC 24V, rated current: 11.5 A, rated power: 205 W, encoder: 1000 PPR) transmits force through the Bowden cable, while a spring (experimentally selected at 21.57 N/mm) is positioned at the end of the load cell (LCM201-500N) to eliminate motor backlash. This design enables the proposed drive system to achieve more precise force control and faster responsiveness compared to conventional PAM-based drive mechanisms.

Four types of sensors were used in the experiment: IMU (Inertial Measurement Unit, EBIMU-9DFV5-R3; E2BOX), EMG (Electromyography, AM530), FSR (Force Sensitive Resistor, UX 402; Interlink), and encoder (AMT103). The PAFO was equipped with two encoders to measure the angles of the two ankle joints and one FSR sensor to detect heel strikes for gait cycle analysis. These sensors were connected to an external microcontroller via CAN communication. The IMU sensor was attached to a vest and worn at the trunk position of the body. It measured the acceleration in the x- and z-axis directions, calculated the left-right and front-back acceleration of the body, respectively, and was low-pass filtered with a cut-off frequency of 40 Hz. For the EMG sensor, signals were non-invasively recorded from three muscles (soleus, peroneus longus, and tibialis anterior). The signals were firstly high-pass filtered at a cut-off frequency of 200 Hz, and then low-pass filtered with cut-off frequency of 10 Hz. And filtered signals were finally processed using a moving average filter for smoothing and to extract the meaningful data.

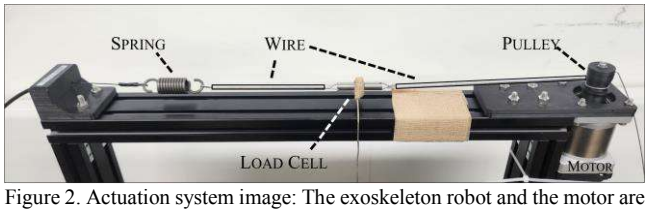

Figure 2. Actuation system image: The exoskeleton robot and the motor are connected by a cable, with a spring, wires, and a load cell in a row.

B. Workspace validation

To determine the workspace of the exoskeleton, the end-effector position was calculated through kinematic analysis. The global coordinate system was set at the Talocrural joint, as shown in Fig. 3, and the DH(Denavit Hartenberg) parameters were derived using the encoder angles as variables. In addition, the end of the exoskeleton sole structure was set as the end effector and plotted in a three-dimensional space. The green area is an operable area(workspace), and the blue dots mean a profile of the end effector during the gait cycle. Since each encoder corresponds to the position of the ankle joints, the coordinates of the end-effector were calculated by substituting the biological ankle joint angles during the gait cycle into the encoder angle variables. As the end-effector trajectory during the gait cycle falls within the operable workspace, the exoskeleton robot is capable of adequately covering human ankle movements during walking.

C. Link Adjustment

There are a total of three links corresponding to the length of the shin of the exoskeleton, and it is designed so that the length can be adjusted. We designed the link by dividing the height of a person into 160, 170, and 180 cm. According to the measurement method proposed by Harless, the ratio of the shin segment according to the height of the person is 0.2484H (H = height) [9]. Therefore, if the shin lengths of a person with heights of 160 cm, 170 cm, and 180 cm are measured as 39.52 cm, 41.99 cm, and 44.46 cm respectively, the corresponding shin lengths for the exoskeleton parts are determined as three. As shown in Fig. 4, the knee brace and PAFO are connected in three ways for the length of the link corresponding to each height. It is designed to fit the length of the shin corresponding to each height, and if the height is 180 cm, the upper two holes of the knee brace link are connected to the red-marked holes on the AFO link, as shown in Fig. 4. For a height of 160 cm, the yellow-marked holes are connected, and for 170 cm, the lower two holes of the knee brace link are connected to the green-marked holes in Fig. 4. Each link length is designed to accommodate height variations within ±3 cm for each target height, allowing for greater flexibility.

III. Control Validation

A. Load cell calibration

The load cell used in the actuation system was calibrated in Newton(N). All motors for controlling PAFO are defined based on torque. To compute the torque for system control, it is essential to determine the tension applied to the motor, which is measured by the load cell. However, since the load cell was obtained through Analog to Digital Converter(ADC) of microcontroller, it must be corrected in the unit of load.

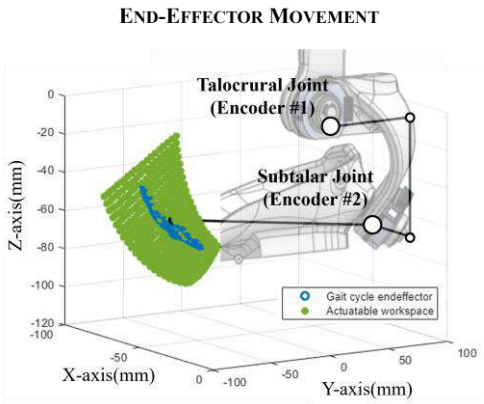

Figure 3. Calculated workspace of the designed PAFO. The green dots indicate the actuatable workspaces, respectively.

Since the manufacturer specified that there is a linear relationship between the load cell and the ADC output value, 1-50kg was measured and linear fitting was performed through MATLAB to calibrate the load cell.

B. Control method

In this study, the performance of the actuator control system must be validated, as it is crucial for assisting two ankle movements during walking through cables while facilitating interaction between the human and the robot. Accordingly, the two cables must meet the required performance level to assist ankle movements appropriately. The performance of Cable 1 and Cable 2, as shown in Fig. 6 was validated compared using commonly used controllers and torque profiles of the elderly and young individuals, respectively.

Cable 1 was evaluated using a commonly used controller as it assists the plantar flexion movement of the ankle. Plantar flexion directly impacts walking dynamics, and there are already many preceding studies. Therefore, we verified the controller performance through the Proportional Myoelectric Controller (PMC), a method that leverages soleus EMG signals to adapt to individual walking patterns[10]. Since this study intends to develop an algorithm that allows the wearer to interact with each other based on muscle activity, this is an appropriate control method to verify the controller performance. The walking speed was determined at 1.2 m/s with reference to another PAFO study, and the profile obtained above was Fast Fourier Transform(FFT) [11]. The results of FFT are shown in Fig.6.

In the case of Cable 2, there are not many prior studies, so the controller performance was verified through the torque difference between the elderly and the young. Cable 2 affects both plantar flexion and eversion movements, but to improve walking stability, assistance for the eversion movement is centered. Since cable2 mainly plays a role of assisting the eversion movement, and there have not been many prior studies on the controller of PAFO that assist this movement. Liu et al. it can be seen that the profile of the eversion-related moments differs between the elderly and the young during the walking cycle [12]. Therefore, we verified the controller performance by setting the profile through the difference in the torque profile that occurred while walking between the elderly and the young through the difference between the two profiles. At this time, the distance between the rotation axis and the

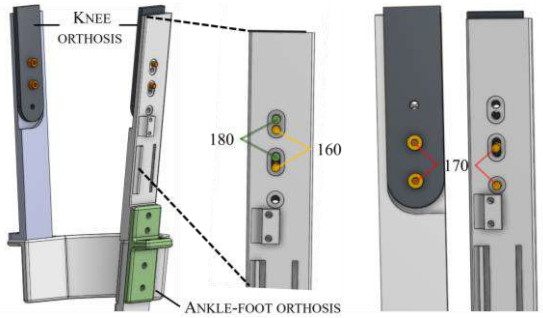

Figure 4. The connection method of the exoskeleton link for individuals with heights of 160 and 180 is shown on the left, while the right figure corresponds to a height of 170.

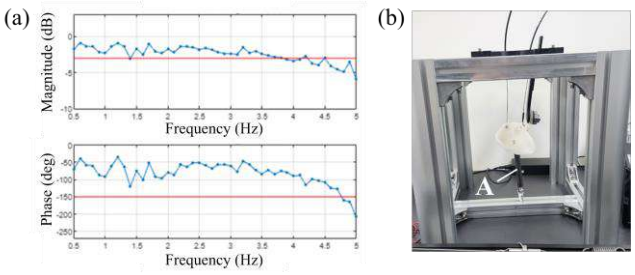

Figure 5. (a) Bode plot result when the amplitude of cable2 is 75N. (b) Closed-loop frequency response experimental setup; A is a spring.

action point where the event torque of the aid occurred was approximately 0.1m, and it was expressed as a force profile, and as shown in cable1, the walking speed was set at 1.2m/s to FFT. This is indicated by AET (Ankle eversion torque) in Fig.6, which shows the torque during the eversion movement.

C. Closed-loop frequency response and results

We conducted closed-loop frequency response experiments for Cable 1 and Cable 2. The target force profiles for these experiments were determined by the peak forces required for the PAFO to assist in ankle torque. The typical population with impaired walking stability is the elderly, whose ankle function gradually declines, leading to reduced walking stability [13]. Svoboda et al. compared the degree of muscle loss in the elderly and found that peak torque decreased by 35.60% for plantar flexion and 33.80% for eversion. Additionally, during walking, the elderly exhibited a 28.0% decrease in plantar flexion torque and a 40.0% decrease in eversion torque compared to younger individuals [12]. Fatigue accumulation also contributes to muscle strength reduction, further impairing walking stability. According to Gutierrez et al., fatigue caused a decrease in peak torque of 18.86% for plantar flexion and 11.86% for eversion [14]. Based on these findings, we determined that a 40% reduction in peak ankle torque during walking in healthy individuals would be sufficient for rehabilitation aimed at improving walking stability. The peak ankle torque during walking for a healthy individual was measured as 88.23 N·m for plantar flexion and 30.37 N·m for eversion. Assuming a moment arm of 0.1 m, we calculated the peak forces for plantar flexion and eversion to be 352.92 N and 11.48 N, respectively. Therefore, in this study, we set the peak force for Cable 1 at 50 N, 75 N, 100 N, 150 N, 200 N, 250 N, 300 N, and 350 N, and for Cable 2 at 50 N, 75 N, 100 N, and 122 N. These forces were used to conduct the frequency response experiments. PID control was applied to the cable system, and the cutoff frequencies of -3 dB and -

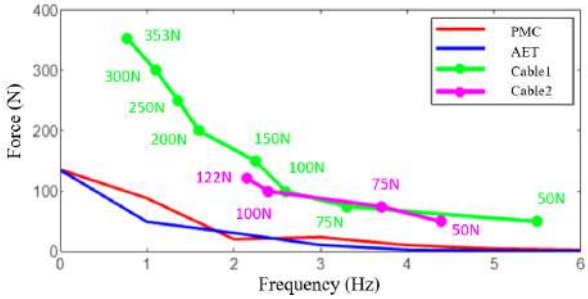

Figure 6. Results of FFT of Proportional Myoelectric Controller (PMC) and Ankle eversion torque difference between young and elderly individuals (AET) and cutoff frequencies of each amplitude from the closed-loop frequency response of the two cables.

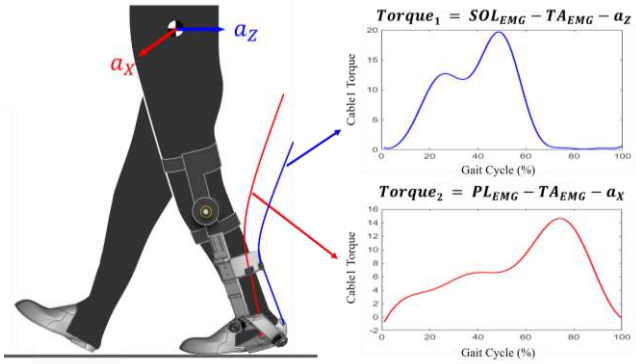

Figure 7. The process of generating torque profiles : It derived from muscle activity and acceleration, are shown in red for cable 1 and blue for cable 2.

150° phase shift were calculated for all experiments, as shown in Fig. 5. In Fig. 5(a), the amplitude of the sinusoidal function is plotted on the y-axis, while the cutoff frequency is shown on the x-axis. For the dynamic changes of the cable during the experiment, we connected a spring to part A of the PAFO, as illustrated in Fig. 5(b). The spring used had a spring constant of 7.75 N/mm.

As a result of the closed-loop frequency response experiment, the cutoff frequencies for cable1 at amplitudes of 50N, 75N, 100N, 150N, 200N, 250N, 300N, and 350N were 5.5, 3.3, 2.6, 2.25, 1.6, 1.36, 1.1, and 0.77 Hz, respectively. For cable2, at amplitudes of 50N, 75N, 100N, and 122N, the cutoff frequencies were 4.4, 3.7, 2.4, and 2.15 Hz, respectively. As shown in Fig 6, the cutoff frequencies of each cable are plotted. Here, cable1 includes the control bandwidth of PMC, and cable2 includes the control bandwidth of AET.

IV. Algorithm Development

We developed a heuristic-based algorithm to enhance walking stability. The algorithm is founded on two fundamental principles: (1) when the muscle to be assisted is activated, more torque is applied, and (2) when both the muscles to be assisted and the antagonistic muscles are activated, the torque is reduced. For example, in the case of assisting plantar flexion, the SOL muscle is the muscle to be assisted, while the TA muscle is the antagonistic muscle. If the activity of the SOL muscle increases, the muscle is considered unassisted, and if the TA muscle is activated, it is deemed over-assisted, leading to a reduction in torque. As illustrated in Fig. 7, we assist both movements of the ankle, including the corresponding antagonistic muscle pairs. Additionally, since the focus is on improving walking stability, acceleration is also

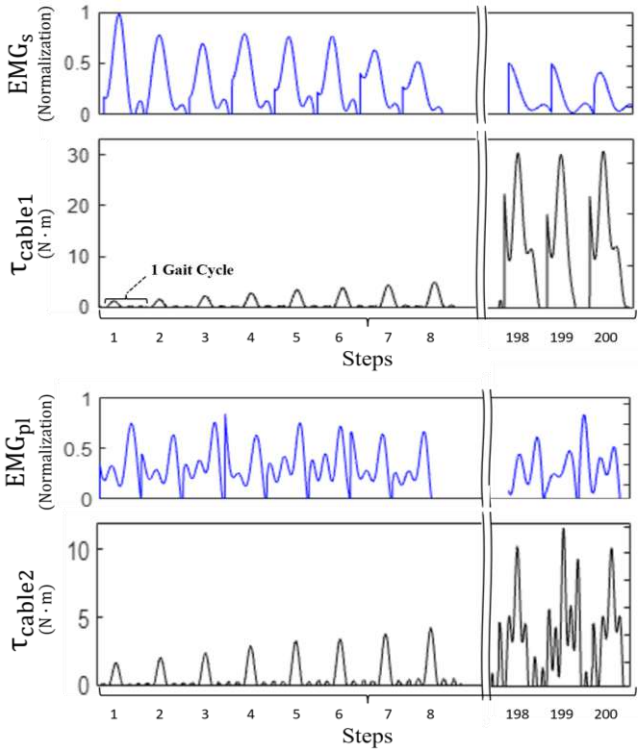

Figure 8. This is an example of how the EMG and torque profiles evolve for two cables. The EMG is normalized to its peak value. (EMG_s and EMG_{pl} mean EMG amplitude signals of soleus and peroneus longus, respectively.)

taken into account. In this context, the z-axis of the acceleration sensor represents the front-back shaking of the body, while the x-axis represents the left-right shaking.

A. Algorithm Formulation

We formulated an equation for each of the two cables. τ_{cable} refers to the torque applied to each cable, n represents the current step, and i represents the index of a particular step. (1) describes the (n+1)th step, which is an adaptive evolutionary algorithm influenced by the nth step. And then, $d\tau_{cable}$ denotes a term that adjusts the torque from the previous step, with a threshold applied to $d\tau_{db}$. Therefore, by adding a memory component to the stepping sequence, the torque profile is designed to converge, as shown in Fig. 8, with the torque gradually increasing at each step until $d\tau_{db}$ no longer changes. Additionally, (1) and (2) apply to cable1, while (3) and (4) apply to cable2.

The term $d\tau_{cable}(i,n)$ represents the muscle activity to be assisted, the antagonistic muscle activity, the previous torque, and the acceleration magnitude, and is designed for both cable1 and cable2. In the case of cable1, $EMG_s(i+d,n)$ is added as a positive term to increase the torque when the SOL muscle activity increases. Additionally, a delay d between muscle activation and the algorithm's operation time was incorporated. To prevent rapid torque increases, $\langle EMG_s(n)\rangle^{-m}$ is introduced to distribute the average EMG value over one step. For antagonistic muscle TA, $EMG_t(i+d,n)$ is included as a negative term to reduce the torque when TA activity increases. Since co-activation of SOL and TA muscles, which are opposite, positively impacts walking stability, the section where EMG_t is not greater than EMG_s is considered as co-activity, and the torque is not reduced. The

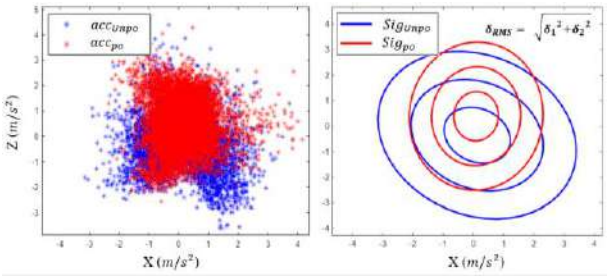

Figure 9. Trunk accelerations was plotted with Gaussian ellipsoid for quantification. The left graph represents the acceleration distribution, while the right one plots the probability circles with standard deviations.

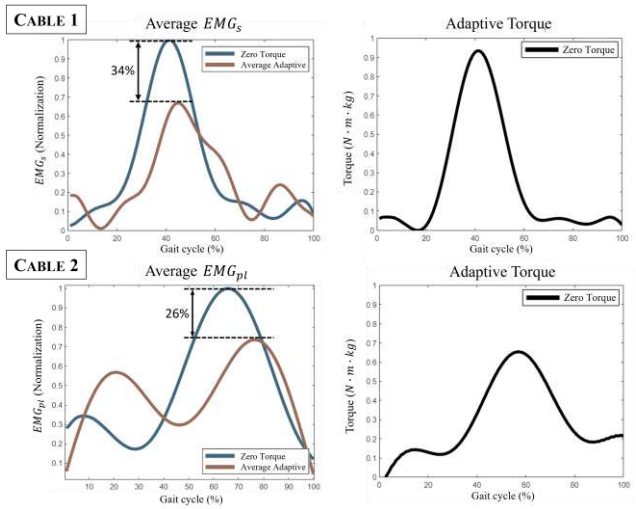

Figure 10. Average EMG profile and average torque profile for the subjects. Different profiles are shown for each of the two cables. The left graph represents the EMG profiles when wearing the exoskeleton in a zero-torque state and after applying the heuristic algorithm. And the right graph shows the torque profile generated after applying the heuristic algorithm.

term $\tau_{cable}(i,n)$ is designed to gradually reduce the influence of previous adjustment patterns on the current torque pattern of the exoskeleton, helping stabilize the system through equilibrium criteria. Finally, a positive term for acceleration along the z-axis is added, as it was found that increased body swaying leads to reduced walking stability, prompting an increase in torque which has threshold at c_{a_z}.

$$\tau_{cable1}(i,n+1) = \tau_{cable1}(i,n) + sgn\big(d\tau_{cable1}(i,n)\big) \cdot \max(|d\tau_{cable1}(i,n)| - d\tau_{db}, 0) \quad (1)$$

$$d\tau_{cable1}(i,n) = k_1 \cdot EMG_s(i+d,n) \cdot \langle EMG_s(n)\rangle^{-m} - k_2 \cdot \max(EMG_t(i+d,n) - EMG_s(i+d,n), 0) - k_3 \cdot \tau_{cable1}(i,n) + k_4 \cdot \max(|\langle a_z(n)\rangle| - c_{a_z}, 0) \quad (2)$$

$$\tau_{cable2}(i,n+1) = \tau_{cable2}(i,n) + sgn\big(d\tau_{cable2}(i,n)\big) \cdot \max(|d\tau_{cable2}(i,n)| - d\tau_{db}, 0) \quad (3)$$

$$d\tau_{cable2}(i,n) = k_5 \cdot EMG_{pl}(i+d,n) \cdot \langle EMG_{pl}(n)\rangle^{-m} - k_6 \cdot \max\big(EMG_t(i+d,n) - EMG_{pl}(i+d,n), 0\big) - k_7 \cdot \tau_{cable2}(i,n) + k_8 \cdot \max(|\langle a_x(n)\rangle| - c_{a_x}, 0) \quad (4)$$

In the case of Cable2, it was designed with the same structure as Cable1, where the muscle to be assisted is the PL, and the antagonistic muscle is the TA, represented by EMG_{pl} and EMG_t, respectively. Additionally, since Cable2 primarily assists with the eversion movement, the acceleration along the x-axis, corresponding to the left and right direction of the body, was applied. At this time, the constant k in the equation was determined experimentally.

V. Experimental Validation

A. Stability Measurements

In this study, stability was assessed using the acceleration values from an IMU sensor attached to the body. The acceleration values along the X-axis and Z-axis were compared using a Gaussian ellipsoid, as shown in Fig. 9. This approach compares the values probabilistically rather than simply using the maximum radius. An ellipse was drawn by calculating the covariance of the two-dimensional acceleration values obtained from the IMU sensor and computing the corresponding eigenvalues. The resulting ellipsoid represents the standard deviation and typically employs the three ratios of Gaussian ellipsoid: 1δ (39%), 2δ (68%), and 3δ (99%). This allows for a quantitatively reliable comparison, and the stability was calculated as the root mean square (δ_{RMS}) of the acceleration values along the X-axis and Z-axis for 1δ. It can be observed that walking stability decreases as δ_{RMS} increases.

B. Experimental Protocol

Three healthy subjects (2 men and 1 woman; 22.7 ± 2.0 yo; 68.3 ± 9.4 kg; 1.75 ± 0.05 m) participated in the experiment. The subjects walked at 0.95 m/s, wearing the brace only on their left leg. Initially, to allow the subjects to become accustomed to the brace, they walked on a treadmill for 5 minutes. Then, adjustment time was provided, and sufficient rest was taken to reduce any effects on the experiment. For the first phase, the PAFO was not powered, and walking data were collected for 5 minutes as a baseline for comparison with the powered condition. Following this, an additional 6 minutes of rest was provided. Afterward, the algorithm interacted with the subjects to create profiles, and the treadmill walking was conducted for 10 minutes. Each subject performed the heuristic-based algorithm three times, with 6 minutes of rest between each trial to minimize fatigue. And this experimental Protocol was approved by the Institutional Review Board of Sejong University. (IRB number: SUIRB-HR-2024-023)

C. Result

EMG values were normalized based on the peak value, and the torque was normalized according to the subjects' body weight. The average data across all subjects was then calculated. As shown in Fig. 10, for cable1, the EMG peak value of the SOL muscle decreased by 34% compared to the previous measurement, and for cable2, the EMG peak value of the PL muscle decreased by 26%. The final torque profiles were then generated, as depicted in Fig. 10.

