Fig. 4. Perceived pain and difficulty scores during tasks with and without the exoskeleton. The top row illustrates the perceived pain scores reported by the four participants across the seven locomotor tasks: stair ascent (SA), stair descent (SD), ramp ascent (RA), ramp descent (RD), sit-to-stand descent (STS-D), sit-to-stand ascent (STS-A), and level walking (LW). Each bar compares the Bare condition (red bars) with the Exo condition (blue bars). The bottom row displays the corresponding perceived difficulty scores for the same participants and tasks, with the same comparison between the Bare and exoskeleton conditions. The data highlight individual variability in the reported pain and difficulty changes, showcasing task-specific and participant-specific responses to exoskeleton assistance.

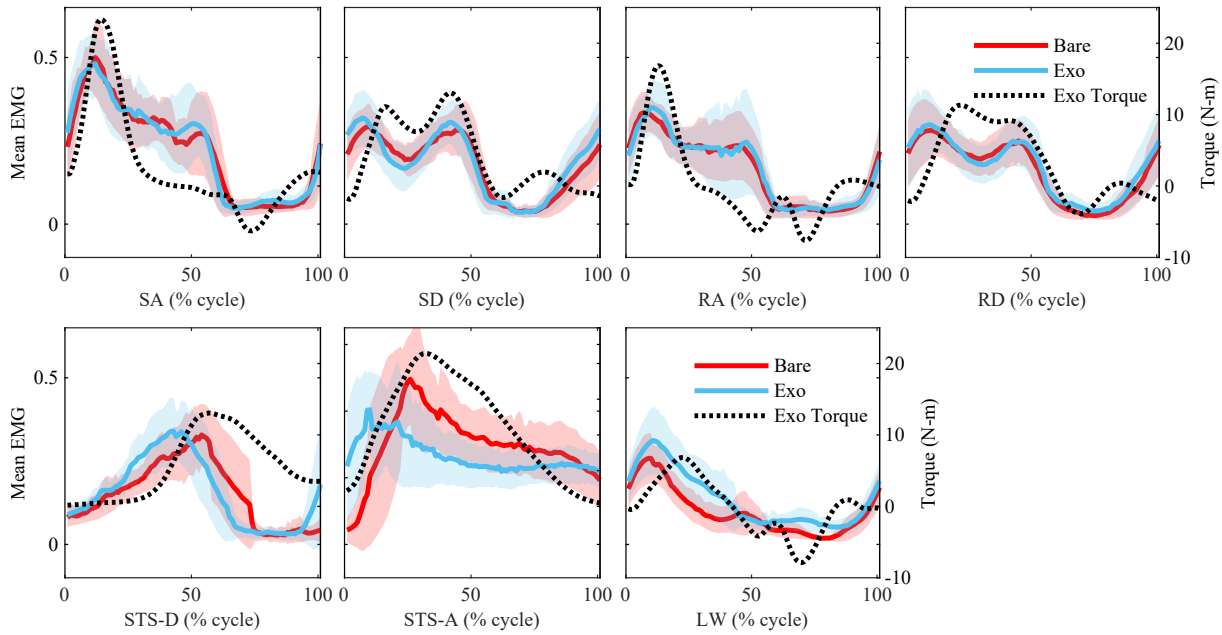

Fig. 5. Mean EMG activation and exoskeleton torque during task cycles. Each plot represents one of the seven locomotor tasks: stair ascent (SA), stair descent (SD), ramp ascent (RA), ramp descent (RD), sit-to-stand descent (STS-D), sit-to-stand ascent (STS-A), and level walking (LW). The red curve shows the mean EMG activation during the Bare condition, while the blue curve shows the mean EMG activation during the exoskeleton-assisted condition. Overlaid on each plot is the mean torque applied by the exoskeleton (black curve), illustrating the relationship between exoskeleton assistance and muscle activation throughout the task cycle.

IV. Discussion

Our study's key finding was that our knee exoskeleton provided *acute* benefits for predominantly patellofemoral OA participants, consistently lowering both their pain levels and the difficulty they experienced during various activities. Traditional unloader knee braces aim to reduce joint loading, but fall short in addressing pain caused by quadriceps muscle action, a limitation that our device directly targets. Unlike spring-based braces, which cannot adjust output torque based on kinematics and ground reaction forces, our system dynamically modulates assistance to inject energy when needed. This is achieved with backdrivable actuators and an intuitive controller that modulates virtual springs, dampers, and gravity-inertia compensation across a range of tasks. This adjustability simplifies tuning and enhances end-user adoption, offering a versatile and practical solution for knee assistance. Moreover, this study addresses the shortcomings of other knee exoskeletons, such as Keeogo and ROAM Ascend. While Keeogo can benefit individuals with knee OA after prolonged use, it has not provided acute benefits, likely due to its highly geared actuators and task-specific controller.

A. Pain and Difficulty Reductions

The most substantial pain reduction was observed during RD, with an average decrease of 1.75 points across participants. This may be attributed to the exoskeleton's capacity to assist the knee in decelerating the body's center of mass, thereby reducing the demand on the quadriceps [23]. In contrast, level walking showed minimal pain reduction, likely due to the lower baseline pain levels typically associated with this activity and its reduced reliance on quadriceps engagement. Unexpectedly, Subject 2 reported increased pain during stair descent. We attribute this to extended loading phases that arise due to hesitancy in utilizing exoskeleton assistance on the riskiest task.

The perceived difficulty of tasks generally correlated with pain levels, although exceptions were observed. For instance, Subject 1 experienced no change in pain during STS-D yet reported an increase in difficulty, suggesting that non-pain-related factors, such as balance or coordination, may have influenced their perception. Similarly, Subject 4 perceived a reduction in pain during RD but noted an increased difficulty, further emphasizing the multifaceted nature of these metrics.

B. Muscle Activity Trends

Muscle activation data revealed notable trends, particularly for STS-A, which exhibited the most pronounced reductions in both mean and peak EMG levels across participants. This aligns with expectations, as the task involves high joint loading and a large range of motion, making it particularly amenable to the exoskeleton's assistive torque. Subjects 1 and 3 showed substantial reductions in peak quadriceps activation during STS-A, SA, and RD, reflecting effective exoskeleton support in mitigating muscular demand. Conversely, Subjects 2 and 4 exhibited less consistent EMG reductions, potentially due to individual differences in balance, motor coordination, or limited acclimatization to the device. These results contrast with our earlier findings in younger, unimpaired users [15], where we observed more consistent reductions in muscle effort. This disparity may indicate that OA participants optimize additional factors, including pain, that influence muscle activation patterns, or they may simply require more acclimation time because older age slows motor adaptation to exoskeletons [24]. Previous work suggests that extended training periods may improve device integration and motor adaptation, thereby enhancing efficacy [25].

An intriguing observation is that pain reduction occurred in some cases despite increases in muscle activation. This challenges the hypothesis that higher quadriceps EMG levels directly correlate with increased joint forces and exacerbated patellofemoral pain. Some studies investigating the neural adaptations with exoskeletons [26], suggest that increased activation may reflect altered muscle recruitment patterns rather than increased joint loading. Future work should further explore the mechanisms underlying pain relief and the complex relationship between muscle activation and joint forces in patients with knee OA.

C. Study Limitations and Future Work

Several limitations of this study warrant discussion. First, the exoskeleton's maximum assistive torque was capped at 25 Nm due to motor constraints, which may have limited its effectiveness for users requiring greater support. This may have been exacerbated by removing the medial thigh plate from the exoskeleton in [15] (to prevent a structural moment in the frontal plane), which may have reduced the effective transmission of assistive torque to the user. Second, task-specific constraints on peak knee extension velocity, particularly during SA, RA, and STS movements, may have introduced variability in kinematic patterns, complicating EMG comparisons across conditions. Developing more precise gait kinematic constraints could improve alignment of muscle activation patterns in future studies, particularly for level walking and descent tasks. Lastly, the potential influence of muscle co-contraction on EMG data should be considered. Co-contraction may have contributed to apparent increases in muscle activation, particularly in tasks requiring stabilization or balance. Incorporating antagonist muscle activation measurements in future analyses could provide a more comprehensive understanding of the exoskeleton's impact on joint loading and pain perception. Future research should focus on addressing the aforementioned limitations while investigating long-term effects, acclimatization processes, and optimization of control strategies for broader clinical and biomechanical applications. Furthermore, future studies should involve larger, more diverse populations to increase the statistical power of these findings.

V. Conclusion

This study provides compelling evidence that backdrivable knee exoskeletons can provide acute reductions in pain and difficulty during a range of locomotor tasks. By addressing several critical limitations of conventional and modern knee-assistive devices, our approach offers new insights into improving knee function and alleviating discomfort. While we cannot definitively link reduced muscle activation to decreased pain, results show the exoskeleton helps users perform previously challenging tasks more comfortably. For example, this relief may enable individuals with OA to engage in physical activities that would otherwise be too painful, fostering muscle strength and potentially slowing the progression of OA. As such, the exoskeleton represents a promising alternative treatment for knee OA. By offering targeted assistance when needed, backdrivable exoskeletons may offer a significant advancement in the non-invasive management of knee OA, with the potential to improve mobility and enhance the quality of life for patients. Further research with larger sample sizes is needed to validate these findings.

***Abstract*— Stroke survivors often experience severe gait impairments that reduce mobility and independence, highlighting the need for innovative and practical rehabilitation solutions. Many existing devices are limited by their high cost, complexity, or invasive nature, making them inadequate for widespread use in clinical and at-home settings. To address these challenges, we introduce the LegExoNET, a passive lower-limb exoskeleton capable of providing both assistance and resistance in ankle dorsiflexion and plantarflexion. During mechanical testing, the torques applied by the device decrease non-linearly with a decrease in ankle angle. The device's lightweight, modular design ensures versatility and accessibility, establishing the LegExoNET as a promising tool for enhancing gait rehabilitation and promoting motor learning. Future work will include expanding to a multi-joint device while incorporating additional functions such as leg propulsion assistance.**

Keywords*— *Passive Exoskeleton, Ankle, Elastic Torque, Dorsiflexion, Plantarflexion, Stroke Rehabilitation

I. INTRODUCTION

Stroke is one of the leading causes of long-term disability [1]. Survivors oftentimes experience abnormal movement pattern and muscles weakness, that manifest into long-term gait impairments [2], [3]. This can hinder mobility and independence, increases fall risk, and promotes compensatory movements resulting in future orthopedic injury.

Gait devices targeted towards stroke are often costly, invasive, and tethered to complex systems, falling short in promoting lasting motor recovery. Functional electrical stimulation, a widely used method for addressing gait impairments like foot drop, relies on sensor technology to determine stimulation timing but can lead to muscle fatigue, potentially limiting its effectiveness in addressing the main causes of movement deficits [5], [6], [7]. Motor-powered exoskeletons can assist in proper foot clearance, but these devices are complex with various sets of motors, electrical sensors, and cables [4], [8]. Plus, they do not require the user's muscles to exert significant effort in moving the limb or ankle, limiting muscle engagement and strength development. Passive ankle exoskeletons have been attempted before, but they are often bulky, provide limited functionality, and lack adaptability for rehabilitation applications. Many designs rely on fixed stiffness mechanisms or pre-set resistance levels, restricting their ability to dynamically adjust torque output based on user needs. Additionally, these devices often require complex attachment mechanisms or rigid structures that limit ease of use [9], [10], [11]. Other commercial devices tend to keep the ankle in a fixed position to stabilize movement, which does little to facilitate functional recovery [12]. There is a critical need for innovative rehabilitation solutions that promote functional recovery through adaptive motor learning strategies.

Skill acquisition is a function of assistance and error augmentation (EA) and occurs during the progression from guidance and assist-as-needed training to independent practice where errors are deliberately increased to enhance learning [13]. Motor learning can occur when assistance is reduced, and difficulty is increased through error amplification. In clinical practice, physical therapists often use resistance bands to target poor eccentric control by manually assisting limb advancement during the swing phase, which is an example of transitioning between these stages [13]. The inclusion of this concept in innovative rehabilitation solutions has the potential to address the essential clinical need for adaptive motor learning strategies that promote functional recovery through tailored error feedback and skill progression.

Our solution is the LegExoNET (Exoskeletal Network for Elastic Torque) a novel, passive lower-limb exoskeleton designed to enhance rehabilitation through various applications, one of such that we describe in this paper is the use of assistance. The LegExoNET acts as an exotendon, storing elastic energy during movement and releasing it to aid propulsion while allowing for free and natural limb motion [14]. It may compensate for deficits like foot drop, provide support against gravity, and promote adaptive motor learning by exaggerating movement errors when desired. The LegExoNET has a lightweight, modular design that allows for stacked elastic elements, enabling greater torque output, adjustability, and seamless integration with the user's natural movement. In this paper, we will explore the design, modeling framework, and mechanical performance of the

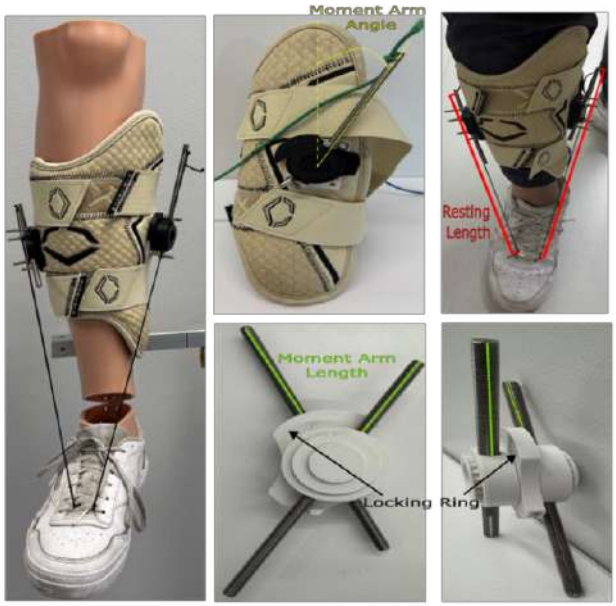

Fig. 1. Architecture of the LegExoNET

LegExoNET based on previously discussed concepts and optimization [15], [16], [17], [18].

II. METHODS

A. LegExoNET Design

The current LegExoNET design aims to achieve two primary functions to enhance rehabilitation: (1) challenge users to stabilize against exaggerated ankle dorsiflexion and a change in leg propulsion forces during the swing phase of gait; and (2) assist users in a movement when needed, facilitating controlled and adaptive engagement.

The LegExoNET is composed of a spring network system of elastic bands that run from the user's shank to a distal point of the user's shoe, attached by threaded rods. The threads allow for seamless adjustability of the moment arm during real-time adjustments. The threaded rods insert into a polylactic acid 3D printed indexed mechanism, which allows the moment arm to pivot freely in 18° increments, allowing granularity for the moment arm angle. A locking mechanism secures the moment arm in place with a locking ring. This configuration allows for real-time adjustments of the moment arm length and angle, and resting length of the elastic bands (Fig. 1). All components are secured to a rigid structure that attaches to the user's shank to ensure stability of the components.

The LegExoNET also includes a unique feature of stacked tension elements, which can increase the elastic torque produced by the spring network system. This enhancement allows for greater support and adaptability, making it highly effective in addressing various levels of resistance across different training applications.

We can achieve the different configurations via our graphical user interface that allows clinicians or patients to adjust the design and structure of the device in real-time, where the therapist is able to adjust the parameters and then held static when the user walks in it. The use of this interface is to obtain the settings for the moment arm length, moment arm angle (theta), and resting length of the bungee based on the user characteristics of height, weight, and device mode. The two modes that are tested in this study are assistance, the elastic band is stretched taut, and no-assistance, the elastic band is at full slack. The use of passive springs (elastic bands) ensures that the device is lightweight, portable, and safe to operate. Moreover, the device does not require any charging or rebooting, providing a convenient and accessible solution for individuals with motor impairments.

B. Theoretical Framework

The mechanics of the LegExoNET device are defined by the torques (τ) generated through the interaction of spring elements with the joint. These torques are calculated as the vector product of the spring element's moment arm (ρ) and the applied force (F), as shown in the equation:

$$\tau = \rho \times F \tag{1}$$

where ρ is determined by the distance between the attachment points on the proximal (X_o) and distal (X_i) segments of the limb. F_s is the force exerted by the spring element, governed by Hooke's Law:

$$F_s = -k(l - l_o) \tag{2}$$

where, k is the spring constant, l is the current length of the spring, and l_o is the slack length of the spring. This spring force function can be replaced by a more complex, nonlinear function to account for different impedance properties, such as those encountered in elastic cords.

In the LegExoNET, multiple spring elements can be combined in "stacks", where each individual spring creates a torque τ_i based on the joint angle θ_s, the attachment points (X_o, X_i), and the spring's impedance function. The total torque produced by all the stacked elements is the sum of their individual torques:

$$\tau_{total} = \sum_{i=1}^{n} \tau_i \tag{3}$$

where n is the number of stacked spring elements. Each of these spring elements contributes to the desired movement or resistance by applying torque that is a nonlinear function of the joint angle and the spring's characteristics, including its slack length, l_o.

To optimize the system, a quadratic cost function minimization approach is used. The goal is to minimize the difference between the desired torque output and the actual torque produced by the system at a set of test points within the configuration space. This is expressed as:

$$Minimum\ Cost = \sum_{k=0}^{N_{Test\ Points}} (\widehat{\tau_k} - \tau_k)^2 + R^2 \tag{4}$$

where $\widehat{\tau_k}$ is the desired torque at test point k, τ_k is the actual torque produced by the system at point k, $N_{Test\ Points}$ is the

number of points used for testing within the configuration space, and R is a regularization term that increases the cost function to penalize undesirable configurations, such as springs that are too long or that may cause unintended attachment penetration or mechanical issues like structural failure.

Additionally, constraints on the spring's geometry, such as limiting the slack length to ensure appropriate tension is maintained during the movement. This approach ensures that the optimization not only produces the desired functional output but also guarantees that the device operates within safe and feasible physical limits.

C. Mechanical Testing

To quantify the mechanical performance of the LegExoNET, we conducted a controlled mechanical test using a mannequin leg model. This test aimed to experimentally determine the torque produced by the device as it interacts with a dynamic ankle joint.

A Mark-10 force sensor (Johnson Scale & Balance Co., USA) was mounted next to the leg and was aligned with the line of action of the device's moment arm (Fig. 2). The moment arm attachment on the force sensor was designed to rotate dynamically, allowing it to freely move as the ankle was manually moved through dorsiflexion and plantarflexion. The dynamic rotation of the moment arm attachment on the force sensor ensured that the force measurement accurately reflected the torque output at various points in the range of motion.

Human motion video analysis software (Kinovea, France) was used to analyze the angle and bungee length change during all trials. The results from this test can help validate the device's ability to deliver appropriate torque for assisting or resisting ankle movements. The data can also inform future adjustments to the bungee cord stiffness or resting length for optimal performance.

III. Results

A. Mechanical Testing

Fig. 3 displays the relationship between ankle torque and angular displacement across each of the three trials. In the photo, the ankle angle is displayed as the teal angle dimension and the spring length is in orange. The overall trend

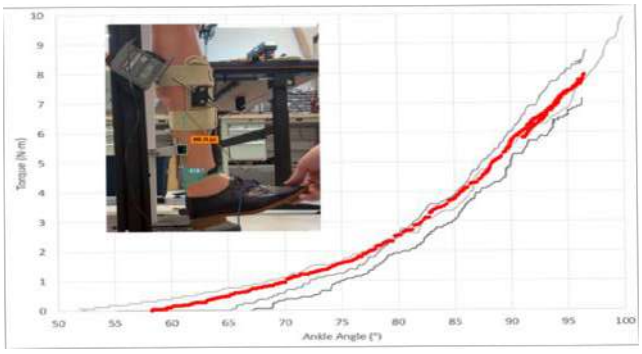

Fig. 3. Torque vs. Angle of the Ankle During Plantarflexion

Fig. 2 Mechanical Testing Experimental Setup

(displayed in red on the graph) demonstrates a consistent pattern of increasing torque with increasing angle. It is important to note that the measured torques were not normalized for mass, so the absolute torque values reported reflect the raw mechanical output of the device.

IV. Discussion

A. Mechanical Test

The torque-angle graph and the response of the leg mannequin model demonstrate a nonlinear relationship, where the bungee cords apply increasing resistance during plantarflexion. This progressive tensioning suggests that plantarflexion range of motion may be restricted, potentially leading to reduced plantarflexor muscle activity. Additionally, based on the observed response of the mannequin model, we noted that upon tension release, the stored energy in the bungee cords facilitated dorsiflexion. This recoil effect after peak plantarflexion (when tension is highest) suggests that the device may assist dorsiflexion by reducing the effort required by the tibialis anterior (TA), potentially offloading the dorsiflexor muscles.

One primary concern when experimenting with bungee cords is the elastic material fatigue over time. Repeated stretching and relaxation of the elastic bands could potentially lead to material degradation, reducing their stiffness and altering the torque output. This effect, known as hysteresis, could result in inconsistent assistance or resistance, especially after prolonged use.

B. Clinical Applications

The advantage of the LegExoNET is its potential ability to be tailored by the user to deliver a wide range of therapeutic forces, whether for assistance or restorative outcomes [20]. One such force includes error augmentation (EA); a training mechanism that employs perturbations or

resistance to intentionally amplify biomechanical errors, which can enhance the feedback provided to the user [21]. This approach increases corticospinal excitability, muscle activity, altered kinematics, and interlimb coordination; ultimately aiming to improve motor learning and movement control [22], [23]. EA creates opportunities for error feedback, which is crucial for refining motor skills. The effectiveness of this mechanism relies on a functional cerebellum, as it plays a key role in developing an "internal model" that enables predictive feedforward adaptations to movement [24]. As errors are introduced, the internal model can be updated based on feedback until the movement error is reduced. Counter intuitively, the temporary introduction of errors can lead to long-term improvements in movement efficiency and control.

The LegExoNET's adaptability may replace the need for therapists to manually apply resistance bands for error augmentation in gait therapy, making it ideal for both clinical and at-home use. We developed a framework that allows us to adaptively modify the torque applied by the LegExoNET device at different points in the gait cycle. This adaptability may enable us to either decrease or increase muscle activity as needed, creating personalized assistance or resistance tailored to an individual's rehabilitation needs while promoting motor learning during gait training.

C. *Future Work and Limitations*

We plan to conduct clinical trials with both able-bodied participants and stroke survivors. Once IRB approval is officially obtained, the device will be tested for its ability to improve gait symmetry and motor learning in stroke survivors. Additionally, we will incorporate EMG analysis to evaluate muscle activation patterns, providing further insight into how the device influences muscular engagement and motor adaptation during gait rehabilitation.

We also plan to collaborate with physical therapists to refine the device and incorporate real-time feedback to further optimize its functionality and usability. This also will lead us to implement a multi-joint network system that can assist with knee and hip torques along with the ankle.

Next iterations of this assistive device could improve by fine-tuning configurations through optimization algorithms to better control where assistance or resistance is applied based on the individual needs of the patient. For instance, optimized configurations could provide targeted assistance during push-off to address plantarflexion weakness or during swing to prevent foot drop resulted from dorsiflexion weakness. Similarly, controlled resistance could be implemented to promote muscle strengthening or motor learning. By incorporating human-in-the-loop optimization techniques, the device could adjust its settings to maximize therapeutic outcomes. These configurations would need to be manually adjusted based on the user's specific needs. The LegExoNET offers a flexible, adjustable approach to assist and enhance gait, allowing for more dynamic and customizable support without restricting natural joint movement.

A limitation of our study was that we focused on a single torque profile configuration, rather than exploring multiple configurations to fully demonstrate the device's adaptability. Future work will expand on this by testing various moment arm and elastic element configurations to verify the range of torques that can be achieved throughout the gait cycle with our device.

V. Conclusion

The LegExoNET device shows potential as both an assistive and restorative device to improve performance of activities of daily living (ADLs). It may help mitigate gait impairments experienced by individuals with neurological impairments. Future designs hope to restore function by strengthening muscles involved in gait, particularly through its customizable resistance and error augmentation features, which promote adaptive motor learning. Initially designed for stroke survivors with hemiparesis, the LegExoNET may also extend its applications to include individuals with spinal cord injuries (SCI), muscular dystrophy, and other neurological diagnoses, helping them achieve greater independence and stability during movement. Its versatility also makes it an ideal training tool for physical therapists, where it provides safe, effective support without requiring constant clinical supervision.

***Abstract*— Cerebral palsy (CP), the most prevalent motor disorder in children, significantly impairs gait, often due to deficiencies in ankle control. Traditional ankle-foot orthoses (AFOs) used in CP management provide passive support but restrict natural ankle motion, resulting in muscle atrophy and limited adaptability. Powered AFOs, while offering propulsion assistance, are frequently bulky and uncomfortable, hindering long-term use. We designed an innovative, biomimetic AFO in our most recent study. Named DE-AFO, this device employs artificial muscles made from an electroactive polymer actuator called dielectric elastomer (DEA) to assist ankle movements in the sagittal plane. DE-AFO features a gait-phase detection controller that synchronizes the artificial muscles with the user's natural gait cycle, mimicking the behavior of biological muscles while maintaining a lightweight, compact, and silent design. This study builds upon the initial DE-AFO model by incorporating the latest version of the commercially available and stacked configuration of DEA (SDEA-1550), which offers enhanced force and displacement capabilities. Testing was expanded to include three participants with spastic diplegic CP to theoretically test and evaluate the updated DE-AFO's (DE-AFO-1550's) effectiveness in compensating for ankle moment deficits. The DE-AFO-1550 could fully compensate for dorsiflexion deficits (100%) during the swing phase and address 75% of plantarflexion deficits during the pre-swing. These findings highlight the DE-AFO-1550's potential as a next-generation, user-centered robotic AFO, capable of significantly improving mobility and quality of life for individuals with CP.**

Keywords—Cerebral Palsy, AFO, Exoskeleton, Dielectric Elastomer, Artificial Muscle

I. INTRODUCTION

Cerebral palsy (CP) represents the most common movement disorder among children, with an observed prevalence of approximately 2 to 3 cases per 1,000 in the general population [1]. Among the primary challenges in CP are deficiencies in ankle control, which significantly impact gait and contribute to instability, slower gait speeds, and increased risks of falls and injuries [2]. Gait generally stabilizes by age four, highlighting the importance of early detection and intervention for optimal motor development [3]. Over time, mobility often declines in individuals with CP, impacting their independence, physical activity levels, and social engagement [4]. Additionally, inactivity due to gait impairments increases the risks of secondary health issues, such as cardiovascular disease, and is associated with a higher mortality rate [5], [6].

Traditional ankle-foot orthoses (AFOs) are frequently prescribed for individuals with spastic CP due to their capacity to provide passive support. However, these devices are predominantly rigid and cumbersome, resulting in restricted ankle mobility and limited active muscle engagement. This design not only diminishes natural movement but also contributes to muscle atrophy and skin discomfort. Furthermore, these orthoses may inhibit sensory feedback and adaptive motor control during ambulation, consequently impacting the overall mobility and stability of the user [7], [8]. In contrast, powered AFOs have been engineered to actively generate torque, specifically aiding the plantarflexor muscles in facilitating the forward propulsion of the center of mass during walking [9], [10], [11], [12]. Despite these advancements, the majority of current models operate using DC motors [13], [14] or pneumatic actuators [15], [16], [17], which are generally ill-suited for proximity to the human body due to their rigid and inflexible structures. This rigidity may further restrict natural joint movement, potentially causing pressure sores and discomfort, similar to the issues commonly observed with traditional AFOs. Additionally, the bulky, heavy, and noisy nature of these powered AFOs reduces user comfort and acceptance, thereby hindering their broader commercialization.