As a result of calculating the gait stability based on the values measured through the IMU using a Gaussian ellipsoid, the stability data for the three subjects is presented in Table 1. When comparing the stability of each subject before and after applying power to the PAFO, it can be observed that δ_{RMS} decreased. Specifically, the δ_{RMS} decreased by 6%, 21%, and 26%, respectively, with an average decrease of 17%. This confirms that walking stability was impaired.

TABLE I. STABILITY OF THE SUBJECTS BEFORE AND AFTER POWERING TO THE PAFO

Stability		Participants		
		Subject A	***Subject B***	***Subject C***
δ_{RMS}	Pre	1.915	1.545	2.002
	Post	1.789	1.216	1.481

VI. DISCUSSION

This study aims to design and control a 2-*dof* PAFO system and to develop and apply a heuristic-based algorithm to enhance walking stability As a result of the experiment, the performance of design and control was proved, and it was confirmed that walking stability was enhanced.

To address the limitation that exoskeleton robots can only be worn by individuals with a specific shin length, we designed the link to accommodate a wider range of shin lengths. The link is adjustable in three lengths based on body segments corresponding to individuals of 160, 170, and 180 cm in height. As a result of actual trials, individuals with heights within ±3 cm of the target could wear the exoskeleton, and the misalignment between the robot and human joint axes was minimized. However, this design is based on standardized body segment measurements, and individuals of the same height may have different shin lengths, meaning that the link lengths might not be optimal for all users and should be addressed with more precise adjustment of the link length.

In addition, we replaced the actuator from PAM to motor control via cable to achieve a higher cutoff frequency than the existing 2-*dof* PAFO, which was confirmed through experimentation. By plotting the cutoff frequency in two dimensions through a closed-loop frequency response experiment, it was confirmed that cable1 includes the control bandwidth of the PMC from previous studies, and cable2 encompasses the control bandwidth associated with the torque differences between the elderly and the general population. This demonstrated that our driving system has a sufficiently high cutoff frequency to control the PAFO, which is crucial for rehabilitation purposes aimed at improving walking stability. Furthermore, it suggests that the difficulty in implementing mobility with conventional pneumatic actuators can be addressed through cable-driven motor control, which may contribute to future commercialization and mobilization.

Pre-clinical experiments confirmed the possibility that the heuristic-based algorithm developed in this study could improve gait stability of the wearers. Gait stability was assessed by analyzing body sway while walking with the PAFO equipped with the algorithm. Comparing the trunk acceleration values using a Gaussian ellipsoid showed that δ_{RMS} decreased by an average of approximately 17%, confirming the algorithm's positive impact on gait stability.

As a result of applying the heuristic-based algorithm developed in this experiment, it showed that the torque profile evolved and the muscle activity of the target muscle had trends of decrease, as intended. However, in terms of the torque profiles, adapting to the wearer and achieving body balance in each experiment proved challenging, with cases where the torque either continuously increased or increased irregularly. This suggests that errors caused by noise in the EMG sensors and the need for additional terms to improve the algorithm's interaction with the wearer. The algorithm was able to prevent the continuous increase of the torque profile by including a term for the muscle activity of the antagonistic muscle and the previous torque; however, this term had limited effectiveness because the TA muscle activity was not well measured during the experiment. To address this, it would be necessary to incorporate an additional negative term to adjust the torque changes more smoothly. Therefore, future studies could focus on integrating foot kinematics, such as the joint angles.

VII. CONCLUSION

We redesigned the drive system of the 2-dof PAFO for higher cutoff frequencies and developed a heuristic-based control algorithm to improve walking stability and reduce body shaking. However, further research is needed to refine the algorithm and establish a stable steady-state torque profile.

Multimodal Sensor System for Continuous Monitoring in Elderly Care: A Pilot Study

Oriella Gnarra[1], Mehdi Ejtehadi[1], Sabrina Amrein[1], Daiki Shimotori[2], Tatsuya Yoshimi[2], Kenji Kato[2], Diego Paez-Granados[1]

***Abstract*—The growing prevalence of chronic health conditions in aging populations highlights the need for innovative solutions in rehabilitation and long-term care. We propose a multimodal system designed to automatically classify Activities of Daily Living (ADLs) and, in the future, support the prevention of secondary health conditions in institutionalized elderly individuals. This system continuously integrates six commercially available wearable and nearable sensors to monitor ADLs over two weeks, ensuring data completeness and maintaining high data quality throughout the trial. In this study, we present pilot data from two residents of a Japanese elderly care facility, demonstrating the proposed system's feasibility and usability. The collected data was comprehensive and robust, with residents showing strong acceptance of the wearable and nearable technologies for long-term use. These findings underscore the potential of multimodal sensory systems to enhance rehabilitation strategies by enabling continuous health monitoring. Integrating ADLs monitoring into rehabilitation programs may facilitate early detection of health changes and support personalized interventions, building on the success of digital health tracking in other clinical domains.**

***Index Terms*—Wearables, Nearables, Data Completeness, Data Quality, Activities of Daily Living**

I. Introduction

The demographic shift towards an aging population creates unprecedented challenges in global healthcare systems. Current projections indicate that the population pyramid will become increasingly concentrated with individuals over 65 within the next five decades [1]. This demographic trend is accompanied by a significant rise in chronic health conditions, including stroke, Parkinson's disease, Alzheimer's disease, and Spinal Cord Injury (SCI). These conditions require long-term, often lifelong, rehabilitation, spanning months to years [2], [3]. Effective management of chronic conditions in an aging society necessitates innovative approaches beyond traditional healthcare models.

Previous research has emphasized predicting morbidities in chronic conditions using data from self-reported surveys and healthcare records [3], [4]. The International Classification of Functioning, Disability, and Health (ICF), established by the World Health Organization (WHO), offers a standardized framework for assessing health and disability in individuals [5]. It provides a holistic approach by evaluating an individual's bodily functions, activities, and participation alongside environmental and personal factors influencing their health. In nursing homes, the ICF is applied through structured assessments conducted by multidisciplinary teams, including physicians, physiotherapists, and occupational therapists. These assessments map ADLs to the ICF framework, enabling tailored interventions to optimize functional health and promote independence among elderly residents [6]. Such frameworks are critical in addressing the complex interplay of aging, chronic conditions, and rehabilitation needs.

While these methodologies provide valuable insights, they have inherent limitations. Self-reported surveys and healthcare records present low-frequency data, which fail to capture dynamic, real-time changes in an individual's physiological or behavioral state. This limitation is particularly critical for individuals with chronic conditions, where early detection of secondary health complications can significantly affect outcomes. Despite its holistic approach, the ICF framework also has limitations. It may not fully capture the subjective experiences of individuals with disabilities, as it focuses on observable functioning. The framework's complexity can make it challenging to implement consistently and objectively across different healthcare settings and professionals. Additionally, the ICF may not adequately capture the temporal aspects of disability, as functioning can fluctuate over time.

In response to these limitations, the field of digital health has emerged, leveraging advanced technologies to facilitate high-frequency data collection and integrating real-world physiological and behavioral metrics into healthcare management [7]. However, tracking health conditions outside controlled environments remains a formidable challenge, especially for populations requiring continuous monitoring [8], such as those with SCI or neurodegenerative diseases [9].

Our collaborative efforts with the Swiss Paraplegic Center in Nottwil, Switzerland, aim to address these challenges by developing digital biomarkers for detecting Secondary Health Conditions (SHCs) in individuals with SCI living in community settings [10]. SHCs, including pressure injuries, cardiovascular diseases, and urinary tract infections, frequently exacerbate existing functional limitations, adversely impacting the quality of life and independence [11]. Monitoring ADLs has proven to be a promising avenue for early detection and progression tracking of SHCs, as changes in ADLs performance often

This research project was supported by the JST Moonshot R&D Program, Grant Number JPMJMS2034.

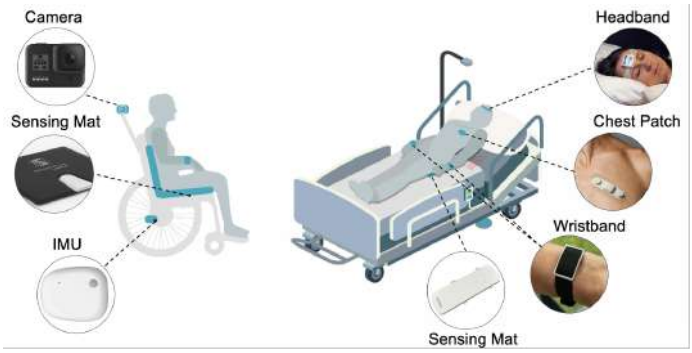

Fig. 1. The multimodal monitoring system comprises three wearables (two wristbands, one chest patch), three nearables (IMU, pressure mat, piezoelectric mat), and two reference systems (video camera, portable EEG).

reflect the onset of health complications [12].

Building on recent advancements in activity monitoring [13], [14], our research has focused on leveraging video-based classification systems and translating these insights into wearable sensor-based monitoring systems for continuous ADLs assessment. Moreover, this approach is not unique to SCI; similar SHCs and activity-based interventions are relevant in other chronic conditions, including stroke, Parkinson's disease, and dementia, which are increasingly prevalent among the elderly population [15].

The Life-logging study, part of the Moonshot program, extends this work by integrating multimodal wearable and nearable sensors into a comprehensive data collection framework for elderly residents in Japanese nursing homes. Our approach includes the future development of algorithms to classify ADLs, map them to the ICF framework, and improve sleep detection through advanced machine-learning techniques. This study aims to contribute to the body of knowledge on managing chronic health conditions and aging populations by providing actionable insights into real-world health monitoring. In this paper, we emphasize the importance of data completeness and quality in longitudinal monitoring, which is critical for reliable ADLs classification, ICF mapping, and sleep detection.

II. Methods

The study was conducted with approval from the National Center of Geriatrics and Gerontology Institutional Review Board (approval number 1692-2023). It involved two male participants aged 73 and 87, both wheelchair users residing in Ai-ko Home Obu, Japan. The first participant had a stroke that affected the mobility of his left, non-dominant (ND) arm; the second participant was diagnosed with Parkinson's disease. Data collection was performed over five consecutive days during two successive weeks, enabling a longitudinal analysis of the participants' ADLs and sleep patterns in a real-world community setting.

A. Sensor System

A multimodal sensor system was employed to capture the participants' physiological data. The system was designed based on prior work in SCI populations, emphasizing user-friendliness, unobtrusiveness, and measurement reliability [7]. The system consisted of three wearable and three nearable sensors, alongside two reference systems, as shown in Tab. I and Fig. 1. Fig. 1 is an updated version of our previously published work [16].

TABLE I
Wearables and Nearables Integrated in the Sensor System.
ECG - Electrocardiography; **PPG** - Photoplethysmography

Sensor	Manufacturer	Modality	Frequency
Headband	HomeSleepTest SOMNOmedics, Germany AG	EEG Acceleration	256 HZ 100 Hz
Chest patch	SDK01 VivaLNK, Campball CA, USA	Acceleration ECG Heart Rate Respiration Rate	5 Hz 128 Hz 1 Hz 1 Hz
Wristband	CardioWatch 287-2 Corsano Health In., Cambridge MA, USA	Acceleration Bioimpedance Emography PPG Respiration Rate	32 Hz 32Hz 1/minute 128 Hz 1 Hz
Piezoelectric Mat	Nemuri SCAN Paramount, Japan	Sleep Stages Activity Respiration Rate Heart Rate	1/minute
IMU	MMS+ Mbient MbientLab Inc, San Francisco, USA	Acceleration Angular Velocity	50 Hz 50 Hz 2000°/s
Pressure Mat	Sensomative, Rothenburg, Switzerland	Pressure Distribution	20Hz
Videocamera	Hero 9 Black GoPro Inc., San Mateo CA, USA	Video	24 Fps

The wearable sensors included two wristbands, one per wrist, for monitoring physiological data such as acceleration, bioimpedance, heart rate, and respiratory rate, and one chest patch for capturing cardiac and respiratory parameters. The nearable sensors included a pressure mat placed on the wheelchair seat to measure pressure distribution, a Inertial Measurement Unit (IMU) mounted on the wheelchair right wheel to track mobility dynamics, and a piezoelectric mat positioned on the bed to assess sleep-related metrics. The reference systems included a video camera, used to record participant activities and serve as ground truth for ADLs classification, and a Electroencephalography (EEG) headband, which provided high-fidelity sleep stage recordings.

This multimodal system was carefully selected to balance comprehensive data collection with participant comfort.

B. Study Protocol

The study protocol comprised three phases: synchronization, training, and longitudinal data collection.

During the synchronization phase, a standardized movement was performed at the beginning and end of each week to ensure accurate alignment of multi-modal sensor data. This

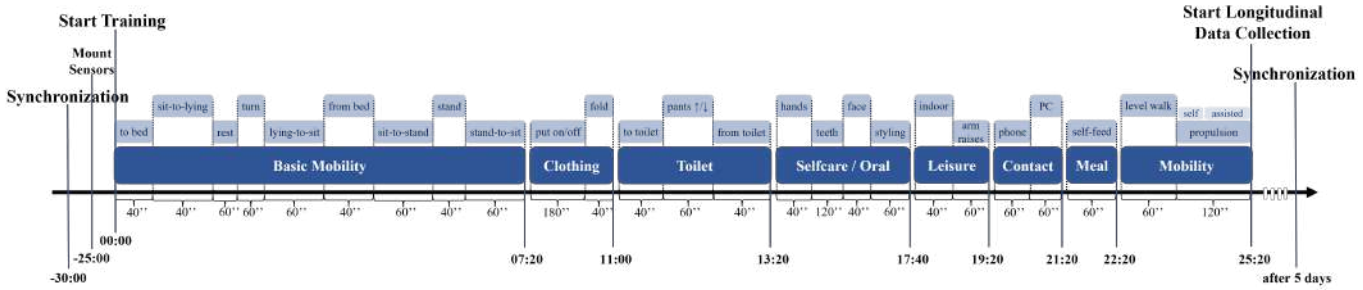

Fig. 2. The study protocol starts with the system time synchronization, followed by the training phase where ADLs are performed, ending with longitudinal data collection and end of synchronization.

movement created patterns across acceleration and pressure signals across all sensors, facilitating precise post-processing synchronization.

In the training phase, participants performed a predefined set of ADLs under the supervision of a researcher. The activities were derived from the ICF core set for SCI [17] and adapted for the elderly population in collaboration with clinical experts. As shown in Fig. 2, the activities were divided into basic mobility (turning in bed, lying to sit, transferring to bed, sitting to stand), grooming (clothing, toileting, self-caring), social activities (leisure and communication or contacts), self-feeding and other mobilities like self or assisted propulsion and level walking. The researcher logged each activity's start and end times using a custom mobile application while the camera recorded video data for validation. This phase lasted approximately 30 minutes. The video camera was removed after the training to minimize intrusiveness.

Participants continued their daily routines during the longitudinal data collection phase while wearable and nearable sensors collected continuous data. This phase extended over five days per week across two consecutive weeks.

C. Data Pipeline

The data pipeline was developed to manage the acquisition, transmission, and processing of multimodal sensor data, as shown in Fig. 3. Most sensors transmit data directly to a smartphone mounted on the wheelchair's backrest. For certain sensors, data was uploaded to the cloud before being relayed to a centralized server, while others routed data through our custom-made mobile application. Efforts are ongoing to standardize and automate this transmission process across all devices. Sensor data was parsed into a unified format and stored in a secure, study-specific database. This pipeline ensured robust data acquisition and storage, supporting the development of advanced algorithms for ADLs classification and sleep stage detection.

D. Data Preprocessing and Feature Extraction

We first filtered the time-series data using a second-order, low-pass Butterworth filter, applying a 3 Hz cut-off to preserve frequency components relevant to human motion activities. We then segmented each signal with a 5-second sliding window and a step size of 0.5 seconds. From each window, we extracted a broad range of time-domain features—including basic statistics (mean, standard deviation, range), amplitude metrics (avarage (avg) amplitude change, magnitude area), energy/entropy measures (logarithm (log) of energy, singular value decomposition (svd) entropy), and fractal descriptors (Higuchi fractal dimension)—alongside frequency-domain features computed via Fast Fourier Transform (FFT) and Welch's method (spectral absolute (abs) deviation order 1, spectral bandwidth order 3, spectral coefficient of variability (var), spectrum log slope, and band-limited power). These features were obtained using the TIFEX-Py toolbox [18]. Subsequently, the extracted features and their corresponding activity labels (level walking vs. assisted propulsion) were evaluated through one-way ANOVA for feature ranking. The resulting F-values were employed to quantify how effectively each feature discriminated between the two activities. In particular, a high F-value indicates that the between-group variance (i.e., the difference across activity labels) substantially exceeds the within-group variance, making that feature a strong candidate for distinguishing between the classes.

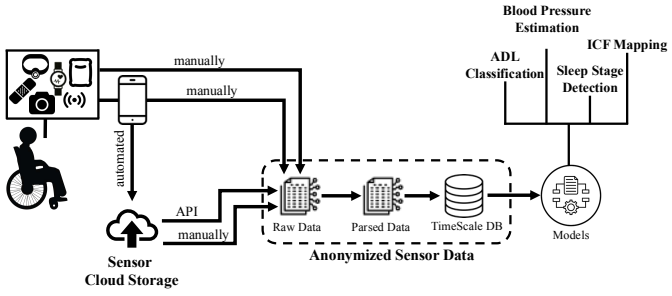

Fig. 3. Data collected by the wearables and nearables are transmitted to the server and parsed for analysis.

E. From ICF to the R4 scale system

The ICF, standardized by the WHO, provides a comprehensive taxonomy to describe functioning and disabilities related to health conditions; however, its practical application is limited by the complexity of its classification system, which includes over 1,400 codes. The Japan Association of Geriatric

Health Services Facilities (Roken Facilities) developed the R4 system as a structured care management system. It is divided into four stages: Assessment (R1): Conducting a multifaceted evaluation of the user's needs and daily functions; Care Plan Development (R2): Formulating individualized care plans based on assessment results; Implementation and Verification of Care Plan (R3): Delivering services in line with the care plan and confirming their execution; Monitoring and Change Evaluation (R4): Regularly monitoring changes in the user's condition and adjusting the care plan as necessary. This process enables an objective understanding of the user's condition, facilitating the provision of appropriate care. Okochi et al. [19] developed two scales to stage mobility and walking functions in elderly individuals based on the ICF codes. To address this issue, the authors selected 33 ICF codes related to mobility, transfer, and walking. They analyzed them using the Rasch model [20] to identify items suitable for a Guttman-type scale, which organizes items hierarchically by difficulty. Two scales were constructed: a *basic mobility* scale and a *walking* scale, each comprising four ICF codes. The scales classify functional performance into five stages, enabling rapid and standardized assessments. Validation demonstrated their applicability across settings, such as nursing homes and day-care centers, without significant differences in sex, age, or study location. The R4 System is designed for all professionals working in Roken facilities, including doctors, nurses, caregivers, rehabilitation specialists, and nutritionists. By tracking user condition changes, the system reflects the ideal state of Roken facilities, contributing to high-quality care.

III. Results

A. Data Completeness

Data completeness was assessed for all sensor modalities, participants, and weeks of recording to evaluate the reliability and feasibility of the multimodal monitoring system in a real-world nursing home environment. Results revealed variation in data completeness across different sensors and participants, with several factors influencing sensor performance, including device misplacement, battery life, and user adherence.

For the first participant during the first week, the chest patch reports 50% of data completeness, with missing data attributed to improper placement or detachment during daily activities. The right (dominant (D)) wristband achieved 97% completeness across all measured modalities, with 3% of data missing due to the daily charging period (approximately 30 minutes per day). In contrast, the left (non-dominant) wristband exhibited a lower completeness rate of 75%, with the final day of recording missing entirely. Only three out of four nights of sleep data were successfully captured. The piezoelectric mat achieved 100% data completeness, demonstrating the robustness and reliability of stationary nearable sensors. The IMU recorded 47% completeness, with significant data loss due to insufficient initial battery charge. The pressure mat reported 99% data completeness, indicating high reliability in pressure distribution measurement during seated activities.

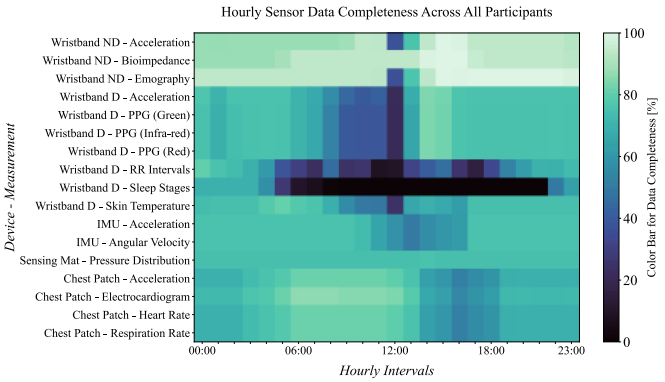

Fig. 4. The heatmap represents data completeness across modalities and participants.

In the second week, the chest patch improved performance with 95% data completeness, suggesting better device placement or participant adaptation over time. Both wristbands performed comparable to the first week, with the right (dominant) wristband achieving 95% completeness and the left (non-dominant) wristband achieving 65%. Extended charging periods accounted for the missing data in the wristband on the non-dominant arm. The piezoelectric mat maintained 100% completeness, reinforcing its reliability across recording periods. The IMU improved to 94%, indicating adjustments in the protocol, such as better initial battery preparation. The pressure mat consistently reported 99% completeness.

For the second participant during the first week, the chest patch demonstrated moderate performance with 55% completeness, similar to the first participant in the first week. The dominant wristband achieved 83% completeness, while the left wristband showed lower reliability at 55%, with only two out of four nights of sleep data successfully captured. The piezoelectric mat retained 100% data completeness, underscoring the value of non-contact sensing for sleep and activity monitoring. The IMU fell below 50%, primarily due to battery life constraints during extended use. The pressure mat maintained high performance with 99% completeness.

In the second week, the chest patch improved to 85% completeness, paralleling trends observed in the first participant. The wristband on the dominant arm achieved 80% completeness, while the wristband on the non-dominant side recorded 68%, with occasional charging issues impacting data continuity. Notably, the left wristband missed the third night of recording. The piezoelectric mat retained 100% completeness, further validating its robustness. The IMU improved significantly to 94%, reflecting protocol adjustments. The pressure mat consistently reported 99% completeness.