Cable-driven exoskeletons powered by DC motors have recently gained attention as more compact and flexible alternatives for AFOs, with devices like ReWalk Restore [18] and Biomotume [19] exemplifying this trend. Despite improved comfort, these systems are still cumbersome to wear and visually conspicuous. In an innovative direction, Park et al. introduced a bio-inspired soft AFO powered by pneumatic actuators, designed to closely mimic the natural muscular structure of the ankle joint. This design supported movement in both the sagittal plane (plantarflexion/dorsiflexion) and the frontal plane (eversion/inversion) [15]. However, current

pneumatic AFOs face limitations, including a substantial weight of approximately 2.5 kg and acoustic noise levels around 65 dB [20], [21], nearing the annoyance threshold of 70 dB (comparable to a washing machine) [22]. These drawbacks emphasize the urgent need for the development of actuators that are soft, lightweight, quiet, and compact, which closely replicate the characteristics of biological muscles. This advancement is essential for improving both the functionality and user comfort of AFO designs.

Soft electroactive polymer actuators, particularly dielectric elastomer actuators (DEAs), present a fast, efficient, and quiet alternative to traditional actuation methods. Renowned for their muscle-like properties, DEAs are increasingly recognized as one of the most promising candidates for soft actuator technologies.

Structurally, DEAs operate as compliant capacitors, comprising a thin elastic dielectric layer sandwiched between two flexible, conductive electrodes. When a DC voltage is applied across the electrodes, electrostatic forces—known as Maxwell pressure—act on the dielectric, compressing it in the thickness direction. This compression results in lateral expansion, generating displacement, force, and mechanical output (Fig. 1A). The simplicity of this mechanism not only allows DEAs to replicate the behavior of natural muscles but also provides significant design flexibility.

Among DEA designs, the stacked dielectric elastomer actuator (SDEA) configuration, developed by Kovacs et al. [23], is a powerful and versatile actuator that most closely resembles human skeletal muscle. This advanced actuator is created by stacking multiple thin, enhanced DEA layers, with each layer functioning similarly to a sarcomere within skeletal muscle (Fig. 1B). This SDEA configuration achieves impressive performance, generating 32 N of isometric force and 15% strain while lifting a 1.1 kg load [24]. We pioneered the benchmark testing of the mechanical properties of these actuators [25], [26]. Since SDEA mimics key characteristics of natural muscle, including the ability to contract longitudinally, provide flexibility, and generate forces and displacements similar to those produced by biological muscles, we referred to it as "artificial muscle".

Guided by insights from customer discovery supported by the NSF I-Corps (project #1906128) [27], we developed DE-AFO, a robotic AFO designed to prioritize user comfort and provide targeted plantarflexion (PF) assistance, two features identified as top priorities by AFO users and physical therapists. At the core of the DE-AFO's functionality is a finite state machine controller and advanced artificial muscles [28]. This setup enables the DE-AFO to detect the timing and direction of the assistive moment required in the sagittal plane and activate the corresponding set of artificial muscles. These muscles are strategically aligned in parallel with the natural action line of the ankle's biological muscles, enhancing their ability to support and facilitate natural ankle movement. To further enhance gait biomechanics, the DE-AFO includes a metatarsal joint, which facilitates a natural foot position during the push-off phase of gait (Fig. 2A), a significant advancement over traditional AFO designs.

For the initial theoretical evaluation of our design, we used ankle moment data from one representative child with CP

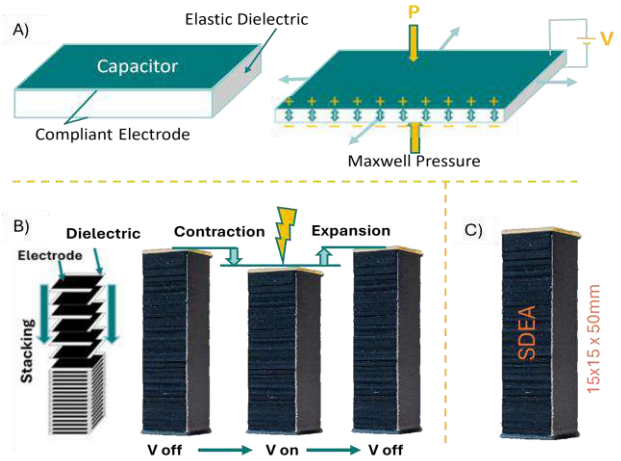

Fig. 1. A) Elastic Capacitor and Maxwell pressure creating displacement. B) Stacked dielectric elastomer actuator (SDEA) configuration consists of multiple layers of elastic capacitors. C) a real SDEA consists of about 2500 layers of capacitors.

(CP01) and seven typically developing (TD) children (Table 1). The results showed that the DE-AFO could compensate for 68% of the subject's PF deficit during the pre-swing phase and fully address the dorsiflexion (DF) deficit during the swing phase [28].

This original DE-AFO model employed CT-SDEAs, which we benchmark tested [25] and was capable of generating 3.3% strain and 10N of force (0.037 MPa of stress). In light of the substantial improvement in the stress and strain capabilities of the latest version of SDEA, the main objective of this study was to evaluate the performance of the DE-AFO powered by the latest SDEA in three children with CP following the similar analysis we reported for the previous version of the actuator [28].

II. Methods

A. Participants

Ankle moment data from three children with CP and seven TD children, originally collected in a separate study, were integrated into this analysis [29]. Participant details are summarized in Table 1. Two participants were recruited from a study approved by the University of Delaware Institutional Review Board (IRB) and registered on ClinicalTrials.gov (NCT05233748). Additionally, one participant from a separate study, approved under the IRB protocol 20459, was included in our analysis. Informed consent and assent were obtained from all participants.

For data collection, participants walked on a treadmill with reflective markers placed on anatomical landmarks of the lower limbs. Gait dynamics were recorded using a motion capture system (Motion Analysis Corporation, Santa Rosa, CA, USA) at a sampling rate of 128 Hz and two force plates (Bertec, Columbus, OH, USA) at 3200 Hz. The collected gait kinematics and kinetics were processed in Visual 3D (C-Motion Inc., Germantown, MD, USA).

B. Original DE-AFO Design

In the original DE-AFO design (Fig. 2), we employed SDEAs from CTsystems (model CT25.0-15-15-71, Compliant Transducer Systems, Dubendorf, Switzerland) as

the motor units of the artificial muscles that powered the device. To mimic the structure of biological muscle fibers, the SDEAs were arranged in series to form artificial myofibrils, enabling the actuator to achieve the required length shortening. Additionally, the force generation capability can be further enhanced by configuring multiple artificial myofibrils in parallel. As an example, a 1 × 3 artificial muscle consists of three SDEAs connected in series to form one artificial myofibril. Based on the manufacturer's report and our benchmark test results, each CT-SDEA can produce a force of 10N and a displacement of 1.17mm [25]. As a result, the 1 × 3 artificial muscle can achieve a displacement that is three times greater than that of an individual CT-SDEA, equals to 3.53mm, and 10N of force [28]. Our DE-AFO device incorporated two sets of 1 × 3 artificial muscles medially and laterally for dorsiflexion assistance and another two for plantarflexion, termed dorsiflexor and plantarflexor artificial muscles, respectively (Fig. 2A). Each artificial myofibril weighed 33.9 g (with each SDEA contributing 11.3 g), resulting in a total mass of 135.6 g for all the artificial muscles in the design. The overall weight of the DE-AFO was approximately 1250 g, which includes 900 g for electronics and 200 g for the mechanical structure.

Table 1. Detailed information on participants' age, gender, height, weight, Gross Motor Function Classification System (GMFCS), and self-selected walking speed (SSWS).

	Age (yrs)	Gender	Height (m)	Weight (kg)	GMFCS	SSWS (m/s)
TD01	16	M	1.78	71.92	-	0.8
TD02	10	M	1.46	32.55	-	0.8
TD03	10	F	1.46	31.95	-	1.2
TD04	12	F	1.59	43.25	-	1.25
TD05	12	F	1.47	36.42	-	1
TD06	14	F	1.55	52.61	-	1.1
TD07	13	F	1.73	56.29	-	1.1
CP01	12	M	1.37	25.89	I	0.9
CP02	12	M	1.52	41.50	II	0.75
CP03	13	F	1.31	32.13	III	0.45

C. *Theoretical Analysis, and Augmented DE-AFO Design*

To evaluate the theoretical performance of the DE-AFO, we examined its ability to compensate for ankle moment deficits in a representative child with CP. The deficit was calculated by subtracting the sagittal plane ankle moment of the CP subject, normalized to body mass, from the normative ankle moment of TD children. The normative data was generated by averaging the sagittal plane ankle moments of seven TD subjects, with each moment averaged over 30 gait cycles and normalized to body mass. To quantify the ankle moment deficit, we determined the difference between the normative TD data and the ankle moment of the CP child. Subsequently, the sagittal plane ankle moment generated by the DE-AFO was computed and compared with the identified deficit. This analysis allowed us to assess the forces required to restore ankle function closer to normative levels and evaluate the DE-AFO's effectiveness in generating the necessary compensatory forces [28].

While the DF requirements were adequately met using two artificial muscles, the initial configuration for PF assistance proved insufficient. To address this, the plantarflexor artificial muscles were replaced with a 4 × 3 configuration consisting of four 1 × 3 artificial myofibrils connecting together (Fig. 2B). This modification increased the system's capacity to approximately 68% of the required PF moment, enabling the DE-AFO to generate near-typical ankle moments and significantly improving functional outcomes for the user. However, the addition of these muscles increased the device's bulk, a drawback noted during user feedback.

D. *DE-AFO Powered by the Latest SDEA: DE-AFO-1550*

In this study, we integrated the latest version of SDEAs, produced by Dätwyler Schweiz AG (Schattdorf, Switzerland), as motor units in our updated DE-AFO. We named these actuators SDEA-1550, reflecting their dimensions of 15 × 15 × 50 mm. Accordingly, for the purposes of clarity, the DE-AFO powered by these SDEAs is referred to as DE-AFO-1550. In our previous research, we evaluated the axial stress and strain capabilities of SDEA-1550 [26]. Our findings demonstrated that the new SDEAs exhibited significant advancements in strain and stress capabilities, with improvements exceeding 200% compared to previous models. In particular, force generation has increased from 10N to 25.84 N, and displacement has risen from 3.3% to 11%,

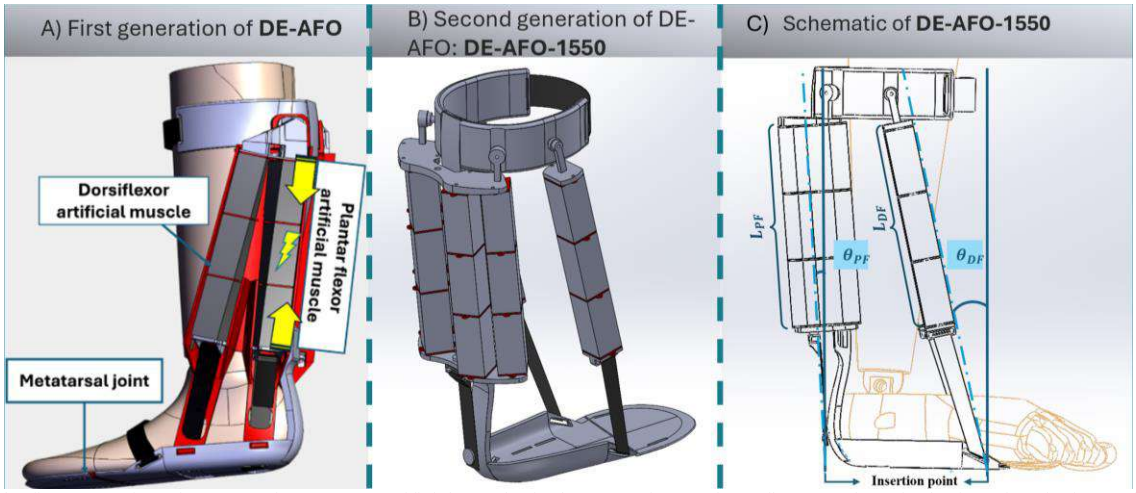

Fig. 2. A) The first generation of DE-AFO features two artificial muscles in the rear acting as plantarflexors and two in the front functioning as dorsiflexors. B) The second version of DE-AFO utilizes four artificial muscles in the rear to provide additional plantarflexion (PF) force, specifically designed to assist children with cerebral palsy (CP). C) Schematic of the DE-AFO-1550. θ_{DF} and θ_{PF} indicate the dorsiflexor and plantarflexor artificial muscles angle to the vertical axis, respectively. L_{DF} and L_{PF} represent the length of dorsiflexor and plantarflexor artificial muscles.

surpassing typical stress values of human biceps [26]. Each myofibril of SDEA-1550 weighs 42 g, totaling 252 g for all of its artificial muscles.

The aim of this paper was to quantify the capabilities of the DE-AFO-1550 in compensating for ankle moment deficits in real-life scenarios. Using the same theoretical procedure applied in evaluating the original design of the DE-AFO, we expanded the analysis by including ankle moment data from two additional CP subjects, CP02 and CP03 (Table 1). By analyzing ankle moment data from those three CP subjects and comparing it with normative data from TD counterparts, we identified the specific PF and DF forces required to compensate for the observed deficiencies. Additionally, by averaging the ankle moments of the CP subjects, we created a virtual subject, CP_{AVG} (Fig. 3C), to represent the collective performance of the DE-AFO-1550 in compensating for ankle moment deficits in children with CP.

For simplicity, we focused on Pre-swing for the PF force and the Swing period for the DF force calculation, where the most assistance is often required.

E. DE-AFO-1550's Ankle Moment and Force Generation Calculation

The averaged ankle moment deficit was calculated by subtracting the observed ankle moment in CP subjects (τ_{CP}) (Fig. 3B) from the TD counterparts (τ_{TD}) (Fig. 3A) which is depicted in Fig. 3D. We calculated the torque deficiency (τ_{Diff}) using the following equation:

$$\tau_{Diff} = \tau_{TD} - \tau_{CP} \tag{1}$$

Fig. 4 provides a detailed comparison of each participant's deficiency, the desired force, and the maximum force generated by the artificial muscles for both DF and PF under real-world conditions. For DF, forces are applied anterior to the ankle joint, while for PF, forces are applied posterior to the ankle joint. The moment arm (MA) of the dorsiflexor artificial muscle (MA_{DF}) and plantarflexor artificial muscle (MA_{PF}) at the insertion point on the footplate were calculated using "(2)" and "(3)":

$$MA_{DF} = L_{Shank} \times \tan(\theta_{DF}) \tag{2}$$

$$MA_{PF} = L_{Shank} \times \tan(\theta_{PF}) \tag{3}$$

Here, θ_{DF} and θ_{PF} represents the angle between the artificial muscles and the superior-inferior axis at their insertion point. Using the ankle angle (θ_{Ankle}), we calculated the length of the front actuators, L_{DF}, and length of rear actuators, L_{PF}, using the following equations (Fig. 2C):

$$L_{DF} = \sqrt{L_{Shank}^2 + MA_{DF}^2 - 2 * L_{Shank} * MA_{DF} * \cos(\theta_{Ankle})} \tag{4}$$

$$L_{PF} = \sqrt{L_{Shank}^2 + MA_{PF}^2 - 2 * L_{Shank} * MA_{PF} * \cos(\theta_{Ankle})} \tag{5}$$

Angles at which forces are applied during walking relative to the footplate:

$$\sin(\theta_{DF}) = \frac{L_{Shank} * \sin(\theta_{Ankle})}{L_{DF}} \tag{6}$$

$$\sin(\theta_{PF}) = \frac{L_{Shank} * \sin(\theta_{Ankle})}{L_{PF}} \tag{7}$$

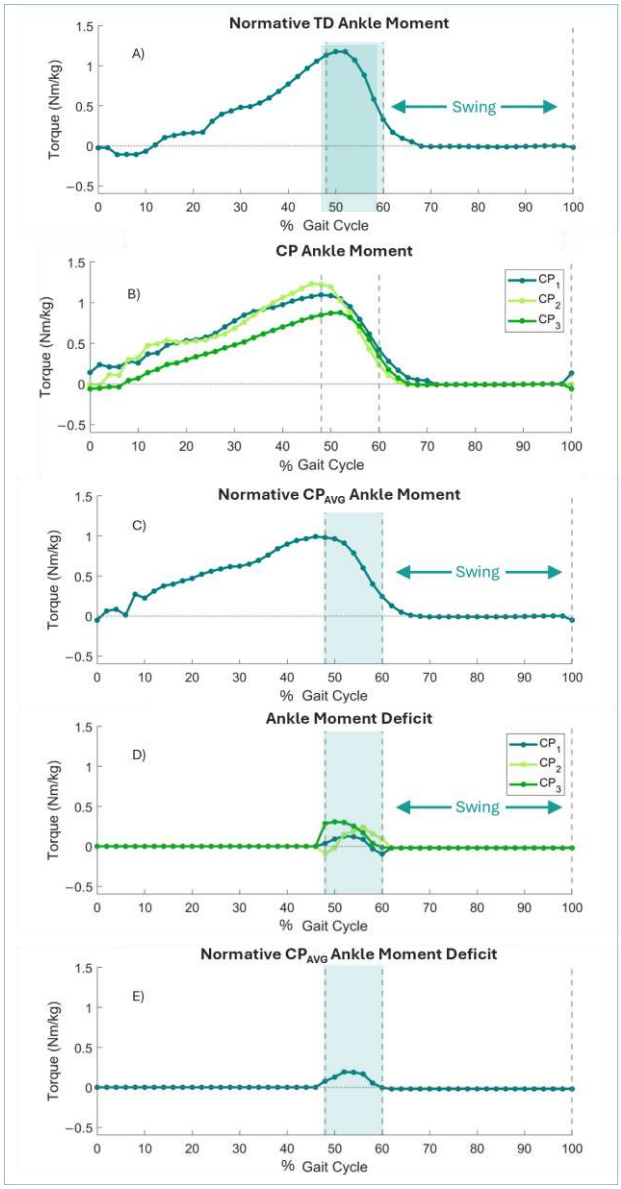

Fig. 3. Ankle dynamic. A) The normative sagittal plane ankle moment for typically developing (TD) children, normalized to body mass, was calculated as the average from seven TD participants. B) Normative ankle moment in the sagittal plane for each child with cerebral palsy (CP), and C) the average of them (CP_{AVG}). D) Ankle moment deficit of each CP subject individually. E) The averaged ankle moment deficit of the CP group was calculated by subtracting CP ankle moments from the TD result.

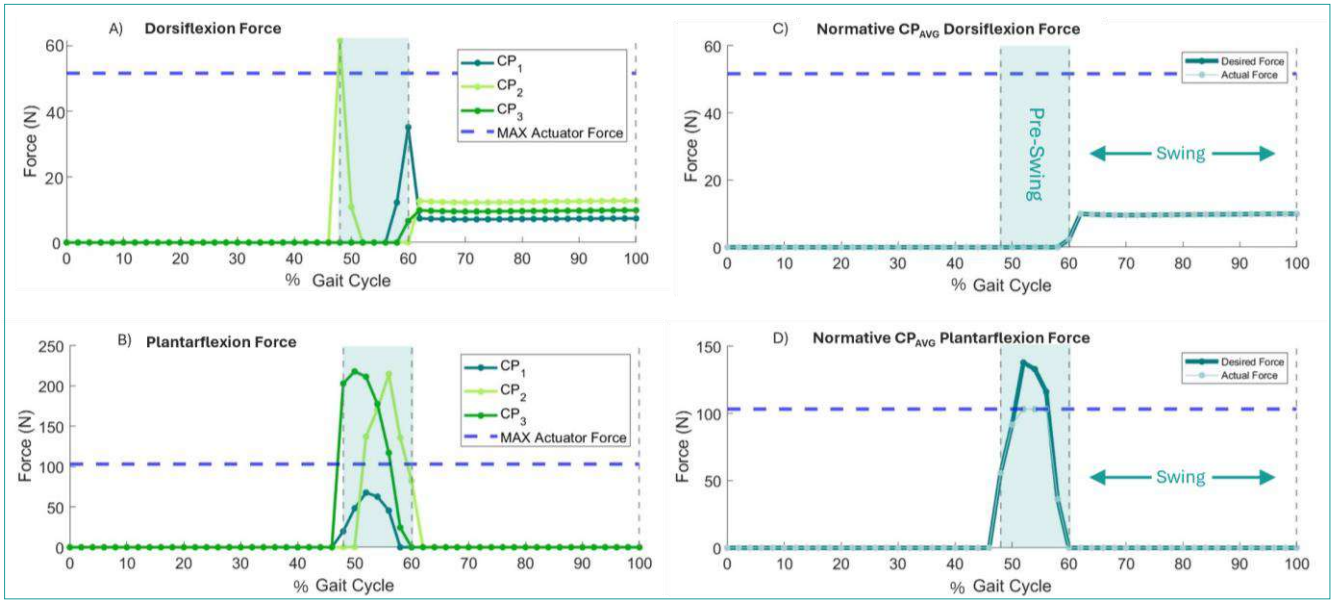

Fig. 4. A) Dorsiflexion force and B) Plantarflexion force deficiencies of each child with cerebral palsy (CP) compared to the maximum actuator force. Average of the Desired force vs actual C) Dorsiflexion Force, and D) Plantarflexion force generated by the artificial muscles of DE-AFO-1550. The dashed line shows the exoskeleton's maximum Dorsiflexion force (51.7 N) and Plantarflexion force (103.5 N).

Desired forces for dorsiflexor and plantarflexor actuators were calculated as follows:

$$F_{DF} = \frac{\tau_{Exo}}{sin(\theta_{DF}) * L_{DF}} \tag{8}$$

$$F_{PF} = \frac{\tau_{Exo}}{sin(\theta_{PF}) * L_{PF}} \tag{9}$$

III. Results

Dorsiflexion Assistance: The system achieves complete compensation for the required DF force throughout most of the swing phase in CP01 and CP03 (Fig. 4A). Specifically, the design generates 51.7 N of DF force (Table 2), significantly exceeding the desired 10 N (Fig. 4C), demonstrating the capability to provide robust support and ensure proper ankle function during this phase of the gait cycle. Furthermore, the device compensates for 84% of the required DF force in CP02, further highlighting its effectiveness.

Additionally, the DE-AFO-1550's DF force generation continued during the swing phase of the gait based on each individual's foot weight and the straight line during the swing phase, ensuring adequate foot clearance throughout the gait cycle (Fig. 4). The DE-AFO-1550 was capable of fully compensating the CP_{AVG}'s DF force deficit (100%).

Plantarflexion Assistance: The maximum force required to assist plantarflexor muscles during the pre-swing phase was calculated as 138 N (Fig. 4D). To achieve a balance between functional support and minimizing bulk around the shank, the DE-AFO-1550's modularity was leveraged to configure four artificial muscles, each capable of generating 25.84 N, resulting in a combined output of 103.5 N. This represents the full compensation of PF deficiency in CP01, 48.2% in CP02, and 47.5% in CP03 (Fig. 4B). The DE-AFO-1550 was capable of generating 75% of the desired PF force of CP_{AVG} which was deemed sufficient for providing meaningful assistance.

Table 2. Shows the dorsiflexion (DF) and plantarflexion (PF) deficit of each representative subject. The maximum capacity of the exoskeleton (Exo) in generating DF and PF forces along with the percentage of deficit compensation achieved by the device are provided.

	CP01	CP02	CP03	CP_{AVG}
DF (N)	35.2	61.5	9.8	10
PF (N)	67.7	214.8	218	138
Max DF Exo (N)	51.7			
Max PF Exo (N)	103.5			
Compensated DF Force (%)	100	84.06	100	100
Compensated PF Force (%)	100	48.2	47.5	75

IV. Conclusion

In this study, we aimed to theoretically evaluate the capabilities of the DE-AFO-1550, a DE-AFO powered by the latest commercially available SDEA (SDEA-1550), in compensating for ankle moment deficits observed in real-life cases of children with CP. By leveraging real-world ankle moment data, the DE-AFO-1550 demonstrated meaningful compensation for dorsiflexion (100%) and plantarflexion (75%) deficits during the swing and pre-swing phases of gait, respectively, showcasing its potential to restore ankle function closer to normative levels. The DE-AFO-1550 incorporates an innovative, lightweight design that adds only 116.4 grams compared to its predecessor, resulting in a total weight of 0.5 kg for the mechanical structure and artificial muscles. Moreover, its strain rate has increased significantly from 660 %/s to 2500 %/s, making it a compelling alternative to traditional AFOs.

Future work will focus on refining the DE-AFO-1550's design by optimizing its bulk by coupling the elastic pushing force of the SDEAs with their active contractile force to magnify DE-AFO's force and displacement in the sagittal plane. Additionally, we will leverage the self-sensing capabilities of SDEAs to develop effective control strategies

for modulating DE-AFO's displacement. Further down the line, clinical trials will be necessary to validate the device's real-world effectiveness and expand its applications to broader populations requiring mobility assistance.

The DE-AFO-1550 and its motor units, the SDEAs, establish a solid foundation for the development of innovative exoskeletons, with potential applications in humanoid robots [30]. This advancement holds the promise of significantly improving the field of rehabilitation robotics and enhancing the quality of life for individuals with neuromotor disorders.

ACKNOWLEDGMENT

This study received support from the National Institutes of Health (NIH) through Grants P20GM109090 and P20GM152301. We also extend our sincere gratitude to the Venture Development Center at the University of Delaware and its Blue Hen Proof of Concept program for their invaluable assistance in the DE-AFO project. Their funding and resources have been instrumental in advancing our research and development efforts.

Measuring Upper Extremity Loading in Passive Exoskeleton-Assisted Gait: A Case Study

Robert Pastor[1], Michal Gloger[1], and Pavel Klouček[2]

***Abstract*— This study investigates upper extremity loading during exoskeleton-assisted walking with the UNILEXA passive exoskeleton using an instrumented platform walker. The goal was to assess upper limb weight-bearing and its implications for rehabilitation. Data were collected from two participants performing walking and standing tasks. During steady walking, the average vertical load on the walker was approximately 30% of body weight, while standing maneuvers showed peaks up to 90%. These results demonstrate that, despite the passive nature of the UNILEXA exoskeleton, upper extremity loading remains within acceptable limits, suggesting its suitability for safe and effective rehabilitation.**

I. INTRODUCTION

Individuals with spinal cord injury (SCI) often rely on assistive devices, such as walkers or crutches, in combination with orthoses or exoskeletons, to facilitate ambulation and rehabilitation [1], [2]. While these devices are essential for mobility, they place significant demands on the upper extremities, particularly the shoulders, as they bear a substantial portion of body weight during movement [2]. Prolonged or excessive loading of the shoulders can lead to secondary complications, including glenohumeral instability, impingement syndrome, rotator cuff injuries, and degenerative joint diseases, significantly affecting the long-term quality of life for individuals with SCI [2], [3]. These risks underscore the importance of optimizing assistive device design and use to reduce upper limb strain while maintaining functional mobility.