Across all recording sessions, the chest patch showed an average completeness of 52%. The right wristband achieved 88.75%, while the left wristband recorded 65.75%. The piezoelectric mat achieved 100%, the IMU reached 71.25%, and the pressure mat maintained high reliability at 99%. These results are visualized in a heatmap (Fig. 4). The heatmap

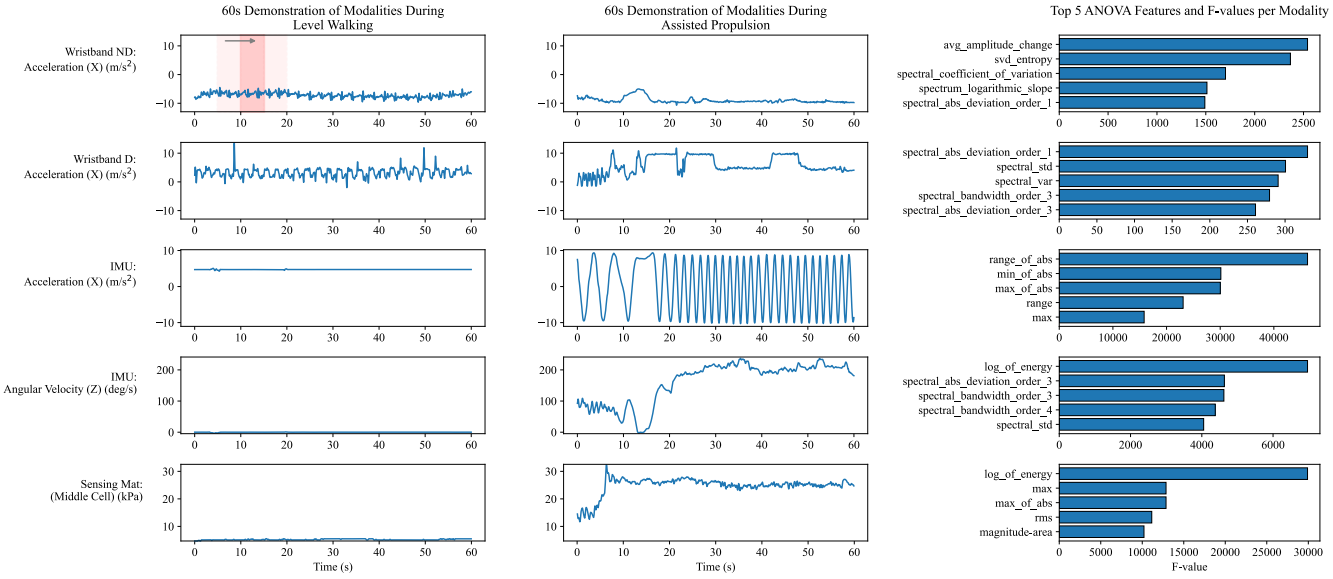

Fig. 5. On the left, selected sensor modalities show different signal patterns according to the performed activities. On the right are the five most discriminative extracted features.

reveals distinct patterns, such as the expected absence of sleep modality data during daytime hours. Devices requiring daily charging, such as wristbands, exhibited predictable data interruptions, typically occurring around 12:00 PM. Notably, some modalities, such as bioimpedance, continued to record intermittent data even when the sensor was not actively worn.

B. Data Quality

Data quality was evaluated by visualizing sensor outputs during the training protocol and inspecting signal integrity across 2 key activities. Figure 5 presents 60-second windows from multiple sensor modalities: wristband accelerometers (X-axis), the IMU on the wheel (X-axis acceleration and angular velocity), and the sensing mat (central pressure cell), during two activities: level walking and assisted propulsion and the top five discriminative features. All modalities were synchronized within each activity.

This figure aims to demonstrate the distinctive characteristics of the sensor modalities for these activities. The top discriminative features collectively capture the signals' amplitude distribution, variability, and frequency content.

Notably, during level walking, the wrist accelerometers show the repetitive hand movements that distinguish the activity, while the periodicity is lacking during self-propulsion. For the wheel IMU, acceleration data indicate wheel rotation, and the gyroscope's Z-axis (normal to the wheel) confirms angular velocity during propulsion, which is absent during level walking when the wheelchair is stationary. Finally, the pressure mat data show zero values during level walking, indicating the wheelchair is unoccupied, while non-zero values during propulsion confirm the participant's presence.

These visual differences, supported by extracted features, highlight the discriminatory power of the sensor modalities for classifying ADLs. This visualization is intended as an illustrative example and is not exhaustive.

C. R4 Scoring

The R4 mapping system, commonly used in Japanese long-term care health facilities, is designed following the ICF and is characterized by its ability to stage and assess individuals' activity and participation levels. Trained staff in the nursing home assigned scores based on observed performance across standardized tasks (Fig. 6). The first participant (Subj_A) scored 2/5 in "Walking", reflecting dependence on a wheelchair with the ability to take a few assisted steps. This participant scored 5/5 for dressing and undressing ("put on/off"), demonstrating full independence in these tasks. The second participant (Subj_B) also scored 2/5 in "Walking" but received a slightly lower score of 4/5 for "put on/off", indicating occasional need for assistance. The R4 scores provided a valuable framework for correlating sensor data with functional outcomes, enabling a deeper understanding of participant capabilities and limitations.

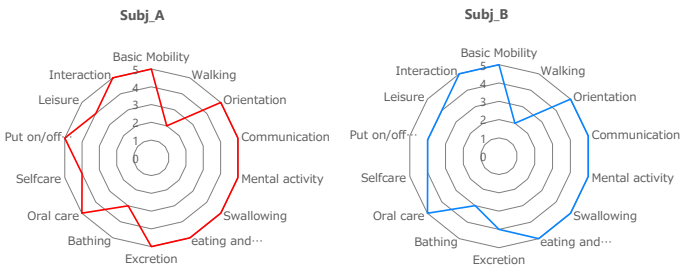

Fig. 6. R4 scoring results for two participants, highlighting differences in functional independence.

IV. Discussion

This study highlights the feasibility of utilizing a multimodal wearable and nearable sensor system for longitudinal monitoring in a nursing home environment. The observed data completeness across sensors demonstrates the practicality of the system, with specific sensors, such as the piezoelectric mat and pressure mat, achieving near-perfect data capture. This underscores the reliability of stationary sensors for continuous monitoring, while wearable sensors showed high variability influenced by device placement, user adherence, and charging requirements. Notably, the system's unobtrusive design and high acceptance among participants align with the broader goal of integrating seamless monitoring solutions in real-world settings.

The findings also emphasize the need for a larger dataset to address the limitations posed by the small sample size in this pilot study. Ongoing efforts to collect data from additional residents will enhance the robustness of our findings, enabling more comprehensive analyses. Specifically, future work will focus on developing machine learning algorithms for automatically classifying ADLs mapped to the ICF. This approach will facilitate objective and standardized assessments of functional health, which are critical for evaluating rehabilitation outcomes.

In parallel, improvements to sleep stage classification algorithms will be pursued, leveraging transfer learning techniques to enhance accuracy and adaptability across diverse populations. By refining these models, we aim to extend the system's applicability to broader use cases, including the early detection and management of SHCs. Ultimately, this work represents a significant step towards integrating multimodal sensing technologies in personalized rehabilitation strategies, addressing the complex needs of aging and chronically ill populations.

Acknowledgment

We thank the National Center for Geriatrics and Gerontology team for their support in the data collection, the Japanese Society for Promotion of Science (JSPS), and the Japan Science and Technology Agency (JST) Moonshot for their financial support in performing the study. We thank the nurses and the residents at the Ai-ko nursing home in Obu, Japan, for participating in the data collection.

Measuring Muscle Activation with the HRX-1 Wrist Manipulation Robot

Joshua Brown[1,7], Aaron Yurkewich[2,7], Maryam Zardbani[3], Lucille Cazenave[4,5], Etienne Burdet[4,7], Ildar Farkhatdinov[6,7]

***Abstract*— A portable robotic system, such as the HRX-1 robot designed for neuromechanics and rehabilitation research, enables motor assessment and training across diverse settings including clinics, laboratories, and home environments. This study presents the findings of wrist muscle activation measurements conducted using the HRX-1 robot in conjunction with surface electromyography (sEMG) electrodes on a cohort of fifteen healthy participants. Participants were seated and instructed to resist and maintain wrist flexion and extension against torques applied to their hand by the robot. Muscle activation data were recorded using two 32-channel high-density surface EMG electrodes placed on the forearm to capture activity from the flexor and extensor muscle groups. The analysis focuses on identifying the number of active regions within the recorded muscle activations under each experimental condition. As expected, flexor muscles were most active during wrist flexion and extensor muscles were most active during wrist extension. There was also no statistically significant change in the number of muscle regions active when torque was increased in each configuration.**

Fig. 1: The prototype 1-DoF joint manipulation robot

I. Introduction

A key effect of musculoskeletal (MSK) trauma and neurological illness is the loss of reliable upper limb function which can have a devastating impact on patients' quality of life. Grasping and manipulating everyday objects is made much more difficult by low muscle power, tremors, spasticity, unilateral weakness and low range of movement. Approximately 5% of the global population experience lasting loss of upper limb function due to stroke [1], while the prevalence of Parkinson's disease, which increases with age, reaches up to 4.8% in those aged 80 or over [2]. Alongside these serious and prevalent conditions, waiting times for physical therapy are increasing in many major healthcare systems [3] due to increasing patient numbers [4] and reduced gatekeeping via primary care [5], [6], whilst early intensive interventions remain essential to enhancing patient outcomes [7], [8].

Robot-assisted rehabilitation has long been proposed as a solution to many of these challenges [9]. Robots can apply forces and torques to resist and assist users, taking the physical role of a therapist, whilst guiding a patient through exercises either autonomously [10], [11] or under the remote control of a therapist [12], [13]. The ability to provide physical therapy without the need for a therapist to be present allows therapy to take place in non-clinical settings such as patients' homes, driving improved patient engagement [14] and increasing access in remote locations such as low- and middle-income countries that often do not have extensive networks of physical therapists or rehabilitation clinics [15].

Robots used in rehabilitation may take many forms, but have some common requirements in terms of power delivery (at least as much force/torque output as their intended user requires), haptic transparency (reduced friction/inertia when not driven, allowing the user to move freely) and ergonomics (must be comfortable to use, matching the user's biomechanics, range of movement and degrees of freedom). Many rehabilitation robots exist as research prototypes and are targeted at specific joints/body parts and specific conditions. For example, MIT's Skywalker robotic treadmill [16] and Imperial College's Hi5 dual-wrist robot [17] are both high cost, high performance room-scale research setups - ideal for scientific exploration of neuromechanics and robotic rehabil-

itation strategies, but not at all suitable for quick clinical or research deployment due to their design, mechanical structure and dimensions. More portable and light weight robotic solutions are required for faster and efficient preparation of neuromechanical and motor rehabilitation research. Desktop-scaled hand exercisers can resist the movement of the wrist and fingers [18]; however, the intricate mechanisms required to apply different forces and movements to different fingers would be difficult to maintain in real-world use.

Using interactive robots for physical therapy also raises the possibility of connecting the robot's sensors (i.e. user movement data) to computer games to promote engagement and reduce nonadherence, a serious limitation of traditional physical therapy [19]. This gamified rehabilitation has been demonstrated extensively with stroke patients, and a variety of upper limb exoskeletons [20], resistance machines [21] but also in contexts such as paediatric cerebral palsy [22] and recovery from hand injuries [23].

This paper presents the application of a portable lightweight HRX-1 robot for applying torques to the wrists of healthy human-participants, allowing biosignals such as muscle activation to be measured and studied. The HRX-1 robot's primary function is to generate controlled wrist flexion/extension torque, however compared to other similar devices [17], [24], [25], HRX-1 robot's key advantage is portability and compact design which enables fast integration, easy transportation and deployment. This paper presents the results of muscle activation from fifteen healthy participants which used the HRX-1 robot for wrist flexion and extension tasks. Surface electromyography recordings were analysed to identify number of muscle activation regions.

II. HRX-1 ROBOT DESIGN

There is clearly a need for a high-performance, portable, easily adaptable haptic robot that can be used in a variety of different rehabilitation and research contexts. A 1-DoF torque feedback robot has been designed based on Imperial College's Hi5 wrist manipulation robot [17]. This offers high torque, position and torque sensing and a variety of control modes in a compact robotic platform, whilst also being modifiable to work with a number of other joints. The HRX-1 robot measures approximately $280\times200\times115$ mm when collapsed for transportation, and weighs approximately 4 kg.

The below describes the design and construction of such a robot that can be used in many different scenarios.

A. Mechanical Design of HRX-1 robot

The key requirement of a portable, modular joint manipulation robot is the ability to exert strong, comfortable, measurable and controllable torques on specific joints, while maintaining high backdrivability. To achieve output torques that can be useful in human movement research, the robot is directly driven by the 600W Maxon EC90 series brushless direct current motor. Torque exerted against the robot by the user is measured with a Transducer Techniques TRT-100 torque sensor mounted on a flanged coupling to the motor shaft. This coupling has a large eccentric protrusion shaped

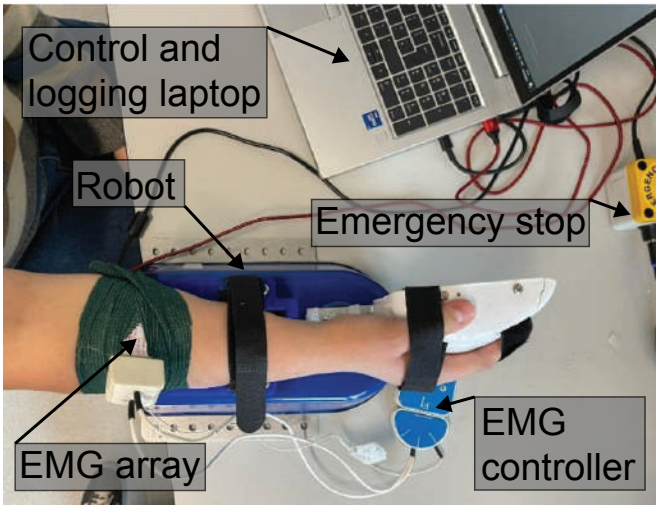

Fig. 2: The experiment setup used to capture s-EMG data of participants using the joint manipulation robot

to interfere with two endstop screws located on a circle around the motor shaft, which can be adjusted depending on the desired range of motion. The handle is mounted to the top side of the torque sensor such that the sensor measures the torque difference between the motor shaft and handle. The handle consists of a thin aluminium frame, ergonomically shaped plastic hand rest (designed for an open palm as this shape is known to minimise contraction in the forearm) and velcro straps to ensure good contact during abduction. The handle is shaped such that for an average-sized hand, the wrist joint will align with the axis of the motor which is essential for safe and comfortable transfer of torque. An arm rest with 8, 80 mm spaced stages of adjustment is mounted on the top of the robot in line with the handle, with more velcro straps to constrain the forearm position and ensure that only the wrist joint is able to move and exert torque against the motor. The robot's key ergonomic features are highlighted in Figure 1.

The need for a portable robot raises the competing goals of low weight and durability. Mechanically, the robot has a steel and aluminium skeleton which secures all load-bearing components, minimizing weight (a low volume of metal overall) whilst maximising rigidity and robustness. This consists of a lower plate to which the motor controller and drive circuit are mounted, and an upper plate which secures the motor and mainboard. Two socket head screws with plastic bumpers are screwed into this top plate, providing range of motion limits that can be adjusted for different users, joints or tasks. Steel supports above the second plate secure a thin, durable plastic cover and the arm rest. This ensures that there is a rigid metal support for the arm, allowing the robot to easily take its weight and keep it in a fixed position relative to the motor.

B. Electronic Configuration

The robot's motion is controlled by a Maxon EPOS4 70/15 controller which offers closed-loop position, velocity and

current control, the latter being most useful and most common in rehabilitation, neuromechanics and pHRI (physical human-robot interaction) use cases. The torque sensor output is calibrated and amplified with a Mantracourt ICA2H signal amplifier. This is delivered to the general-purpose analog/digital input/output ports on the controller which can be read by PC-based software, and exposed to other electronic devices/dataloggers via an I/O connector on the back of the robot.

The motor/handle position is read by a Maxon 6400 cpt (counts per turn) encoder which is fixed to the top of the motor. This is again wired to the motor controller and exposed to custom controllers and other hardware via I/O. The robot connects to a computer over USB and is powered by a standard 19.5 V laptop power adapter, both connected to ports on the back of the robot. The power supply can optionally be routed through an emergency stop button which will open the power supply circuit and disengage the motor in the event of a problem.

C. Software Integration and Control System

By default, the robot's onboard motor controller can receive torque output commands from either Maxon's C++ SDK or the EPOS4MATLAB wrapper, allowing the robot to be easily integrated with MATLAB's other scientific computing tools and supported data acquisition hardware. The robot's onboard torque sensor and encoder can also be read in this way, allowing the user's exertion on the handle and joint position to be measured and logged or used in interactive applications. Either method runs over a USB connection to a computer at up to 500 Hz which is sufficient for applications where, for example, the robot needs to produce pre-defined torque curves or impulses, which are common in neuromotor rehabilitation exercises.

III. Electromyography Evaluation of Wrist HRX-1 Robot

To evaluate the robot's ability to exert controllable torque on joints, a user study was performed using surface EMG to measure muscle activation in participants trying to resist the robot's manipulation. Fifteen adult participants were recruited to take part in this study (male and female, ages 20-35). Two participants were left-handed. None self-reported any neurological or musculoskeletal impairment. All participants gave informed consent prior to taking part. The study received ethical approval from the Imperial College Research Ethics Committee with certificate number 21IC6935.

A. Setup

The prototype force feedback robot was placed on a standard-height work desk in front of and to the right of the participant. It was connected to a laptop computer running Windows 10 and MATLAB over USB. Two 32-channel HD surface EMG electrodes (GR10MM0804e electrodes, Sessantaquattro acquisition system, OT Bioelettronica) were attached to the participant's forearm to record flexor and extensor muscle group activation at 2 kHz. The participant's forearm was strapped to the arm rest of the robot, and their hand strapped to the open palm handle. The experiment setup is shown in Figure 2.

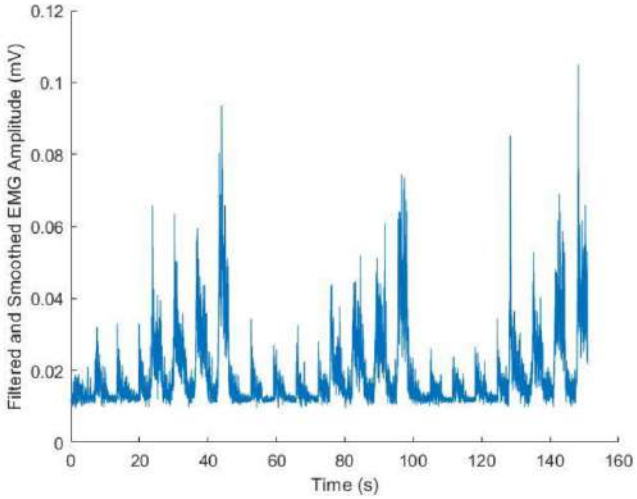

Fig. 3: Sample participant data showing an increasing EMG amplitude during wrist manipulation target tracking tasks at increasing resistance levels

B. Procedure

The initial calibration consisted of three repeats of wrist extension and flexion at a fixed angle of 30° while resisting an increasing torque at four different levels: 0.4 Nm, 0.8 Nm, 1.2 Nm, 1.6 Nm. Each repeat starts off by flexion exercises, holding at each torque level for 3.5 s with 3 s of relaxation between trials to prevent fatigue. After flexion at the highest resistive torque level, the extension trials start (no rest when switching from flexion to extension). Again, wrist extensions are held for 3.5 s at each increasing torque level with 3 s of rest between trials. The rest period is increased to 6.5 s between repeated blocks of trials.

C. Signal Processing and Data Preparation

All data processing has been done in MATLAB. First, a high-pass filter with a passband frequency of 5 Hz is applied on the raw EMG data. Then, outliers are eliminated using a Hampel filter where data points more than two standard deviations away from the local median within a window size of seven are replaced by that local median. At this stage, an envelope filter is applied using the root-mean-square method with a sliding window of 101 data points. The upper envelope signal is what is used for all further investigations. The data was sectioned into trials, separating each trial of each repeat at each torque level and wrist movement. Regional maxima are found by averaging the EMG amplitude recorded by each channel in each of these trials. Heatmaps were created by smoothing and interpolating the data using MATLAB's imresize and imshow commands. The regions corresponding to the top 25% mean EMG amplitude in each case were considered as the number of active regions for that trial.

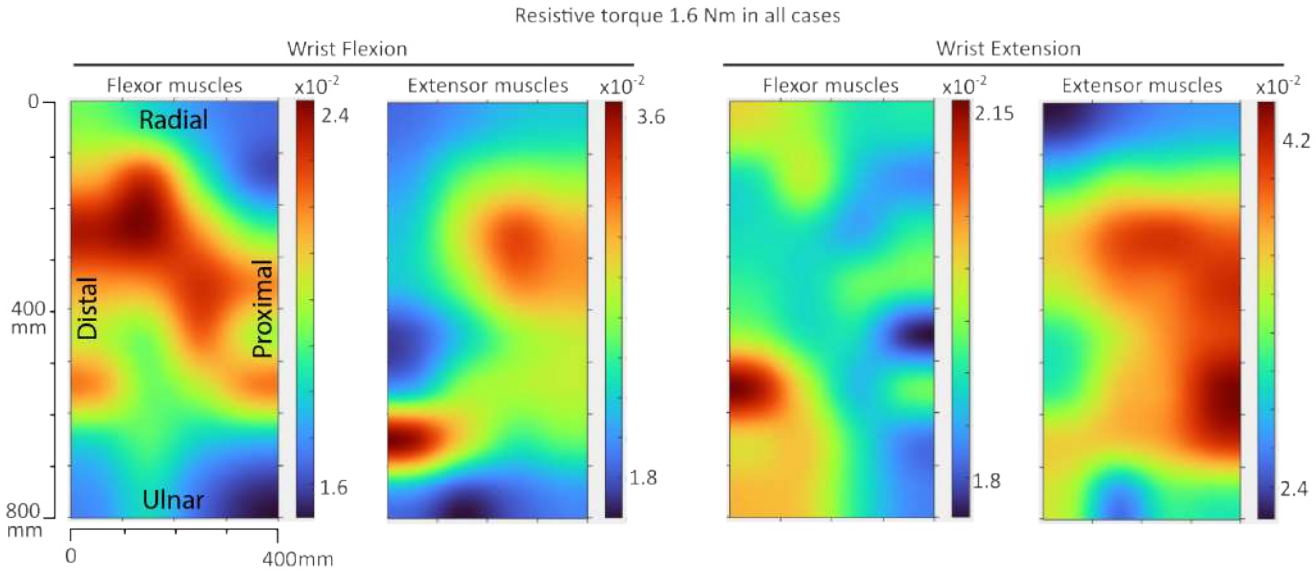

Fig. 4: EMG array heatmaps from electrode arrays positioned across the dorsal (extensor) and ventral (flexor) side of the forearm during wrist flexion and extension tasks

D. Results

Each participant's EMG signal for an active region electrode, after the filtering approach described above, is shown in Figure 3. The main parameter of interest in this study was the average number of active muscle regions when performing the same task at increasing torque levels. The heatmaps of EMG array data and the active region computed are shown in Figures 4 and 5. These heatmaps show that the greatest EMG activity is generated in the flexor muscles during wrist flexion and the extensor muscles during wrist extension. During wrist flexion, the flexor activity is greatest nearest to the elbow (proximal end of the forearm, top of image), suggesting that the flexor carpi muscles that control wrist motion are engaged more than the flexor digitorum muscles that control finger motion. One-way ANOVA tests were performed and there was no statistically significant difference between any of the groups ($p>0.3$ in all cases), showing that the number of active regions does not on average differ when the resistive torque is increased. The results show that the robot targets the wrist muscles specifically and the average number of active regions in the forearm does not increase when the resistive torque is increased, suggesting that the user continues to employ the same motor strategy.