Although force plates are commonly used to measure ground reaction forces in gait analysis, they pose a logistical challenge when combined with a platform walker, because the walker wheels create an additional contact point that can invalidate force-plate measurements. To address this, we aimed to capture upper limb load during UNILEXA-assisted walking by developing an instrumented platform walker that isolates the forces transmitted through the user's arms.

Instrumented walkers and crutches are capable of measuring a range of parameters related to gait and rehabilitation. There have been multiple instrumented assistive devices developed to assess upper extremity reaction forces for patients with walking impairments. Most of the articles in literature use instrumented walkers [4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14] or instrumented crutches [7], [12], [15], [16], [17], [18], [19], [20], [21], though other approaches—such as force sensors built into footwear [22]—have also been explored . Across these studies, researchers have employed various measurement methods when instrumenting walkers. While some researchers use load cells [6], [7], [17], [23] , some chose a more cost effective solution with strain gauges [4], [5], [9], [10], [12], [13], [18], [19], [20] or force sensitive resistors [14], [16], [21]

Haubert et al. [7] compared three-dimensional shoulder joint forces during assisted ambulation using crutches versus a front-wheeled walker in individuals with incomplete spinal cord injuries. They observed significantly greater superior shoulder joint forces and rates of loading during crutch walking compared to walker-assisted gait, despite similar walking velocities. Their findings underscore the need to consider shoulder joint demands when selecting assistive devices for individuals with upper extremity weakness or pain.

Bachschmidt et al. [4], [5] developed a six-degree-of-freedom force-sensing walker to characterize upper extremity kinetics and kinematics during assisted gait. The system utilized strain gauges and finite element modelling to address structural cross-talk and measure forces and moments applied by each hand independently. Their work revealed significant upper extremity demands during walker-assisted gait, emphasizing the need for optimized walker designs to improve efficiency and user safety.

A. Objective of the Study

The previous research in the literature has primarily focused on the instrumentation of front-wheeled walkers and walking frames. To the authors' knowledge, there has been no previous research involving instrumented platform walkers, sometimes referred to as walking tables with forearm support.

In this article, we aim to assess the weight distribution on a platform walker during walking with the UNILEXA exoskeleton. Because the lateral motion of a platform walker can invalidate force-plate measurements when the walker rests on the plates, we developed an instrumented platform walker to measure upper extremity weight-bearing and weight transfer between the walker and the exoskeleton. This device seeks to offer further insight into upper extremity forces during a gait cycle with lower-limb assistive devices.

This paper serves two purposes: (1) to describe the design and calibration of the novel instrumented platform walker and (2) to present an initial feasibility study involving two individuals with SCI. While the small sample precludes broad statistical generalization, the results provide preliminary evidence regarding upper extremity loading when using the UNILEXA exoskeleton with a platform walker.

II. MATERIALS AND METHODS

A. Instrumented Walker

The walker, originally a FOLLO FUTURA AS model, was extensively modified to allow detailed force measurement . Initially, we intended to instrument the original walker frame to avoid excessive modifications, but it was not rigid enough to allow precise force measurements and avoid excessive crosstalk between the force sensors. Therefore, the walker was modified with a welded frame featuring four support sliders for height adjustment. The handles and armrests were attached to two 25 mm thick aluminum plates, with four three-axis Kistler piezoelectric force sensors (model 9027C) installed between them. The system has a measurement range of 10 kN per sensor. This setup ensured the stability of the measurement system under various load conditions. Fig. 1 shows an image of the instrumented walker.

Measurements were acquired using a Dewetron DEWE-2602 analyzer at a sampling rate of 1 kHz, ensuring high temporal resolution for capturing the dynamic behavior during activities. Data processing was conducted using FlexPro software, with additional filtering applied to reduce noise and account for minor signal drift.

The walker was transformed into a dynamometer system capable of measuring forces and moments in six degrees of freedom. The force sensors were mounted at four key locations on the walker (front left, front right, rear left, and rear right) to capture forces in the three orthogonal directions (X, Y, and Z). Fig. 2 provides a top-down view of the sensor placement with dimensions. The dynamometer system was designed to isolate these forces and measure moments with minimal crosstalk, using strategic placement and calibration protocols.

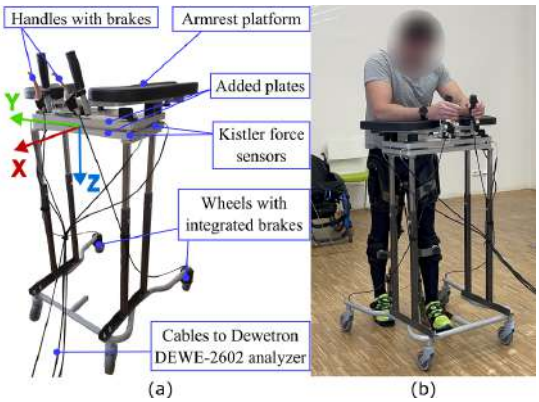

Fig. 1. a) Parts of the instrumented walker. b) Participant P01 with UNILEXA and the instrumented walker.

B. Calibration

Sensor preloading was crucial to ensure accuracy and reduce crosstalk between sensors. To achieve this, we placed standardized weights (10 kg and 20 kg) directly over each sensor axis, as well as in intermediate positions offset from the centre, thereby testing various load distributions. Because

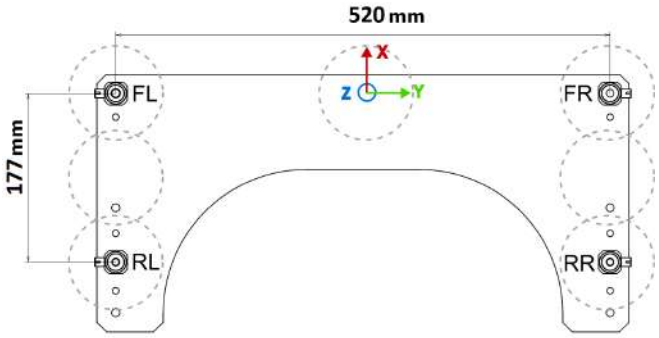

Fig. 2. Top-down view of walker platform. Sensors positions (FR-Front left, FR-Front right, RL-Rear left, RR-Rear right. The coordinate frame for force calculations are shown by the X and Y arrows. Dashed circles show the locations used for calibration with known weights.

of the symmetric construction, we performed small adjustments to the manufacturer-provided calibration constants to minimize measurement deviations. The final calibration ensured that the measured force matched the known weight within approximately 5%. Lateral calibration was verified by tensioning each sensor axis with a calibrated force gauge, confirming minimal influence from sensor preloads. These steps reduced crosstalk and yielded a linear response across the load range. Data were sampled at 1 kHz and processed in FlexPro. A 10 Hz low-pass Butterworth filter was then applied to remove high-frequency noise, consistent with typical gait analysis practices.

C. Experiment Setup

The laboratory setup was designed to simulate a straightforward and repeatable walking task. A 6-meter length was marked on the floor, and participants began from a designated starting point. Each participant walked the measured 6 meters, performed a 180 turn, and then walked back to the starting point. The setup was inspired by the 10-Meter Walk Test (10MWT), where typically the middle 6 meters are measured, with an additional 2 meters for acceleration and 2 meters for deceleration. However, in our case, we omitted the classic 2-meter sections for acceleration and deceleration due to equipment limitations—specifically, the numerous cables attached to the instrumented walker. This omission was not critical, as walking with the UNILEXA exoskeleton and a platform walker is not a very dynamic movement, and typical acceleration or deceleration phases are less applicable. The gait cycle itself includes moments when the participant is moving at zero velocity. Despite these modifications, the results should still be comparable with other studies involving the 10MWT with SCI patients, exoskeletons, or orthoses.

D. Participants

The participants were individuals with SCI and were recruited based on their prior experience with the UNILEXA exoskeleton. Participant P01 is a regular user of the device and has the exoskeleton in his home, where he uses it

for exercise. Participant P02 is in her early days of using the exoskeleton and used it for 3 previous session with a physiotherapist. The measurements were conducted as part of their normal visit with our physiotherapist, during which they would typically walk in a similar manner. For this study, they used the instrumented walker, which was the same type as their usual platform walker but equipped with additional sensors for force measurement. Both participants were less than two years post-injury (Time After Onset, TAO), with an American Spinal Injury Association (ASIA) score of A and a lesion level at T7. No control group was included, as the study aimed to document upper extremity loading in SCI individuals using their usual assistive devices. Participants were fully briefed on the study's aims and procedures and signed informed consent before taking part in the measurements. Table I presents the demographics of the participants involved in the study.

TABLE I

DEMOGRAPHIC DATA OF PARTICIPANTS.

Participant ID	Sex	Age	Weight [kg]	Height [cm]	Lesion	AISA	TAO
P01	M	37	95	190	T7	A	2Y
P02	F	45	68	173	T7	A	2Y

E. Data Acquisition

The height of the instrumented walker was adjusted so that each subject's elbow rested comfortably on the armrest while maintaining an upright posture. Following the initial standing maneuver, subjects were instructed to briefly suspend their full body weight on the walker. The resulting force was recorded and used as a reference for the subject's body weight, with the exoskeleton weight (9 kg) subtracted from the measured value.

Participant P01 completed the 6-meter walk test 8 times, whereas participant P02 completed it fully only once before fatigue occurred. As this measurement was included as part of their normal physiotherapy session, we did not ask the participants to push themselves beyond their comfortable exercise level. We also plan to use this case study as a guide for future studies that will take user fatigue levels into consideration. Participant P01 performed the trials in sets of 2; walking 6 m, rotating, walking back, and then resting for 15 minutes before repeating the trials.

The duration of each walking trial was measured using a stopwatch. The stopwatch was started when the participant began their first step and stopped when the front wheels of the walker crossed the six-meter mark.

F. Data Processing

The measured force data were cropped based on the recorded stopwatch times. The mean and standard deviation for each trial were calculated using the NumPy Python library. The data for the stand-up plot were synchronized using a common inflection point on the force curve

III. RESULTS

A. Standing Up

The forces recorded during standing showed significant vertical load on the walker. Seven instances of standing up were recorded for participant P01, Fig. 3 shows the force curves on the walker synchronized with the time of standing up from the wheelchair. Participant P02 showed a similar trend, but with proportionally lower forces due to their lower body weight.

Both participants demonstrated that nearly their entire body weight was momentarily transferred through the walker during the standing motion, with approximately 90% of the body weight contributing to a peak in vertical force. Fig. 4 presents selected standing force curves for each participant, normalized by their body weight. The data indicate that placing the hands on the walker armrests transfers roughly 20% of the participant's weight to the walker. This force peaks during the stand up and decreases after the knees of the UNILEXA exoskeleton are locked. For the more experienced participant (P01), the vertical force ultimately drops to about 40% of body weight. At this point, the user begins relying less on the walker as they shift more of their weight to their legs, which are supported by the exoskeleton's structure.

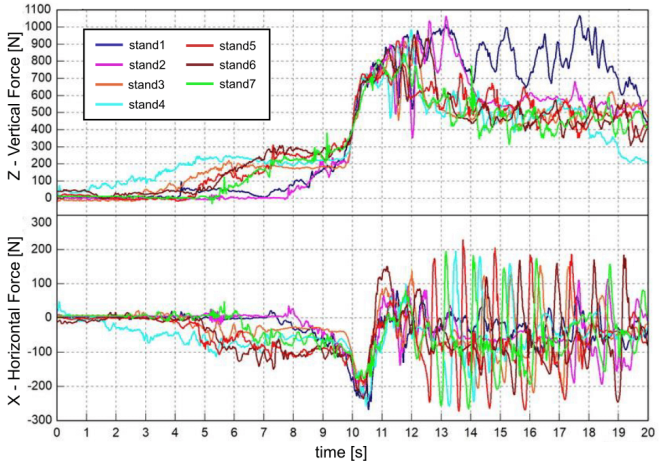

Fig. 3. Force curves on the walker synchronized with the standing-up motion for participant P01.

B. Weight Shifting and Hanging

During weight shifting exercises, a test was conducted in which the participant transferred weight between legs while using the walker for support. The results showed an asymmetrical force distribution depending on which leg bore the weight. Fig. 5 displays the forces during the balancing exercise and full weight hanging, which were then used for body weight data normalization. The figure shows the net force in the Z direction as the sum of all sensors, as well as separate sums from the left and right sensor pairs to illustrate weight shifting during the balancing exercise.

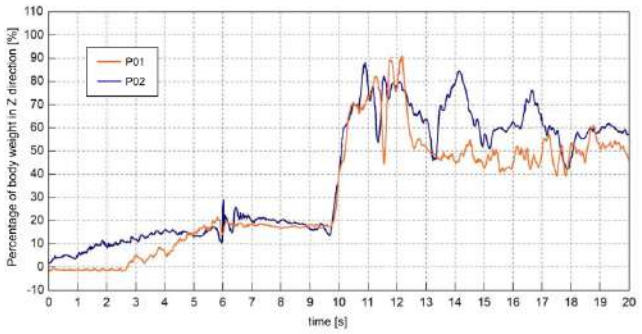

Fig. 4. Selected force curves (not averaged) showing vertical load on the walker for both participants during the standing maneuver, normalized to percentage of BW.

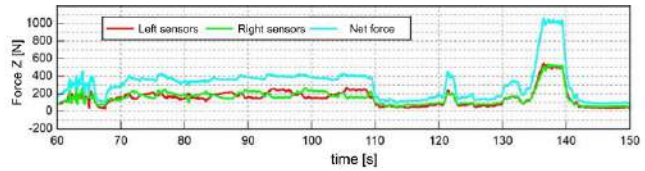

Fig. 5. Balancing exercise (from 70 to 110 s) and full body-weight hanging (from 135 to 140 s) with participant P01

C. Walking

The participants walked for six meters, then rotated 180 degrees, and walked back the same length. Fig. 8 shows one of the recorded trials with participant P01. The first six meters are shown between 170 and 300 seconds, then the participant rotated until 350 seconds, and then walked back. A detailed plot of the first six meters from this trial is shown in Fig. 9, and a detailed view of the rotation is shown in Fig. 10.

For participant P01, the average load on the walker was measured to be approximately 30% of body weight. During the trials, a gradual increase in walker load was observed, with an average of 27.8% Body Weight (BW) transferred to the walker during the first walk and 35.3% BW during the last walk. This increase can likely be attributed to a rising level of fatigue over the course of the trials. Table II lists the walking time, along with the maximum, minimum, mean, and standard deviation of the weight supported by the walker, expressed as a percentage of body weight for participant P01. The data in the table are visualized in Fig. 6 and Fig. 7. An interesting observation from the time measurements is that, since the trials were performed in sets of two, the first walk in each set was always significantly slower than the second. The participant increased their comfortable walking speed during the trial but, after resting for 15 minutes, resumed at a slower pace.

D. Turning

Turning introduced significant lateral forces, which were captured during trials. During a 6-meter walk with a turn, forces in the lateral direction fluctuated based on the turning direction and how the users manoeuvred the walker. Fig. 10 shows a relatively stable load in the Z direction, fluctuating slightly around 350 N, but at the same time a frequent load transfer between the left and right sides. In the X and Y directions, a sustained application of lateral loads is evident, which induces a moment to rotate the walker.

TABLE II

SUMMARY OF WALKING TRIALS (P01)

Trial	Time [s]	Min [%BW]	Max [%BW]	Mean [%BW]	SD [%BW]
Walk1	2:51	8.4	49.6	27.8	8.0
Walk2	2:00	13.4	50.9	29.8	7.5
Walk3	2:20	17.0	56.6	32.4	8.7
Walk4	1:34	12.7	56.4	33.0	9.0
Walk5	2:16	12.3	53.9	30.7	8.7
Walk6	1:44	10.3	53.7	32.9	9.3
Walk7	2:12	15.9	54.9	34.1	8.6
Walk8	2:00	13.1	57.6	35.3	9.2

TABLE III

SUMMARY OF WALKING TRIALS (P02)

Trial	Time [s]	Min [%BW]	Max [%BW]	Mean [%BW]	SD [%BW]
Walk1	3:26	18.1	77.5	51.7	9.9

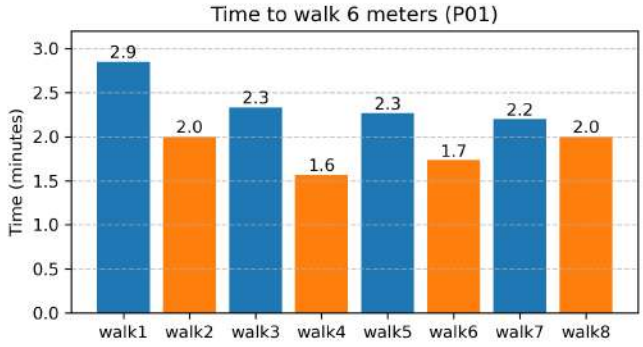

Fig. 6. A bar graph displaying walking times for each trial. Blue bars indicate a walk immediately following a rest pause, after which the participant rotates 180 degrees and walks back, represented by orange bars.

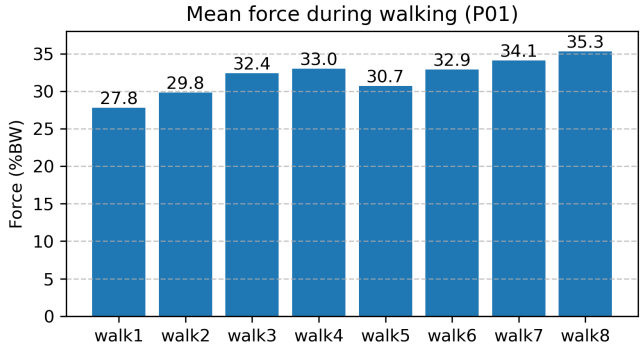

Fig. 7. A bar graph visualizing the mean of the walker load (as a percentage of body weight) for each trial.

IV. DISCUSSION

This study provides a case study of upper extremity loading during walking with the UNILEXA passive exoskeleton,

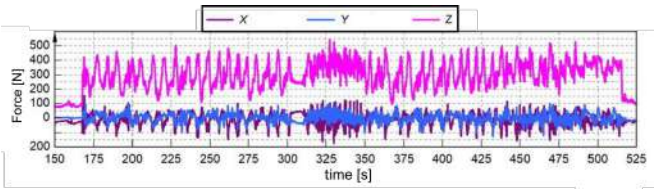

Fig. 8. The net force exerted by participant P01 during a full walking trial (walk3), showing the initial 6-meter walk, 180-degree rotation, and return path.

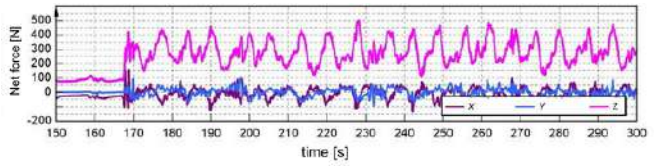

Fig. 9. Forces during the initial 6-meter segment of the walk3 trial for participant P01.

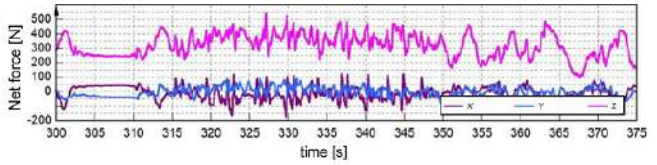

Fig. 10. Lateral and vertical forces on the walker during a 180-degree turn (walk3), showing load distribution changes.

using an instrumented platform walker. Our data reveal an average vertical load of approximately 30% of body weight during steady walking, with peaks reaching up to 90% during standing maneuvers. This peak corresponds to the participant's mass above the knees—the portion they must lift to engage the knee locks—after which they can relax as the exoskeleton supports the lower limbs. Additionally, we observed a gradual increase in upper limb loading across successive walking trials, likely attributable to user fatigue. These results suggest that, even with the UNILEXA exoskeleton being a passive device, users are not excessively overloading their upper extremities during ambulation.

The observed upper extremity load of 30% for participant P01 aligns closely with values reported in walker-assisted gait studies. For instance, Simoneau et al. [13] measured upper limb efforts in walking frames and found comparable loading values in the range of 25–35% of body weight depending on walker height and handle positioning. In contrast, Haubert et al. [7] observed significantly higher shoulder forces during crutch-assisted ambulation, often exceeding 50% of body weight due to concentrated loading on fewer contact points. These findings highlight the advantage of platform walkers in distributing forces more evenly, potentially reducing shoulder joint strain compared to crutches. However, participant P02—who was using the exoskeleton for only the second time—exhibited a mean load of 51.7% BW, more akin to crutch ranges, suggesting that limited proficiency may lead to greater reliance on the walker. A longer-term study would be needed to confirm whether additional training reduces this upper extremity load to levels closer to participant P01's or other walker users. Importantly, the relatively moderate loading observed overall supports the conclusion that the UNILEXA exoskeleton, when used with a platform walker, enables safe and controlled gait without excessive strain on the user's upper limbs.

During the standing motion, peak loads in our study reached 90% of body weight for a brief moment. This is consistent with observations by Khuna et al. [3], who noted that high upper extremity forces during sit-to-stand transitions are critical for stability but pose risks of shoulder overuse injuries. While these forces are momentarily high, the exoskeleton appears to effectively assist users in stabilizing themselves post-transition, reducing prolonged upper extremity strain. In participant P01's trials (Fig. 3), the initial stands involved slower knee locking—likely due to the legs needing an initial stretch or warm-up—which kept more weight on the walker for longer. Once the knees could lock more readily, the force on the walker dropped sooner.

V. CONCLUSION

This study demonstrates that the combination of the UNILEXA passive exoskeleton and a platform walker allows for safe ambulation without excessive upper extremity loading. The average upper limb load of 30% of body weight during walking is within acceptable ranges reported in previous walker studies and significantly lower than loads observed with crutch-assisted gait. Because platform walker use is the primary modality with UNILEXA, these results suggest that it supports efficient weight distribution and may reduce the risk of overuse injuries to the upper extremities. Nonetheless, further studies are needed to determine whether these findings generalize to other methods of ambulation with the exoskeleton, such as parallel bars, frame walkers, or crutches.

As a case study with two participants, the findings are not generalizable to the broader SCI population. Future studies should involve larger sample sizes and direct comparisons with other assistive devices to validate these results and better understand the relative benefits of the UNILEXA exoskeleton and platform walkers in SCI rehabilitation. Additionally, further refinement of sensor calibration protocols is necessary to minimize crosstalk and enhance measurement accuracy during dynamic tasks. Despite these limitations, the preliminary findings highlight the potential of this device combination for effective and safe rehabilitation.

ACKNOWLEDGEMENT

This work was carried out at the expense of MEBSTER s.r.o. The authors would like to thank Pavel Klouček for his contributions to data collection and processing.

CONFLICT OF INTEREST

This research was conducted as part of the development of the UNILEXA exoskeleton, manufactured by Company MEBSTER, which provided the devices and oversight during the measurements. The measurement and initial data analysis

were performed by VUTS, with further analysis and interpretation conducted by the authors.

***Abstract*—Artificial hands are developed and employed widely for solving challenges in present-day robotics, with an increasing number of such systems being integrated into our daily lives. For humanoid or human-centric applications in medical or industrial sectors demanding increased naturality, biomimetics offers a promising approach. However, replicating biological structures and functions to the detail commonly results in excessive complexity in both design and production, preventing widespread adoption. This work presents a biomimetic hand developed with the use of modern procedural design methods and additive and textile production technologies, evaluated with a modular actuator frame through grasp and gesture demonstrations and finger trajectory analysis. The results aim to exemplify how leveraging these advancements may enable the creation of naturally compliant robotic devices with intricate functionality, while simultaneously satisfying the industrial requirements for robustness, cost-effectiveness and production scalability, therefore bringing the universal applicability of such systems within reach.**

***Index Terms*—biomimetics, robotic hand, humanoid robotics, prosthetics, textile technology, 3D braiding**

Fig. 1. The Anatomically Accurate Biomimetic Hand with various layers of covering (textile skin, underlying hard covering and removed covers).

I. Introduction

Replicating hand functionality is one of the most widely investigated cornerstones of present-day robotic development efforts. The efficiency and application versatility of teleoperated or autonomous humanoid robots largely depend on the abilities and dexterity of their hands, while the manipulator designs of industrial and collaborative robotics have long been borrowing ideas from living systems to solve various gripping tasks [1]. In the upper-limb prosthetics industry, increasing embodiment is considered a key factor in combating high abandonment rates [2] [3], for which a high degree of human-likeness is desired in both function and aesthetics.

The motivation to design better anthropomorphic hands is therefore understandably high, with a wide range of devices being developed for an even wider range of applications [4]. However, in terms of replicating all the intricacies that make our hand such a versatile tool, existing solutions are still approximate at best. This can be mainly attributed to the conventional methods of mechanics and robotics that still drive most design approaches, and which are usually based on greatly simplifying the complex biomechanical structures for the sake of adhering to the often strict constraints of volume and power, while also having to ensure scalable production.

This either leads to highly simplified, elementary mechanical behavior, as can be observed in most upper-limb prostheses or soft robotic hands (which are widely researched but are less common in the industry due to their fragility); or necessitates integrating numerous sensors, actuators and overly complex assemblies to attain higher levels of dexterous functionality. In both cases, however, the compliance and tactility, or to put it more generally, the human-like nature of the movements suffers the consequences, keeping the solutions at a distance from the ideal of the biological hand.

Highly biomimetic approaches in both structural design and material composition have been experimented with to address this problem [5] [6], as closely replicating the hard and soft tissues and biomechanics of our anatomy using hybrid systems of rigid and soft robotic components inherently promises increased performance in this respect. Yet, these often face durability issues due to the popular choices for soft materials

†Equal contribution.

Cadaveric studies were conducted in accordance with the approval of the local ethics committee (ETT-TUKEB, Reference No. IV/3633- 1 /2021/EKU).

(such as rubber and silicon), and share the inherent complexity of biological systems, being composed of layers upon layers of interconnected tissues, leading to challenging design and production problems and time-consuming assembly processes.

Nevertheless, the potential functional improvements this approach promises are quite significant, as the fields of both humanoid and medical robotics are advancing rapidly, and are in need of more naturalistic solutions towards improved integration into both user body-image and society. Its widespread adoption could very possibly depend on whether the two most pressing issues, those of durability and production efficiency, can be solved.

With the advancement of technology, however, all this is becoming possible. Procedural methods allow us to design modeling processes instead of mere parts, with a well-construed system being capable of algorithmically synthesizing elaborate, organic geometries based on descriptive data. Additive manufacturing has long been accessible to assist in their realization, while the digitalization of textile technologies is also rapidly emerging, carrying within the potential for producing and integrating components that are soft, flexible and strong at once. This paper proposes a robotic hand and methods developed for its design and production, to exemplify leveraging these advances towards improving both durability and manufacturability, while avoiding any significant reduction in the functional delicacy and complexity that embody the primary values of biomimicry.

II. Biomechanical Structure

Out of all prehensile solutions evolved by nature, the feature that makes our hand with the opposable thumb most distinctive is its remarkable versatility, characterized primarily by two factors: adaptiveness and dexterity. While the former is a consequence of soft tissues surrounding a rigid skeletal frame enabling our fingers to compliantly wrap around any object, the latter can be directly attributed to our intricate ability to coordinate our joint movements.

A. Parametrically Generated Skeleton

Biomechanical systems are generally based on articulating joints, characterized by contacting convex and concave surfaces of various shapes gliding and rolling about each other. These have several beneficial properties compared to traditional couplings used in mechanical constructs, which together effectuate the movement characteristics of biological organisms human perception deems ”natural”.

First and foremost, their movement trajectories are not constrained around one or more fixed axes, but follow the curvature of the articulating surfaces instead, allowing for specialized motion trajectories in each joint, and highly variable ranges of motion (RoM) across each degree of freedom (DoF). Second, the stiffness of the joints varies across the different stages of the motion, as a result of the ligaments becoming tensioned due to the distances changing between their attachment points, contributing to dynamic stabilization and further DoF constraints to reinforce grasping.

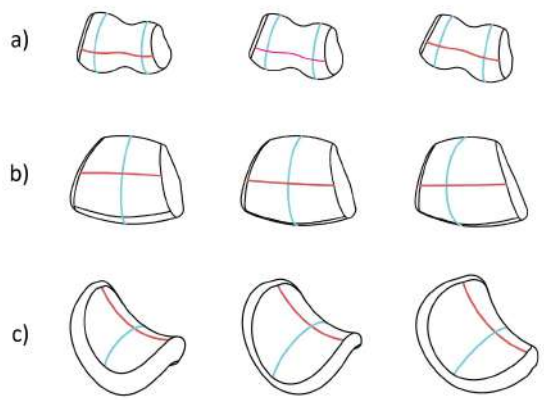

Fig. 2. Articulating joint head geometries generated by the developed procedural modeling algorithm, showing varying parameters for conical obliqueness in ginglymoid (a), tilting range of motion in condyloid (b), and rotation curvatures in saddle-shaped (c) joints.

Such influences are clearly exemplified by the prehensile center-oriented conical obliqueness at the flexed interphalangeal (IP) joints, by the second, tilting DoF of condyloid metacarpophalangeal (MCP) joints becoming almost entirely constrained in flexion except for slight pronation-supination, and by the opposition-enhancing automatic axial rotation arising during flexion in the saddle-shaped trapeziometacarpal (TMC) joint of the thumb [7].

As small as each of these features seem on their own, their cumulative effect is quite significant - articulating joints are one of the primary enablers of adaptive grasping capabilities of the human hand, synergizing with the soft tissues to allow our fingers to envelop objects in a much more compliant manner than any conventional robotic gripper to date, no matter how anthropomorphic they might be on the outside.

Recognizing these advantages, several experimental designs were attempted in the past to integrate these articulation-related characteristics into robotic systems without resorting to over-simplification [8] [9] [10]. However, due to the complex nature of the joint surface geometries, these are usually based on pre-existing skeletal mesh models acquired mostly via medical imaging. The results can be highly natural and effective, but the method is very difficult to scale, as control over properties or functional parameters is virtually non-existent - each joint variant would have to be designed manually, constantly bearing the consequences of the heuristic approach.

Therefore, to realize such integration while respecting the need for design controllability, a procedural articulating joint generator was developed using the 3D design and scripting capabilities of the PTC Creo 11 CAD environment, for the automated modeling of anatomically correct surfaces from just a few key parameters (joint size, desired movement ranges and distortions, etc), based on extensive literature research and cadaveric studies. The system allows for deep personalization by taking input parameters based on measurements or the analysis of 3D scans or medical images, and as shown in Fig. 2, it is capable of generating each joint type occurring in the

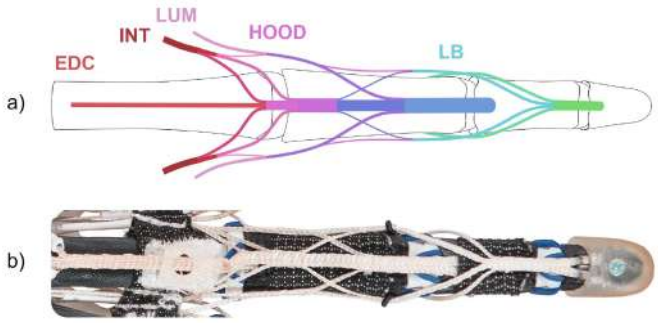

Fig. 3. Color-coded schematic drawing of the tendinous system's anatomical structure with key functional segments identified (a), and its braided realization attached to a long finger (b).

fingers, with inherent degrees of freedom, naturally oblique movement axes and optimized surface geometries.

The generator outputs production-ready skeletal components, with all features required for mechanical assembly already included. In the current prototyping process, an abrasion-resistant, self-lubricating material (igus iglidur i150) was used via easily accessible FDM technology. Joint ligaments were realized by simply threading elastic ropes (Paracord, elastic cord) through holes made in their anatomical attachment points, to retain the variable stiffness property.

B. 3D Braided Tendon Network

The movement of the joints in each human finger is controlled by the interplay of six extrinsic and intrinsic muscles on average (nine in case of the thumb). Instead of directly attaching to the bones, however, these form an elaborate branching structure commonly referred to as the finger extensor system [11] [12] [13], through which each muscle is connected to several areas across multiple phalanges. The geometry of this network accentuates the synergistic-antagonistic behavior of the muscles - generally, each of them has a primary role, but their effects are largely dependent on the actual joint positions, and the level of contraction in specific other muscles.

A prime example for this is the threefold role of the interosseous (INT) muscles [14]. When operating independently, they are the dedicated actuators of finger tilting, but their synchronous contraction causes the full extension of the IP joints via the lateral bands (LB) of the network when the MCP joint is kept extended by the long extensor (EDC). When the MCP is flexed, however, the interossei pull downward upon the so-called extensor hood enveloping the base of the proximal phalanx instead, resulting in a significant enhancement to flexion strength due to their optimal lever arm. In this state, their independent contraction is unable to activate finger tilting due to the constraints of the MCP joint, eliciting slight axial rotation instead. Besides reinforcing our movements, the interossei act as a modifiers on the effects of the forearm muscles. Because of their presence, the EDC does not need to have a direct extending effect on the IP joints - it is allowed to be kept taut while the long flexors (FDP and FDS) activate, resulting in our ability to reliably perform the "claw-finger" posture - the interossei thus effectively allow us to indirectly "turn off" our flexors' influence on our MCP joints.

Similar in behavior but opposite in effect, the lumbrical (LUM) muscles have an increased lever arm acting upon the LB while bypassing the hood structure, so they are used to redistribute the forces of the long flexors and extensors towards flexing the MCP and extending the IP joints simultaneously. This enables the formation of the "beak hand" posture, and has a significant role in delicate manipulation tasks.

The effects of the intrinsics are even more prominent in the thumb [15], where they are responsible for the independent control of adduction, abduction, pronation and supination at both the TMC and MCP joints. Their activity ensures a smooth and controllable transition between flexion-extension and opposition-anteposition.

These example interactions show that intrinsic muscles act as dynamic switches on the activity of the stronger extrinsics, able to redirect their effects to enable or reinforce certain movements at will. The interconnections of the tendinous network contribute greatly to our natural finger tones and trajectories, resulting in dexterous functionality becoming severely impaired when deliberately omitting these features from artificial hands, as is often the case.

Attempts at replicating this intricate system all face the same challenge: producing such complex, branching geometry that also shares the most important property of biological tendons: high load-bearing capacity. Several methods have been tried during the recent years [16] [17] [18], supporting the endeavor by achieving significantly increased human-likeness, but each had to make a costly tradeoff: the tendon system either has an elaborate fabrication and assembly process involving time-consuming manual steps such as crimping, gluing or knotting, or it is simple in production but remains hindered by its fragility, like laser-cut silicone components.

In search of a solution eliminating these issues, a custom 3D braiding environment was developed, capable of producing branching rope structures quickly and effectively due to a visual and script-based design and control system and automated patterning capacities. The machinery is based on variation braiding technology [19], which essentially entails a matrix of conventional fixed-track maypole rope-braider [20] units interconnected by switches capable of adjusting the pathways the yarn carriers take, changing the patterns of the produced braids on the fly. This allows for the realization of homogeneous 3D structures with high tensile strength, without significant weak points or obstructions at branch junctions.

The tendinous systems for our hand prototype were produced using this method, as multi-branching constructs of polyester multifilament fibers, the braided microstructure of which adequately mimics the tenacity and behavior of collagenous connective tissue. As shown in Fig. 3, the braided network was designed to include all anatomical substructures, with the intent of accurately replicating the biomechanics of the flexor, extensor, interosseous and lumbrical tendons, while satisfying requirements for both load-bearing and simple, scalable production.

C. Covering Soft Tissues

Biological tendons are guided along the fingers in synovial tendon sheaths, acting as pulleys to redirect muscle torque to the target phalanx regions. Similar ligamentous structures assist in holding the palmar bones together. As shown in Fig. 4/a, these are replicated separately for each phalanx as simple pull-on sleeves of bilayered, semi-elastic, UHMWPE (ultra-high molecular weight polyethylene) reinforced nylon fabric to maintain ease of assembly. An additional laminated UHMWPE layer envelops the tendons to ensure low friction and high tensile strength, while the simple sewing pattern enables quick bulk-manufacturing on any conventional sewing machine.

Fat and muscle pads are equally essential for truly compliant grasping - these were realized experimentally as lightweight, 3D printed, elastic lattice structures of spatially varying density, designed and optimized in the implicit 3D modeling and simulation software nTopology for assisting flexion and bulging in the appropriate areas during grasping, analogous to the functionality of palmar creases. The palmar, thenar and hypothenar padding-complex is shown in Fig. 4/b.

Soft, removable skin is sewn in a long, layered glove pattern with insets at the joints to facilitate wrinkling and reduce wear and tear, used for protection and for holding the lattice padding in place. The glove is made using a thin spacer-mesh fabric material to provide further padding and a comfortable texture.

III. Actuator System

In terms of motorization, it is important to address that different target use cases have different requirements. The electrophysiological control interfaces currently available on the prosthetics market are unable to acquire and supply delicate control signals, and device volume is also severely constrained, so the placement of multiple motors for each finger would be infeasible. True dexterity is not on the table - grasping versatility and reliability are, alongside ergonomic factors such as weight, aesthetics and compactness. Therefore, the goal in prosthetic hand development is to restore grasping performance, while simplifying the actuator system as much as possible. In humanoid or telerobotic systems, space and weight are much less limiting constraints, while dexterous functionality can be fully utilized owing to the employment of advanced autonomous or wearable control interfaces. Replicating the intricate capabilities of the biological hand by increasing the number of controllable DoF thus becomes a focus point.

The purpose of the presented biomimetic system is to provide a platform with exceedingly human-like functionality, easily configurable for various applications. The described biomechanical structure is therefore effectively able to fulfill the requirements of both environments: in the case of complex manipulation tasks, each tendon can be connected to actuators while still exploiting certain antagonistic relations to reduce the total number of motors in the system, while in cases where the need for compactness dominates, it is sufficient to actuate only the primary flexors and extensors - the extensor network, alongside a number of elastic interconnections (Fig. 5/a) can passively ensure partially maintaining their reinforcing effects,

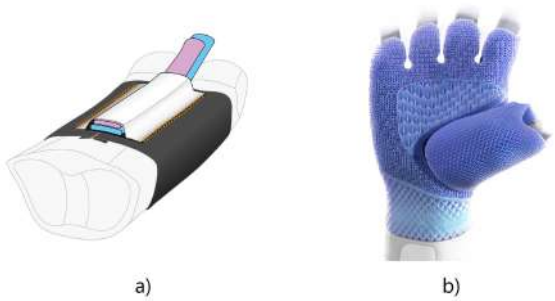

Fig. 4. The tendon sheath and pulley of the hand prototype realized as a simple, sewn pull-on sleeve (a), and the palmar fat and muscle tissues mimicked by selectively compliant, varying-density lattice structures (b).

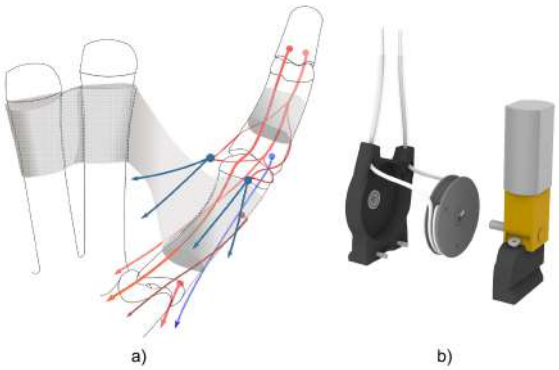

Fig. 5. Anatomical model of the thumb actuator tendons based on [7] (a). In our compact frame, tendons in blue are passivated by elastic connections, while in the extended version, all can be actuated. Exploded view of a single actuator unit with its antagonistic tendon-driving winch mechanism (b).

and enabling a highly adaptive grasping performance due to their contributions to finger tone and natural trajectories.

To demonstrate the extensive capabilities of this biomechanical system, a modular forearm frame and actuation system was developed. It can be configured for single or double-layered construction, each layer capable of housing 6 actuators, with the rotatable wrist area holding room for up to 4 more. High-power, N50 and coreless 12V DC micromotors with worm gearboxes of various gear ratios (range of 100-300:1) are used with winch drums of variable sizes to allow setting the extents of tendon speed and displacement, while attaining high gripping forces and even higher holding torques (Fig. 5/b). The motors are mounted by dovetail joints, ensuring easy removal and reconfigurability. The tendons are connected to the motor housings by PTFE tubes, realizing a Bowden mechanism. Each motor is capable of driving 2 tendons, formulating an antagonistic relation between them.

The electronic control unit is centered around an STM32 MCU, with a dedicated FPGA chip for processing the magnetic encoder signals of each motor, and capabilities to indirectly estimate applied load via motor current measurements. The system can be powered by 2-6 cells of 2900 mAh Li-ion batteries, and can communicate with external IoT agents through the Bluetooth (BLE 4.2) module of an ESP chip, rendering both versions completely wireless and portable.

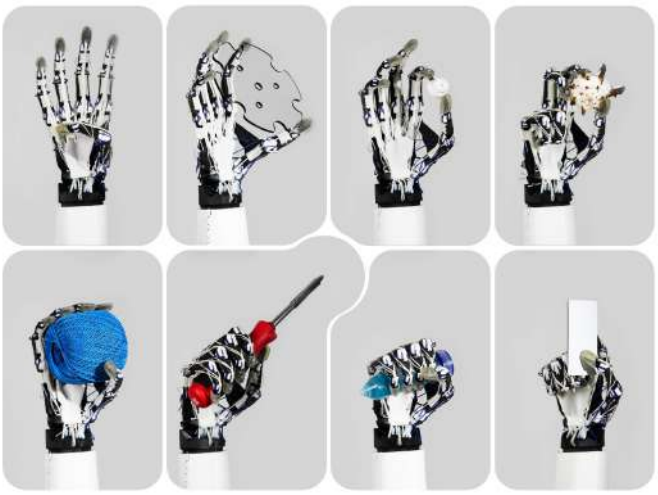

Fig. 6. The Biomimetic Hand performing selected classified grasps [23] and demonstrating maximal thumb opposition, capabilities available in both compact and extended actuator configurations.

Fig. 7. The hand demonstrating finger tilting, claw and beak hand postures, enabled by the intrinsic activity of the extended actuator system.

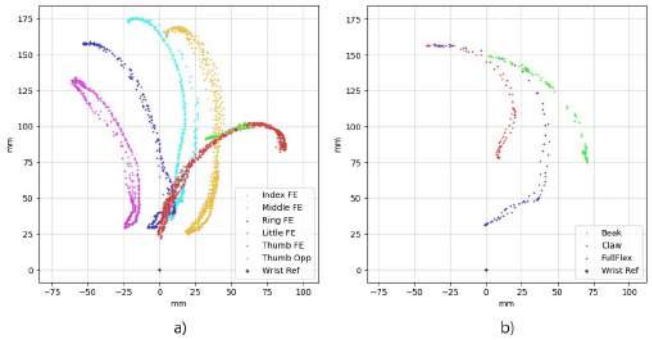

Fig. 8. Color-coded fingertip trajectories: latero-frontal projection of full flexion and extension of each digit and thumb opposition using the compact actuator frame (a), and lateral view of the ring finger's advanced trajectories enabled by the extended frame (b).

IV. Results and Evaluation

The developed hand has 17 active and 12 passive DoF in its joints, including thumb opposition and wrist movements. The speed and strength of its fingers were evaluated using a 120 FPS camera and a Tinius Olsen 5ST universal testing machine equipped with a 5kN load cell, averaged across 10-10 repetitions. It has a closing speed of $\sim$0.5s and a grip strength of $\sim$15N during the full flexion of each individual finger, with further reinforcement possible by the simultaneous activity of the independent intrinsics in the extended system. The load-bearing capacity of the braided tendons at different cross-sectional areas was also examined, and the breaking load was found to be $\sim$20kg for the thinnest (lumbrical, 0.9 mm^2), and $\sim$170kg for the thickest (flexor, 8.4 mm^2) segment.

Besides reinforcing that biomimetic hands are able to reach operating speeds and forces similar to anthropomorphic robotic hands built by more conventional methods, these tests also show that the tensile properties of artificial tendons produced via braiding can possibly match those of their biological counterparts, with both cross-sectional areas and breaking stresses falling into the same magnitude [21].

Two variants of a modular actuator system were constructed: the smaller version aimed at prosthetics houses 7 motors, 1 for each finger's flexion-extension, and additional 1-1 for thumb opposition and wrist rotation. This allows for independent finger control along natural trajectories susceptible to passive influences, resulting in the fingers wrapping compliantly around any object obstructing their path with sufficient resistance. Independent intrinsic muscle control and active finger tilting is lost as a tradeoff, but the stability and adaptivity of grasping is still significantly increased due to the human-like nature of the biomechanical construction. With such a low number of actuators, the complete, life-sized compact system weighs 1.2kg, less than the average human forearm [22]. With the hand itself weighing below 300g, and the battery pack (currently 300g) being highly variable, the frame is light enough to be considered adaptable for prosthetic use-cases.

The extended version for humanoid or telerobotic applications has a less strictly constrained, but still favorable total weight of 1.45kg, and 16 motors contained within the forearm, with the potential to allow for independent flexor and extensor activities, and a fully actuated thumb capable of traversing its complete biological workspace. Intrinsic muscles are antagonistically coupled, enabling active finger tilting, alongside a fully actuated 3 DoF wrist. Besides having similar, highly adaptive grasping capabilities, this version is built to truly exploit the biomimetic design towards realizing human-like dexterous capabilities.

The functional capabilities of the hand were evaluated by performing the GRASP taxonomy [23] as demonstrated in Fig. 6, using a manual, button-based controller configured to drive individual and/or simultaneous motor activity as needed. Using the compact actuator system, the hand was capable of performing 28 out of 33 classified grasps, with the only exceptions requiring controlled finger tilting and independent intrinsic muscle activity (these being: adduction grip, tripod variation, inferior pincer, light tool, and parallel extension). The extended actuator frame, however, enabled the hand to perform all listed grasps, and also to produce the claw and beak postures (Fig. 7) made possible by the active intrinsics (attainable by extensor-flexor synergy enabled by the presence of the interossei, and independent or extensor-assisted lumbrical actuation respectively).

Fingertip trajectories were also analyzed via motion tracking over video captured by a single camera setup. A stable reference marker was placed at the palm and a moving marker

at the tip of each finger. Recordings were taken of individual finger activities with 5 uninterrupted repetitions at 25 FPS. In Fig. 8/a, trajectories were projected to 2D and plotted for each digit's full flexion-extension and separate thumb opposition using the compact actuator configuration, while in Fig. 8/b the additionally performable claw and beak finger trajectories were isolated using our extended setup.

The results show high repetition accuracy with trajectories visibly and generally comparable to cadaveric measurements [24], with highly similar full flexion and extension sweeps. This shows a clear improvement on reliability in mechanical performance without regard to directionality, despite the vastly different volar and dorsal tendon configurations, demonstrating the effectiveness of our anatomically inspired methods in replicating natural motion characteristics.

V. Conclusion and Future Work

In this work, a life-sized biomimetic hand was developed and prototyped, with 3D printed bones and articulations generated by a procedural algorithm based on key parameters, 3D braided tendons produced by a custom variation braider, and textile-reinforced soft tissues. The biomechanical significance of the included articulations and tendinous components was explained from an anatomical perspective, and a modular actuation frame was designed and realized in a compact and an extended version with varying levels of muscular inclusion, each targeted at applications requiring different levels of dexterity. Capabilities were evaluated through grasp and gesture demonstrations and finger trajectory analysis, to highlight the advanced functions and natural compliance enabled by the mimicry of anatomical structures and degrees of freedom.

The results aim to highlight that by today, design and manufacturing methods have advanced to a level that makes the production of such geometrically and functionally complex systems feasible. Combining procedural design with 3D printing enables the quick and efficient realization of customizable organic functional structures. Textile solutions can be leveraged to include advantages of soft robotics, while maintaining high durability. And owing to the ongoing digitalization of advanced technologies such as 3D braiding leading to less time-consuming assembly processes, cost-efficient and scalable production is also within reach, supporting the integrability of biomimetic systems across a wide spectrum.

In future work, advanced control algorithms will be implemented to coordinate actuator co-activity for the automated control of complex movements. The mechanical capabilities of the model will be further evaluated and improved, including performance when connected to actual prosthetic and teleoperation interfaces, and iterations on the initial padding and skin designs for enhancing grasping robustness. Finally and most importantly, successive developments on skeletal modeling and textile/fiber-engineering will be carried out to further enhance the design and production efficiency of such highly biomimetic devices, towards increasing the presence and recognition of intuitively natural robotic platforms in both medical and industrial settings.

Evaluating the Relationship between Motor and Cognitive Impairment and Lesion Size and Location Post-Stroke Using CT Scans*

Reem M. Azar[1], Natalia Stroutinsky Sobotka[2], Pamela Cacchione[3], Rochelle J. Mendonca[4], Michelle J. Johnson, *Member, IEEE*[5]

Abstract— **With stroke being the leading cause of disability worldwide, there is a need to improve current rehabilitative care. Stroke causes brain damage in the form of a lesion, resulting in both cognitive and motor deficits. Clinicians often rely on functional behavior to determine treatment directions; however, behavioral deficit may not represent the neural damage. Understanding how the neural damage influences the behavioral impairments with stroke subjects could allow clinicians to provide a more personalized therapeutic plan. Focusing on global accessibility, CT-scans were used to image the lesion given that it is an affordable imaging modality that is used world-wide. Eleven chronic stroke patients were mapped into functional groups by their motor and cognitive behavior and their CT-scans was used to quantify lesion volume and define how the volume location mapped unto the whole brain areas at different granular levels. Our main findings were that lesion size may not be a good indicator of behavioral deficit. These results suggest that assessing brain areas more granularly may show larger differences in behavior.**

I. Introduction

Stroke is one of the most common causes of death and disability worldwide, with annual treatment costs reaching approximately 53 billion dollars in America alone [1]. In an ischemic stroke, blockage of a cerebral artery leads to reduced blood flow and oxygen in the brain. The loss of blood (and oxygen) leads to a cascade of events that eventually lead to neural cell death. Like wounds in other systems in the body, the immune system will clean up the damage in the brain and lead to the formation of a lesion (which can result in both motor and cognitive deficits). To assess this damage clinically, medical professionals typically use either Computerized Tomography (CT) or Magnetic Resonance Imaging (MRI) [2,3]. While MRI offers superior tissue contrast, CT scans remain the more globally accessible and cost-effective option for stroke diagnosis and assessment [2]. Since CT scan primarily visualizes changes in tissue density, the damaged area may not be clear in the early acute stage of stroke as the cell clean-up process is still underway. While several studies have assessed lesion size and location and behavior using CT scans, these studies focus on relationships between specific regions of interests and outcome behaviors, rather than exploring the whole brain [4-6]. The limitation of this approach is that there may be regions of the brain that are overlooked. Since the brain is deeply interconnected, any disruption in any brain networks due to stroke may lead to deficits in both motor and cognitive performance. Upper limb impairments are often more severe than lower limb impairments, mainly due to most strokes involving the middle cerebral artery, which mostly spares the lower limb [7-10]. Studies show that 77% of stroke survivors have upper limb motor deficits and about 40% also have at least mild cognitive deficits [11]. Despite this, there are few studies that look at the prevalence of concurrent motor and cognitive deficits, but of the studies that have, they found that motor performance is affected by cognition and low/moderate cognition can mask high motor performance [12-14].

The literature has also extensively shown that there is a relationship between brain structure and function [15,16]. Many studies focus on correlating lesion metrics to behavioral outcomes using a dichotomized metric (i.e., good vs. severe) of a single assessment, which is not effective since there is evidence that both cognitive and motor impairments result from stroke. Robotic-based rehabilitation typically relies on decreasing motor impairment and assumes that these changes arise from use-dependent brain plasticity. It is not always clear who is the best candidate for robot-based therapy or what is the best treatment strategy. There is an urgent need to improve robot-assisted rehabilitation devices to ensure that patients are getting the most appropriate and personalized therapeutic plan. Given that cognitive impairment can mask motor performance, it is essential to understand the effect lesion metrics have on motor and cognitive behavior post-stroke.

In this paper, we explore the relationship between structure and function in stroke patients. We deployed a validated lesion segmentation approach to harness neural features from retrospective CT scans and explore their relationship to both motor and cognitive behavior acquired

from clinical assessments of 11 stroke subjects. We seek to 1) confirm that we can acquire lesion metrics from CT scans and 2) explore the relationship between lesion features (size and location) and motor and cognitive behavior in stroke subjects.

II. METHODS

A. Participant Screening

Participants were primarily recruited from an urban hospital comprehensive stroke center and from inpatient/outpatient rehabilitation centers (CBR/GSPP). To be included in the study, participants were at least 3 months post-stroke with a confirmed ischemic stroke diagnosis, including a diagnosis of hemiparesis. Patients had to have a CT scan that can be accessed retrospectively. All patients had to be able to provide informed consent. All participants must present with some motor impairment and function, with a Fugl-Meyer UE score between 15 and 60. Furthermore, their upper arm manual muscle strength scores must be greater than 1 and their upper arm spasticity less than 4 based on the Modified Ashworth scale. Patients must also present with less than 33 on the NeuroQoL Depression measure. Eleven patients (57.4 ± 10.3 years) were included in this study, with 9 patients identifying as male and 2 subjects identifying as female. Table 1 shows their demographic data.

B. CT Scan Selection

The lesion development studies have shown that a stroke lesion evolves over time until the stroke becomes chronic (>three months) [17,18]. After initial injury, the lesion will appear bigger in volume due to swelling, however, the size will eventually settle into its chronic phase with the formation of the glial scar. To the knowledge of these authors, only one study to date has assessed behavior and lesion metrics at the acute and chronic time points. This study suggests that research collected from one time point of stroke may be applicable to other timepoints (with aphasia specifically). Although the results cannot be generalized to all human behaviors, there is other evidence in the literature that suggests that initial lesion volume can predict behavior [15,16]. For the purposes of this study, chronic scans were selected when available and acute scans were used otherwise.