IV. Discussion

The key objectives of the HRX-1 robot are: to be portable, such that it can be easily moved to clinical research sites or patients homes; powerful enough to use for human movement research; and easily connected to other sensors and equipment.

The design of the HRX-1 robot is substantially more compact and lighter than existing comparable systems. For example, whilst the Hi5 bimanual torque feedback robot does not have published size or weight characteristics it is a room-scale device [17], whilst the EDUSA Pro-R (the commercial successor to the IIT WristBot) measures $75\times129\times90$ cm and weighs 65 kg, including a permanently connected computer and display [26]. The smaller size and weight of the HRX-1 means that it can be comfortably carried in a large backpack when walking or cycling, or in hand luggage with most airlines. This supports the robot being used at multiple study locations for clinical or in-home research, as well as used at conferences and exhibitions for live demonstrations of research projects.

Published data on human wrist strength is highly variable, however values up to 12 Nm have been reported for midpronated (neutral) male wrist flexion and extension [27], [28]. Wrist strength in populations with musculoskeletal or neurological illness is known to be substantially lower, with conditions such as stroke reducing wrist flexion/extension torque to values in the range of 2.5 Nm or lower [29], [30], and ageing by up to 40% [31]. Whilst the 4 Nm generated by the HRX-1 would not be able to match or overpower a healthy user's wrist, it can produce meaningful resistance (or assistance) to movement and is well scaled for unwell or aged users. Torque outputs from existing wrist manipulation robots are known to be lower, with the MIT-MANUS having a maximum published 1.43 Nm flexion/extension torque [32] and a more recent, lightweight wrist robot based on twisted string actuation offering up to 2.4 Nm [33]. Recent applications of the HRX-1 robot for combined physical assistance and functional electrical stimulation demonstrated promising results for the robot to be used as a rehabilitation device in clinical settings [34], [35], as well as a research tool for human-robot interaction research [36], [37], [38].

Integration with other sensors is supported by built-in analog and digital input/output connections to the robot

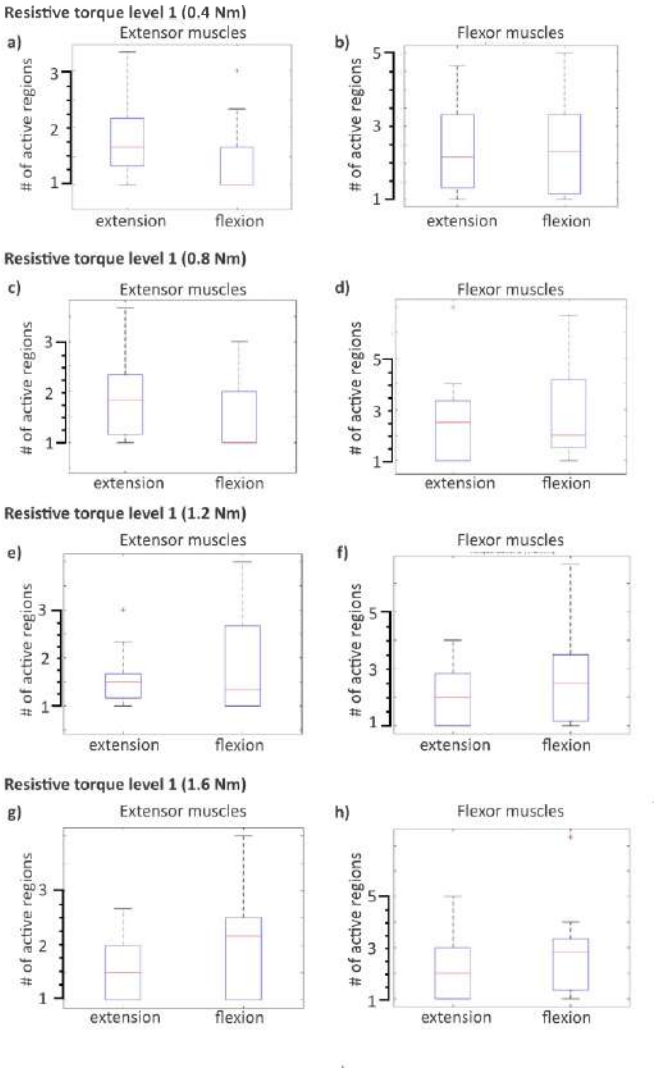

Fig. 5: Boxplots showing the number of identified active EMG regions for extensor and flexor muscles during wrist flexion and extension tasks at increasing levels of torque resistance.

controller, allowing a range of sensors to be directly connected and read. The use of a MATLAB programming environment also allows the robot and more complex PC-connected sensors to be controlled via the same software program, with the option of synchronising datastreams from the robot and sensors in hardware using pulses from the robot's built in input/output. Whilst it would be impossible to achieve compatibility with every possible external sensor, these approaches allow the robot to be used harmoniously with many popular accelerometers, gyroscopes, EMG, EEG, force/torque and pressure sensors.

V. Conclusion

The one-degree-of-freedom wrist manipulation robot presented in this study was evaluated through surface electromyography measurement tasks. The findings demonstrate that the HRX-1 robot satisfies the requirements for a portable, high-performance, and modular torque feedback robotic system. The device successfully generated sufficient torque to support experimental studies involving sEMG recordings in healthy participants.

Integration of the wrist robot with a multi-channel sEMG measurement system provided reliable data acquisition and facilitated research-relevant analyses. Specifically, the system enabled the identification and localization of activation regions corresponding to the extensor and flexor muscle groups during wrist movements.

Design of a Low-cost VR-Based Robotic Pedal System with Dynamic Resistance and Muscle Activity Feedback

Claudia Simon Rueda[1], Peter Snow[1], Rodrigo Mendez[1] and Rui C.V. Loureiro[1]

***Abstract*— This paper presents the design and usability evaluation of an affordable, virtual reality (VR)-integrated robotic pedal system aimed at enhancing lower-limb rehabilitation through interactive gaming. Key features include real-time cadence monitoring, dynamic resistance adjustment, and muscle activity tracking via electromyography (EMG) sensors. A usability study with 7 healthy participants, demonstrated increased cadence and symmetry scores in VR conditions. Clinician feedback supports the device's potential for at-home rehabilitation, though EMG sensor calibration remains a key improvement area.**

I. INTRODUCTION

As global demographics shift, the aging population continues to grow rapidly, with over 10% of individuals worldwide aged 65 or older in 2022, projected to increase to 25% by 2100 [1]. Age-related declines in mobility, muscle strength, and coordination significantly impact independence and quality of life for many older adults, raising the demand for effective, accessible neurorehabilitation solutions [2]. Neurorehabilitation, historically reliant on conventional methods such as range-of-motion (ROM) and muscle-strengthening exercises, has evolved to include advanced, sensor-driven approaches aimed at improving motor function and engagement [3].

Pedaling-based rehabilitation was first introduced to neurorehabilitation protocols during the mid-20th century, gaining attention for its ability to engage multiple lower-limb muscle groups in rhythmic, repetitive motion conducive to neuromuscular adaptation [4]. Studies have shown that pedaling stimulates the primary motor cortex and cerebellum, helping restore coordinated muscle activities that support motor recovery [5]. Cycling metrics, including cadence (RPM), speed, and symmetry, are commonly used to assess exercise intensity, endurance, and coordination, all critical to optimizing outcomes in cycling-based rehabilitation [6], [7].

Current pedaling-based devices vary in accessibility, interactivity, and cost. Basic pedaliers are affordable (under £50) and portable, yet they lack adjustable resistance and feedback mechanisms, limiting their rehabilitative effectiveness [8]. Stationary bikes offer an intermediate option, with prices around £200 and simple metrics like cadence. However, they lack the adaptability and immersive feedback critical for effective rehabilitation, particularly in at-home settings [9]. Some smart exercise bikes with integrated gaming, provide real-time feedback and multiplayer functionality but are costly (often over £1,000) and subscription-based, making them inaccessible for many patients and lacking specialized rehabilitation features such as electromyography (EMG)-based muscle biofeedback [10].

At-home, low-cost solutions offer substantial potential for addressing these gaps, supporting effective rehabilitation by reducing costs, improving accessibility, and increasing adherence [11]. These devices must be designed to accommodate various user needs and capacities, incorporating real-time feedback, low-power sensors, and intuitive interfaces to maintain user engagement. By integrating features like dynamic resistance and VR-enhanced biofeedback, low-cost devices can bring essential therapy tools into the home, supporting routine rehabilitation and potentially alleviating strain on healthcare systems [12].

This study introduces a VR-integrated robotic pedal-based rehabilitation device that combines an affordable cadence sensor with a dynamic resistance system and EMG-based feedback for real-time monitoring of muscle activity. Unlike existing low-cost devices, this system dynamically adjusts pedal resistance in response to virtual terrain changes, creating a more realistic and engaging experience, allowing different exercise intensities throughout the session. By integrating EMG sensors to assess muscle activation and provide symmetry feedback, the system encourages balanced specific muscle engagement rather than just exerted force like other devices. As an experimental device, there was interest in seeing muscle activity. This design addresses gaps in cost, functionality, effectiveness, modularity, and usability, aiming to improve patient adherence and outcomes through gamified, accessible rehabilitation.

II. USER REQUIREMENTS AND DESIGN SPECIFICATIONS

The VR-based pedal rehabilitation device was developed in response to user needs for affordability, ease of setup, and seamless integration with virtual environments. Key user requirements included a low-cost, adaptable design suitable for a range of seating configurations (e.g., bed, wheelchair, bench) as well as a setup that could support both leg and arm exercises.

In designing to meet these requirements, a comprehensive review of existing cost-effective pedaling devices revealed limitations in current models, particularly regarding the lack of real-time biofeedback. To address this, the device was

This work was supported by the La Caixa Postgraduate Fellowship, awarded to Claudia Simon Rueda, and University College London.

[1]Claudia Simon Rueda, Peter Snow, Rodrigo Mendez and Rui C.V. Loureiro are with Aspire Centre for Rehabilitation Engineerinf and Assistive Technologies, University College London, WC1E 6BT London, UK {claudia.rueda.23, p.snow, rodrigo.mendez.21, r.loureiro}@ucl.ac.uk

created with modular, replaceable components and constructed from low-cost materials and additive manufacturing techniques, ensuring accessibility while allowing for customization and potential upgrades. The device's configuration minimizes loose wiring, enabling simple assembly and disassembly for various therapeutic settings.

III. System Design and Methods

The centralized control hub is an Unreal Engine 4 (UE4) cycling game that processes sensor inputs and adjusts the virtual environment and pedal resistance in real time, as seen in Fig. 1. It consists of a SparkFun microcontroller and an Arduino Nano interface with EMG sensors and a motorized gear system to monitor muscle activity and dynamically modify resistance. Using two microcontrollers allows for efficient handling of the separate demands and ensures precise, real-time responsiveness. Additionally, a Bluetooth Low Energy (BLE) cadence sensor transmits data to a Python script, which synchronizes the user's pedaling with the avatar's movement in UE4. The system, compatible with a Windows Mixed Reality HMD for 3D immersion, exports session data for research analysis or clinician review.

A. Hardware

The hardware design integrates sensors and actuators in a pedalier [13] that work in conjunction with the VR environment to capture user metrics and dynamically adjust resistance as seen in Fig. 2.

1) Cadence: A Magene S3+ Speed/Cadence Dual-Mode sensor [14] was chosen for measuring pedaling cadence due to its Bluetooth Low Energy (BLE) capability, which ensures low power consumption and stable data transmission at a rate of 2 Hz. The sensor is mounted on the crank arm of the pedal system, transmitting real-time RPM data to a Python script that processes and forwards this information to the VR interface in Unreal Engine (UE). The cadence data determines the speed of the virtual cycling avatar, providing a responsive and realistic experience for the user.

The system's cadence detection performance was analyzed by measuring the delay and accuracy of cadence data transmission from the BLE cadence sensor to Python and later to the VR environment in Unreal Engine 4 (UE4) and averaging the results of 3 trials. Accuracy was assessed by pedalling to a metronome at 30, 40, 50, and 60 BPM. Delay measurements were obtained by recording timestamps at three points—when pedaling began, when Python registered non-zero cadence, and when Unreal Engine (UE) did the same.

2) Motor-driven gear mechanism: The system uses 2 hybrid NEMA 17 0.44Nm stepper motors [15], chosen for their optimal size-to-torque ratio, paired with A4988 drivers [16] to control pedal resistance. This dual-motor setup was necessary to generate enough torque to fully screw the resistance knob in to notice the change in resistance. Adjusting resistance enables dynamic simulation of terrain changes, enhancing the VR experience by simulating uphill

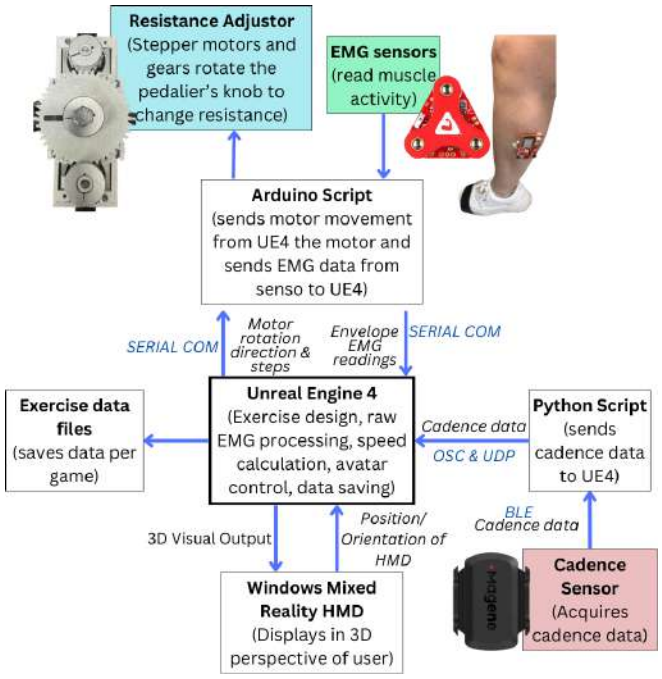

Fig. 1. System architecture illustrating the interaction between hardware components (cadence sensor, EMG sensors, motor-driven gear system) and software elements (Arduino and Python scripts, Unreal Engine 4, Windows Mixed Reality HMD). Data flows through serial communication, Bluetooth, BLE and OSC/UDP protocols to synchronize user inputs with the VR cycling environment.

Fig. 2. Hardware configuration of the VR cycling system, showing key components including the Magene S3+ cadence sensor, motor-driven gear mechanism, and adjustable resistance knob. Collar shafts securely attach the PLA gears to the motors and knob, and the electronics storage box secures the Arduino and motor drivers.

or downhill resistance. The motors are powered by a 24V external power source, while an Arduino Nano microcontroller handles motor control, synchronizing resistance levels with the virtual terrain in real time.

A 3:1 spur gear mechanism transfers the rotation from the motors to the pedal resistance knob, with this ratio enhancing the mechanical advantage and providing enough torque to allow the precise control of resistance levels. The PLA gear mechanism is encased in a 3D-printed housing of the same material designed to provide stability. Each slope condition in the game is encoded within Unreal Engine and transmitted to the Arduino Nano via serial communication, instructing the motor to rotate clockwise or counterclockwise to adjust resistance based on the simulated terrain.

3) EMG: Muscle activity is monitored through two Myoware 2.0 Muscle wireless sensors [17], [18] positioned

on the gastrocnemius lateralis of each leg. These low-cost wireless sensors (70 $) are more affordable than expensive commercial EMG systems designed for intense exercise. Given the altered biomechanics in the seated position on the chair, this muscle plays a primary role in generating plantarflexion torque, which is central to pedaling dynamics in this setup [19]. These sensors, attached via disposable electrodes, provide real-time muscle activation data, highlighting any asymmetries in leg use. The Myoware sensors are connected to a SparkFun Thing Plus ESP32 microcontroller, which transmits data to the VR environment through Bluetooth.

To analyze symmetry, the system computes a symmetry score based on the normalized difference in activation levels between the left and right legs. The EMG signals are first smoothed using a moving average to reduce noise and capture consistent muscle activation trends. The symmetry score is then calculated as [20]:

$$\text{Symmetry Score} = \left(1 - \frac{|EMG_{\text{left}} - EMG_{\text{right}}|}{EMG_{\text{left}} + EMG_{\text{right}}}\right) \times 100 \quad (1)$$

This score, expressed as a percentage, provides real-time feedback visualized within the VR environment to encourage balanced muscle engagement and support users in achieving their rehabilitation goals.

B. Software: VR environment

The software component combines real-time data processing and VR simulation to create an interactive rehabilitation experience. Data from the cadence and EMG sensors feed into the VR game developed in Unreal Engine 4.27.

The VR cycling game, developed using the Unreal Engine Vehicle Advanced Pack, features an animated bike and cyclist, where the avatar's pedaling speed is directly controlled by the user's cadence input. This synchronization between physical pedaling and virtual speed provides realistic feedback, enhancing immersion and engagement. The cycling path includes hills up and down, which trigger resistance changes and encourage users to adapt their pedaling speed, simulating real-world cycling conditions.

To increase user motivation and adherence, the VR environment incorporates gamification features such as coin-collecting boosters and speed multipliers, all providing auditory feedback. These boosters are activated when users collect designated items during the game. For instance, collecting a speed booster doubles the avatar's speed for 10 seconds, encouraging users to take advantage of it and pedal faster to get more coins. These features align with gamification principles by providing a balance of challenge and reward, fostering long-term engagement and helping users reach their rehabilitation goals [11]. Fig. 3 shows the game environment as seen from the cyclist perspective.

C. Usability Study

After prototyping, a usability study aimed to evaluate the system's usability, user experience, and performance with seven healthy participants (4 men, 3 women) recruited with

Fig. 3. Game main screen. Coin related features and active multipliers (if any) on the left top corner. Time, distance and a time progress bar are centered at the top. Speed, cadence and symmetry score on the top right corner. Below is a symmetry bar - green with symmetric scores and red with a "Dominant" label if asymmetric. The bottom left graph shows the evolution in speed and the bottom right graph the evolution of muscle activity for both right (red) and left (green) legs.

UCL ethical approval (ID: 6676/007). Participants had no lower limb injuries and completed two randomized 5-minute pedaling sessions: one in a VR environment and one non-gamified, to simulate typical at-home rehabilitation settings.

The study protocol included electrode placement and EMG calibration exercises, followed by a randomized sequence of two pedaling sessions and a 5-minute rest in between. Performance data on cadence, muscle activity, and a symmetry score were recorded, while additional VR-specific data (e.g., distance traveled, terrain type) provided further insights. User experience was assessed with a 17-question electronic questionnaire focusing on comfort, ease of use, engagement, and motivation.

The usability study included a comparative analysis of VR-enabled pedaling sessions against non-gamified sessions. Quantitative metrics collected, including cadence consistency and symmetry score from EMG data, showed marked differences between the two conditions.

Data analysis was divided into two primary components:

1) Comparison of VR vs. Non-gamified experience: Paired t-tests were conducted on cadence, EMG values, and symmetry to quantify differences in physiological responses between VR and non-gamified pedaling conditions. Motivation, engagement and user preference were further analyzed with questionnaire responses to assess user-perceived differences.

2) VR Environment Evaluation: ANOVA tests were applied to examine variations in cadence and EMG values across different in-game terrains - thus distinct resistance levels -, and under conditions with or without in-game speed and coin multipliers. Symmetry progression over time was also analyzed to understand the impact of this live feedback on symmetry correction. Additionally, subjective evaluations of ease of use, ease of learning, and user satisfaction provided insights into system usability and participant experience.

Feedback from a post-study interview with a physical therapist offered professional insights into the system's potential applications in rehabilitation and highlighted opportunities

for gamified therapy advancements.

IV. Results

A. Hardware Performance

*1) **Cadence Delay and Accuracy**:* High accuracy was shown at faster pedaling speeds (40–60 BPM) with errors under 0.7%, but dropped significantly at 30 BPM (error 16.26%), suggesting a poor performance at lower speeds.

The average delay between real-time activation and detection in Python was 2.62 seconds, aligning closely with the 3-second delay specified by the vendor—a typical lag in cadence sensors due to their inherent data-processing mechanisms. As seen in Fig. 4, further delay from Python to UE is under 0.2s, ensuring near-seamless integration with the VR system.

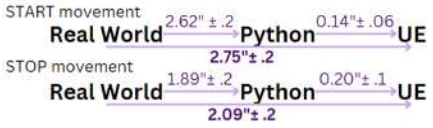

Fig. 4. Cadence latency breakdown for when initiating and stopping movements across the Real World, Python processing, and UE, with times indicated in seconds

*2) **Cycling Pattern in muscle activity**:* The cycling pattern was evaluated to assess how closely the system emulated a natural cycling movement. The data collected on pedal strokes, measured by both cadence sensor readings and muscle activation levels, aligned closely with established cycling biomechanics literature. Specifically, the cadence readings and leg muscle activation profiles, as seen in Fig. 5 mirrored the general trend reported by [21], who documented ideal cycling form characteristics for rehabilitation contexts. The system's ability to replicate a realistic cycling pattern supports its potential utility in rehabilitation settings where the simulation of natural movement is essential.