C. Lesion Segmentation

Currently, the gold standard for lesion identification is through manual segmentation [19] by using digital imaging and communications in medicine, DICOM files. A lesion is a hypodense area on the CT scan that appears on multiple z-slices (indicating a volumetric loss). To manually segment the lesions, we followed the guidelines published from Liew et al., 2018 [20]. We used ITK-SNAP, an interactive tool developed for medical imaging segmentation, to create the lesion masks [19, 21]. The Montreal Neurological Institute (MNI) is the standard template used in literature, and it was developed from 152 young adult healthy MR brain scans, making these templates larger on average than brains of stroke patients [22]. To register individual brains to a uniform space, Rorden et al., 2012 developed an age specific template from CT images that can be accessed easily through the Statistical Parametric Mapping (SPM Version 12) Clinical toolbox in MATLAB [23]. Since the SPM Clinical toolbox relies on average size brains, we used an atlas that matched the SPM template dimensions (157 X 189 X 136). To ensure proper template matching, images were normalized using the following bounding box:

-90, -126, -72

90, 90, 108

There is an array of brain atlases to choose from. Since we are analyzing the whole brain, we limited ourselves to atlases that can label the whole brain, covering both cortical and subcortical areas. To accomplish the goal of capturing Brodmann areas and subcortical brain regions, we used the Automated Anatomical Labeling Atlas 3 (AAL 3). The AAL is one of the most widely used atlases in neuroimaging studies, and the AAL 3 is the most updated version of this atlas [24, 25]. The AAL 3 provides structural parcellations of some subcortical brain nuclei (such as the thalamus), giving us an opportunity to examine extensive subcortical involvement in the future. The AAL3 used matched bounding box parameters of the SPM12 toolbox.

D. Whole Brain Analysis

The brain is complex, and thus can be analyzed at various levels. We analyzed the brain in an increasingly granular function. At a broad level, the brain is divided into the right and left-brain hemispheres. The two hemispheres are mostly symmetrical, however, there are some asymmetries that may lead to differences in function [26]. At the next level of division, we will explore the involvement of depth levels of the brain. The brain is divided into cortical, subcortical, and brain stem regions (technically, the brain stem is not a part of the cerebrum, but it is a vital territory of the nervous system that can be affected by stroke). The next level of division of the brain are the lobes of the cerebrum, which are traditionally four lobes (frontal, parietal, temporal, and occipital). The brain anatomy goes beyond the cerebrum with both the cerebellum and brain stem, which are considered two separate lobes. With an increased understanding of the brain, more lobes have been established: insula and limbic lobes, however, the existence and boundaries of the limbic lobe are not universally accepted [27].

Lastly, the most granular division we looked at is seven main brain networks that each have evolving functions. Importantly, few brain areas deal with specifically either

TABLE I. PARTICIPANT DEMOGRAPHICS

ID	*Age*	*Sex*	*Race*
001	39	M	Asian
003	56	M	White
005	35	M	Black or African American
007	48	M	Black or African American
008	24	F	White
009	51	F	Black or African American
010	70	M	Black or African American
012	47	M	White
013	49	M	White
023	59	M	White
047	40	M	Black or African American

domain, however, five areas are mostly *correlated* with cognitive functions (temporal and junction lobes, Default Mode Network (DMN), Dorsal Attention Network (DAN), and Salience Network (SAN). The temporal lobe is mainly involved with communication and sensing the world. The junction lobe represents areas that do not fall in any specific lobe, and these areas are mainly involved in communicating between different brain areas. The SAN is mainly involved in executive functioning and processing of stimuli and communicated with the DMN. The DMN is mainly involved in memory processing and memory retrieval, as well as resting-state activity, which is essential for overall brain function. Lastly, the DAN mainly processes visual stimuli to focus attention.

E. Clinical Assessments

The clinical assessments used in research settings are different than those acquired by therapists in hospital settings. To save time and acquire general motor and cognitive impairment status, clinicians prefer short and rapid assessment and may not use the research state of the art. To assess cognitive impairment, Montreal Cognitive Assessment (MoCA) was used. The MoCA is used to measure impairment in visuospatial/executive function, naming, memory, attention, language, abstraction, delayed recall, and orientation [28]. Specifically, the MoCA has been used in patients with stroke to measure cognitive impairment and was able to detect more people who had chronic stroke when compared to other state-of-the-art assessments, with a maximum score of 30 [28]. The Fugl-Meyer upper extremity (FM-UE) scale is a widely used and stroke-specific measure of both upper extremity impairment [29]. The FM-UE is the most used scale to measure post stroke upper extremity impairment within research settings [30]. The FM UE assesses reflex activity, movement control, and muscle strength, with a maximum score of 66. Certified and trained individuals scored clinical assessments.

F. Functional Subgroups

Clinical score cut offs for motor and cognitive assessments determine motor and cognitive functional status. These functional subgroups distinguished between high to low motor and cognitive function. An FM -UE score of 48 and below was used as the cutoff for moderate-to-low UE function and a cutoff score of 26 and below was used to indicate moderate-to-low cognitive function [31]. To simplify the labeling, we divided the groups into high and low function. We can then classify the subjects into four functional subgroups: high motor/high cog, high motor/low cog, low motor/high cog, and low motor/low cog. Figure 1 illustrates the functional subgroup stratifications.

III. RESULTS

All data were collected under guidance and with approval from the University of Pennsylvania Internal Review Board (IRB) from two approved studies: 849090 and 823511. The images were all acquired retrospectively using the electronic, medical records system used by the Penn Medicine Hospital Group. Given the small sample size, all results presented are to show potential relationships. Table 1 shows subject demographics.

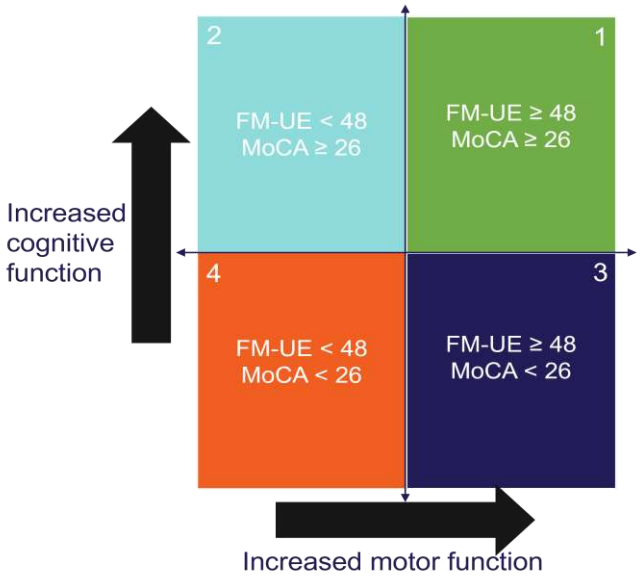

Figure 1: Motor and cognitive cut off scores that define the functional subgroups

A. Functional Subgroups

Table 2 displays UE-FM and MoCA scores for each participant as well as their functional grouping. Figure 2 displays each participant in their functional subgroup. Due to the small sample size, there is not an even distribution of subjects across the groups. There is *one subject with low motor and low cognitive function and no subjects in the group with low motor and high cognitive function*. Subject 23 lays right on the cutoff point between high and low cognitive function, being categorized as a person with high cognitive function.

B. Overall Lesion Segmentation Results

We were able to successfully extract and normalize lesion features from CT scans for eleven subjects. The same individual segmented all scans blindly (without indication of where the lesions were). All images were traced in the axial brain view. Figure 3 shows the lesion development of a subject with a large stroke: the lesion mask is in red. This subject has a mostly cortical stroke with minimal extension into subcortical areas. All subjects' brains and respective lesions masks were normalized according to the method described above. These scans display warping since they are normalized to a general space, with smaller slice thickness.

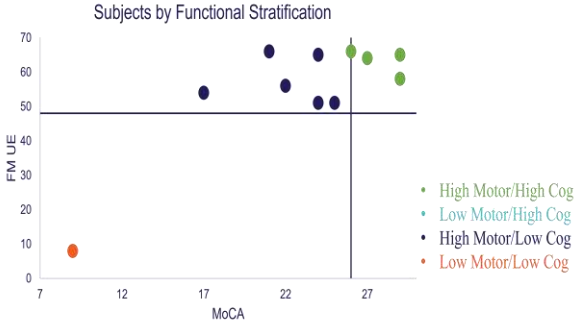

Figure 2: The functional subgroup division of our population

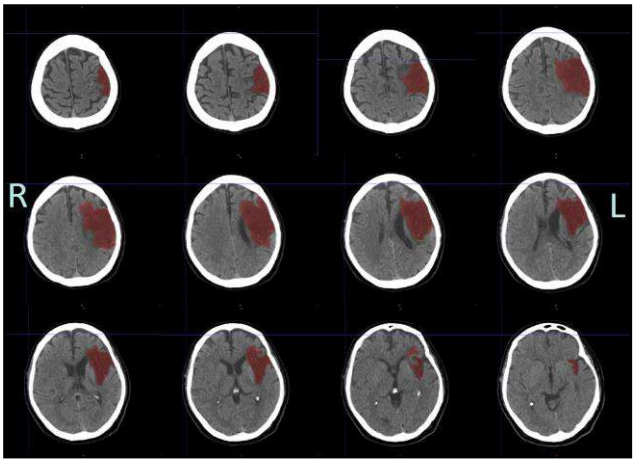

Figure 3: Subject 23's lesion development in axial view. The lesioned area is marked in red.

As mentioned, acute scans were used when chronic scans were not available, which was the case for four of the eleven subjects (subjects 001, 003, 010, and 012). Identifying the stroke lesions from CT scan was not always possible. For example, the CT scan for subject 001 showed a clear stroke, while the other three did not have clear lesions. One subject (subject 010) had MR scans available for cross analysis. These MR scans showed that the lesion was located dorsally right on the brain's surface. It is most likely that the scanner did not pick up the lesions at the surface.

C. *Lesion Size*

Table 2 presents the lesion volumes per subject, and there is no indication that there is a relationship between volume and motor and cognitive deficit in our population. The person with the most severe behavioral deficits had a small stroke (Subject 007) and the person with the largest stroke had high motor and cognitive function (Subject 023).

D. *Lesion Location*

Of the nine subjects with visible lesions, seven (77.8%) presented with left-hemisphere strokes and two (22.2%) with right-hemisphere strokes. All subjects (100%) exhibited contralateral motor impairment, where upper extremity deficits occurred on the opposite side of the lesion location. There were *no clear* differences in groups and hemisphere involvement.

At the next level of analysis, brain depth, after overlaying the atlas, initial analysis showed no lesions in the brain stem region. However, further analyses showed that there were indeed subjects with stroke damage, however, atlas coverage of subcortical areas was a limiting factor (fig. 4). Navigating to the red arrows on the side-by-side figures, there is a cerebellar stroke that the AAL3 did not capture in its overlay. There were also no differences among the functional groups in both cortical and subcortical involvement.

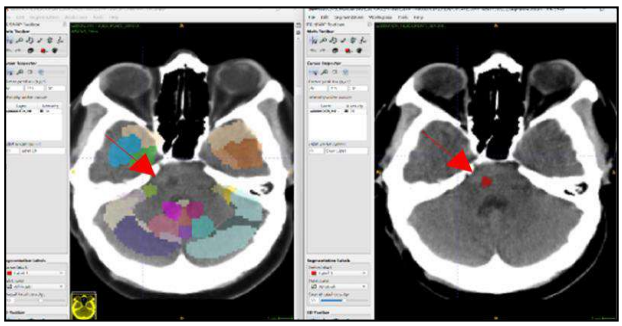

Figure 4: Subject 012 atlas overlay and lesion mask side-by-side

There is indication that the parietal, temporal, and junction areas have varying involvement among the three groups (as the low motor, high cog group had no subjects), with the high motor/low cog group displaying the greatest involvement in these areas (fig. 5 (a)). Importantly, the low motor/low cog group did not display lesion involvement in these lobes.

At the brain network level, both low cog groups displayed higher involvement in the Salience Network when compared to the other groups (fig. 5 (b)). The low motor/low cog subject displayed about 2mL of lesion involvement in the salience network, which is around thirty percent of the entire lesion size. The high motor/high cog group had lesions impacting this network.

IV. Discussion

The two goals with this study were to confirm that we can acquire lesion metrics from CT scans (at varying timepoints) and explore the relationship of lesion metrics to both motor and cognitive behavior. To our knowledge, there are no studies that look at whole brain analysis and combined motor and cognitive assessments, as we do in this study.

We were able to successfully acquire lesion metrics from one subject with only an acute scan, but were unsuccessful in acquiring lesion metrics from the other two subjects. One of the two subjects had an MR scan, where we were able to find that the small stroke was on the brain's surface. Due to the slice thickness used in CT scans, it is most likely that the scanner did not capture the small lesion. This limitation is present regardless of scan time point, but without a chronic CT scan for this subject, we cannot confirm that the lack of visible lesion was not due to the scan time point. The other subject that lacked a visible lesion did not have other scans available, so we cannot confirm the existence of a lesion.

Our study corroborated previous findings in the literature

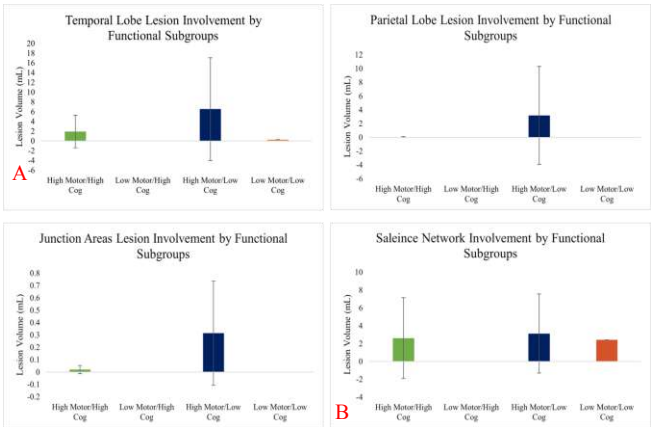

Figure 5: Lesion involvement results. A) Lesion involvement in the Temporal, Parietal, and Junction Lobes across the four groups. B) Lesion involvement in the Salience Network across the four groups.

TABLE II. CLINICAL ASSESSMENT AND LESION CHARACTERISTICS FOR THE PARTICIPANTS

ID	*Lesion Volume (mL)*	*FM*	*MoCA*	*Group*	*Scan Time*	*Lesion Location*
001	1.257	65	24	3	Acute	L
003	0	65	29	1	Acute	NA
005	0.584	51	24	3	Chronic	R
007	7.292	8	9	4	Chronic	L
008	0.232	58	29	1	Chronic	L
009	0.715	64	27	1	Chronic	R
010	0	56	22	3	Acute	NA
012	0.058	51	25	3	Acute	L
013	140.1	54	17	3	Chronic	L
023	167.095	66	26	1	Chronic	L
047	50.772	66	21	3	Chronic	L

that lesion size alone is not an indicator of function [32]. Inversely, the subject (Subject 007) with the most severe impairment had a subcortical lesion with involvement in the temporal, insular, and basal ganglia domains. Given this subject's severe motor impairment, we expected that this person would have some involvement of the motor cortex (cortical lobe), however, we are not surprised by the result since the basal ganglia and insula are involved in facilitating motor functions, rather than executing them (motor cortex). Additionally, this person has aphasia, meaning it is possible that their cognitive score is not indicative of their cognitive function, but rather, their ability to understand and communicate (due to the aphasia).

In this study, we took a gradual approach to assessing lesion location involvement in behavior. The brain is interconnected and brutely dividing areas to correlate with just motor and cognitive functions is difficult at broad levels in the brain, however, the gradual digging deeper in our analysis allows us to ensure we do not miss general findings. Given that both hemispheres are involved in both motor and cognitive tasks, we were not surprised to find that there is no indication of a relationship between hemispheres and resulting behavior. Similarly, we were not surprised that at different cortical depths, there was no relationship indicated between brain area and behavior. We were limited in assessing the brain stem region since the atlas did not capture those brain areas. When we continued to look more granularly and identified brain areas (temporal and junction lobes) that are more involved in cognitive functions, the high motor/low cognitive group had lesions in these areas. In other words, we found that the group that had high motor/lower cog function had lesion involvement in brain areas involved in cognitive function. We did not see similar involvement in the low motor/low cog group, however, given the potential effect of aphasia on the MoCA, it is possible his low MoCA score is not indicative of his actual cognitive function.

When we looked even deeper at brain networks, we identified three brain networks involved in mainly cognitive functions: Default Mode Network, Salience Network, and Dorsal Attention Network. Our results showed that both low cognitive functioning groups had lesions in the salient network (SAN). Interestingly, subject 23 (high motor/high cognitive group) had some involvement in the SAN. Subject 23 (fig 3) had a largely cortical stroke and presented with a MoCA of 26 and FM of 66, indicating high motor and high cognitive function. This subject has regained full motor function, while retaining mild cognitive deficit, specifically in the visuospatial/executive domain, supporting the previous literature that mostly cortical strokes display larger behavior recovery post therapy [33]. Given that his deficit is in the executive functioning domain, we are not surprised that he has lesion involvement in the SAN. This finding suggests that we should look beyond the raw assessment scores and investigate the specific motor and cognitive domains.

Another interesting finding is that the high motor/low cog function group had more involvement of the parietal cortex than the other groups. This result is unexpected considering how deeply woven the parietal cortex is with motor cortex. At the same time, the parietal cortex is also deeply connected with cognitive areas (sensory processing). This finding further corroborates that there is a need to look at individual brain areas based on functional domains (Brodmann Areas). During the lesion segmentation process, we also found that several subjects with a lesion had no overlap with the AAL3 (subjects 008, 009, and 012). Although these subjects had visible lesions, their lesion involvement across all brain areas was zero. This result is due to lack of overlap with the atlas used. Although the AAL3 is one of the most used and developed whole brain atlases, it has low coverage of the cerebellum and brain stem areas. It also has incomplete coverage of the whole brain, often missing borders.

This work targets structural changes in the brain post stroke, however, there is evidence of reorganization of the brain post stroke [34]. Brain plasticity involves synaptic remodeling and reorganizing, which cannot be visually detected using a CT scan. One non-invasive technique that can detect neuroplasticity post-stroke is an electroencephalogram (EEG), which measures electrical activity in the brain. EEG can detect brain plasticity post-stroke by detecting changes in electrical activity across the brain regions [35]. Understanding brain reorganization post-stroke by using tools such as EEG would enhance our current work of understanding lesion location's role in behavior post-injury.

The biggest limitation of our study is the current sample size. With our current sample size, we could not perform any

correlation analyses, severely limiting the impact of this work. We also were limited in the number of subjects with motor impairment, with only one subject meeting the criteria for low motor function. While we used the gold standard assessments for measuring motor and cognitive impairments, we place aphasic patients at an extreme disadvantage. In future considerations, we will use the MoCA for people with aphasia.

V. Conclusion

In this paper, we explore relationships between structure and function between the brain and behavior leveraging affordable tools. Although our small sample size cannot provide correlational data between brain area and behavior, we demonstrate that there is a need to continue this work. Our results show that there may be a relationship between lesion location and behavior.

Financial Conflicts of Interest

***Abstract*— Ankle proprioception is important for gait control and is often impaired after stroke. It is currently unclear if conventional gait training can improve ankle proprioception. Here we used a novel robotic device, Ankle Measuring Proprioceptive Device (AMPD), to quantify key aspects of ankle proprioception before and after four weeks of gait training delivered to 24 individuals who were in the chronic phase of stroke. We implemented two assessments with AMPD to quantify passive and active and dynamic/static proprioception. For the Crisscross assessment, AMPD moved the ankles past each other and the participants pushed a button to indicate when the ankles passed each other, thereby testing passive, dynamic proprioception. For the Joint Position Reproduction (JPR) assessment, AMPD moved the impaired ankle in a random pattern and the participant tracked with their unimpaired ankle, thereby testing active, dynamic proprioception. We also incorporated static periods into JPR to quantify static position sense. At baseline, active and passive ankle proprioception errors, as well as static and dynamic errors, were significantly increased compared to age-matched controls and were moderately correlated. Gait training improved only static ankle position sense, with greater improvement for more severely impaired individuals. These findings suggest that stroke damages multiple aspects of ankle proprioception in an interrelated manner. In contrast, conventional gait training improved only static ankle proprioception ability. This suggests a need for an array of training methodologies to comprehensively retrain ankle proprioception.**

Keywords— stroke, ankle proprioception, gait therapy, robotic

I. Introduction

An estimated one in four people worldwide will experience a stroke in their lifetime [1], with ~60% of survivors experiencing frequent falls, balance limitations, reduced walking speeds, asymmetric gait, and motor coordination problems [2], [3], [4]. In a recent survey, improving walking and balance ability was the top priority of 589 people post-stroke [5]. Therefore, understanding the causes of gait impairment and how best to target those causes is a key goal in rehabilitation research.

One of the most significant contributors to gait impairment after stroke is foot drop, which is caused by a reduced ability to actively dorsiflex the ankle during the swing phase of gait. Weakness of the impaired ankle, present in ~30% of people post-stroke [6], strongly predicts reduced gait velocity [7], [8]. However, sensory deficits of the lower extremity are also common after stroke, occurring in about a third to half of people [9], [10]. Poor lower extremity proprioception has been linked to poor gait [11], [12], reduced balance ability [9], [11], [13], falls [9], [11], and decreased endurance [14], with ankle proprioception being a strong predictor of balance ability in chronic stroke [13]. This predictive ability makes sense from a theoretical perspective, as the body's feedback control systems and learning systems depend on accurate sensory information. Thus, treating both the motor and sensory aspects of ankle function is important goal for gait

rehabilitation after stroke.

However, conventional gait rehabilitation mostly focuses on motor related capabilities, such as active range of motion, strength, endurance, and overall walking [15]. Currently, it is unclear if conventional gait training improves proprioceptive impairment, with some studies reporting that conventional gait therapy significantly improved ankle proprioception [16], [17] and other reporting no improvements in ankle proprioception [18], [19]. These mixed results could arise because the exercises performed during conventional gait training do not sufficiently challenge the proprioceptive system, and/or the proprioception assessments used are not sensitive enough.

To the latter point, a recent review through empirical evidence highlighted that measure of proprioceptive accuracy are characterized by method-specificity [20]. This review found no studies reporting significant correlations between different errors measured with different proprioceptive tests. Of note, however, these studies primarily focused on populations of young, unimpaired individuals.

Here, we sought to quantify the effect of conventional gait training on ankle proprioception in chronic stroke, we well as whether proprioceptive errors measured with different assessments correlate after stroke. We used a robotic device to improve objectivity and sensitivity of proprioception testing, and used it to implement tests of passive, active, dynamic, and static ankle proprioception.

II. Methods

A. Participants

The people with stroke studied here were the control participants in a clinical trial of brain-computer interface, functional electrical stimulation for foot drop [21]. An extensive list of the inclusion and exclusion criteria followed are in Biswas et al.[21], however a subset of the inclusion criteria most relevant to the current study were: (1) age 18-80 years, (2) radiologically confirmed stroke more than 26 weeks prior, (3) gait velocity < 0.8 m/s, (4) presence of foot-drop, and (5) walk > 10 m with or without assistive device at a supervised level. Control participants received conventional gait therapy.

For comparison, we also recruited age-matched controls who had not experienced a stroke and evaluated their ankle proprioception. The University of California, Irvine Internal Review Board approved the procedures and participants provided informed consent.

B. Ankle Measuring Proprioceptive Device (AMPD)

For this study we used two versions of the Ankle Measuring Proprioceptive Device (AMPD, Figure 1). Both versions are platform-based robots that have the ability to individually adjust each foot pedal's impedance state to be either rigid (in which case the ankle position is controlled by a linear motor) or transparent (in which case the linear actuator is not connected to the ankle). For more details on the AMPD robots see [22].

To assess ankle proprioception with AMPD, participants sat in an upright position with the hip and knee bent at 90 degrees such that the shank was perpendicular to the ground, the center of the lateral malleolus was aligned to the rotational shaft, and the feet were adjusted to hip width (Figure 1). AMPD records seating parameters with sensors so they can be repeated.

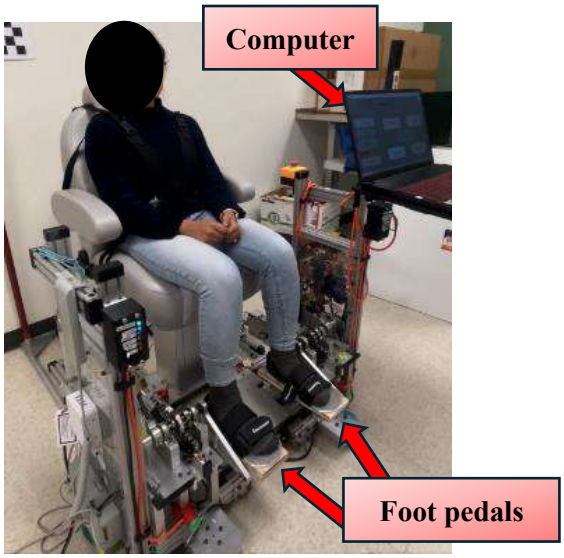

Figure 1. A picture of a volunteer seated in the correct position in AMPD. Both foot pedals can be driven robotically or moved freely by the participant, depending on whether a rack and pinion is engaged between a linear motor and the pedals.

C. Crisscross Assessment of Ankle Proprioception

The Crisscross test of proprioception is a novel test of passive proprioception sense developed by our laboratory initially for the fingers [22]. Crisscross measures the ability to predict the moment that two, passively moved, body parts cross. Key features of Crisscross are it: does not require the participant to have active movement ability and is thus a test of passive proprioception sense; requires detection of both movement speed and position to anticipate the crossing moment; does not require memorization; and focuses on self-observation of the movement of related body parts obviating the need for internal coordinate transformations into visual space. In initial studies employing Crisscross with the fingers, we found it was sensitive to aging [15] and presence of a prior stroke [5]. It also predicted the ability to benefit from robotic finger training [4].

To implement Crisscross for the ankles, both foot pedals of AMPD were placed in their rigid mode and then AMPD moved the left and right ankles in opposing directions, creating a crossing event (Figure 2 top). For each ankle crossing trial, participants were instructed to press a handheld button when they perceived their ankles to be at the same angular position.

Before starting the Crisscross test, a licensed physical therapist assessed each participant's passive range of motion (ROM) by manually moving each ankle to a comfortable dorsiflexion and plantarflexion position within the robot, with the robot in transparent mode. The maximum dorsiflexion and plantarflexion positions for both ankles were recorded and used as the range of motion for the test. The crossing

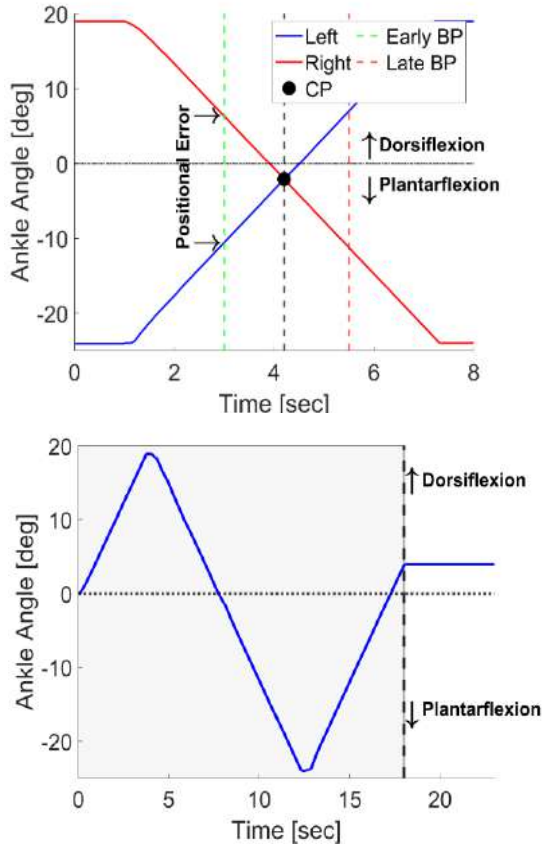

Figure 2. Examples of ankle trajectories for Crisscross and JPR. Left: A single crossing position (denoted by black circle) during the Crisscross test generated by 2AMPD. Right: The impaired ankle trajectory of a single JPR dynamic (before dotted black line) and static period (after dotted black line). **CP** = Crossing Position

workspace for both ankles was set to be identical and equal to the workspace of the ankle with the smallest passive ROM. Once the workspace was set, we divided it into five distinct zones to ensure a uniform distribution of crossings: extreme plantarflexion (>60% PF), moderate plantarflexion (60-20% PF), neutral position (20% PF - 20% DF), moderate dorsiflexion (20-60% DF), and extreme dorsiflexion (>60% DF). Next, the assessment was explained, and participants experienced an example test that consisted of four crossings with vision of the ankles, verbally confirming that they understood the test. Subsequently, participants performed 10 ankle-crossing trials with their vision occluded by a lapboard. Crossing speed (4-8 deg/sec) and position were pseudorandomized.

D. Joint Position Reproduction (JPR) Assessment

JPR is a common methodology in proprioceptive testing in which one joint is moved and then the participant is asked to replicate the movement with the same joint or another joint. For this study we implemented a contralateral JPR test that did not require memorization. To implement JPR, we set one foot pedal to be in rigid mode and the other to be in transparent mode. AMPD then guided the passive, impaired ankle through a predetermined motion, while the participant actively moved their unimpaired ankle to match the impaired side. We designed the test to have two parts, dynamic and static periods. Dynamic periods consisted of AMPD driving the impaired ankle at a constant velocity (5°/s) through its available dorsiflexion and plantarflexion range. Dynamic periods were randomly interrupted by static periods where the robot stopped moving the ankle at a pseudo-random set of positions. Participants were instructed to match the angular position of the stationary impaired ankle by making fine adjustments with their unimpaired ankle for as long as they wished, pushing a button when finished. The robot initiated a dynamic period after they pushed the button. Participants first completed an example JPR test with vision of the ankles that consisted of two dynamic and static periods, verbally confirming that they understood the test. Then, with vision occluded by the lapboard, they completed four dynamic and four static periods.

E. Conventional Gait Therapy

Participants received conventional gait therapy three times a week for four weeks in two-hour sessions. Activities were customized by a physical therapist and included passive/active range of motion, resistance, balance, and overground walking exercises. Participants were asked to refrain from engaging in outside physical therapy during the study.

F. Data Analysis

For Crisscross, proprioceptive error was defined as the absolute angular difference between the left and right ankles at the moment of button press. If a participant did not push the button a trial, this trial was excluded from analysis.

For the dynamic period of the JPR test, proprioceptive error was define as the average of the absolute angular differences between the ankles throughout the movement period. For the static period, proprioceptive error was calculated as the absolute angular difference between the impaired and unimpaired ankles at the moment of button press.

Statistical analyses were conducted using Matlab R2023. Proprioceptive errors for each proprioceptive assessment were normally distributed (Shapiro Wilks, $p > 0.05$), so we used parametric tests, including two-tailed student t-tests for comparisons between baseline and end of therapy proprioceptive error, and Pearsons's correlation. An alpha of 0.05 was considered significant.

III. Results

We used a robotic device to quantify ankle proprioceptive ability in 24 people in the chronic phase of stroke, before and after they received 24 hours of conventional gait training over 4 weeks. Table 1 provides a clinical overview of the participants.

Table 1. Baseline characteristics of the participants with a stroke.

	Average ± SD
Age	59.8 ± 12.4
Months Post Stroke	42 ± 32
NIH Stroke Severity Scale [0 42]	7.0 ± 3.2
Lower Extremity Fugl Meyer [0 34]	19.0± 5.3
10M Walk Test (m/s)	0.45 ± 0.22
Sex M/F	10/14

A. *Effect of Stroke on Baseline Ankle Proprioception*

At baseline, stroke participants demonstrated significantly greater errors in all proprioceptive tasks compared to the age-matched unimpaired adults (t-test, $p < 0.01$). Specifically, the stroke group produced an average error of $17.2° \pm 7.2°$ for the Crisscross test, and $12.9° \pm 8.0°$ and $11.7° \pm 5.7°$ for JPR static and JPR dynamic test, respectively. In contrast, the age-matched controls produced an average error of $9.3° \pm 3.5°$ for the Crisscross test, $6.8° \pm 2.9°$ and $6.7° \pm 2.4°$ for JPR static and JPR dynamic test. For each proprioceptive measure, 42%, 33%, and 46% of the stroke participants had a mean proprioceptive error greater than 2 standard deviations (SD) of the age-matched participants. Crisscross error was moderately correlated with JPR static and JPR dynamic error (Fig. 3).

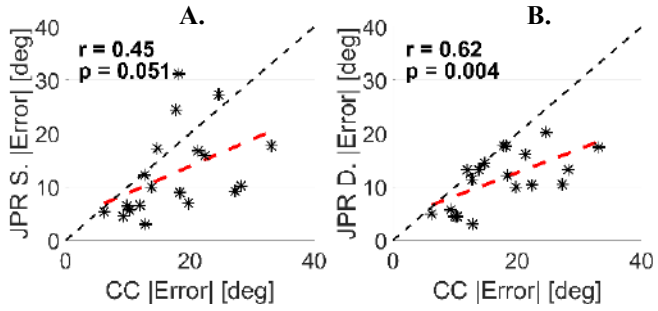

Figure 3. Relationships between average absolute Crisscross error (x-axis) and JPR static and dynamic error (y-axis) at baseline. Red, dashed lines show linear fits. Black, dashed lines represent a slope of 1.

B. *Effect of Conventional Gait Therapy on Proprioception*

The average change from baseline to end of therapy for Crisscross, JPR static, and JPR dynamic errors was $0.7° \pm 5.5°$, $-3.3° \pm 6.5°$ and $-1.0° \pm 3.5°$, respectively. None of these changes were significant ($p > 0.05$), although the reduction in JPR static error approached significance ($p = 0.07$). When we plotted baseline versus end-of-therapy errors for each participant (Fig. 4), for JPR static error we noticed that one individual's EOT proprioceptive error was 2 SD than the mean for the group. Removing this outlier, we found that the change in JPR static error from baseline to end-of-therapy was significant ($p = 0.04$) .

We defined a threshold for identifying impaired proprioception as 2 SDs of the age-matched error found in uninjured participants and found it to be 12.5° for JPR static error. The six individuals with a baseline JPR static error exceeding 12.5° demonstrated significant improvement at the end of therapy assessment, reducing their error by an average of $9.0° \pm 3.2°$ ($p = 0.005$). Moreover, the six participants showed significantly greater improvement compared to stroke participants within the two standard deviations of the age-matched error ($1.0° \pm 1.4°$, $p < 0.001$). Individuals with greater than 2 SD of Crisscross or JPR dynamic error did not reduce their error, however (Fig. 4 left and right).

IV. Discussion

We assessed the ankle proprioception of 24 participants in the chronic phase of stroke using two robotic proprioceptive assessments (Crisscross and JPR) before and after a four-week gait therapy program that incorporated conventional treatment exercises. We found that, as a group, the stroke participants had significantly impaired ankle proprioception at baseline, and that different types of proprioception (active vs. passive) were moderately correlated. Although conventional gait therapy did not significantly improve Crisscross error or JPR dynamic error, it did result in a significant improvement in JPR static error when we applied a standard outlier removal. Notably, the participants with the poorest static ankle position sense at baseline showed a significantly greater improvement in static error by the end of the therapy assessment. We will now discuss these results as well as directions for future research.

A. *Ankle Proprioception after Stroke*

It was not surprising to us that ankle proprioception was impaired after stroke, as several studies have reported this finding (e.g., [23], [24]). However, to our knowledge, this study was one of the first to test multiple aspects of ankle proprioception after stroke and find that they are moderately correlated. Many tests for assessing proprioception have been developed using manual techniques, simple mechanical technologies, or robots [20], [25]. A recent review counted

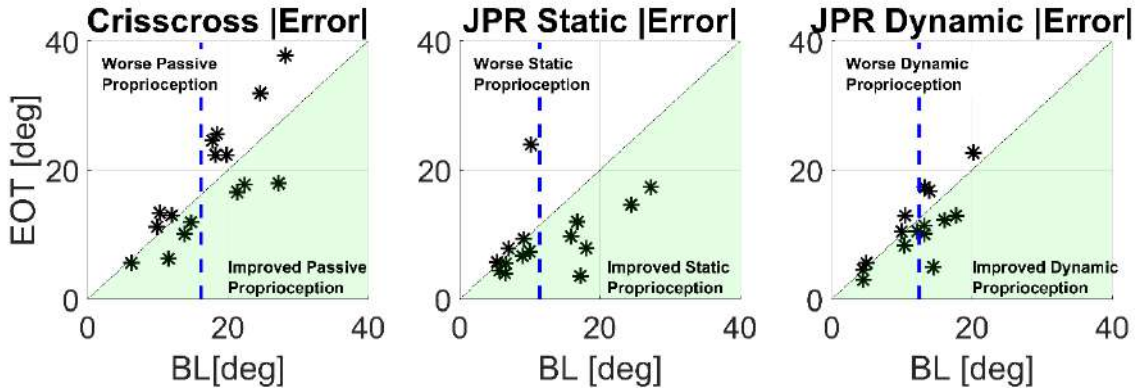

Figure 4. Robotic proprioceptive measures at baseline (x-axis) and end of therapy (y-axis). The dotted blue lines represent a threshold for detecting substantially impaired proprioception, defined as a mean error greater than 2 SDs of the error age-matched controls, for each proprioception assessment. EOT: End of Therapy; BL: Baseline

over 1,300 different types of proprioceptive measurements [20], and highlighted that results obtained with one method rarely generalize to another method. However, the studies analyzed in that review focused primarily on populations that were either young unimpaired individuals [26], [27], [28] or individuals with peripheral nervous system damage [29], [30]. Here, we found "method generalizability" for people with stroke.

A possible explanation for generalization of proprioception assessments is that similar neuroanatomical substrates and computational processes are involved in performing each assessment. Both Crisscross and JPR assessments share components of movement discrimination, movement speed and direction sense, and interhemispheric communication. Considering interhemispheric communication alone, stroke causes connectivity abnormalities between hemispheres [31], resulting in heightened influence of the contralesional hemisphere in motor tasks [4], [32]. Perhaps this altered relationship affected the sensory processing needed for both Crisscross and JPR, causing their errors to be correlated.

B. Response of Ankle Proprioception Ability to Gait Therapy

Ankle proprioception ability did not significantly improve following four weeks of conventional gait training for Crisscross and JPR dynamic error. This suggests that conventional therapy may not sufficiently challenge the dynamic aspects of proprioception required for these assessments, such as predicting angular positions and speeds during continuous motion. A recent meta-analysis of proprioceptive learning found that it is task-specific [33].

For proprioceptive training, a common strategy is to remove visual input so that participants cannot compensate with vision. This was not a focus of the conventional gait training used here. Further, exercises that require a person to make conscious and repeated judgments about limb position and movement are also not commonly employed in conventional gait training.

The stroke participants significantly improved only their JPR static error. The conventional gait therapy implemented for this study incorporate balance exercises at slow speeds under weight-bearing conditions, potentially enhancing static proprioceptive sense.

When we focused on the subset of individuals with particularly poor static angle proprioception ability (defined as > 2D of control error for the JPR test), we found that they improved their ankle proprioception more, compared to the individuals with smaller baseline errors. These individuals may simply have had greater room for improvement, but it is notable to use that poor ankle proprioception does not mean poor relearning ability, in contrast to the motor system for which it has been observed that the most severely impaired individuals respond less to training [34]. Future research should focus on identifying the neuroplastic responses that help proprioception improve, potentially providing new targets for rehabilitation.

V. Conclusion

By using a robotic device to implement two types of proprioceptive assessments, this study provided novel insights into sensory impairment and training after stroke. Stroke impairs ankle proprioception in a way that affects both dynamic and static, and passive and active proprioceptive ability, in a coordinated way. Conventional gait training does not appear to be an effective way to retrain ankle proprioception ability, except maybe static position sense.

These results suggest a need for an array of training methodologies and technologies that can work together to comprehensively retrain ankle proprioception. We believe it is crucial to address not only motor impairment but also sensory impairment to optimize rehabilitation outcomes after stroke. Conventional gait therapy could be supplemented with targeted proprioceptive exercises to facilitate comprehensive sensory motor recovery. Robotic devices can not only play a role in improving proprioception assessment but also proprioception training for example by replacing visual elements of training games with robotically-driven, proprioceptive elements [35].

Development of an Affordable Self-Stretching Passive Device for Treatment and Assessment of Spastic Wrist and Fingers Post-Stroke

Jacob Kim [1], Reem Azar [2], Nova Meng [3], Michelle J. Johnson, Member, IEEE [4]

Abstract— **Stroke, a condition in which blood flow has been restricted to parts of the brain, has been known to cause spasticity, a condition in which the muscles abnormally tense up through an overactivation of the stretch reflex. One low-cost solution to this problem is the use of self-operated passive stretching devices that can be operated with minimal assistance. The goal of this project was to develop and evaluate a new self-stretching wrist and finger device using an iterative design cycle. The device was designed with the following two stretching mechanisms: a rotating dial and an inflatable grip. Three stages of the device prototypes were developed: early, late, and final. After each stage, a usability survey was conducted with a group of healthy controls to rate 0-10 in criteria of overall comfort, unexpected pain, upper arm muscle tension, and device security of the arm. After, design changes were made to address common feedback. In the end, we saw that prioritizing the reduction of pain, decrease of unnecessary upper arm muscle tension, and increase of device security of the arm proved to be valuable measures of increasing overall device comfort. In addition, electromyography (EMG) data was collected with a healthy control subject to verify that the device was able to properly initiate the wrist flexors and extensors through the flexion and extension movement, and that each muscle group was isolated properly to their respective movements through the device.**

I. Introduction

Stroke occurs when blood supply to a region of the brain has been interrupted or reduced, preventing the brain tissue from receiving proper oxygen and nutrient supply from the brain [1]. Hemiplegia is the most common sequela of stroke that is described as a one-sided paralysis of the body. Damage in the upper motor neurons (UMN), which can be caused by stroke, multiple sclerosis, or spinal cord injury, will lead to a loss of lower motor neuron (LMN) inhibition. This lack of balance can lead to the muscles being tight, stiff, and resistant to movement, causing hypertonicity and exaggerated reflexes (hyperreflexia), often leading to the velocity dependent spasticity [2].

Unfortunately, while physical therapy is still a widely used practice in treating spasticity, a recent study found that about 33% of the 500 post-stroke patients studied did not receive any physical therapy, while about 50% of them did not receive occupational therapy. Even worse, those who received any therapy had only 6 to 8 sessions, while certain minority populations received disproportionately lower amounts of therapy in general [3].

One solution to address accessibility to physical rehabilitation is technology-assisted therapy. State-of-the-art spasticity assessment devices such as the Neuroflexor, Portable Spasticity Assessment Device (PSAD) utilizes electromyography (EMG) to quantify muscle activity throughout stretching motions while applying external force [4,5]. As for therapy devices, various options exist such as the Saebo flex, FlintRehab music glove, and the Saeboglove exist that functions as a glove that can also stretch each finger individually [6]. While many of these devices offer a unique method of treating or assessing spasticity, its price often stands as an obstacle for many low resource areas. Thus, one of the main objectives is to ensure that the price of the prototype will be much lower than its state-of-the-art alternatives.

The overall structure of the paper will follow a 4-step systematic design and analysis plan as seen in figure 1. Ultimately, the purpose of this technical proof-of-concept paper is to describe the iterative development process of the device through its multiple stages of usability testing and confirm the device's ability to properly activate the wrist flexors and extensors through EMG.

II. Passive Self-Stretching Spasticity Device

Our design goals were to create a self-operable passive device to treat and assess spasticity in the wrist and fingers. The device was required to support two essential stretching motions: wrist flexion/extension and finger flexion/extension (fig 2).

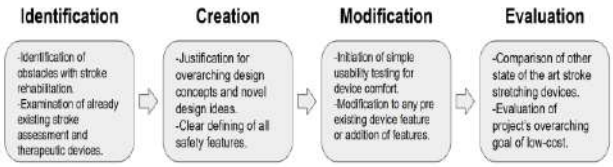

Figure 1. Flow chart of the paper's systematic plan

To stretch the wrist, we relied on a rotating dial system as seen in figure 2A. in which the center of rotation would be placed around the wrist joint, while the dial moves alongside the flexed or extended wrist from a -90° to +90°, with 0° being the wrist positioned straight alongside the forearm. Thus, patients would be able to use a screw to lock their wrist at a certain angle during stretching, while moving their wrist manually by pushing a tab connected to the rotating platform. This rotation system did not stray away from other common wrist stretching devices in the field, but it did emphasize specifically isolating the flexion and extension movement from other motions such as supination or pronation [7]. Figure 3 shows the flexed and extended configurations.

To stretch the fingers, we relied on an inflatable grip system as seen in figure 2B in which patients would grasp a deflated ball that is able to be inflated using a pressure bulb. Though the implementation of an inflatable grip as a mechanism of stretching provided a novel factor to this design, it was based on pneumatic systems that existed in other fields of rehabilitation [8]. As the ball inflates, the hand gripping the ball would also open and extend the fingers. As the ball deflates, the spastic stretch would force the fingers to flex and close the hand. Figure 4 shows the grip handle in two different configurations.

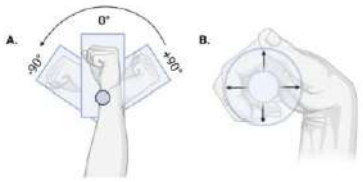

Figure 2. Diagrams for the isolated movements of the device. A) Wrist flexion and extension based on a rotating dial mechanism with the axis of rotation based on the wrist joint. B) Opening and closing of the fingers based on an expanding and deflating grip

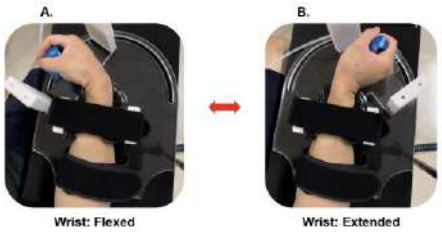

Figure 3. Device at flexed and extended configurations. A) At a negative angle, the wrist is flexed B) At a positive angle, the wrist is extended

A. Design Philosophies

Throughout the design process, multiple factors regarding spasticity, usability, and comfort were considered. However, we prioritized two requirements for the device's operability: independent operation and built-in safety.

Previous iterations of the wrist dial consisted of using a stepper system, in which wrist flexion and extension was only allowed in increments of +5° or -5°. However, we noticed that this design not only made the operation of the device much more difficult but the stretching process much more rigid. Instead, we diverted our design to a free moving 180° dial, with users being able to secure their wrist at any angle. Although wrist stretching devices in the field have varying degrees on just how much the wrist can flex or extend, we determined that 180° proved to be enough range of motion for the wrist to fully extend or flex [9,10]. We also realized that providing a free range of motion for the wrist would be beneficial for most patients, as it spastic limbs may not have been able to move 5° at a time.

Since the device allows for a free range of motion for wrist extension and flexion, users can stretch their wrists freely, it is inherently safe. Since patients are in full control of their wrist with no added force, the likelihood from injury is minimal to none while being able to operate the device independently without external assistance.

The inflatable grip was designed to allow spastic patients to easily operate and adapt to the device. Due to the grip's malleable nature, patients can freely adjust their fingers while the handle expands into a ball. Additionally, as the ball deflates, the spastic fingers dig into the silicone grip, allowing for not only a comfortable grip but also a complete flexion of the fingers. The handle is entirely operated by a simple hand pump, which makes the entire operation easily operable with the other non-spastic arm, which most spastic patients are able capable of [11].

The degrees of freedom provided were enclosed in a structure that would secure the forearm and allow the user to correctly place their wrist and fingers into the proper testing and treatment position each use. Figure 5 shows the three evolutions of the device. To ensure that users can use the device for long periods of time while the device remains suitable for variable degrees of spasticity, it was essential that any muscle tension should be incurred only in the proper stretching zone of the wrist extensors and flexors.

Figure 5. Pictures of early, late, and final stage prototypes

Additionally, certain patients of high spasticity may experience higher levels of discomfort during stretching sessions, so the upper arm should be as comfortable as possible without incurring any additional tension [12]. We wanted to avoid any room for the wrist to supinate or pronate, as well as any other external movements that could allow for compensation of muscle groups. Only through securing the wrist and forearms properly could proper motions be performed through the proper muscle groups, allowing for the affected spastic muscle groups to stretch rather than unaffected muscle groups compensating and alleviating activation [13].

B. Device Safety

Throughout the development of the device, it was important to note that the safety mechanisms were built-into the overall design of the device rather than being an external compartment.

Safety of the device was maintained through its self-moving mechanism, meaning all and any component of the device would move directly by the user, without the interference of any movement from the device. We ensured that the device would not contain any motorized or spring-loaded compartments, with both the dial and hand pump operable through the unaffected arm. We also ensured that the device would not contain any sharp edges through proper sanding of the acrylic, while ensuring that variable padding sizes would be available for small, medium, and large so that padding would not constrict the user's arm excessively. Additionally, the silicone ball and the support structures were tested for structural and material stability by loading excessive pressure / forces physically as well as increasing the overall infill and construction durability throughout the design process.

III. Method

A. Usability Testing

The device went through three development stages. At the end of each stage users were asked to experience the device and provide feedback. Usability surveys were given to healthy users to evaluate factors that affect the device's comfort. In this survey, subjects were asked to rate their experiences on a scale of 0-10 in the criteria shown in Figure 6. At each stage 5 new healthy subjects were interviewed and asked to report their scores anonymously, with a total of 15 participants.

It is essential to note that all data collected was deidentified and no personal health information was collected at all. An IRB exemption has been submitted under category 3, and future studies relating to this project will be enrolled under existing IRB as a modification to IRB protocol #849090. The purpose of the usability tests is not to represent a comprehensive usability test, but rather as a design aid. Although the device is meant for post-stroke patients, we wanted to focus on safety and usability of the device. Prior to testing with a sensitive population, we wanted to ensure our device was usable with a healthy population. While post-stroke patients would face different usability concerns compared to healthy subjects, we wanted to improve the overall usability and comfort of the device, which would translate to post-stroke patients as well. In the future, we plan to confirm that the usability features we added with healthy subjects will benefit the usability of post-stroke patients as well.

In the survey, overall comfort was the overarching criteria that encompassed three subcategories of usability: pain, muscle tension, and device security. Most obviously, pain is an important criterion of usability that helps us prioritize any design failures. Muscle tension, more specifically, unnecessary upper arm tension, was chosen as a key criterion for usability because a wrist and finger stretching device should not incur any tension in the upper arm, most importantly in the biceps, triceps, and deltoids. Device security was also chosen as one of the categories of usability as we wanted to prioritize the device's effectiveness in promoting the correct flexion and extension movement [14].

Alongside the survey, subjects were asked to give feedback on potential design improvements. After each round of surveys, design changes were made to address these concerns.

B. Muscle Activation Testing

After the finished development of the final stage prototype as seen in figure 7, EMG data was collected to analyze if the device was able to properly activate the wrist flexors and extensors, mainly the respective carpi radialis muscle groups. Although we understand that muscle activation will vary between healthy and post-stroke users, the current stage of the project aims to confirm that the device's movements can elicit the necessary muscle groups.

The user was seated comfortably in a chair with the device on their right arm and was asked to perform the flexion and extension movement through the device. The user was instructed to perform their maximal flexion and extension movements in 5 second intervals, starting out with a 10 second baseline of no movement. Raw surface EMG data was from 8 muscles of the upper limb using two four-channel sensor motes (Trigno Quattro, Delsys, Inc., Natick, MA, USA). The selected muscle groups were the biceps, posterior deltoid, anterior deltoid, middle deltoid, triceps, wrist flexors, wrist extensors, and brachioradialis.

To remove any low frequency noise, the raw EMG data was first put through a high pass filter at 10 Hz to remove any low frequency noise. Baseline offset was removed by subtracting the median of the overall signal and the resulting signal was then rectified to correct for negative values. The signal was then passed through an envelope with a window size of 80 to smooth the data for better visualization. A rolling window outlier removal method was applied with a window size of 100 and a threshold of three standard deviations away from the mean of the window. Lastly, for each subject, each of the eight channels was individually normalized to the highest signal value recorded for that channel across all ROM trials for that particular subject. Collected EMG data was then plotted in respect to activation (mV) to trial time (seconds) with the data normalized to the max muscle activation per muscle group.

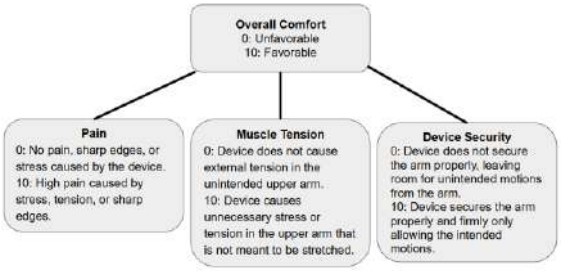

Figure 6. Flowchart of survey questions. The measured criterias were: Overall Comfort, Pain, Muscle Tension, and Device Security

Figure 7. Picture of how the user was seated for EMG collection process

IV. Results And Discussion

A. *Usability Surveys and Improvements*

Although iterations between early, late, and final stage prototypes differed in some respects, each usability survey added a key design change. Figure 9 shows that the Early-Stage Prototype had an average assessment value of 2.6 (comfort), 0.4 (pain), 7.6 (muscle tension), and 2.6 (device security).

One feedback pointed towards the fact that although the device did not cause pain, too much muscle tension was present in the upper arm, most notably the deltoids and biceps. To address this, extended elbow padding was added for an increase in arm security and alleviating unnecessary shoulder tension. This way, users could put the entire weight of their arm onto the device without having to use any force from the shoulders (fig 8 (a)).