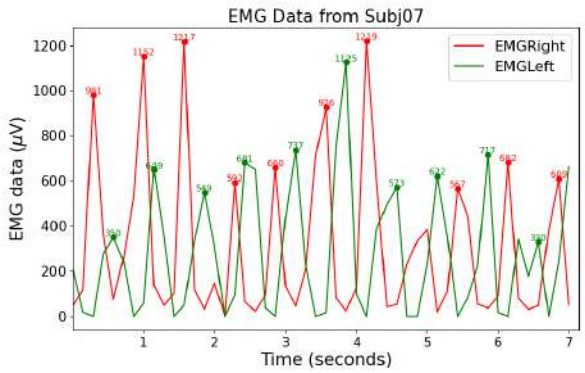

Fig. 5. Pedaling EMG data: Muscle activation patterns for the right and left legs during pedaling, recorded from Subject 07. The EMG data illustrate periodic activation peaks corresponding to pedal strokes

TABLE I
Comparison of VR and Non-Gamified Metrics

Metric	VR	Non-gamified	P-value
Cadence (rpm)	88.02	83.34	0.041*
EMG (μV)	208.94	153.51	0.106
Symmetry Score (%)	72.06	60.22	0.007
Engagement (out of 5)	4.1	2.4	0.0009*

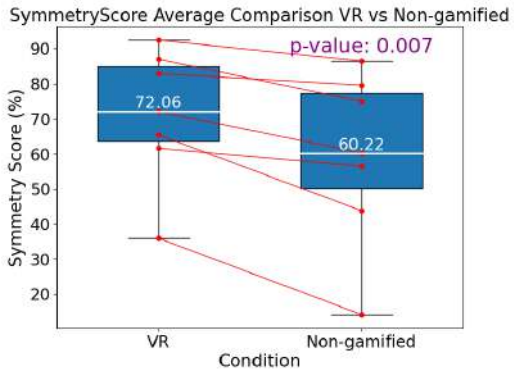

Fig. 6. Box plot with overlaid individual data points comparing average symmetry scores between VR and non-gamified conditions with a paired t-test.

B. Usability Testing of the System

*1) **Comparison of VR vs. Non-gamified experience**:* The comparison between VR and non-gamified metrics seen in Table I shows that VR significantly increased cadence, with a value of 88.02 rpm compared to 83.34 rpm for non-gamified ($p = 0.041 < 0.05$). This represents a 5.6% increase in cadence when using VR. Symmetry score was also significantly higher (p=0.007) for VR (72.06%) than for non-gamified (60.22%) as seen in Fig. 6. Mean muscle activity did not differ significantly between the two conditions ($p = 0.106$). Notably, VR also led to a higher engagement score (4.1 out of 5 for VR vs. 2.4 for non-gamified, $p = 0.0009$), with all users explicitely selecting the VR experience. These results suggest that VR increases cadence and engagement compared to non-gamified pedaling sessions. The observed evolution in Symmetry Score for participants throughout the session is very variable and there is no evidence of a clear trend of improvement in neither of the pedaling sessions.

*2) **VR Environment evaluation**:* Cadence and electromyography (EMG) values were evaluated across downhill, flat, and uphill terrains as seen in Table II. Cadence values showed no significant difference between terrains, with averages of 69.01 rpm (downhill), 67.25 rpm (flat), and 66.30 rpm (uphill) ($p = 0.425$). In contrast, EMG activity exhibited significant variation, with the highest median values recorded for the uphill condition (229.33 μV), followed by downhill (197.77 μV), and the lowest on flat terrain (160.28 μV), showing a statistically significant difference ($p = 0.0031$) as seen in Fig. 7. These findings suggest that while terrain type does not significantly influence cadence, it has a substantial impact on muscle activation.

TABLE II

CADENCE AND EMG VALUES ACROSS DIFFERENT TERRAINS

	Downhill	Flat	Uphill	P-value
Cadence (rpm)	69.01	67.25	66.30	0.425
EMG (µV)	197.77	160.28	229.33	0.0031*

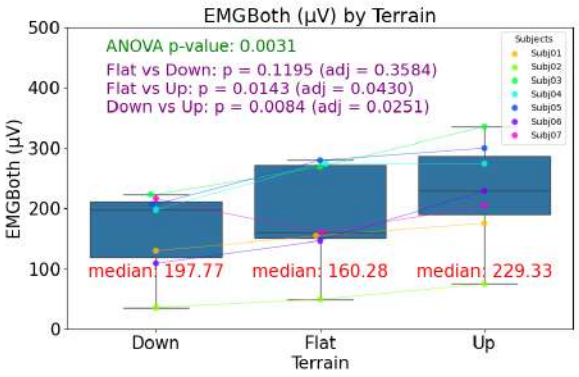

Fig. 7. EMG by terrain

TABLE III

CADENCE AND EMG METRICS ACROSS MULTIPLIER CONDITIONS

Metric	None	Both M	Coin M	Speed M	P-value
Cadence (rpm)	88.09	71.00	70.50	63.13	0.09
EMG (µV)	204.59	232.03	178.78	208.05	0.17

Table III presents cadence and EMG metrics across different multiplier conditions: no multiplier, both multipliers, coin multiplier, and speed multiplier. Neither cadence nor EMG values showed statistically significant differences across these conditions (p = 0.09 for cadence and p = 0.17 for EMG), indicating that the presence or type of multiplier did not substantially impact these metrics. Although the data suggest slight trends—such as a decrease in cadence with the speed multiplier (63.13 rpm) and higher EMG with both multipliers (232.03 µV)—these variations were not strong enough to reach significance. This suggests that multiplier conditions, as tested, may not have a meaningful effect on cadence or muscle activation. However, participants reported that the multipliers provided additional incentive during the activity, showing that such features have motivational benefits even if they do not significantly impact physiological metrics.

*3) **User experience**:* Qualitative feedback from the participant questionnaire highlighted positive reception towards the VR game's immersive and interactive aspects. All participants noticed the increased resistance when pedaling uphill, rating it 3.8/5 smooth and realistic and all but one (85%) noticed the decreased resistance going downhill, with 3.07/5. Participants reported that visual feedback (e.g., avatar movement, graphs) and game elements (e.g., boosters, coins) enhanced their motivation, which aligns with principles of gamification shown to improve engagement in physical therapy contexts [22].

C. Clinician feedback

Clinical feedback highlighted the potential of the device not only for at-home but also for inpatient rehabilitation, noting that it could be especially valuable in hospital settings where patients often risk muscle waste due to prolonged periods of inactivity. This portable device could be used directly from a patient's room—or even from the bed if mounted appropriately—reducing the need for visits to the hospital gym with a fixed schedule. The clinician emphasized that many patients lack motivation to exercise independently, often finding solo pedaling sessions boring and difficult to sustain without supervision.

They saw value in the EMG monitoring feature, as targeted muscle activity tracking could enhance patient awareness and facilitate a stronger mind-body connection.

Additionally, they suggested a mobile app version of the system, eliminating the VR component, to increase adaptability and make the device easier to integrate into inpatient settings where resources may be limited.

V. DISCUSSION AND CONCLUSION

The cadence sensor performs with high accuracy ($< 0.7\%$ relative error) at moderate to high cadences (≥ 40 rpm), making it well-suited for users with standard cycling speeds. However, it becomes less reliable at very low cadences (16.3% error at 30 rpm), limiting its applicability for certain rehabilitation patients with lower pedaling rates. While accuracy is not specified by the vendors, further comparisons with other models and sensors, such as IMUs, could expand its potential user base.

The data transfer to the system adds minimal additional delay. The delay is primarily noticeable at the start and end of pedaling, but does not impact the session itself. Additionally, a 3-second countdown at the beginning of the game effectively masks the initial lag, helping synchronize initial pedaling with virtual movement.

The muscle activity sensors captured gastrocnemius lateralis activation, with alternating muscle activity between legs resembling literature´s ranges of values [21]. Although basic calibration was undertaken for this project, further work will be carried out on implementing additional filters and calibration to normalize sensor readings and enhance measurement consistency.

The system successfully integrates the hardware components with the software, leveraging communication protocols that allow seamless data transfer between the VR environment and sensors and motors. The cadence sensor continuously monitors the user's pedaling speed, relaying real-time data to the game, which adjusts the in-game avatar's movement to match the user's cadence. This synchronization ensures that the virtual experience mirrors the user's real-world performance. Additionally, the resistance adjustments based on terrain changes—uphill or downhill—through the stepper motors, offers users an immediate physical response,

increasing or decreasing the effort required to pedal. The real-time feedback displayed on-screen, including visual cues related to muscle activity and symmetry, allows users to track their progress during the session. This immediate feedback and dynamic interaction create an immersive experience, enhancing user engagement and motivation, as stated by all participants. Overall, participants were satisfied with the VR session and preferred this to the non-gamified experience.

Results on pedaling performance show that the inclusion of VR elements significantly increase the user's cadence and symmetry. This agrees with [22], who demonstrates that a VR environment can increase exercise adherence and intensity by lowering perceived exertion that encourages users to push beyond their usual physical limits. It is also consistent with research [23], which found that interactive and feedback-rich environments can help correct asymmetries in motor function, likely through real-time visual and auditory feedback that encourages even effort distribution between limbs. With these results, developing a game specifically for upper limb rehabilitation could significantly enhance the system's versatility. For instance, designing virtual environments that simulate rowing, swimming, or other upper body movements could broaden the applicability of the system, making it more inclusive for different pathological conditions. This approach aligns with findings that demonstrated the potential of VR-based robotic rehabilitation systems to engage patients in targeted upper limb therapies [24].

Within the VR experience, there were significant variations in muscle activity with changes in resistance, particularly increasing during uphill terrain. These resistance changes did not alter cadence, with participants possibly focusing on keeping a constant cadence while increasing or reducing their effort. This ability to modulate resistance and thus muscle activation, allows for targeted strengthening and endurance training, enabling rehabilitation programs to be designed with varying intensities that adjust both muscle activity and resistance throughout the session and rehabilitation scheme, ensuring progression while preventing overexertion.

The system's ability to export session data opens future possibilities to integrate it into clinical practice. By providing detailed records of cadence, resistance, muscle activity, and symmetry, therapists could monitor progress, tailor rehabilitation plans, and enable remote adjustments, supporting the expanding field of tele-neurorehabilitation. Cybersickness was not specifically studied, it was unlikely to be an issue due to the seated position and short session duration. Future research could explore its impact on prolonged use.

Overall, the usability study and performance evaluations underscore the effectiveness of a VR-enhanced cycling system in promoting balanced, consistent pedaling mechanics. By providing real-time feedback and utilizing gamification elements, the system demonstrates significant potential as a therapeutic tool for neurorehabilitation and at-home exercise regimens.

Muscle synergies during gait of functionally-dependent subacute stroke survivors before and after robotic rehabilitation

Agnese Cherubini, Clara Sánchez Del Valle, Natacha León, Jesús Tornero, Juan C. Moreno, Clara B. Sanz-Morère

Abstract— **Stroke affects the neuromuscular control of humans, influencing muscle coordination and consequently gait patterns. Robotic devices can be useful to improve walking function and kinematics after stroke, but there is not much research related to muscle coordination through muscle synergies. This is the first study in which muscle synergies have been studied in functionally-dependent subacute post-stroke patients (FAC <2) in a robotic rehabilitation context. We analyzed muscle synergies during gait of three post- stroke patients before and after 2 months of robotic rehabilitation and correlated the results with functional improvements and kinematic changes. After the rehabilitation, patients walked faster, more independently, with normalized gait patterns and different muscle coordination. However, the results obtained underline the importance of a patient- specific therapeutic approach guided by the combination of multi-level metrics.**

I. INTRODUCTION

Stroke is an age-associated neurological condition that will drastically increase in the next decades due to the worldwide extended life expectancy (1,2). Stroke is the second most common cause of death and the first cause of disability worldwide (1). Post-stroke patients present lower walking speed, stance and swing time variations and an altered coordination of lower limb muscle activity, which are essential for balance and stability (3,4). Stroke also has a significant impact on the reduction of quality of life (5). For motor recovery of post-stroke patients, many technological devices have been developed for rehabilitation (2). Robotic rehabilitation is an increasingly used type of gait training, as it shows many advantages for both patients and therapists, increasing the frequency of repetitions of the walking therapy and consequently leading to improvements in locomotor functions (6). The effects of robotic rehabilitation on post-stroke patients have been studied using various metrics, such as functional improvements, kinematics, muscle activity, and corticomotor excitability (7). Another possible biomarker to study the effects of rehabilitation on post-stroke patients is muscle coordination, studied by deriving muscle synergies for electromyographic signals (3,7). Muscle synergies are the result of the synergistic activation of several muscles as a single functional unit. Research suggests that the central nervous system simplifies the simultaneous activation of different muscles, allowing them to function in a coordinated manner with a common specific goal (8). Currently, many studies have analyzed muscle synergies during gait in both healthy (8,9) and stroke patients (10,11). Post- stroke patients exhibit poor neuromuscular control, which leads to a reduced inter-muscular coordination characterized by altered muscle activation patterns (10). These alterations are associated with changes in muscle synergies number, electromyography (EMG) reconstruction and Variance Accounted for (VAF) (7). Research has shown that alterations of muscle synergies in post-stroke patients correlate with deficits in both biomechanical and clinical assessments (2,4,10). However, most of the studies have been conducted with stroke patients who underwent conventional therapy (12) and analyzed muscle synergies mainly while walking on a treadmill (4,5,10). Only a reduced number of research studies have examined muscle synergies changes in the context of robotic rehabilitation, and only four were related to lower limb rehabilitation (2,13–15). Of those, none were related to subacute stroke survivors, as two were related to chronic patients with high motor functions, which were able to walk independently with minimal supervision (13,14) and two explored muscle synergies in acute post-stroke patients (10-18 days after the stroke) with limited walking independence (2,15). The limited use of muscle synergies as a biomarker for stroke rehabilitation may be due to 1) the technical complexity of measuring EMG activity in patients with reduced gait abilities, 2) the complexity of analyzing intersubject variabilities due to the different neurophysiological conditions between each patient (7), 3) the need of additional complementary biomarkers such as kinematics or corticomotor excitability to understand muscle synergies in a global rehabilitation framework. Thus, though muscle synergies during gait have been widely accepted as an indicator for motor coordination (3,7), several aspects related to their utility in stroke rehabilitation assessment are still unclear.

In this research, we analyzed muscle synergies during gait of three subacute post-stroke patients with low functional abilities before and after two months of robotic rehabilitation. The main goal of this paper is to analyze and quantify how motor coordination can be modified in subacute post-stroke patients after a robotic therapy and to study whether this approach could be a viable means of tracking motor control changes and to observe progress in subacute stroke patients

This research is part of the NIMBLE project PID2021-123657OB-C31, funded by MCIN/AEI/10.13039/501100011033 and by the European Regional Development Fund.. Co-funded by grant RED2022-134319-T and by the European Union with grant DTS23/00047, funded by MCIN/AEI/ 10.13039/501100011033. A.C, N.L and J.T are with Hospital Los Madroños (Madrid, Spain). with low motor functions. Finally, we aim to determine if muscle synergies during gait are related to functional outcomes and kinematics improvements, following a multi-level approach (2,16).

Our hypotheses include that after the rehabilitation 1), patients will obtain higher scores on clinical scales, 2) patients will modify kinematics walking patterns, 3) patients will modify their muscle coordination and motor control during gait, considering both time-dependent and time-independent components. Finally, the analysis of these multi-level metrics may provide a clearer understanding of the clinical meaning of the modified muscle coordination.

II. Materials and Methods

A. Protocol design

Three subacute stroke participants were enrolled for a 2-month clinical study in which they received robotic gait therapy with the Walkbot Premium (P&S Mechanics, Seoul, Korea), a robot-assisted locomotor training system (6) and daily conventional prescribed rehabilitation, including physical, occupational, speech and cognitive therapy. Robotic rehabilitation was carried out five times a week, for 45 minutes, in which they received at least 30 minutes of active walking therapy. Assessment sessions were carried out before the start of the study (PRE) and at the end of the study (POST). The assessments included the Functional Ambulation Category (FAC), Functional Independence Measure (FIM), the 10-meter walking test (10MWT), and electromyography activity (EMG) and kinematic data collection during natural overground walking. For the 10MWT, two runs were carried out at the patient's self-selected speed. Patients walked on a 14-meter corridor, but only the 10 central meters were considered to avoid the acceleration and deceleration phases. EMG data were recorded during the 10MWT from 16 bilateral muscles: Gluteus Medius (GlMe), Rectus Femoris (ReFe), Vastus Lateralis (VaLa), Biceps Femoris (BiFe), Semitendinosus (Sem), Tibialis Anterior (TiAn), Gastrocnemius Medialis (GaMe) and Soleus (Sol) by means of the wireless Trigno Research + system (Delsys Inc., Boston, MA) integrated in Xsens MVN (Movella Inc., Henderson, NV). Though most of the studies in literature measured EMG activity using optoelectronics gait analysis systems, we selected a system based on inertial measurement units (IMUs) that provide practical and faster setting up, suitable for patients with lower motor functions that need physical support by a physical therapist. EMG sensors were placed based on the SENIAM recommendations (17).

B. Patient recruitment

Inpatients whom have experienced a single stroke event between 28 and 200 days prior to enrollment, present with hemiparesis, have a minimum cognitive level (Token Test > 8), and were at least 18 years old were eligible for recruitmentPatients could not participate if they had any orthopedic, cardiorespiratory or neurological pathology that could limit walking (painful arthritis, osteoporosis, heart failure, uncontrolled hypertension, severe cognitive damage…). Other exclusion criteria for gait training with the robotic Walkbot device included non-healing ulcers or active infections, a maximum height of 200 cm and a maximum weight of 135 kg. The study was accepted on the 12th of April 2023 by the Ethical Committee of the Severo Ochoa University Hospital with the code NIMBLE_Stroke_HLM.

C. Data analysis

Kinematic data of the sagittal plane of hip, knee and ankle joints were recorded at 60 Hz with the Xsens MVN (Movella Inc., Henderson, NV) and segmented based on left and right heel strike events, manually indicated by expert researchers based on kinematics and acceleration signals obtained from the IMUs. Data from each gait cycle were resampled with 100 samples and averaged between steps.

EMG data were recorded at 2.148 kHz and were filtered with a 4th-order Butterworth high-pass filter at 20 Hz and a 4th-order Butterworth low-pass filter at 400 Hz. Additionally, the EMG data were de-meaned, rectified, and then re-filtered with a 5 Hz low-pass filter to obtain the envelopes. Finally, as kinematics and EMG data were synchronized, EMG data were segmented based on the same events obtained for kinematics. For all patients, the 20 central cycles of the smoothest walking run were selected.

Muscle synergies were computed separately for the most affected side of each patient using the SynergyLAB interface developed by Barroso et al., 2014 (18). This software applies the Non-Negative Matrix Factorization and delivers the time-dependent (H) and time-independent (W) coefficients calculated from the EMG data. The optimal number of synergies was selected by studying the quality of the reconstruction with the Variability Accounted For (VAF) for each muscle (VAFmuscle) and the total (VAFtotal). Based on literature, the threshold chosen was 75% for VAFmuscle and 90% for VAFtotal (19).

III. Results

Three subacute post-stroke patients were enrolled for this study (Table 1). Clinical scales are summarized in Figure 1.

Table 1.Characteristics of the patients. Stroke type H refers to hemorrhagic and I to ischemic.

	Patient 1	Patient 2	Patient 3
Gender	F	M	M
Age	76	68	76
Affected side	R	L	L
Days from stroke	58	134	107
Stroke type	H	I	I
Initial FAC	1	1	0
Initial FIM	93	104	107

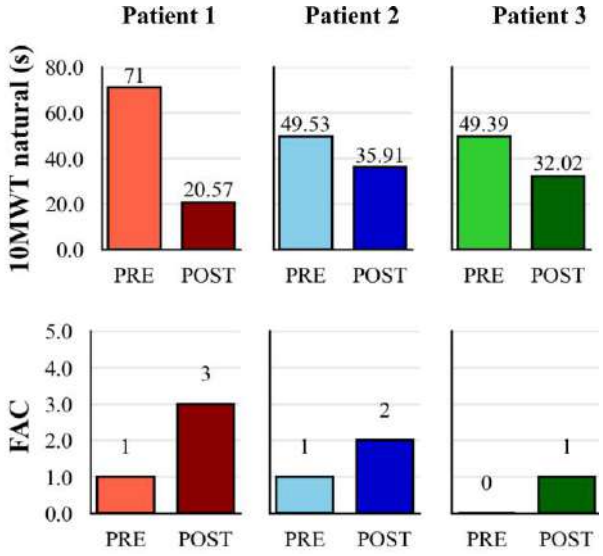

Figure 1 Clinical Scales outcomes during the PRE and POST sessions of all three patients for the 10-meter walking test (10mWT) and the Functional Ambulation Category (FAC).

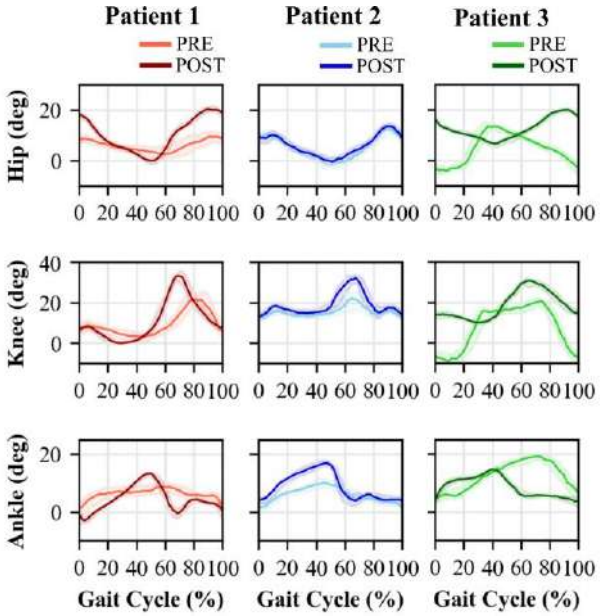

Figure 2 Sagittal kinematics for the Hip, Knee and Ankle of the affected side of each Patient throughout the gait cycle during the PRE and POST sessions of all three patients.

All patients improved their walking speed by 72%, 27% and 35% and FAC by 2, 1 and 1 respectively.

The sagittal kinematics of the affected side of all patients are shown in Figure 2. The RoM of Patient 1 and Patient 2 changed from the PRE to the POST session. For Patient 1, notable improvements included an increased hip, knee and ankle RoM (respectively by 55, 30 and 35%). Patient 2 did not show changes in the hip RoM, but we observed changes of 38 and 43% in the knee and ankle RoM, respectively. The walking patterns of all patients were more physiological after the rehabilitation. They showed a higher knee flexion during the swing phase, a more pronounced ankle dorsiflexion during the stance phase and, for Patient 1, a higher hip flexion at heel strike. The kinematics patterns of Patient 3 at the level of the hip and the knee were inverted compared to a normalized gait pattern during the PRE session, but they were normalized after the rehabilitation with a positive knee flexion and a flexed hip at heel strike.

Regarding muscle synergies, as shown in Table 2 the optimal number obtained was 4 for Patient 1, as 3 synergies did not allow for an accurate EMG reconstruction (the VAFtotal was lower than 90 % and a VAFmuscle lower than 75% in the PRE). On the other hand, for both Patients 2 and 3, 3 synergies would have been enough for a precise reconstruction of muscle synergies. However, to allow the comparison between the 3 patients, we selected 4 synergies for the analysis. Figure 3 summarizes the results of the muscle synergies analysis. The time- dependent variable H shown in Figure 3A, changed between the PRE and the POST sessions in all 3 patients. For Patient 1, anticipation of muscle activation was observed in Synergies 1, 2 and 3: the peak activity in the POST session occurred at 3% of the gait cycle, compared to 19% in the PRE session for Synergy 1; at 40% instead of 48% for Synergy 2 and at 62% instead of 72 % for Synergy 3.For Patient 2, an extra peak of activation occurred in the Synergies 1 and 3 in the POST session compared to the PRE at 64% and 39% of the gait cycle, while Synergy 2 and 4 remained similar. For Patient 3, the pattern of the synergies changed considerably. In Synergy 1, an anticipated activation occurred shifting from the peak of activation from 31% of the gait cycle in PRE to 8% of the gait cycle in the POST session. Moreover, the activation peaks were more pronounced in the POST session for Synergy 2 and 3. Figure 3B shows the time-independent variable W. For Patient 1 and Patient 2, the patterns of activation remained similar throughout the rehabilitation process in all 4 synergies. Patient 2 showed a co-activation of ReFe, VaLa, GaMe and Sol can be observed in Synergy 2 with a Synergy 1 mainly dedicated to GlMe. In contrast, for Patient 3 we observed an activation of the GlMe in Synergy 1 during the PRE session that shifted to Synergy 4 in the POST session.

IV. Discussion

In this research, we analyzed the effects of a 2-months robotic therapy in the muscle synergies of the affected leg of 3 subacute stroke patients with low gait independence and mobility (FAC of 1 for both Patient 1 and 2, and FAC of 0 for Patient 3 at admission) during overground walking. To the best of the authors' knowledge, this is the first time muscle synergies have been studied for this type of patient after robotic gait rehabilitation. Moreover, muscle synergies were related to the functional and kinematic changes observed during the rehabilitation program, as part of the

Table 2 Variability Accounted For (VAF) in % for all muscles (VAFtotal) and for the minimum VAFmuscle of all 8 muscles. Bold indicates the values that are below the quality threshold of 90% for VAFtotal and 75% for VAFmuscle.

VAF (%)		PRE		POST	
		3 syn	4 syn	3 syn	4 syn
Total	Patient 1	**87**	93	93	96
	Patient 2	92	95	91	94
	Patient 3	90	94	92	95
Muscle	Patient 1	**74**	86	89	92
	Patient 2	82	92	86	89
	Patient 3	76	77	80	91

multi-level characterization of the recovery process of stroke survivors proposed by the NIMBLE project (16).

Clinical scales and kinematics showed 1) a higher walking speed, 2) a more independent ambulation, 3) a higher sagittal RoM and (4) a normalized sagittal gait pattern. These results are consistent with the observed functional improvements after robotic rehabilitation (20).

The number of muscle synergies chosen was 4, even though for Patients 2 and 3, it would have been more appropriate to select 3 synergies according to the VAFtotal and VAFmuscle of both PRE and POST sessions. This decision was made to allow the comparison between patients, as in previous studies (2,8,10). Muscle synergies evolved throughout the rehabilitation process for all patients, though the changes observed were different for each patient. Patient 1 showed mainly changes in the time dependent component H, Patient 2 in both dependent H and independent component W and Patient 3 mainly in the independent component W. Patient 1 presented an earlier activation of Synergy 1, 2, 3, consistent with the changes in muscle synergies observed in the literature when increasing walking speed (5). Also, we observed a higher activation peak of Synergy 2 and 4, during the stance phase, which could be related to a stronger activation of hamstrings and triceps surae muscle due to an increased body weight loading on the affected leg, leading to a better preparation for the swing phase (15). For Patient 2 we observed a modified activation of Synergy 1, which mainly represented the GlMe activation. In the POST session, a second peak appeared during the initial swing phase, probably due to the hip abduction carried out by the patient to compensate for his limited knee flexion (around 30 deg), a characteristic pattern in post-stroke patients known as hip hiking (21). A higher activation of Synergy 3, related to TiAn, was also observed during the stance phase of the POST session. This could be a compensatory strategy to increase the propulsion force that seems to be lost due to the reduced

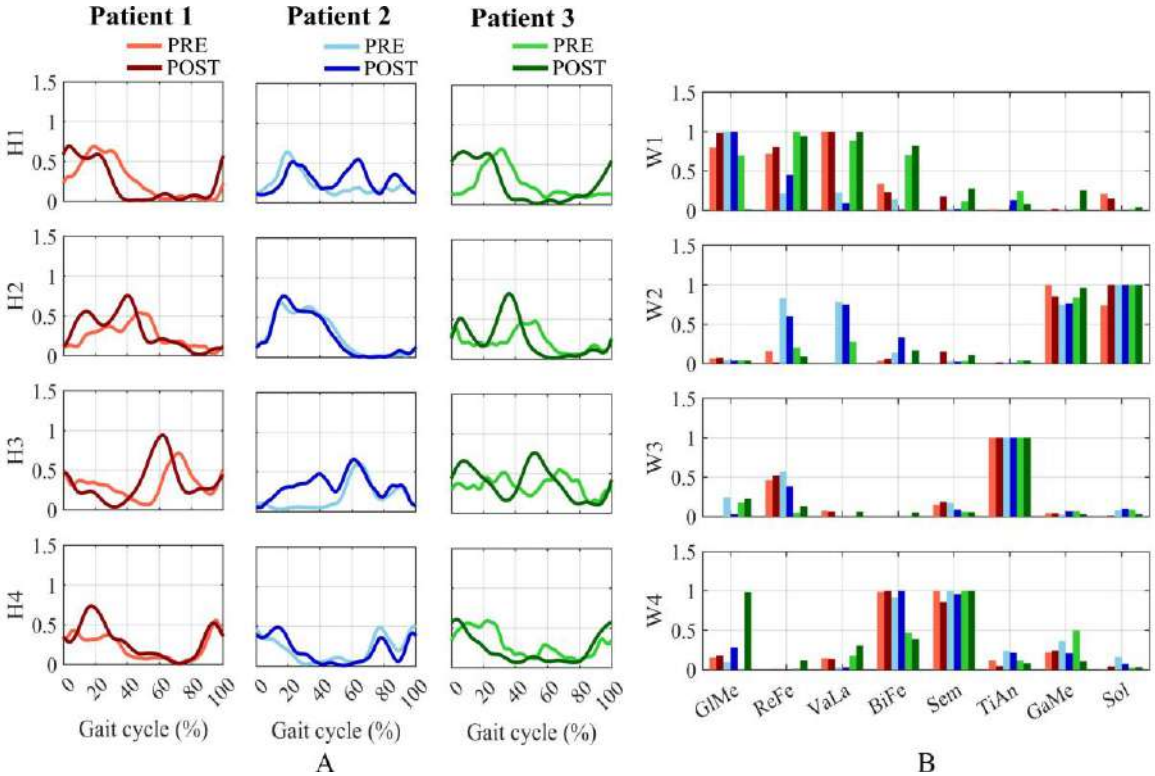

Figure 3 A. Time- dependent variable (H) across 4 synergies throughout the gait cycle during the PRE and POST sessions of all three patients. B. Time- independent variable (W) showing muscle activation patterns across 4 synergies during the PRE and POST sessions of all three patients. Red, blue and green colors refer to the affected side of Patient 1, 2 and 3 respectively. H equal to 1 refers to a synergy being 100% active during that Gait cycle %. W equal to 1 refers to the muscle being 100% part of that specific synergy.

hip extension during stance (5). Patient 3 exhibited a synergy shift of the time-independent component W of the GlMe from Synergy 1 to Synergy 4 from PRE to POST. This is an unexpected change that could be explained by the inability of Patient 3 to control individual muscles, leading to a strategy of simultaneous multiple-muscle activation to maintain control during the stance phase (12). This could also explain the similarity of the time-dependent components H, which are very similar between Synergy 1 and Synergy 4. These changes are consistent with the changes observed in the kinematics of Patient 3, who walked with a flexed knee and hip and has a tendency of ankle dorsi-flexion during the stance phase and plantar flexion during the swing phase.

The comparison of the current results with the literature is not straightforward. First, only two studies have analyzed muscle synergies of subacute stroke survivors during a single session. One was related to overground curved walking, which might affect the muscle coordination, and the other analyzed merged muscle synergies (12,22).Though it is beyond the scope of this research, considering the classification presented in (12), we can consider Patient 2 as Subtype 1, where GaMe and Sol are merged with quadriceps activation and Patient 3 as Subtype 3, with a slight coactivation of GlMe, hamstrings and quadriceps in early stance. The subtypes of these patients did not change after the rehabilitation. However, the subtype classification was mainly based on the time-independent component W and does not consider the time-dependent component H where some positive changes were observed for Patients 2 and 3 post-treatment. Some studies have analyzed the effects of rehabilitation on stroke survivors with several devices such as a treadmill with body weight support (10,23), an exoskeleton (2,14,15) or a Functional Electrical Stimulator (24). Most of them conclude that the optimal number of synergies changes after rehabilitation from 3 to 4 synergies and that, if the synergy number does not change, it might be related to a change in improved synergy timing (10). Though the optimal number of synergies did not change in our study, we observed changes in the time-dependent component H which is consistent with the literature. It is noteworthy that most of these studies are related to chronic patients (10,14,23,24) or assessments are carried out on a treadmill (11,25). Only two studies, in the literature, were conducted with acute post-stroke patients with low motor function (FAC < 3 and FIM < 78) and a similar multi-level approach protocol. They found the number of muscle synergies was similar between limbs in the POST session with an increased similarity between lateral synergies of patients after robotic intervention. They associated these improvements with better walking speed, step cadence, stance duration percentage of gait cycle. Comparing the muscle synergies of Patients 1, 2, and 3 with the healthy subjects of Gizzi et al. (8), we observe a tendency towards more normalized patterns in the POST session. However, the comparison of our results with the literature is not straightforward. In fact, most research studies tend to have specific protocols such as: 1) different sets of muscles (for example including the adductor muscles or not including the soleus), 2) different number of cycles, 3) different algorithms for synergy extraction. Standardizing the measuring protocols might be practical to compare results between research groups. This study presents several limitations. First, this study was tackled as a case study due to the limited sample size. Increasing the sample sizes could help generalize findings to a greater subacute stroke population. Moreover, to record the kinematics of these patients, IMUs synchronized with surface EMG sensors were employed. Although this is not the gold-standard strategy typically used in research, this approach enabled data collection in these patients, as they needed continuous or intermittent physical therapists help during the PRE session. One study analyzed muscle synergies during overground walking with low-mobility patients while measuring kinematics with the optoelectronic gold-standard method. They used the All in one Walking Trainer body weight support device for safety, allowing patients to walk independently and avoiding marker occlusion. However, considering that with FAC lower than 3 external assistance for walking is needed, it might be possible that, in that study, patients were being held by the body weight support, reducing the weight of the patient, increasing balance, modifying the natural walking pattern and thus affecting muscle synergies. Employing IMUs could have affected kinematics accuracy and gait cycle segmentation, as kinematics and acceleration signals were used instead of marker position, which is a more accurate method. However, IMUs allowed patients to walk with external assistive devices, since in the POST session, they all switched to a cane or walker, which could have influenced their stability and security, and subsequently impact their walking pattern, walking speed and muscle coordination. Though great care was taken to correctly place the electrodes in the same place in every session by the same physical therapist, it is not possible to determine whether results might be affected by sensor placement, crosstalk or uncommon muscle coordination due to the stroke. Additionally, the comparisons with the less affected side and with a control group were not carried out in this study (2). Similarly, our multi-level approach considered functional and kinematics changes for a global understanding of the effects of muscle synergies in patients' walking abilities, but other metrics such as gait scores (28) or corticomotor excitability (13,16). These three aspects could be considered in future research.

Our robotic-assisted gait therapy incorporates the two main conditions to promote functional neural recovery. In addition to movement repetition for intensive training, it enables task- specific practice, which may drive central nervous adaptations (26). Further research could be carried out to isolate robot-dependent and activity-dependent plasticity to provide additional insights into the optimal rehabilitation treatment for each patient.

V. Conclusion

Our research presents for the first time the muscle synergy of low-mobility post-stroke patients during overground walking after a gait rehabilitation treatment with a robotic exoskeleton. Even if results are not generalizable, our hypotheses were verified: (1) patients walked faster with higher independence after the rehabilitation, (2) the kinematics patterns were normalized after the therapy, (3) muscle modules were modified, each patient responding differently to the rehabilitation. The addition of functional and kinematics metrics allowed for a more comprehensive understanding of muscle synergies. In this study we observed meaningful changes in the time-dependent and time-independent components of muscle synergies, all consistent with the kinematics patterns of the patients, patient-specific muscle coordination and muscle adaptations during rehabilitation. This emphasizes the importance of patient-specific approaches in gait therapy guided by the identification of multi-level metrics. Finally, the therapy proved to be effective in improving functionality, kinematics, and muscle coordination of subacute stroke survivors.

***Abstract*—Individuals with grasping impairments face significant challenges in performing daily tasks due to reduced hand function. Existing supernumerary robotic fingers (SRFs) often rely on electronic components that limit their usability through added weight and power constraints. This work introduces the first body-powered wrist-driven SRF (bpSRF), a design that addresses these limitations by removing all electronic components. The proposed bpSRF weighs 52 g and is mostly made of 3D printed parts. Using body-powered actuation principles, the extra finger is driven by wrist movements, offering a practical, affordable, and lightweight solution for hand augmentation. The bpSRF has two degrees of freedom, enabling users to perform enhanced grasping techniques with minimal learning curve. Experimental validation with five healthy participants showed high success rates and rapid learning of novel grasping patterns for tasks involving large or multiple objects that typically require two hands. The design offers a workspace volume approximately three times larger than a human thumb, potentially expanding users' manipulation capabilities. This research contributes to a new paradigm in assistive technology, presenting a lightweight, cost-effective, and open source SRF that can enhance grasping abilities for individuals with motor impairments while also offering augmentation possibilities for healthy users.**

***Index Terms*—supernumerary robotic finger, assistive technology, body-powered, hand augmentation, 3D printing**

I. Introduction

Individuals with grasping difficulties face constant challenges, as impairments in hand dexterity and strength hinder their ability to perform daily tasks. Spinal cord injuries [1], trauma, stroke, cerebral palsy, and other neurological pathologies result in motor impairment [2], further contributing to the loss of manipulation ability. Up to 60% of stroke patients experience loss of hand sensory and/or motor function. In addition, chronic motor disorders make it difficult to utilise the hand for everyday functional tasks, such as donning shirts, tying laces, and gripping objects. [3].

Currently, a variety of assistive technologies are available to aid people with grasping difficulties. Hand exoskeletons [4] and soft gloves [5] are used in to assist the movement of finger joints, with the latter being safer and more comfortable for the hand. Recently, supernumerary robotic fingers (SRFs) have emerged as a promising alternative. SRFs are a type of wearable technology that, by adding one or more extra robotic fingers to the hand, can compensate for the lack of fingers mobility in persons with hand impairment or, in healthy persons, augment standard human manipulation with novel 6-fingered or 7-fingered grasp patterns [6].

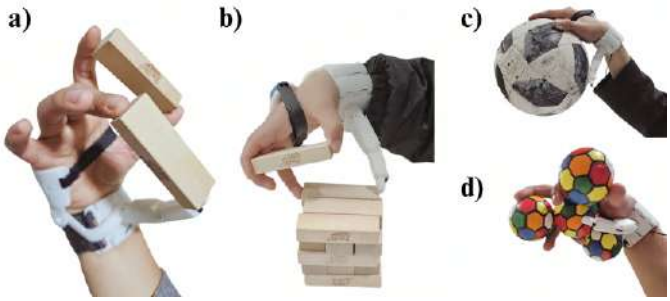

Fig. 1. The bpSRF prototype in different grasping tasks: (a) double pinch grasp, (b) augmented spherical grasp, (c) Double pinch grasp in Jenga tower building task and (d) grasping multiple objects in one hand.

SRFs are typically wrist-mounted, working alongside the natural fingers for grasping assistance and augmentation [7]–[23]. For patients with grasping limitations, such as those suffering from hemiparesis due to a stroke, SRFs usually act as a surrogate artificial thumb [7]–[12]. For example, patients can grip objects by forming a cylindrical grasp between the SRF and the palm. Additionally, in healthy individuals, SRFs extend the natural capabilities of the hand, making it possible to form grasp patterns capable of holding large objects or manipulating several small ones [13]–[23], feats that are normally attainable bimanually. Therefore, SRFs can enhance the capabilities not only in people with grasping disabilities but also in healthy individuals.

Current SRFs offer many advantages, but their widespread adoption could also be limited by the inconveniences associated with the electronic components they require. The actuators and batteries, which are often placed outside the SRF itself [8], [18], considerably increase the weight and limit the time it can be worn before causing discomfort. For example, in [11], the actuation system accounts for 146g, representing 51% of the total weight. Similarly, in [7], the actuator alone comprises 69.5% of the SRF's total weight. In the context of assistive applications, it is crucial to minimise the weight of SRFs to prevent discomfort and potential orthopedic injuries to users.

A potential workaround to current electronics size and

weight limitations could be drawn from the principles of body-powered prosthetics. Body-powered upper-limb prostheses draw power from healthy limb movements through cables that control the closing and opening of the terminal device, which could be a hook [24] or an artificial anthropomorphic hand [25]. In fact, over the last decade, 3D-printed body-powered prostheses have gained wide popularity due to their low-cost and ease of replication [26]. Even without electronics and complex controllers, body-powered prostheses offer high functionality and intrinsic force feedback via the driving cable reaction forces over the wearer's body. Crucially, at the Cybathlon 2016 Arm Prosthesis Race, a body-powered device defeated even the most advanced bionic prostheses in the world [27]. In the same manner, a body-powered SRF would also offer the advantage of minimal weight and intrinsic feedback while keeping their functionality.

Although recently developed SRFs have experimented with novel design strategies, none of these devices are driven by the body. A manually actuated SRF was also proposed [14], but driving it required the use of the contralateral hand. This could prove cumbersome for the user and defeats the purpose of movement augmentation, which is to add extra degrees of freedom (DoFs).

To address current limitations and promote more widespread and continuous use of SRFs, this paper proposes a novel body-powered wrist-driven SRF (see Fig. 1). The body-powered SRF (bpSRF) does not require any electronic components or external power, weighs only 52 g, and can be easily manufactured by 3D printing. It is driven by wrist flexion/extension and abduction/adduction movements through a cable mechanism. This design can potentially improve the capabilities of users with grasping impairments, but who preserve wrist mobility. In healthy individuals, the bpSRF offers the possibility to execute novel grasping patterns and expand the workspace volume of the hand as shown in Fig. 1. To our knowledge, this is the first SRF that fully utilises body-powered actuation, setting it apart from all previous designs.

II. Design Process

The bpSRF mechanism was designed to operate directly through the user's own body movements, dramatically reducing the complexity of the system and its weight compared to externally powered SRFs. This simplicity leads to a shorter learning curve, allowing users to quickly adapt and integrate the bpSRF into their hand control motor strategies. Intrinsic haptic feedback will occur naturally through the physical interaction between the bpSRF and the user's hand and wrist, as it happens with body-powered prostheses [28]. Furthermore, the body-powered principle provides immediate actuation with no latency between user command and device motion.

Maintaining a lightweight design without compromising performance is a crucial design goal for a wearable SRF. Previous SRFs weigh between 100-286 g for one additional robotic finger [8], [10], [12], [15], [19], [21], [29], between 229-650 g for two additional robotic fingers [7], [16], [18], [30], [31], and 96 g for one additional manually-actuated robotic finger [14]. Common approaches to lower the overall weight of the system include underactuation [11], [14], the use of soft materials [9], and even origami-inspired structures [10]. In contrast, the bpSRF proposed weighs only 52g, comprising mostly 3D-printed parts of easy assemble, driving cables, and Velcro straps for attaching it to the user's hand (see Fig. 3).

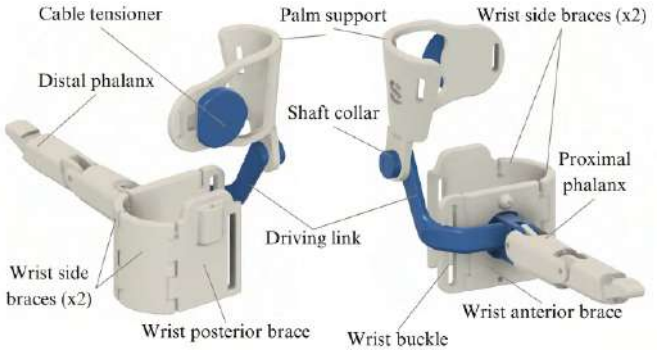

Fig. 2. Components of bpSRF: Featuring the wrist mount, linkage connector, lateral hand-shaped piece, tension adjustment piece and the proximal and distal links

A. Body-powered actuation

The bpSRF design is highly inspired by the model from [25], in which the prosthetic fingers form a 4-bar linkage mechanism that is actuated by cables. The 4-bar linkage was chosen for its ability to emulate natural finger movements and requiring less cable excursion to achieve full finger flexion while maintaining simplicity in its mechanical design. The bpSRF features two degrees of freedom (DoFs): flexion-extension and abduction-adduction, both driven by wrist movements. It is actuated through a cable mechanism in a similar fashion to wrist-driven partial hand prostheses [26]. When the wrist is flexed, the actuation cable is pulled and the finger is flexed. Conversely, wrist extension allows the bpSRF to return to its initial extended position due to the elastic cable (see Figure 3). The actuation cable is fixed in the distal phalanx, passes through the proximal phalanx, then enters the wrist

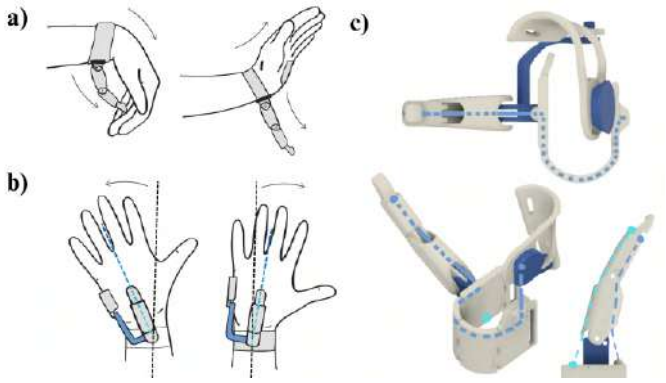

Fig. 3. Body-powered driving principle of the bpSRF. (a) By flexing the wrist, the bpSRF also flexes and by extending the wrist, the bpSRF also extends, (b) The second DoF of the bpSRF is akin to finger abduction-adduction and is driven by the wearer's palm when moving in ulnar or radial deviation, (c) Driving cable path through the 3D-printed components.

anterior brace and the side braces, and then exits through the wrist posterior brace. Finally, the cable can be manually tensioned with the cable tensioner in the dorsum of the hand over the palm support. Proper cable tension is important in body-powered devices as it directly influences the actuation force distribution across the mechanism. Adjustable tension allows users to fine-tune the device according to their own strength and comfort level, ensuring that the robotic finger moves in harmony with their natural fingers.