We believe that extending the elbow padding prevented the user from exerting any additional forces to keep their arms placed within the device – a design choice that seems to be prevalent in many other arm therapeutic devices [9, 15]. This ultimately helps reduce activation of the upper arm – most notably the triceps, biceps, and deltoids – which may be a priority for higher spastic patients who may need to focus on stretching their wrist and fingers rather than exerting needless energy to simply keep their arm placed within the device – a common design trend in upper limb spasticity assessment devices [10].

Figure 9 shows that the Late-Stage Prototype had an average assessment value of 8 (comfort), 0.2 (pain), 1 (muscle tension), and 9.2 (device security). After making these changes, the user experience improved. This finding helps us understand that reducing muscle tension and pain in the shoulder and elbow muscles and increasing comfort in terms of the secure positioning of the wrist is crucial to designing a more sustainable stretching device. To address this, detachable padding was added for patient variability in wrist sizes for a comfortable and tighter fit. This way, the user's wrists could be properly secured without leaving room for movement (fig 8 (b)). We believe that limiting pronation and supination movement from the flexion and extension movement will allow for proper targeting of the flexor and extensor carpi radialis, aiding in focused stretch rather than the compensation of nearby unaffected muscle groups [16].

Figure 9 shows that the Final Stage Prototype had an average of 9.6 (comfort), 0.06 (pain), 0.4 (muscle tension), and 9.4 (device security). We noticed that subjects were much more comfortable with the more permanent materials (abs plastic / acrylic) used in the final stage prototype as well as the extra stability and reinforcement provided. In addition, subjects found the device much more comfortable to use as well as operate, all while causing very minimal to no pain or unnecessary tension in the upper arm. To address this, we slanted the arm rest, improving overall ergonomics and reducing tension in elbow, biceps, and triceps for longer periods of time. This way, users did not have to exert any force to keep their arm placed within the device (fig 8 (c)). We believe that allowing patients to place their forearms in a slanted slope will allow for a more natural stretching position, in which instead of a 90° elbow joint the user can orient a smaller or larger angle at the elbow, alleviating any tension at the elbow joint. This helps the user focus on the stretching of the wrist and fingers without interference from fatigue or pain from the elbow joint.

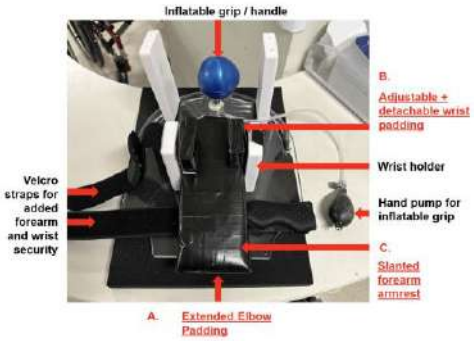

Figure 8. Labeled picture of the final stage prototype. Red and underlined features are key additions added after a usability testing stage.

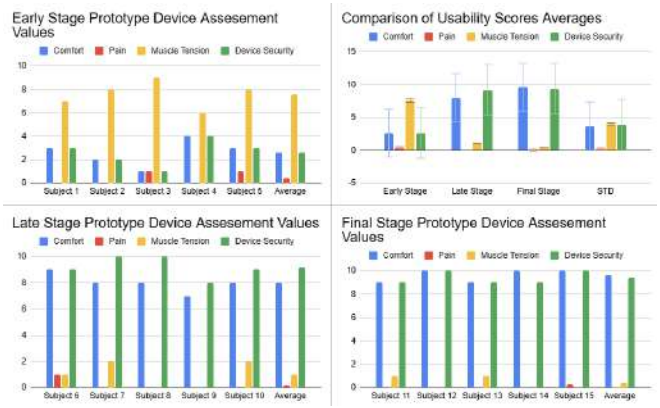

Figure 9. Early, Late, Final and Averages of de-identified pilot usability testing

As seen with Figure 9, each design addition and usability surveys, the device was able to improve its overall comfort through the minimization of pain, decreasing of unnecessary upper arm muscle tension, and increase of device security of the forearm, meaning that the users were able to stretch comfortably and securely without invoking the activation of the biceps or triceps, which are not included in the intended stretching muscles.

B. EMG Data

From the preliminary EMG data, we noticed distinct peaks of flexor and extensor activation between the movements. As seen in figure 10 C, the extensor carpi radiales was first shown to activate for around 5 seconds after the 10 second baseline, which was followed by another 5 second activation of the flexor carpi radialis. This activation pattern of around 5 seconds per movement and muscle group correlates to our movement, as the patient was instructed to first extend then flex their wrists then continue alternating from one motion to the other.

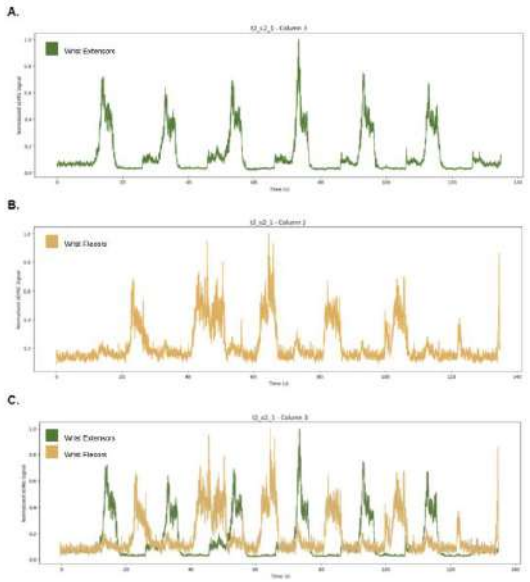

Figure 10. EMG data collected from healthy control during wrist flexion/extension movement. A) muscle activation recorded for wrist extensor. B) muscle activation recorded for wrist flexor. C) Combined extensor + flexor muscle activation data.

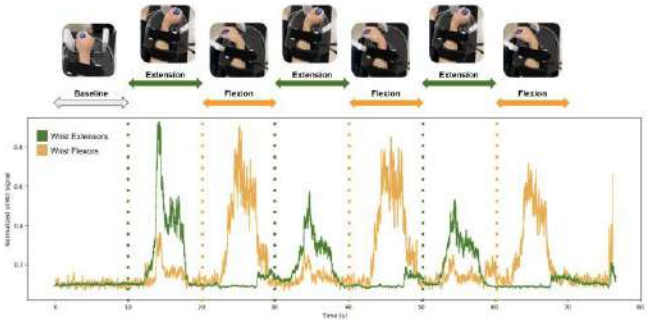

Figure 11. Labeled digram of EMG data representing matching muscle activation (extensor/flexor) and motion performed (extension/flexion).

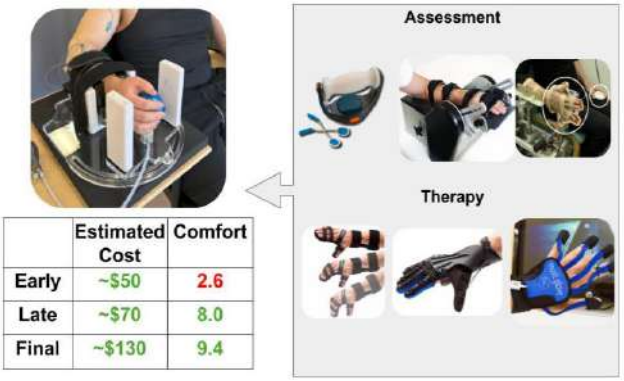

We were able to confirm that the device was able to properly elicit the correct muscle group activation with its corresponding movement. When the user was extending their wrist through the device the extensors were able to activate, while the flexors activated when the user flexed the wrist (fig 11). We also confirmed that the device was able to activate the muscle groups significantly above the baseline recordings, which was the first 10 seconds of the data collection in which there was no movement from the user in a relaxed position.

C. State of the Art Comparison

While the device is still in its early stages of development, the initial purpose of the device was to serve as a low-cost assesement and therapeutic device.

Since the device relies on a passive system that is controlled manually, price is one of the main advantages comapared to some of the state-of-the-art hand spasticity devices. We set out cost threshold to be $780, which was the reported mean total cost of physcial rehabilitation in a study conducted in a cash-based physical therapy clinic by Pulford et Al. [17]. All stages of the prototype had estimated costs to be under the threshold with our final prototype costing around $130, which is significantly less than other types of hand-spasticity devices such as the Saebo Hand Spasticity Treatment Kit (~$335) [18].

Another design advantage to our passive system is its emphasis on self-operability. Our inflatable handle system allows for the user to sllide in their fist through a soft silicon pillar, without having to individually correct the positioining of their fingers as seen in figure 3a. This feature is advantageous compared to the more common glove design, in which users may have much more difficulty putting the glove over their spastic fingers indivdually. Additionaly, common spasticity glove devices such as FlintRehab music glove and the Saeboglove all cost much more than our prototype (~$350-499) [19, 20].

	Estimated Cost	Comfort
Early	~$50	2.6
Late	~$70	8.0
Final	~$130	9.4

Figure 12. Table of estimated cost per prototype and state of the art stroke therapeutic and assesement devices.

V. Conclusion

This paper documents the development of the device through its key early, late, and final stages as well as a verification of the device's ability to properly activate the correct muscle groups. Key requirements considered were that the device be self-operable, affordable, and usable as both a therapeutic and assessment tool. This was achieved. The device's passive system does not rely on any electronics or motors ultimately allow for the device to not only be affordable but safe and easy to operate, showing its novelty in the field of pre-existing devices that traditionally utilize electronic systems [4,9]. Thus, we determined that the safety of the device was adequate and that only hazards were from improper set up of the device.

Additionally, EMG data of the device in-use showed that the device was able to stretch the proper flexor / extensor muscle groups but also compatibility with the commonly used EMG system as an assessment tool for spasticity as well. This shows that the device can work both in-home and in the clinic both as a therapeutic or assessment tool. In the future, we want to test out the muscle activation of post-stroke patients as well, analyzing the differences that may occur from compensation as well as velocity-dependent stretch.

Future directions of the device will focus on the attachment of additional sensors (potentiometer, pressure sensor, load cell) to further help analyze spasticity in a quantitative manner. Although the device will maintain its low cost and independent operation, the attachment of potentiometer and pressure sensors will help us understand the exact pressure enacted by a spastic hand and the velocity of the wrist. Finally, the continued development of this device can also serve as a vital treatment and assessment options for spasticity in low-resource areas – not just in the clinic, but in the home as well.

Acknowledgment

Additionally, this study has been submitted for IRB exemption under Category 3, while any future studies have been submitted for IRB protocol #849090.

We would like to thank the University of Pennsylvania School of Engineering and Applied Science Office of Diversity, Equity, and Inclusion (ODEI) for their support of this project as well as members at the Rehabilitation Robotics Lab.

***Abstract*—Treating post-stroke individuals with physical devices (mechanoceuticals) has produced mild but significant recovery. While it is widely recognized that therapy should focus on movement error, there is currently no model of relearning that can inform the design of longer-term treatment. We present a case study dubbed Error Fields, a personalized robotic therapy for stroke survivors, based on a mathematical model of each person's unique response to error, used to diagnose and address specific deficits. After three days of Error Fields treatment, errors significantly decreased compared to baseline demonstrated by shift in error distributions. In contrast, three days of practice with the robotic system without treatment showed no significant error reduction. Comparing Error Fields sessions to null treatment sessions also revealed significant improvements in error levels.**

***Index Terms*—Personalized Robotic Neurorehabilitation, Stroke Neurorehabilitation, Models of Motor Re-learning**

I. Introduction

Learning is a critical mechanism for post-stroke motor recovery, yet the ability to relearn movement skills varies greatly among individuals. Rehabilitation robotics offers tools that enhance motor recovery, and have shown benefits when used in upper-extremity retraining in the stroke population even in isometric conditions [1]. However, most systems strictly guide the user, which limits exploration, prevents mistakes, and lack personalization for each stroke survivor's specific movement impairments [2]–[6]. This highlights the need for techniques that allow individuals to experience and correct their own errors which can promote learning, adaptation, and neuroplasticity [7]–[9].

Error augmentation (EA) has emerged as a promising strategy to enhance relearning by amplifying movement errors to drive adaptation and has shown significant potential [7]–[10], in upper-extremity rehabilitation [11]. However, EA does not account for individual differences in how people respond to errors; thus, personalized training tailored to each person's error sensitivity is crucial. Building on this principle, we developed a customized technique called Error Fields (EF) training, where users learn by leveraging their own errors. This approach employs a statistical model based on a individual's movement errors, which is inverted to amplify their most frequent errors for targeted training [12]. Preliminary results from our planar-reaching experiment showed that EF training reduces error magnitude in healthy participants compared to those undergoing error augmentation or null treatment [12]. Also EF has been implemented in 3D for neuro-typical subjects undergoing a haptic curl force fields shown that subjects who recieved EF had higher error reduction commpared to null treatment [13]. Despite these advances, planar robotic training lacks the sensory richness and functional relevance of real-world 3D actions. [14]. By contrast, immersive 3D training systems promote natural variability in arm movements—a key driver of motor learning [15], [16]. While EF training has demonstrated superior learning outcomes in planar tasks [12], it has not yet been tested in 3D settings or with stroke survivors. In this study, we evaluated EF training in a 3D robotic reaching task with a single stroke survivor. We hypothesized that EF treatment would reshape error distributions, leading to a significant reduction in errors across sessions. Additionally, we hypothesized that EF training would increase kinematics of subjects affected arm and improve clinical outcomes.

II. Methods

This is a case example of a clinical trial, here we narrate enrollment and protocol policies of the clinical trial.

A. Apparatus

We used the Barret Upper-Extremity Robotic Trainer (Burt®) [17] (Fig. 1a,b), which provides real-time, 3D haptic feedback and forces for unrestricted upper-extremity movements. We also used our in-house made LookingGlass 3D augmented reality system [18]–[20] (Fig. 1a,c) and active shutter 3D glasses that allow the stereoscopic representation of virtual objects, as well as a view of the subject's hands and arms through a semi-silvered mirror. We used Unity® software to provide a real-time graphical interface with the Burt® and monocular cues to the depth [21] (Perspective, Occlusion, Shadow, Relative Height, Texture Gradient) in the scene (Fig. 1a). We matched the viewpoints across subjects to the scene (Fig. 1a) by calibrating the seating and head position to the LookingGlass system as well as the stereoscopic camera system in Unity. The calibration ensured that the cursor (the green object in Fig. 1a) always matched the subject's hand position. We also provided gravity compensation to cancel the weight of subjects arms. We also used Movisense® *Move 4* accelerometer device [22] strapped to the subject's wrist for at-home observation of their arm kinematics.

B. Enrollment

Experimental protocols were approved by the Northwestern University Institutional Review Board (STU0021500). Informed consent was obtained. Eligible participants had to be at least 8 months post-stroke, hemiparetic with some elbow and shoulder movement, and not concurrently receiving any upper-extremity therapy or enrollment in another research study. Subjects were excluded if they have the following conditions: bilateral paresis, Severe tactile deficits using the Two-Point Discrimination Test, Severe proprioceptive deficits using the proprioception screen, Severe spasticity (Modified Ashworth ¿3), Aphasia, cognitive impairment, or affective dysfunction that would influence the ability to perform the experiment, Visual deficits (BIVABA confrontation testing, Snellen eye test, Stereo Fly Test, Star Cancellation Test), diffuse/multiple lesion sites or multiple stroke events, Botox injection to the affected upper extremity within the previous 4 months and Inability to provide an informed consent.

C. Protocol

A cross-over design study in which each participant receives both EF and null treatment is chosen to account for the effect of subject inter-variability. In this study, participants complete a total of 9 visits across nine weeks (Fig. 1e) and participant is randomly assigned to one of 2 groups; Group 1 completes the reaching experiment with Error Fields (EF) applied in visits 5-7, and simple practice (Sham) applied in visits 2-4. Group 2 receives the opposite treatment (Sham in visits 5-7, EF applied in visits 2-4). Upper extremity evaluations are to be completed by a licensed occupational therapist at visits 1 (baseline), 8 (post), and 9 (follow-up) using the Upper Extremity Fugl-Meyer Test (UEFM), Action Research Arm Test (ARAT) and Box and Block Test (BBT) [23].

Subject practice successive 10-cm-long reaches, using a cursor with diameter of 0.5 cm terminating at sphere targets with diameter of 2 cm witin a fixed-size constrained 3D random walk goal-directed reaching pattern (Fig. 1d) in a $20 \times 20 \times 20$ cm box. Subjets were given 5 seconds to complete a reach. Four "Practiced" directions (d_0, d_1, d_2, d_3) as shown in Fig. 1d are seen for the majority of the experiment schedule (Fig. 1f). In order to test generalization of learning we have the subject perform reaching in the unpracticed directions (d_4, d_5, d_6, d_7) which are 180^o opposites of practiced directions (Fig. 1d) in two *"Un-Practiced"* phases of experiment schedule (Fig. 1f). We calibrate the extreme bounds of target positions (Fig. 1d) to a subject's existing movement range such that regardless of handedness the center of medial-lateral axis is in front of the subject's sternum. We believe such a design allows for a true unbiased assessment of any 3D treatment across a subjects existing range of motion.

The most pure evidence for changes in the feedforward motor plan are reportedly observed within the first 300 milliseconds of a volitional movement [24], [25], before visual and proprioceptive feedback has reached the motor cortex. Our primary interest is in assessing changes in the feedforward motor plan, we require a parameter that monotonically increases to track movement progress and detect movement onset in real-time. We selected the path distance of the movement trajectory instead of time because path distance reflects the subject's volitional intent, whereas time is an external metric that can complicate onset detection and movement tracking. We chose for a 10 cm reach, the path distance threshold values of 5 mm and 105 mm based on the aggregates of pilot data from both healthy and stroke subjects, we call this the "launch window". To detect onset in real-time, we set this rule: onset of movement is detected when path distance is bigger than 5 mm and speed is bigger than 3 mm/s. Subject is allowed to plan movements before executing them. At end of the reach, visual and auditory feedback are provided for half a second based on the subjects maximum speed during the launch window. If subjects maximum speed is inside the acceptable range $[0.1976\ m/s\ ,\ 0.5138\ m/s]$ a "good" visual and auditory feedback was presented, other feedbacks in similar fashion are presented for "Slow" and "Too-Fast" reaches. These values were determined based on pilot data of post-stroke subjects for 10 cm reaches. The experiment schedule consists of 7 phases with 590 movement trials (Fig. 1f):

Familiarization phase (#1): subjects are familiarized with the environment and robot making reaches in practiced directions with 10 repeat-per-directions (RPD), data from this phase is not used in analysis.

Baseline phases (#2-3): are placed to make pre-training assessment of error levels for both practiced and un-practiced directions, each of these phases have 5 RPD.

"Evaluation" phase (#4): which has 30 RPD with practiced directions was used to create a statistical profile of movement errors for each path distance during the launch window of movements.

"Training" phase (#5): when a subject is under the "Error Fields" condition they receive EF therapy force (60 RPD, practiced directions). No force catch trials are used to assess learning(16 RPD with a 1/5 chance).

Null phases (#6-7): are placed to make post-training assessment of error levels be made in practiced and un-practiced directions, each of these phases have 5 RPD.

D. Error Definitions

Three types of movement errors were analyzed, all represented in an error vector ($\mathbf{e}(t)$): Extent Error ($\mathbf{e}_{ext}(t)$), Horizontal ($\mathbf{e}_{hor}(t)$) and Vertical ($\mathbf{e}_{ver}(t)$). Errors (Fig. 1g) are described in Error reference frame $[E]$ and where t is path distance. Horizontal and Vertical errors represent the real-time distances of hand position from ideal line connecting start to target positions. Extent Error ($\mathbf{e}_{ext}(t)$) is defined as the difference in position between the ideal hand position, i.e. $x_{MJ}(t)$ described along x-axis of direction frame $[i]$ for a direction d_i according to Flash and Hogan's minimum jerk profile [26], and the projection of the actual hand position on the ideal line. The ideal time of a reach is 650 milliseconds, and extent error measures lead or lag error of subjects in reaching targets. To calculate errors, we first transformed

robot end-effector position $\mathbf{x}(t)$ described in left-handed Unity reference frame $[U]$ (Fig. 1g) to right-handed frame $[i]$ for movement direction d_i described in $[U]$, origin of $[i]$ is strapped to ideal start position $\mathbf{x}_S$ and its x-axis points towards target $\mathbf{x}_T$. Homogeneous transform $\rho_i(t) = T_{iU}\mathbf{x}(t)$ was used where T_{iU} consisted of rotation R_{iU} and translation $\mathbf{p}_{iU}$. Rotation is given by $\mathrm{R}_{iU} = [\mathrm{d}_i, -<\mathrm{d}_i \times \mathrm{g}>, <(-\mathrm{d}_i \times \mathrm{g}) \times \mathrm{d}_i>]^\top$ in which g is the gravity vector described in $[U]$ and $<>$, $\times$ and $^\top$ are unit vector, cross product and transpose operators respectively. Translation is given by $\mathbf{p}_{iU} = -\mathbf{x}_S$. Values of second and third components of ρ_i vector equal values of horizontal and vertical errors. To calculate Extent error $\mathbf{e}_{ext}(t)$, we strapped origin of $[E]$ to $x_{MJ}(t)$:

$$\mathbf{e}(t) = \begin{bmatrix} \mathbf{e}_{ext}(t) \\ \mathbf{e}_{hor}(t) \\ \mathbf{e}_{ver}(t) \end{bmatrix} = \begin{bmatrix} \mathrm{I} & \mathbf{p}_{Ei}(t) \\ \mathbf{0}^\top & 1 \end{bmatrix} \rho_i(t) = T_{Ei}(t) T_{iU} \mathbf{x}(t) \tag{1}$$

where $\mathbf{p}_{Ei}(t) = [-x_{MJ}(t), 0, 0]^\top$. An ideal movement description in $[U]$ follows minimum jerk trajectory and traverses on ideal line connecting $\mathbf{x}_S$ to $\mathbf{x}_T$ (orange trace in Fig 1h), such movement described in $[i]$ traverses along x-axis from 0 to 0.1 according to $x_{MJ}(t)$, however in the error frame $[E]$, an ideal movement trajectory always remains stationary at origin of $[E]$. This is the basis of ideal error distribution Q described in $[E]$ and defined by $Q \sim \mathcal{N}(\mathbf{0}_{3\times1}, \mathbf{0}_{3\times3})$ where $\mathcal{N}(\mu, \Sigma)$ signifies multivariate Gaussian distribution with mean vector μ and covariance matrix Σ.

E. Treatment Forces

During the Evaluation phase (Fig. 1f), errors were profiled during the launch window, according to direction and path distance, to construct a path-distance-dependent ensemble statistic 3-dimensional Multivariate Gaussian distribution of errors for each direction according to the distribution function:

$$p = \frac{1}{\sqrt{(2\pi)^3|\Sigma|}} exp((\mathrm{e}-\mu)^\top \Sigma^{-1}(\mathrm{e}-\mu)) \tag{2}$$

where μ and Σ are ensemble mean and covariance of all movements belonging to direction $\mathbf{d}_i$ during the Evaluation phase. This creates a set of pre-training distributions for each path distance during launch window, we denote that set as $\mathbf{P} = \{P(t) \sim \mathcal{N}(\mu(t), \Sigma(\mathrm{t})) \ \forall \ t\}$. Fig. 1h shows an instance of such distribution for direction d_1 at a path distance during the launch window shown in Unity refrence frame $[U]$ where the yellow dots represent mean of error vector i.e. $\mu(t)$ and yellow ellipsoid shows uncertainty of error i.e. $\Sigma(t)$ for intermittent exposure trial in the Evaluation phase. Fig. 1h also shows ideal movement trajectory $x_{MJ}(t)$ (orange dots) from start to target, and black dot-traces here show error vectors $\mathbf{e}(t)$. During the Training Phase, a therapeutic force vector will be applied during launch. For Error Fields this will be $\mathbf{f}_{EF}(t) = \lambda p(t)\mathbf{e}(t)$ described in $[E]$. λ is a direction-dependent constant corrective gain such that the overall force applied to the subjects hand never exceeds 20 N. Transform T_{UE} were used to apply forces to subject hand in $[U]$ which is shown in Fig. 1h as solid black arrows for a trial at end of training, note that EF force are clearly along direction of error vectors $\mathbf{e}(t)$ and are augmenting error. Sham treatment has no therapeutic force. EF force effectively applies more forces when instantaneous Mahalanobis distance i.e. $(\mathrm{e}-\mu)^\top \Sigma^{-1}(\mathrm{e}-\mu)^\top$ between error $\mathbf{e}$ and pre-training distribution $\mathcal{N}(\mu, \Sigma)$ is small which pushes likelihood of error p closer to 1, meaning subject is repeating a movement error. We hypothesized that by applying EF, post-training error distributions denoted by $\mathbf{R} = \{R(t) \ \forall \ t\}$ would shift away from pre-training error distributions and move closer to ideal distribution Q at origin of Error frame $[E]$ signaling motor learning.

F. Analysis

1) Error Distribution Analysis: Since EF primarily uses distribution of errors along a movement direction to apply therapy forces, we also created a novel assessment to quantify shifting of distributions. We measured distance of all distributions in the pre-training set $\mathbf{P}$ from the ideal distribution Q. We chose Wasserstein-2 distance metric for multivariate Gaussian distributions [27] with considers mean and variability to calculate distance between two distributions. Since we always want to calculate distance of an error distribution from ideal distribution Q, the equation of Wasserstein-2 distance simplifies to $W_2(P(t), Q) = \sqrt{||\mu_{P(t)}||^2 + \mathrm{Tr}(\Sigma_{P(t)})}$. Essentially distance is squared root of sum of squared norm of mean and summation of all error variances. We calculated such distances for all members of pre-training set and post-training set. We declare the subject has "learned" if distances of pre-training distribution from ideal distribution are higher than those of post-training distributions. We declare a worsening for the reverse situation.

2) Trial-to-Trial Error Reduction: : We used following metrics for each trial: "Maximum Error Amplitude" i.e. $max(||\mathbf{e}(t)||) \ \forall \ t$ & "Launch Deviation Angle" is angle between the vector starting at position of movement onset and position at first speed peak and the ideal line. We used median bootstrapping with replacement (1,000 iterations) to estimate errors. We then compared overall error levels and error reduction across sessions under EF and Sham using bootstrapped error estimates.

3) At-Home Kinematics Analysis: We performed signal conditioning on acceleration by wavelet de noising, removing mean and passing through a band-pass filter ($[0.5\ 12]\ Hz$). We then analyzed distributions of acceleration and calculated differences across histogram counts.

III. Results

We enrolled a 55-year-old male with hemi-paretic chronic stroke who was left-hand affected but right-hand dominant.