B. Ergonomy

The bpSRF was designed to integrate ergonomically with the hand. Anthropometric data from adult male hands guided the dimensions of the proximal and distal phalanges, ensuring effective grasping assistance while minimizing strain. Its grasp diameter range accommodates the size of objects that users typically interact with in their daily activities, including common household objects such as utensils and tools.

Most SRFs are positioned on the ulnar or radial side of the wrist. In this case, the placement of the base of the finger was carefully considered to avoid interference with the natural fingers. By positioning the bpSRF on the anterior side of the wrist and opposite to the palm, we allow a natural interaction between the bpSRF and the user's hand, minimizing obstruction and promoting its intuitive use as an additional 'thumb'. Moreover, this positioning leverages wrist flexion-extension and radial-ulnar deviation, translating these movements into the two DoFs of the bpSRF.

The parts in contact with the hand are meant to fit a variety of sizes and shapes of human hands. The palm support was designed in small (S), medium (M) and large (L) sizes. Each of them varies slightly in length and width to prevent discomfort during prolonged use. The wrist bracelet, as it is made of rigid plastic, was divided into four sections with relative movement that can adjust better to the compliant skin tissue.

C. Kinematics

Fig. 4 shows the two DoFs of the bpSRF about its base: flexion-extension and abduction-adduction. These DoFs have ranges of motion of approximately 60° and 50°, respectively, although these would depend on subject-specific mobility. As seen in Fig. 4a, the bpSRF flexion-extension DoF is driven by the palm support and the driving link in blue. In this manner, 15° of wrist flexion are converted through the cable tension and the 4-bar linkage in the robotic finger into a 60° finger flexion. Additionally, the robotic finger is capable of abduction and adduction about its rotating base, a movement driven by the ulnar and radial deviation movements of the wrist. This second DoF enhances the ability to grasp and manipulate objects by accommodating different orientations of the fingers in the coronal plane. Although the driving link mechanism allows for full 360° rotation of the robotic finger around its base, in this representation only the angles corresponding to the maximum radial and ulnar deviations according to [32] are shown.

The motion trajectory of the bpSRF, defined by a four-bar mechanism, moves from maximum extension (opening) to maximum flexion (closing) until it comes into contact with the palm. Fig. 5a illustrates the trajectory of the fingertip during flexion-extension. The blue shaded area represents a circular object grasped between the fingertip of the middle finger and the distal tip of the bpSRF, which could have a diameter of about 208 mm. For this estimation, it was assumed that the geometric center of the circular object must be within the boundary marked by straight perpendicular lines that represent the normal forces from each fingertip. Objects with slightly larger diameters could also be grasped by applying greater gripping forces.

Based on the bpSRFs estimated ranges of motion, its working volume was computed as a three-dimensional mesh (see Fig. 5b). This method yields a workspace volume of approximately 97.64 cm³. In comparison, the standard range of motion of a human thumb has an estimated functional workspace of 32-73 cm³ [33]. Hence, the bpSRF provides an increase in workspace volume ranging from 34% up to 205% compared to a natural human thumb.

III. Prototype Implementation

The majority of parts of the bpSRF can be 3D printed. The assembly of the different parts only requires metal pins, Velcro straps, and fishing braid wire. The metal pins are all 2.5 mm in diameter but with variable lengths depending on the parts it connects. To ensure friction-free movement between adjacent and connecting parts, a tolerance was added to several dimensions of the bpSRF before 3D printing. Table I presents a comprehensive summary of the materials and printing specifications, as well as the mechanical features of the resulting prototype.

For donning, the device is secured using Velcro straps, with the bpSRF base positioned on the anterior side of the wrist. The shaft of the driving link is inserted in the palm support. Then, the rigid cable is wrapped around the cable tensioner until it is sufficiently tightened and correctly positioned. For doffing, the cable tensioner is released, the palm support is removed from the pin, the Velcro straps are unfastened. All the files required for 3D printing components, a detailed list of

TABLE I
MATERIALS AND MANUFACTURING SPECIFICATIONS FOR THE BPSRF

Parameter	Specification
Materials	- PLA (3D printed). - 1.2 cm-width velcro straps. - 3.5 cm-width velcro straps - 2.5 mm⌀ galvanised aluminum pins for joints in four lengths: 5 x 33 mm, 1 x 17 mm, 1 x 14 mm, 2 x 8 mm. - 2 mm⌀ elastic wire. - 0.36 mm⌀ fishing braid wire.
Printing Parameters	- Layer height: 0.2 - 0.24 mm. - Infill percentage: 15%. - Print speed: 60 mm/s. - Support structure: Tree.
Mechanical specifications	- Total weight: 52g. - Assembled finger length: 93 mm. - Wrist brace dimensions (when unfolded): 138L x 50H x 5T mm.

materials and assembly instructions are available as an open repository at https://github.com/RenatoMio/bpSRF.

IV. EXPERIMENTS

A. Payload Characterization

The performance of the bpSRF was evaluated using a digital portable dynamometer (Opalux, OP-607) to quantify the actuation force (i.e., cable tension) and the payload relationship. The setup consisted of disconnecting the driving cable from the cable tensioner and instead tying it to the hook of the dynamometer with minimal initial tension (see Fig. 6a). Additionally, a MPU6015 inertial measurement unit (IMU) was placed on the hand side and used to verify that the hand palm was aligned with gravity (see Fig. 6b). The dynamometer was stabilised on the hand dorsum and zeroed, and the orientation of the hand was verified through the IMU reading before taking measurements (see Fig. 6c).

In this experiment, the resistive vertical force during an augmented cylindrical grasp between the palm and the bpSRF was measured. The trials were performed in three conditions, one per each bpSRF size (S, M, and L), and with five repetitions per condition. The payload consisted of a plastic bottle attached to calibrated metal weights, which increased

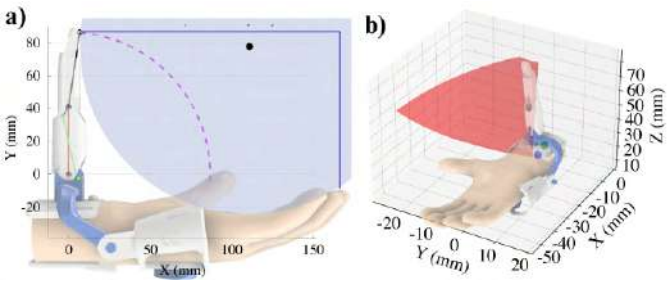

Fig. 5. Kinematics of the bpSRF. (a) Sagital view of the fingertip of the bpSRF trajectory during flexion. The shaded circular area represents the largest graspable object. (b) Angular workspace of the bpSRF.

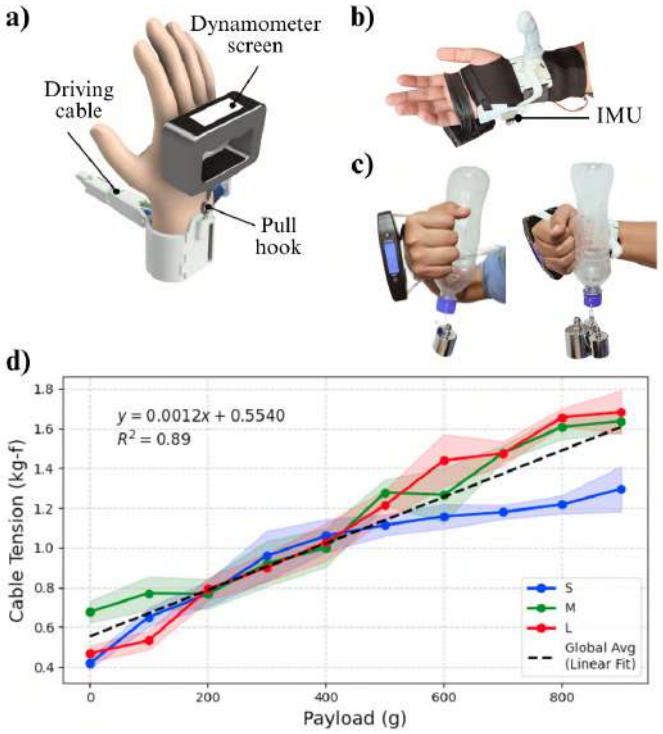

Fig. 6. Performance characterization. a) Digital dynamometer setup. b) View of the setup before adding payload with inertial sensor over the side of the palm. c) Setup after adding payloads of 200g and 800g. d) Payload vs Cable tension characterisation for each size version of the bpSRF. The shaded areas represent standard deviations (n=5) and the dashed line represents the result of linear regression across all trials.

from 0 g (no added weight) to 900 g in increments of 100 g. In this range, there is a linear relationship (coefficient of determination $R^2 = 0.89$) between the payload and the actuation tension of the cable (see Fig. 6d). At no added weight, 0.4 kilograms-force (kg-f) of tension are the minimum required to fully close the bpSRF, while at 900g of payload an average tension of 1.6 kg-f is used. This equates to an increase of 0.12 kg-f in tension per 100 g of payload, which highlights the efficiency of cable routing.

B. Grasping assessments

Pick-and-place experiments were conducted with five healthy participants (mean age = 23.2 ± 2.71 years, 2 females). All participants were right-handed and reported no neurological or motor impairments. The experiments were carried out in accordance to the Declaration of Helsinski and with approval of The Ethics Committee from the Pontifical Catholic University of Peru, with code 002-2023-CEICVyTech/PUCP. The grasps considered were previously described in [6] and are as follows:

- Augmented spherical grasp: a collaborative grasping technique in which both natural fingers and the SRF work together to grasp a large spherical object. The goal is to open the entire hand and fingers to maximise contact area, allowing for a better grip on the object. In our experiment,

we used a soccer ball with a diameter of 16 cm and a weight of 433 g.

- Augmented cylindrical grasp: a collaborative grasping technique in which both natural fingers and the SRF work together to grasp a large cylindrical object. Instead of the natural thumb, the SRF performs the opposition again the palm to grasp the object. In our experiment, we used a 3 liter empty bottle with a diameter of 19 cm.
- Simultaneous multi-grasp: When the natural fingers and SRF work together to execute two distinct conventional grasps in the augmented hand. In our experiment, participants performed a pinch grasp on a Jenga wooden block using the SRF and an adduction grasp on a standard playing card simultaneously.

In these tasks, only the augmented hand is used and the participant must remain seated. Each task lasts 1 minute, with a 30-second break in-between (see Fig. 7a). The objects are initially placed at Point A and must be moved to Point B (see Fig. 7). Participants were positioned midway between the starting and target locations. They are required to pick up, lift, and move each object as quickly as possible from A to B and from B to A. The task begins when the user starts a stopwatch and ends when the time runs out. A trial is considered a failure if it is not completed, if the correct grasp is not performed, or if the object falls. In any of these cases, the participant must restart the trial from their last position (A or B).

In general, all participants became proficient in executing the augmented grasps with just one minute of practice per task. On average, participants succeeded on 8.8 ± 2.9, 11.4 ± 3.6 and 7.2 ± 3.0 attempts per minute with average success rates per task of 81.5%, 91.0% and 98.5% for the ball, bottle, and multi-object grasping tasks respectively. Moreover, as shown in Fig. 8, participants kept reducing the time required to complete an attempt, with average durations of 5.38 ± 1.79s, 4.11 ± 0.95s and 6.96 ± 1.65s over their last three attempts for the ball, bottle, and multi-object grasps tasks, respectively. These results are an indication of early stages of motor learning in hand and bpSRF coordination. Finally, all participants reported minimal fatigue overall during this short experiment, although many grasping cycles were performed, which supports the idea that wrist-driven actuation was comfortable to use.

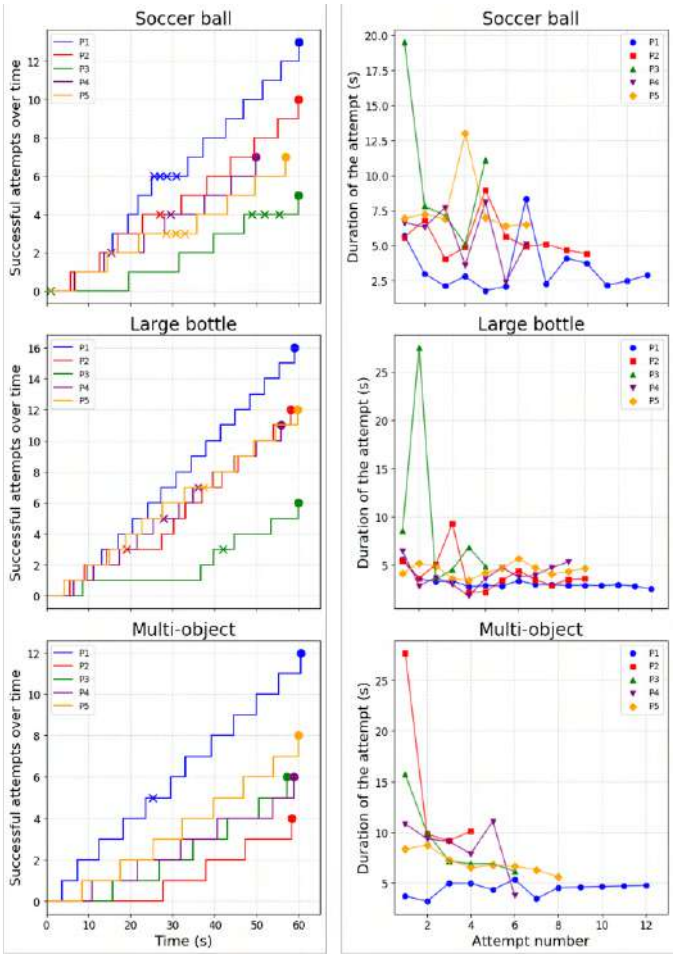

Fig. 8. Results from the grasping experiments. Each line represents a participant. On the cumulative attempts plots, the circles at the end of each line represent the ending time (last successful attempt within the allotted 60 seconds) while the X's represent instances in which participants droped the object and had to star over from the initial position

V. Discussion & Conclusions

The results confirm that the bpSRF effectively addresses key limitations of previous SRFs, particularly in terms of weight, simplicity, and usability. Its lightweight design of only 52g, achieved through 3D printing and body-powered actuation, sets it apart from electronically powered counterparts that typically weigh more than 100g and up to 286g-325g per added finger. Eliminating electronic components also reduces maintenance requirements, making the bpSRF a practical and low-cost option for both assistance and augmentation.

The assessments demonstrated the mechanical reliability of the bpSRF in terms of cable force transmission and its ability to support various manipulation tasks. The intuitive, wrist-driven operation of the bpSRF naturally integrates with hand biomechanics, enabling users to learn and apply novel grasping patterns with minimal effort. In particular, the multi-grasp tasks highlight its potential for applications requiring coordination between natural fingers and the SRF.

As the first body-powered SRF, this work introduces a novel approach to hand augmentation by removing the reliance on electronic components. The open source release of the bpSRF also provides a platform for further research into the biomechanical and neurocognitive effects of movement augmentation. Future work will explore long-term usability, its effects on upper-limb kinematics, and durability in diverse real-world tasks.

A Shared Control Approach to Safely Limiting Patient Motion Based on Tendon Strain During Robotic-Assisted Shoulder Rehabilitation

Italo Belli[1,2,*], Yuxuan Hu[1], J. Micah Prendergast[1], David Abbink[1,3], Ajay Seth[2], and Luka Peternel[1]

***Abstract*— Combining biomechanical modeling with robotic physiotherapy is a promising direction to provide real-time insights during the rehabilitation of patients with musculoskeletal injuries, such as rotator-cuff tears. One aspect is to prevent re-injuries caused by high strain in the injured tissues while allowing patients to perform the required rehabilitation exercises. In this paper, we propose a novel shared control method for robots to limit unsafe patient movements, through physical guidance based on a strain-space representation of the human rotator cuff. The method provides motion corrections through two complementary predictive modules. The first module exerts a lower degree of intervention and is analogous to rumble strips or speed bumps for cars on the road. In this case, an impedance controller induces variable damping to slow down the patient's movement when a danger zone is approached. The second module produces a higher degree of intervention and is analogous to lane-assist in cars. In this case, the robot plans an optimal deflection trajectory and temporarily takes over control of the movement to avoid an unsafe situation. We performed experiments with a healthy participant acting as a patient and evaluated the effect of different human-robot interaction modalities on the resulting human movement in terms of avoidance of high-strain areas of the rotator-cuff tendons and contact forces exchanged.**

I. Introduction

Musculoskeletal injuries can occur during many daily activities, ranging from workplace and household tasks to sports. Such injuries negatively affect the quality of life of those who suffer from them, limiting their comfort, mobility, agency and productivity in their daily life as well as at workplaces. Elderly populations are particularly susceptible to such injuries due to weakening of the musculoskeletal system and general reduction in muscle mass that occurs with age. One of the most typical injuries occurs in rotator cuff muscles that keep the upper arm (humerus) in the socket of the shoulder blade (glenoid of the scapula). The prevalence of rotator cuff injuries is estimated to be as high as 22% in the general population [1].

Traditional therapy in treating injuries to the shoulder involves sessions with human physiotherapists. Nevertheless, re-injuries are common [2], and demand for the therapy often exceeds physiotherapists' capacity, which can further affect the recovery times and completeness of recovery. To this end, robots provide a good solution to augment the capacity of human physiotherapists. Existing works in robotics for physiotherapy enable the generation of prescribed rehabilitation movements [3], as well as learning these movements from expert human demonstrations [4]. These strategies are excellent in automating the movements of human physiotherapists.

Authors are with the Cognitive Robotics[1], BioMechanical Engineering[2] and Sustainable Design Engineering[3] departments at Delft University of Technology, Delft, The Netherlands.

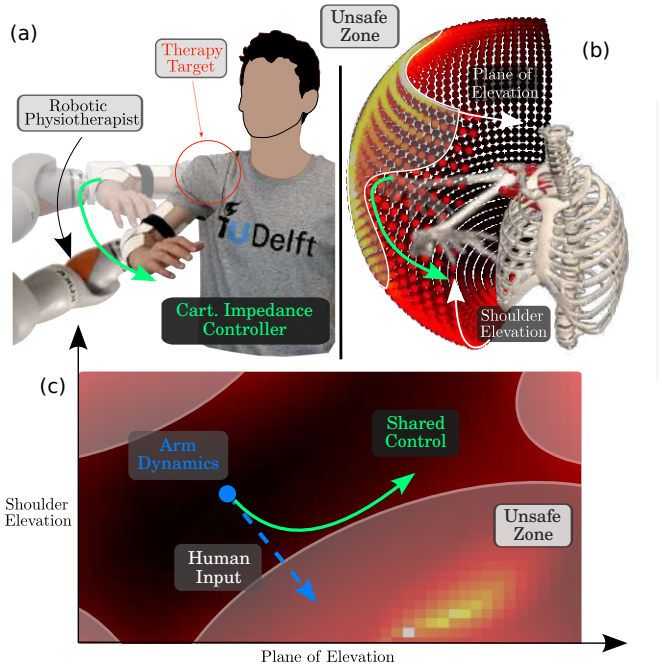

Fig. 1. An overview of the proposed robot-assisted shoulder physiotherapy system. (a) The robot end effector is connected to the human elbow with a customized brace, allowing the robot to limit human motion when necessary. (b) Shoulder strain map is pre-calculated from a high-fidelity musculoskeletal model to determine unsafe movement zones. (c) The current and predicted human arm pose are projected in the strain map to formulate the planning scene. When potential injury is detected, optimal movement in the elbow is achieved through shared control from the robot physiotherapist.

Nevertheless, repeating prescribed or learned movements can be limiting when addressing the specific needs of every patient.

Musculoskeletal models are a valuable addition to the robot motion and force sensors, enabling personalized insights into what is happening inside the human body during the interaction [5]. Most of the existing studies employ models offline, for example, to quantify assistance needed by a human operator [6]–[8] or reduce human metabolic cost in walking-assistive devices [9]–[11]. Some recent studies also explore the use of models in an online manner, where they are integrated into the robot control loops for real-time adjustments of robot assistive movements [12]–[15].

Our previous work [13] developed a method that mapped tendon strains on the human state space using an OpenSim musculoskeletal model to create so-called "strain maps", which chart the high-strain areas where re-injury could occur. The approach employed an offline optimization to create the low-strain therapy trajectories used to navigate the strain maps in real time. A significant advancement was recently made with BATON [16], which enabled an online

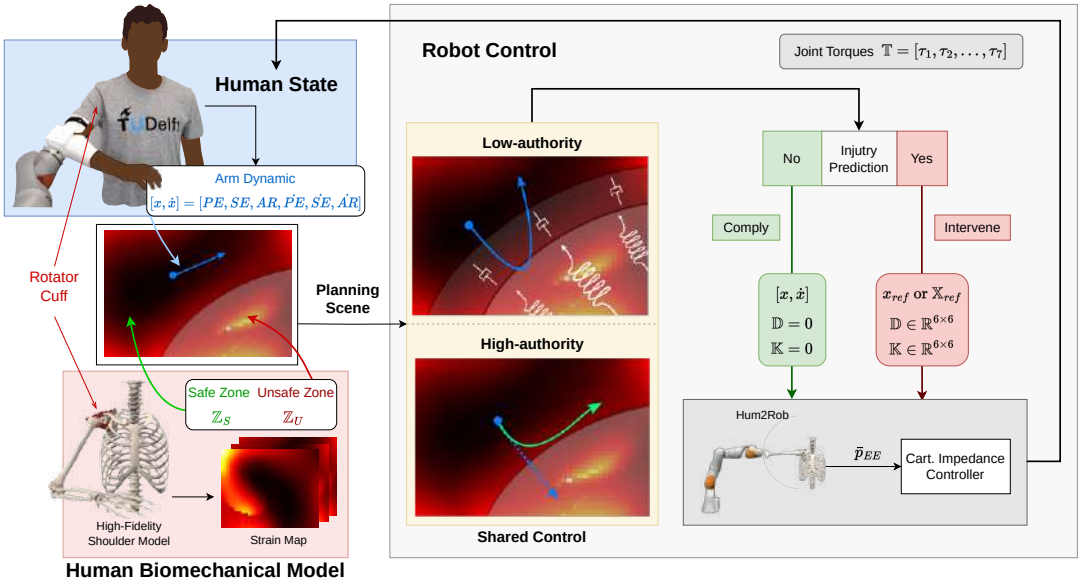

Fig. 2. Diagram of the proposed real-time system for safely limiting human motion during rehabilitation, on the basis of a high-fidelity OpenSim shoulder model. The two shared control modules receive the current state of the human shoulder and their corresponding strain maps to identify dangerous situations and output commands for variable impedance control of the robotic arm. Low-authority guidance is achieved by damping human velocities approaching unsafe high-strain zones. High-authority guidance relies on deflecting human motion away from the danger zones by actively tracking an optimized reference trajectory. These modules are complimentary and can be selected based on the therapy requirements and user preferences.

trajectory optimization and accounted for real-time changes in strain space by considering both the strain behavior and the human arm dynamics. Notably, these approaches focused on optimizing robot-led therapy, which is suitable for early-stage shoulder rehabilitation. Since patients take a more active role as therapy progresses [17], safety and potential re-injury concerns should be addressed while specifically promoting patient-led exercises. In this context, shared control is a promising solution that allows the patient to retain authority over the movement [18], [19], while a robot therapist monitors and potentially intervenes to limit unsafe motions. A simple solution to patient-robot interaction during rotator-cuff rehabilitation was proposed in [15], where the robot provided a "safety net" during physiotherapy by segmenting the dangerous high-strain zones and generating haptic boundaries around them, thus preventing patients or therapists from entering these unsafe regions. Although this offered a promising first step toward a biomechanics-aware safety approach to patient-led physiotherapy, potentially unsafe situations could still occur if a haptic boundary was contacted with high velocity or at a high angle. Therefore, an open challenge is how to predict potential impacts with high-strain zones in advance and avoid them before they occur.

To address this challenge, we developed a method based on shared control that allows the user to perform rehabilitation movements freely, with the robot intervening whenever an incursion into a high-strain danger zone or a high-impact collision with a haptic boundary is about to occur. We propose two distinct predictive modules, each handling the robot's intervention in a different manner. In the first module, the robot exerts lower authority, similar to "rumble strips" or "speed bumps" for cars on the road. In this case, the impedance controller induces variable damping when a danger zone is approached in a potentially unsafe direction to slow down the movement. In contrast, the second module exerts higher authority, akin to lane departure correction autopilot (e.g., "lane assist" or "lane centering") in cars. In this case, the robot plans an optimal deflection trajectory and temporarily takes over control of the movement to avoid an unsafe situation. The two modules are complementary, where the advantage of the first is that it takes away less control from the patient/therapist, while the second module provides a smarter and more assertive way of avoiding unsafe situations. Each module can be selected based on the specific exercise, stage of therapy, user confidence, etc. To demonstrate the key aspects of each, we performed experiments with a healthy participant acting as a patient and evaluated the effect of the different human-robot interactions on the resulting human movement in terms of avoidance of high-strain areas and contact forces exchanged.

II. Methods

Figure 2 illustrates the proposed system with key elements. The human modeling and strain map computation element provide insight into the human musculoskeletal system and allow the physiotherapy robot to navigate away from dangerous high muscle strains. Human state estimation is performed in real-time from the robot's onboard sensors, to monitor human safety. The robot controller implements our two novel modules for predictive guidance to avoid dangerous zones in the strain maps, leveraging a low-level impedance controller that governs physical human-robot interaction. Finally, we present our experimental setup. Each of the key elements is described in the following subsection.

A. Human Biomechanical Model and Strain Maps

To capture the biological properties of the human shoulder, we employ a high-fidelity musculoskeletal model of the

human shoulder complex [20] developed in OpenSim [21], [22]. In particular, we are interested in the behavior of the rotator cuff tendons, spanning the glenohumeral joint and connecting the humerus to the shoulder blade. Therefore, we obtained a reduced-order model of the human shoulder, capturing the mobility of the glenohumeral joint alone in terms of three rotational coordinates (PE: plane of elevation, SE: shoulder elevation, and AR: axial rotation), while retaining the information about the relevant muscles and tendons contained in the original model. As such, the variables that define the configuration of the human model are:

$$\boldsymbol{x} = [\boldsymbol{q},\ \dot{\boldsymbol{q}}]^\top, \quad \text{with} \quad \boldsymbol{q} = [PE, SE, AR]^\top \tag{1}$$

where PE, SE, and AR are defined as the Y-X'-Y'' sequence of intrinsic Euler angles in the fixed shoulder reference frame [20], and $\dot{PE}, \dot{SE}$ and $\dot{AR}$ are their corresponding derivatives with respect to time. Similar to our previous work [13], [16], we employ the OpenSim functionalities to pre-compute the relationship between human pose and strain σ of the tendon(s) of interest, generating "strain maps" that carry the same information as the original model, but much quicker to access. By defining a threshold on the strain value, we leverage this data to identify elliptical unsafe zones $\mathbb{Z}_U$ on the map, corresponding to configurations of the human arm that should be avoided during therapy. Since rehabilitation mostly occurs with a limited speed of movement, the dependency between the fiber velocity and the strain level was neglected.

Movement in the human state space obeys the equations of motion of the corresponding multibody skeletal system. As OpenSim natively provides this information only numerically, we resorted to OpenSimAD [23] as an instrumented version of OpenSim to automatically generate differentiable outcomes and functions from our reduced-order shoulder model. We obtained a differentiable representation of the forward and inverse dynamics functions relating the evolution of the human state $\boldsymbol{x}$ to the generalized torques $\boldsymbol{u} \in \mathbb{R}^3$ applied to the model's degrees of freedom:

$$\dot{\boldsymbol{x}} = f_{\mathrm{FD}}(\boldsymbol{x}, \boldsymbol{u}), \tag{2}$$

$$\boldsymbol{u} = f_{\mathrm{ID}}(\boldsymbol{x}, \dot{\boldsymbol{x}}) \tag{3}$$

The use of model-based human skeletal dynamics was recently proposed as a strategy for real-time planning of biomechanical-aware trajectories on strain maps [16] and brings the benefit of accounting for subject-specific parameters both regarding tendon behavior and human inertial properties.

B. Human State Estimation

We developed a human state estimation module to inform our control algorithms about the current state of the human subject during therapy. Our subject wore a custom-made brace during our experimental validation, connecting them rigidly to the robot's end-effector (Fig. 2). As such, the estimation of the current human state $\hat{\boldsymbol{x}}_t = [\hat{\boldsymbol{q}}_t,\ \hat{\dot{\boldsymbol{q}}}_t]^\top$ can be achieved based on the Cartesian pose $\boldsymbol{p}_{\mathrm{EE}} \in \mathbb{R}^6$ of the end-effector (EE), assuming a fixed orientation of the human torso and negligible movement of the scapula. The interested reader is referred to our previous work for a full derivation of the human pose and velocities ([16], Section II.D).

C. Robot Control

The interaction between our rehabilitation robot and the human subject is shaped with an impedance controller [24] running at 200 Hz, whose parameters are adjusted in real time according to the estimated human state. Specifically, the commanded force at the end-effector $\boldsymbol{F}_{\mathrm{EE}} \in \mathbb{R}^6$ can be defined as:

$$\mathbf{F}_{\mathrm{EE}} = \mathbf{K}_t(\overline{\mathbf{p}}_{\mathrm{EE}} - \mathbf{p}_{\mathrm{EE}}) - \mathbf{D}_t\dot{\mathbf{p}}_{\mathrm{EE}} \tag{4}$$

where the end-effector reference and actual pose are $\overline{\mathbf{p}}_{\mathrm{EE}}$ and $\mathbf{p}_{\mathrm{EE}}$, respectively, and $\mathbf{K}_t,\ \mathbf{D}_t \in \mathbb{R}^{6\times 6}$ are the desired, time-dependent stiffness and damping matrices in Cartesian space. The selection of $\overline{\mathbf{p}}_{\mathrm{EE}}$, $\mathbf{K}_t$, and $\mathbf{D}_t$ ultimately determines the level of authority of the robotic therapist on the movement performed by the human subject, and modifies the control authority of the human during therapy. As such, we present two different modules for tuning the controller's parameters and, effectively, the robot's intervention authority. Both modules combine a prediction of the future human state based on the current human state and determine if future movements will be safe. If the predicted motion will be unsafe (resulting in higher tendon strains), the robot physiotherapy will provide force-based feedback/corrections to the human subject, with lower or higher authority.

1) Low-Authority Shared Control: The human subject retains control of their movements as much as possible, provided that they stay within the safe boundaries defined by the strain maps. In addition to the safe and unsafe zones, we also introduce "damped zones" which represent regions in the human state space that are near, but not yet within, an unsafe zone. At time step t, we perform a biomechanical-safety check on estimated human pose $\hat{\boldsymbol{q}}_t$, projecting it on the strain maps to assess if it lies in a safe, damped, or unsafe zone. Accordingly, we define three conditions (captured in Algorithm 1):

- if $\hat{\boldsymbol{q}}_t$ is safe, then stiffness and damping of the controller are set to zero, permitting free subject movement;
- if the subject's pose lies in a damped zone, then we analyze their velocity $\hat{\dot{\boldsymbol{q}}}_t$. If $\hat{\dot{\boldsymbol{q}}}_t$ points away from the closest unsafe zone, then the movement is safe, and free movement is enabled. Otherwise, the damping in the physical human-robot interaction is increased, setting low stiffness $\mathbf{K}_{\mathrm{low}}$ associated with damping exceeding the critical one $\mathbf{D}_t = 2r\sqrt{\mathbf{K}_{\mathrm{low}}}$ (where we employ the ratio $r > 1$). In this way, the subject receives haptic information for safer direction of movement;
- if $\hat{\boldsymbol{q}}_t$ lies within an unsafe zone, the closest point on the elliptical contour $\mathbb{C}_U$ of the zone is set as a reference point in human coordinates, and tracked with $\mathbf{K}_t = \mathbf{K}_{\mathrm{high}}$, $\mathbf{D}_t = 2\sqrt{\mathbf{K}_{\mathrm{high}}}$. In this way, the human subject is pushed to the nearest safe point by the robot intervention (similar to [15]).

2) High-Authority Shared Control: This modality uses a kinematic prediction of the future human state based on the current human state $\hat{\boldsymbol{x}}_t$, performed over a receding time

Algorithm 1 Low-Authority Shared Control

Given: Unsafe Zone $\mathbb{Z}_U$, Damped Zone $\mathbb{Z}_D$
Input: Human State $\boldsymbol{x}_t = [\boldsymbol{q}_t, \dot{\boldsymbol{q}}_t]$
if $\boldsymbol{q}_t \in \mathbb{Z}_D \setminus \mathbb{Z}_U$ **AND** $\dot{\boldsymbol{q}} \to \mathbb{Z}_U$ **then**
  $\boldsymbol{K}_t \leftarrow \boldsymbol{K}_{low}$
  $\boldsymbol{D}_t \leftarrow 2r\sqrt{\boldsymbol{K}_{low}}$
  $\boldsymbol{x}_{\text{ref}} = \boldsymbol{x}_t$
else if $\boldsymbol{q} \in \mathbb{Z}_U$ **then**
  $\boldsymbol{K}_t \leftarrow \boldsymbol{K}_{high}$
  $\boldsymbol{D}_t \leftarrow 2\sqrt{\boldsymbol{K}_{high}}$
  $\boldsymbol{x}_{\text{ref}} = \boldsymbol{x}^\star$, with $\boldsymbol{x}^\star = \textbf{argmin}_{\boldsymbol{x}}$ distance$(\boldsymbol{x}_t, \mathbb{C}_U)$
else
  $\boldsymbol{K}_t \leftarrow \boldsymbol{0}$
  $\boldsymbol{D}_t \leftarrow \boldsymbol{0}$
end if
Return: $[K,\ D,\ \boldsymbol{p}_{\text{EE}}(\boldsymbol{x}_{\text{ref}})]$ to Robot Control

horizon T, to find the estimated future subject's trajectory $\hat{\boldsymbol{X}} = [\hat{\boldsymbol{x}}_{t+1},\ \hat{\boldsymbol{x}}_{t+2}, ...,\ \hat{\boldsymbol{x}}_{t+T}]^\top$. The future trajectory is analyzed to determine whether it intersects any unsafe zone. When $\hat{\boldsymbol{X}}$ is entirely safe, free movement is enabled by setting zero Cartesian stiffness and damping matrices, similarly to II-C.1. If, instead, the current movement leads the subject to any unsafe zones, the algorithm determines an alternative trajectory $\boldsymbol{X}^\star$ by defining an optimization problem that minimally deflects the predicted trajectory but ensures that no unsafe configuration is reached. The robot temporarily takes control of the motion, setting $\mathbf{K}_t = \mathbf{K}_{\text{high}}$, $\mathbf{D}_t = 2\sqrt{\mathbf{K}_{\text{high}}}$, and tracks $\boldsymbol{X}^\star$ so the human is deflected to a safe configuration where free movement is enabled again (see Algorithm 2).

Below, we specify the cost function and constraints that constitute the optimal control problem to be solved over the generic time interval $[t, t+T]$ to find $\boldsymbol{X}^\star$.

Cost Function: we propose three terms that an optimal deflection of the human movement should minimize, ensuring that the latest human intention is respected as much as possible and that forces and accelerations be low to mitigate human discomfort:

- $L_1(\boldsymbol{x}_t, \hat{\boldsymbol{x}}_t) = w_{\text{pos}}\gamma^t||\hat{\boldsymbol{q}}_t - \boldsymbol{q}_t||_2^2 + w_{\text{vel}}||\hat{\dot{\boldsymbol{q}}}_t - \dot{\boldsymbol{q}}_t||_2^2$, which weights the distance between a given human state and the predicted one, potentially with different weights for the human coordinates position and velocities. Note that a discount factor $\gamma < 1$ is employed, to permit larger deviations as time progresses;
- $L_2(\hat{\boldsymbol{x}}_t, \boldsymbol{u}_t) = w_{\text{torq}}||\boldsymbol{u} - f_{\text{ID}(\boldsymbol{x}_t, \boldsymbol{0})}||_2^2$, accounting for the difference between the generalized torques exerted on the human model and the torques that would guarantee equilibrium of the future trajectory;
- $L_3(\dot{\boldsymbol{x}}_t) = w_{\text{acc}}||\dot{\boldsymbol{q}}_t||_2^2$, weighting the instantaneous acceleration of the human model.

Constraints: the set of constraints that we employ formalize the requirements that $\boldsymbol{X}^\star$ should satisfy:

- *Initial Condition*: Trivially, the deflected trajectory should start from the current human state;
- *Tendon Safety*: The human pose should not cause excessive strain on the healing tendon(s), leading to the requirement $\boldsymbol{q}_t \notin \mathbb{Z}_U$;
- *Dynamic consistency*: For each instant in time, the system's accelerations need to respect the dynamics of the human skeletal system, resulting in $\dot{\boldsymbol{x}}_t = f_{\text{FD}}(\boldsymbol{x}_t, \boldsymbol{u}_t)$;
- *Terminal Conditions*: At the end of the optimization interval, we require that the human speed be zero and that the torques on the human model match the equilibrium ones. This results in $|\dot{\boldsymbol{q}}_T| \leq \varepsilon_{\text{vel}}$, $||\boldsymbol{u}_T - f_{\text{ID}}(\boldsymbol{x}_T, \boldsymbol{0})||_2^2 \leq \varepsilon_{\text{torq}}$, where suitable tolerances $\varepsilon_{\text{vel}}, \varepsilon_{\text{torq}}$ are used. Moreover, the final human state should be far enough from the contour of the closer unsafe zone, to guarantee that the movement can be continued safely by the human subject: dist$(\boldsymbol{x}_T, \mathbb{C}_U) \geq \delta$.

Through orthogonal collocation techniques [25], the problem formalized above is cast into an equivalent Non-Linear Programming problem (NLP) that structure-exploiting solvers can solve.

For slow movements and relatively short T, the human skeletal dynamics specified by (2)-(3) could introduce more involved computations without significantly affecting the quality of the optimal deflection $\boldsymbol{X}^\star$. We tested this hypothesis by considering an alternative version of the NLP where the strain maps are navigated by a virtual point-mass system instead, actuated by ideal forces. The accuracy of this approximation, evaluated through computer simulations, is presented in Section III-A.

Algorithm 2 High-Authority Shared Control

Given: Unsafe Zone $\mathbb{Z}_U$
Input: Human State $\boldsymbol{x}_t$
$\hat{\boldsymbol{X}} \leftarrow$ **pathPrediction**$(\boldsymbol{x}_t)$
if $\exists \boldsymbol{x}_i \in \hat{\boldsymbol{X}} \mid \boldsymbol{x}_i \in \mathbb{Z}_U$ **then**
  $\boldsymbol{K}_t \leftarrow \boldsymbol{K}_{high}$
  $\boldsymbol{D}_t \leftarrow 2\sqrt{\boldsymbol{K}_{high}}$
  $\boldsymbol{X}^\star_{ref} \leftarrow \textbf{argmin}_{\boldsymbol{X}_{\text{ref}}} \mathcal{L}(\boldsymbol{X}, \boldsymbol{X}_{\text{ref}})$
else
  $\boldsymbol{K}_t \leftarrow \boldsymbol{0}$
  $\boldsymbol{D}_t \leftarrow \boldsymbol{0}$
end if
Return: $[K,\ D,\ \boldsymbol{p}_{\text{EE}}(\boldsymbol{X}^\star_{\text{ref}})]$ to Robot Control

D. Initial User Testing

Before conducting proof-of-concept experiments, we solicited the input of a physiotherapist for qualitative feedback on the interaction. Initial trials with the PT were deemed to be overly "aggressive" during motion correction. To account for this, steps were taken to better tune the controller parameters, (i.e., tuning the weights in the cost function and increasing the sampling frequency of the reference trajectory) to avoid this perceived behavior.

E. Experimental setup

A healthy subject participated in our experiments and interacted with a KUKA LBR iiwa 7 through our custom arm brace, allowing simultaneous human state estimation and physical human-robot collaboration during a simulated rehabilitation session. Our experimental protocol was approved by the Human Research Ethics Committee of TU

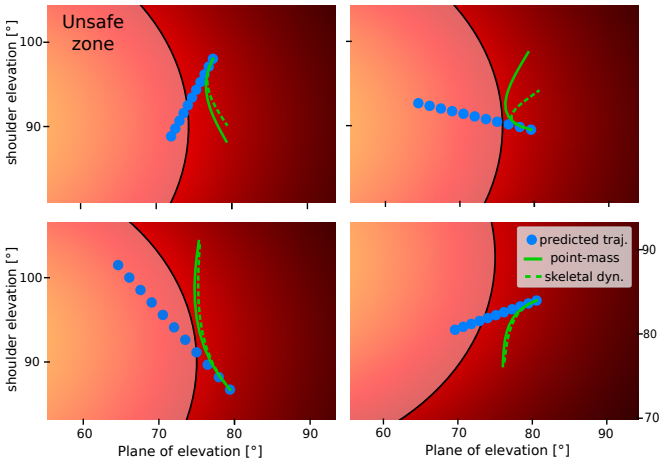

Fig. 3. Simulation comparison of optimal deflections generated by the high-authority module, contrasting the results when using the human model's dynamics (dashed green) versus a virtual point mass (solid green) for navigating the strain map.

Delft. To demonstrate the key functionalities of our method and ensure the repeatability of the experiments, we locked the AR degree of freedom and considered a custom strain map with one time-invariant unsafe zone. The subject was instructed to maintain a constant torso orientation during the interaction to satisfy the assumption of Section II-B. We selected $k_{high,t} = 400\frac{N}{m}$ and $k_{high,r} = 20\frac{N}{[rad]}$ as high translational and rotational stiffness respectively, while low values were set to $k_{\mathrm{low,t}} = 20\frac{N}{m}$ and $k_{\mathrm{low,r}} = 5\frac{N}{[rad]}$.

By removing the damped zone in the low-authority module, we effectively recreated the haptic boundaries considered in our previous work [15], to measure the performances of this baseline controller in terms of robot-commanded forces when the unsafe zone was reached (Section III-B). Then, we set $r = 4$ to increase the damping of the controller, so that our subject could receive anticipatory haptic feedback before impacting the unsafe zone. In the high-authority module, we selected $T = 1$ s and divided it into 10 discrete steps, and up-sampled the resulting optimal deflection to the required frequency for the controller. When the deflection was executed, the system also played a sound to promptly inform the subject that they should comply with the robot's corrective movement.

During these proof-of-concept experiments, the subject interacted with the robot by moving their arm through a natural range of motion. They were then directed to move towards the prescribed unsafe region while the resulting trajectory and forces were recorded. The subject repeated this for both deflection modalities to analyze the effectiveness of our method. Computations were performed on a Dell Latitude 7420 laptop with an i7-1185G7 processor, interfaced with a Dell workstation with an Xeon W-2123 processor dedicated to the impedance controller. Our code is available at *https://github.com/itbellix/biomechanical_safe_deflection*.

III. Results

A. Evaluation of the approximated dynamics

We employed computer simulations to evaluate the differences between the optimal deflections produced by the NLP presented in Section II-C.2 when the strain maps are navigated with the human model's dynamics or by the virtual point mass. We selected 100 random initial conditions for human poses and velocities, to represent the different ways that a subject would move toward an unsafe zone, and computed the optimal deflection proposed by the NLP in the two cases. Figure 3 exemplifies the results obtained, given the kinematic prediction of the human trajectory computed from the randomly selected initial state. Overall, we observed a RMSE of about $2°$ between the last point of the two trajectories. The NLPs employing human skeletal dynamics required an average solution time of 740 ms (failing to converge in $4/100$ instances), whereas the NLPs with virtual point mass approximation could be solved in 12 ms on average, with 100% convergence rate. For these reasons, we opted to use the second approximation in the experiments performed with our physical robot, the results of which we present next.

B. Baseline controller

We ran our baseline controller [15] and recorded the forces generated by the robot on the human as a consequence of collisions with the unsafe zone during subject-led movements. The peak force magnitude that we observed exceeded 17 N, with the subject executing similar movements as during the rest of our experiments, but receiving no feedback or deflection from the robot before hitting the unsafe zone.

C. Shared control modalities