A. Error Distributions Improved After Error Fields

Fig. 2a shows the medians of error distribution distances in pre- and post-training for each practiced direction. Although on some treatment visits post-training distances were higher than pre-training distances, the overall trend demonstrates an

error reduction and shifting of error distribution towards the ideal distribution. To be specific distances of distributions at the end of EF treatment week were significantly closer to ideal than distances of distributions on baseline visit by 1.5 cm (Kruskal-Wallis $p = 0.02$, $df = 1$, $F = 5.3$, $CI = [0.6, 7.4]$). Fig. 2a also shows that subject retained learning when we compare pre-training distances at baseline visit to pre- distances on treatment visit 4 which is the begin of Sham treatment week (Kruskal-Wallis $p = 0.0209$, $df = 1$, $F = 5.3$, $CI = [0.61, 7.3]$). However when we compare distances of distributions from baseline to end of Sham treatment week, no significant difference is observed (Kruskal-Wallis $p = 0.185$, $df = 1$, $F = 2.08$, $CI = [-0.89, 5.89]$) signaling that simple repetitions were not enough. A significant difference in distribution distances was observed when baseline and post evaluation visits are compared (Kruskal-Wallis $p = 0.02$, $df = 1$, $F = 5.332$, $CI = [0.6, 7.39]$), this shows overall improvement due to both treatment and getting better at task.

B. EF treatment week shows superior Error reduction

We analyzed maximum error amplitude and launch deviation angle using bootstrapping, due to page limitation we only present results for maximum error amplitude, launch deviation angle results showed very similar patterns. Fig. 3 shows that analysis across difference section of experiment schedule. The comparison plots 3b,e,h,k show comparisons of error levels within EF treatment week, comparisons 3d,g,j,m show comparisons of error levels within Sham treatment week and comparisons 3c,f,i,l show comparisons of error reduction under EF and sham treatments. Comparisons in Fig. 3c,f,i,l show that Error Fields has significantly higher reduction than Sham treatment when comparing baseline phase to null phase (Kruskal-Wallis $p < 1 \times 10^{-10}$, $df = 1$, $F = 418$, $CI = [477, 579]$). Also EF treatment had significantly higher error reduction than sham when comparing early training to late training (Kruskal-Wallis $p < 1 \times 10^{-10}$, $df = 1$, $F = 49$, $CI = [130, 231]$) although this was to be expected given that EF augments some errors. Comparing baseline and null phases in the un-practiced directions show EF treatment had lower reduction compared to Sham treatment (Kruskal-Wallis $p < 1 \times 10^{-10}$, $df = 1$, $F = 385$, $CI = [-557, -456]$). Another interesting find is that when comparing late-evaluation to null phase, EF also had lower error reduction compared to Sham (Kruskal-Wallis $p < 1 \times 10^{-10}$, $df = 1$, $F = 385$, $CI = [-557, -456]$). To save space, we are not presenting statistics of within-week error levels, although significant lines drawn on Fig. 3.

C. At-Home Changes of Kinematics

Fig. 2b,c,d show log-normalized distribution of subject's acceleration after baseline visit, visit 4 (end of EF treatment week) and visit 7 (end of Sham treatment week). Fig. 2e shows difference between counts on each bin between end of EF treatment and Baseline visit, Fig. 2f and g which show differences in counts from baseline to end of EF week and Sham week respectively, all show worsening in histogram counts. We cannot determine if reduction of acceleration is result of practice with robot or not.

TABLE I
CLINICAL SCORES

Evaluation Visit	ARAT	UEFM	BBT
Baseline	7/57	17/66	0/150
Post	6/57	17/66	0/150
Follow-Up	7/57	17/66	0/150

D. Clinical Assessments show no change

No changes are seen in the clinical scores (table I).

IV. DISCUSSION

This study is part of larger blinded, randomized controlled trial, and compares the reduction of movement errors, shifting of error distributions and across 2 training conditions each with 3 sessions: Error Fields personalized therapy, and null treatment (Sham) while practicing three dimensional reaches. Although the results generally support the effectiveness of the Error Fields treatment over simple practice, this support is not without reservations. For example reduction of distances of error distributions evaluated by our Wasserstein distance analysis, from begin of EF week compared to its end (Fig. 2a) although positive (apprx. 5 mm) is not significant. Also the overall decrease of distances could be at least partly due to practice. This will be further scrutinized when we analyze performance of other subjects who receive Sham treatment first and EF treatment later. Also distribution analysis of subject's kinematics while at home, provides mixed results. Although improvements attributed to EF or practice were observed, they did not reach the Minimum Clinically Important Difference (MCID), as indicated in table I. However this study is meant to assess feasibility of this EF treatment for stroke subjects rather than a longitudinal investigation. In Fig. 3e, the reduction in errors for the EF condition was smaller compared to the Sham condition when late-evaluation were compared against the null phase. This may be because the three EF therapy sessions occurred earlier in time, possibly allowing improvement by pure practice during the EF evaluation week. By the time the Sham sessions took place, these improvements had likely stabilized, resulting in a smaller relative reduction in error levels for the EF condition. Also, when comparing the un-practiced baseline to the un-practiced null phase, EF displayed a lower reduction in errors (Fig. 3l). This could be due to the fact that the un-practiced directions were opposite of those that had been practiced, and EF treatment was administered only to practiced directions. As a result, the generalization of learning to un-practiced directions was negatively affected.

Overall, these preliminary findings from just stroke survivor validate the foundations for our larger study with our novel personalized robotic treatment and we anticipate stronger trends and analysis to be presented when the results of our larger clinical trial are presented.

***Abstract*— Based on recent advancements in neuro-adaptive control, we evaluated a novel iterative algorithm for generating customized training forces. The objective was to study the motor adaptation required to compensate for robot-generated perturbations during an upper-limb reaching task. We hypothesized that the adaptation process would induce changes in the brain's feed-forward command, dynamically reshaping the neuromuscular system to refine movement patterns and result in trajectory alterations. The results indicate that after a training period with these robot-generated forces, trajectories undergo modifications due to internal model adaptation, leading to improved performance measured in terms of position error. This experiment explores motor learning in different directions and compares two conditions: 1) curl force field, a velocity-dependent perturbation applied to deviate trajectories, and 2) Error Field force, a customized force specifically designed to address and correct trajectory errors. The findings highlight the effectiveness of the Error Field force in enhancing motor learning and show the potential of customized robotic perturbation forces for improving motor performance in personal activities and advancing neurorehabilitation techniques.**

I. INTRODUCTION

Robot-assisted training offers significant potential for enhancing motor skills and facilitating rehabilitation by providing highly accurate, sustained practice over long periods of time, automatically measuring progress, and producing a wide range of forces and motions. All of these can be implemented to facilitate learning, including the recovery of multi-joint arm coordination, which is frequently lost after stroke, spinal cord injury, or traumatic brain injury.

This study investigates how robot-generated forces, that augment errors based on individual trajectory deviation patterns, can enhance motor adaptation in upper-limb movements. We hypothesize that participants trained with the Error Field (EF) force will exhibit greater error reduction compared to training without it. This study employs an Error Field paradigm where the system collects real-time kinematic data from the participant's movements and generates forces designed to disturb the arm motion during the reaching task exercises [1], [2]. Conducted with 10 neurotypical subjects, it serves as a preliminary investigation for a larger study involving a broader range of reaching points and a stroke survivor population, along with [2] and [3]. Previous research suggest that subjects learn an internal model of the perturbing force field rather than simply learning an appropriate temporal sequence of muscle activation [4], [5]. The first experimental evidence of internal models in motor learning emerged from studies on reaching movements in force fields. These experiments revealed that subjects gradually developed the ability to predict and cancel the applied forces along their trajectories [6]. Furthermore, when the force field was suddenly removed the subjects exhibited after-effects, unintended deviations that provided evidence of an induced internal model adaptation [7]. These after-effects demonstrate that individuals do not simply react to perturbations but learn to predict their functional form, altering the dynamics of the controlled system [6].

In this study, we investigated how the customized Error Field force enhances motor learning in the upper limb, focusing on the two forces applied during the experiment:

1) *Curl force field:* A velocity-dependent perturbation that scales with movement speed to simulate spasticity-related motor impairments in the neurotypical population [8].
2) *Error Field force (EF):* A force based on the subject's trajectory errors, where the robot identifies hand deviations from the ideal path and applies force according to the error distribution. The EF paradigm operates on the principle that emphasizing errors during training enhances learning more effectively than directly correcting them [9].

The concept of error is central to this work and is defined as the deviation of the actual movement trajectory from the ideal trajectory during the experiment. The analysis focuses on the error amplitude (also known as extent error), which represents the difference between the hand's position at each time instant and the ideal trajectory profile, defined by the minimum jerk model [10][11].

II. MATERIALS AND METHODS

The experiment involved reaching tasks where participants were asked to reach a target appearing on the screen with their dominant hand while holding the end effector of the BURT robot, seen in Fig. 1.

A. Participants

Ten subjects ranging in age from 22 to 30 years participated in the study (9 right-handed and 1 left-handed). The inclusion criteria were that participants had to be 18 years or older, had no history of stroke, and were capable of providing informed consent. The exclusion criteria were

participants with severe medical conditions, impairments in upper extremity movement, range of motion, strength, or coordination, or visual deficits that could have impacted the experiment. This study was approved by the Northwestern Institutional Review Board (STU00215000), and participants provided written informed consent.

B. BURT robot

The study employed the b.u.r.t.® upper-extremity robotic training (BURT) [12], a three-degrees-of-freedom robotic arm that provides real-time 3D haptic feedback and forces. This design transmits torque to the joints through a system of cables connected to motors, all of which are located at the robot's base. Its lightweight design and high backdrivability ensures efficient force transmission and control [13]. The system is user-friendly, easy to access and offers a large adjustable range of motion. The measurement apparatus involved the participant sitting on a chair placed in the same position relative to the screen and robot, with always the same head positioning with respect to the LookinGlass for consistency (Fig. 1).

C. LookinGlass

LookinGlass is the name of the augmented reality interface used with the BURT and was employed to project the reaching task game in a three-dimensional view [14], [15]. The system consists of two coupled panels: the top panel is a 3D television that generated the image, while the bottom panel is a see-through mirroring glass, allowing the user to see their hand behind it (Fig. 1). A pair of active 3D glasses enabled the perception of the 3D image. The main advantages of this system are its portability, ease of setup, and adjustability to the user's height, making it versatile for various applications.

D. Experimental protocol

The experiment involved a planar reaching task with a series of targets positioned within a defined 20 cm squared workspace, aligned horizontally in front of the user's chest, allowing free arm movement. Targets were sequentially generated using a random walk pattern, constraining movements to two sets of three directions, classified as practiced and unpracticed. These directions, visible in the colored radial arrows in Fig. 1, Fig. 2 and Fig. 3, represented the minimum number of movement directions to ensure adequate plane exploration. The experiment consisted of 560 trials, with each requiring a straight 10 cm hand movement from a starting position to a target. To mitigate muscle fatigue and maintain performance, every 15th trial there was a rest period with no movement required, lasting up to a minute and a half. The 560 trials were divided into nine phases, each serving a distinct purpose in the study, as detailed below and visualized in Fig. 2.

1) *Familiarization:* This phase consisted of the first 32 movements in the practiced directions, exploring the workspace without any applied forces. It allowed the participant to get familiar with the robot and the visual interface.
2) *Unpracticed Intermittent Exposure:* Involved 32 movements in the unpracticed directions. A curl force was applied intermittently to one randomly selected movement in each group of five consecutive movements.
3) *Baseline:* Consisted of 16 reaching movements in the practiced directions, without any perturbation forces.
4) *Intermittent Exposure:* 160 trials in the practiced directions with the curl force applied to one randomly selected trial in each group of five consecutive trials.
5) *Training:* This phase differentiated the EF and Control group protocols as follows: in the EF group, the EF force was applied in addition to curl force in 190 randomly selected trials, while the simple curl force trials were still present across the phase. Additionally, some trials had no force applied. In contrast, the Control group received only the curl force, with no EF force applied.
6) *Post Force-On:* 16 trials in the practiced directions with the curl force always on.
7) *Unpracticed Post Force-On:* 16 movements in the unpracticed directions with the curl force always on.
8) *Post Force-Off:* 16 trials in the practiced directions with no force.
9) *Unpracticed Post Force-Off:* 16 trials in the unpracticed directions with no force applied, marking the end.

Fig. 1. Experimental set-up showing the participant holding the BURT's robotic handle while performing the task, displayed on the LookinGlass screen via 3D glasses. The multi-colored radial arrows on the right represent movement directions performed during the experiment, with blue, yellow, and red for practiced directions and green, orange, and purple for unpracticed directions. The bottom right plot shows a subject's reaching trial example with forces on, with the hand icon marking the start position, the trajectory ending at the target position, a dashed line for the ideal path, and the actual movement shown.

E. Intervention

The robot program was developed in Unity game engine, providing both a graphical front-end and algorithm back-end. In order to perform the experiment correctly, subjects were instructed to perform the 10 cm target reaching movement with a quick launch speed to prevent unnatural muscle contraction, which could affect the feed-forward motor command essential to the study. Then a color-based visual feedback at the target indicated whether their peak launch speed fell within the 0.28–0.44 m/s desired range, where range values have been determined from aggregate of pilot data based on the velocity-dependent curl force magnitude produced. During the experiment participants first experience a velocity-dependent curl force field, designed to simulate the spasticity-related conditions by inducing velocity-triggered trajectory deviations resembling involuntary muscle contraction. They were randomly assigned to two groups: the Control group, which received only the curl force field, and the Error Field (EF) group, which experienced both the curl force field and the additional EF (training) force. Initially, the curl force field was applied intermittently in a semi-randomized pattern, while during the training phase, it was consistently applied to most movements. The curl force field f_C was calculated as follows:

$$f_C = B\dot{x} = \begin{bmatrix} 0 & 0 & -\lambda \\ 0 & 0 & 0 \\ \lambda & 0 & 0 \end{bmatrix} \begin{bmatrix} \dot{x_1} \\ \dot{x_2} \\ \dot{x_3} \end{bmatrix} \tag{1}$$

where λ is a constant value that regulates the environment's viscosity (calibrated to ensure the total generated force does not exceed 20 Newtons), and $\dot{x}$ represents the velocity, obtained as a derivative of the position along the three spatial directions. When the curl force field is applied during a specific trial, it remains active for the entire duration of the movement. Since this force depends on velocity, it is unpredictable because when you first visualize the target and prepare to start the movement, the velocity and thus the force is zero, preventing the upper-limb's pre-compensation and consequent involuntary contraction.

The Error Field force $f_T(t)$ is defined as follows:

$$f_T(t) = \lambda p(t) e(t) \tag{2}$$

and unlike the curl force field, it is not velocity-dependent but instead it is proportional to the probability of error $p(t)$, the error matrix $e(t)$ and the viscosity factor λ, based on [1], [2], [16]. The Error Field force is intended to affect only the feed-forward component of the movement, and is therefore applied exclusively during the launch phase, approximated as the first 300 milliseconds following the movement onset in [17], [18].

F. Data analysis

Data analysis was performed in Matlab (MathWorks, Inc., Natick, MA), generating a file for each subject with detailed movement data, including timing, phase, arm position, target coordinates, velocities, applied forces, and trajectory errors. The analysis focused on error amplitude, measuring hand deviation from the ideal trajectory, as it effectively captures both position and velocity. Particularly, it was analyzed only the launch phase (first 300 ms from movement onset), in order to study the feed-forward control. To avoid skewing results computing the averages with near-zero values at movement onset, it was considered in the analysis only the maximum value of the errors. A decrease in error amplitude across trials would support the motor adaptation hypotesis, reflecting improved accuracy with practice in particular during the Training phase. The statistical analyses performed involved a paired t-test and a non-parametric bootstrap, with a 95% confidence interval and an α value of 0.05, with normally-distributed data.

III. RESULTS

The EF group exhibited a significantly higher error reduction during the Training phase compared to the Control group (black dots/circles in Fig. 3, early vs late training comparison), along with significantly larger induced after-effects (Fig. 4), demonstrating the efficacy of the exercise in enhancing motor control and validating the benefits of EF treatment for neuromuscular adaptation. The following sections present the key research questions and corresponding analyses to assess the effectiveness of the Error Field (EF) force.

A. Does the curl force field cause error?

To mimic the spasticity-related conditions observed in patients with motor deficits, we applied a velocity-dependent curl force. Its effectiveness was validated by the direct effects, which are errors increase when participants first encountered the perturbation, particularly observable during the Intermittent Exposure phases when the force field was intermittently activated. The amplified error amplitude in these phases, visible in the circled-dots in Fig. 2, highlights the perturbation's impact on movement trajectories.

B. Does the Error Field cause larger error reduction?

To evaluate whether the Error Field (EF) group exhibited greater learning due to the additional EF force during training, we analyzed error amplitude across trials. As shown in Fig. 3, the EF group (filled dots) demonstrated a greater error reduction during the Training phase compared to the Control group (circles). This reduction was significantly higher for the EF group (1.2 cm average) than for the Control group (0.27 cm average) across all movement directions (statistical p-value < 0.05), as seen in the early vs. late-training comparison (black dots vs. black circles).

Focusing on specific directions in the Training phase in Fig. 3 for the EF group, the forward direction (blue) showed a clear and substantial reduction in error, far outpacing the trend observed in the Control group, where performance actually worsened across the phase. In the back-right direction (yellow), the EF group demonstrated a high and fast error reduction, clearly visible in the descending regression curve. Interestingly, the Control group also exhibited a similar

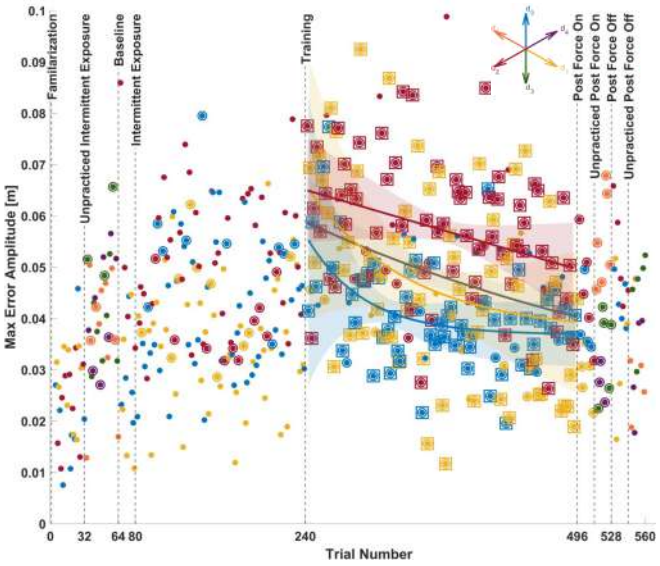

Fig. 2. Plot of the maximum error amplitude during the movement launch of each trial throughout the experiment, collected from one EF group subject. Each dot represents the maximum error per trial, with colors for directions and shape for the condition: simple dot (no perturbation), dot with a circle (curl force applied), and dot with both a circle and square (curl force + training force). During the Training phase, four exponential regression curves depict error trends, with shaded areas for standard deviation. The black curve represents the regression fit across all directions.

trend, despite being exposed only to the curl force field and expected to adapt less than the EF group. This suggested that the training force did not significantly enhance error reduction in the back-right direction. Therefore, the back-left direction, which showed the highest error amplitude on average, did not exhibit any error reduction throughout the training phase, indicating no learning in that direction. However, this result may have been influenced by one particular subject in the EF group, whose error in the back-left direction dramatically increased during the training phase, altering the overall trend for the group. This subject was treated the same as all other participants and was not excluded as an outlier, which may have influenced the overall tendency of the EF group in the back-left direction, especially given the small group sizes and high inter-subject variability. Fig. 2 clearly shows that the EF subject analyzed there demonstrated a noticeable error reduction in this direction (red), a pattern also observed in other subjects of the same group. This highlights the limited statistical power of studies with small sample sizes, which are highly susceptible to inter-subject variability.

Another effect of motor adaptation is illustrated in Fig. 4, which depicts the distribution of error with speed in the context of the speed-accuracy trade-off, originally introduced by Fitts' law [19]. The observed decreasing accuracy with increasing speed validates this principle. A comparison of force-on trials in the pre- and post-training phases (Intermittent Exposure and Post Force On) further highlights this effect. In fact, the top two subplots in that figure show that the EF group (left subplot) achieved greater accuracy improvements after training, particularly in trials within the targeted launch peak speed. This suggests that training with the Error Field force enhanced motor adaptation to the curl force field, resulting in more refined movement patterns under the spasticity-simulated condition, where the force field remained active in all analyzed trials. In other words, participants achieved higher accuracy in the presence of simulated spasticity. Additionally, trajectory rose plots reveal that the EF group demonstrated greater accuracy, with reduced movement deviations, especially in directions associated with higher learning, such as back-right and forward. While both groups showed similar accuracy improvements in the forward direction, the EF group exhibited a more pronounced improvement in the back-right direction. However, in the back-left direction, results were skewed by that one EF subject whose performance unexpectedly declined across training, disproportionately influencing the data for that direction.

Fig. 3 illustrates the pre- and post-training error data, during the Intermittent Exposure and Post Force On phases. This analysis revealed that the control group showed no improvement in terms of error amplitude, as the median error increased from pre- to post-training. In contrast, the Error Field group maintained a steady median error, which decreased slightly, though not enough to conclude a significant reduction.

C. Does training affect unpracticed directions?

Another critical aspect of motor adaptation was assessing the training's effects on unpracticed directions, which provided valuable insights into generalization, a key indicator of learning [8]. While the Training phase focused solely on the standard directions, subjects were also required to perform movements in unpracticed directions during both pre- and post-training scenarios. The Unpracticed phases shown in Fig. 2 (Unpracticed Intermittent Exposure, Unpracticed Post Force On and Unpracticed Force Off) illustrated a small but notable averaged reduction in error for these unpracticed directions, pointing toward potential generalization effects. However, the observed improvements were limited, likely due to the induced after-effects immediately following the sudden removal of the force field. These afte-effects deviated the trajectories and influenced the results, masking the potential benefits of training. A longer post-training phase with forces-off would have been ideal to allow the induced trajectory deviations to wash out and provide a clearer picture of how movement precision improved in unpracticed directions, offering stronger evidence of generalization and the lasting impact of training.

D. After-effects and washout

The experimental protocol included several no-force trials, even during the first phases with the forces on like Intermittent Exposure phase and Training phase. These no-force trials, particularly in the final phases of the experiment, were crucial for assessing residual changes in the internal model

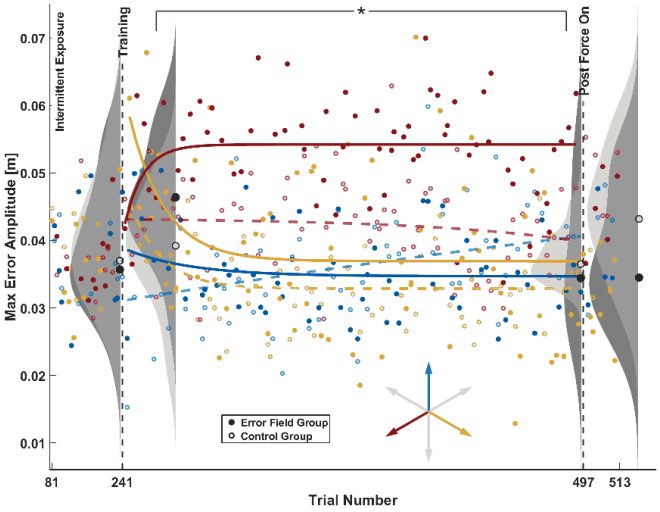

Fig. 3. Maximum error amplitude during the launch phase for all subjects across pre-training, training, and post-training. Each dot represents the median maximum error per trial, showing overall trends for each group. Solid dots and solid lines indicate the Error Field group, while semi-transparent circles and dashed-lines represent the Control group, with exponential regression fits. Colors differentiate the directions, with black dots/circles representing direction-independent analysis. The background shows a distribution analysis comparing pre- vs. post-training and early vs. late training. A horizontal line with an asterisk marks significant error reduction differences between groups.

induced by the training forces. By comparing these trials to their corresponding pre-training phases, any observed differences in error behavior could be attributed to the influence of the forces on the internal model, demonstrating the presence of after-effects as a phenomenon of anticipation of the force with an adjustment in the feed-forward joint torques [7]. This phenomenon was illustrated in Fig. 4, revealing a clear increase in error, manifested as a decline in accuracy, during the no-force trials between the pre- and post-training phases. This trend suggested the presence of after-effects and a shift in behavior consistent with the expected internal model adaptation. Notably, these after-effects were significantly bigger in the Error Field group compared to the Control group, as shown in the bottom plots of Fig. 4 (statistical p-value < 0.05). Comparing the Baseline and Post Force Off phases, identical no-force conditions before and after training, the blue dots (Baseline) showed higher accuracy than the red dots (Post Force Off) for the Error Field group (bottom-left subplot). The related rose plot, which displayed the median movement trajectories for all subjects in the practiced directions, further highlighted this effect. In the Error Field group, the post-training trajectories hooked in the opposite direction of the pre-training trend for some directions, strongly indicating induced after-effects. This decline in accuracy and the hooked trajectory could be attributed to the internal model adaptations to the training forces, supporting our hypothesis. However, the limited number of no-force trials at the end may have prevented washout of the after-effects, preventing re-adaptation.

IV. DISCUSSION

This research explores an adaptive training approach in robot-assisted motor learning, focusing on implicit learning through repeated hand-reaching movements under perturbing forces. These forces initially disrupt task performance, increasing execution error and prompting the motor control system to adapt and compensate for them. Over time, this adaptation resulted in improved movement trajectories as the participants learned to better control the movements after practice. The terms motor learning and motor adaptation are used interchangeably in this study, as in [5], described as the motor system continuously updating its model of the environment to compensate for external perturbations. This method targeted the nervous system to generate new motor commands, recalibrate control mechanism and enhance performance under force disturbances. This adaptive trick effectively encourages motor system adjustments, demonstrating the potential for improving motor learning outcomes. Furthermore, the study provides empirical support for existing theories of force-field adaptation and feed-forward control [7], [16], [8], applying them to practical, robot-assisted interventions.

Despite validating the main hypothesis, certain uncertainties remain. Specifically, the curl force field simulates spasticity-related motor impairments by introducing a velocity-dependent distortion, serving as a preliminary model. However, spasticity varies across individuals due to complex factors, such as afferent input to spinal motor neurons, which our model does not account for. Nonetheless, as shown by the direct effects in the Intermittent Exposure phases, the curl force field fulfilled its intended purpose of creating an unpredictable velocity-dependent perturbation. Additionally, the EF force was designed to act within the first 300 milliseconds of movement to minimize feedback contributions from the nervous system. Although the duration may have been sufficient for spinal reflexes to influence outcomes [7], [20], synchronization challenges arose due to differing frequencies between Unity's internal clock and the robot's controller clock, leading to minor delays in force application. While these delays were small, on the order of a few milliseconds, they compensated across sampling periods, ensuring no significant impact on the study's findings.

This experiment assumes that the small number of participants minimizes the impact of variability, though individual differences in movement execution and musculoskeletal biomechanics introduce inherent variability. Variations in arm configuration affect muscle usage and responses to applied forces, ranging from no reaction (the ideal scenario) to stiffness adaptations that alter mechanical properties. Different body biomechanics introduce mass, inertia, and strength variability between subjects, while handedness adds another source of uncertainty since a left-handed subject has a different arm biomechanical alignment with the movement directions compared to a right-handed subject. Additionally, the hour-long duration may cause fatigue, leading participants to adjust their posture, such as changing the distance

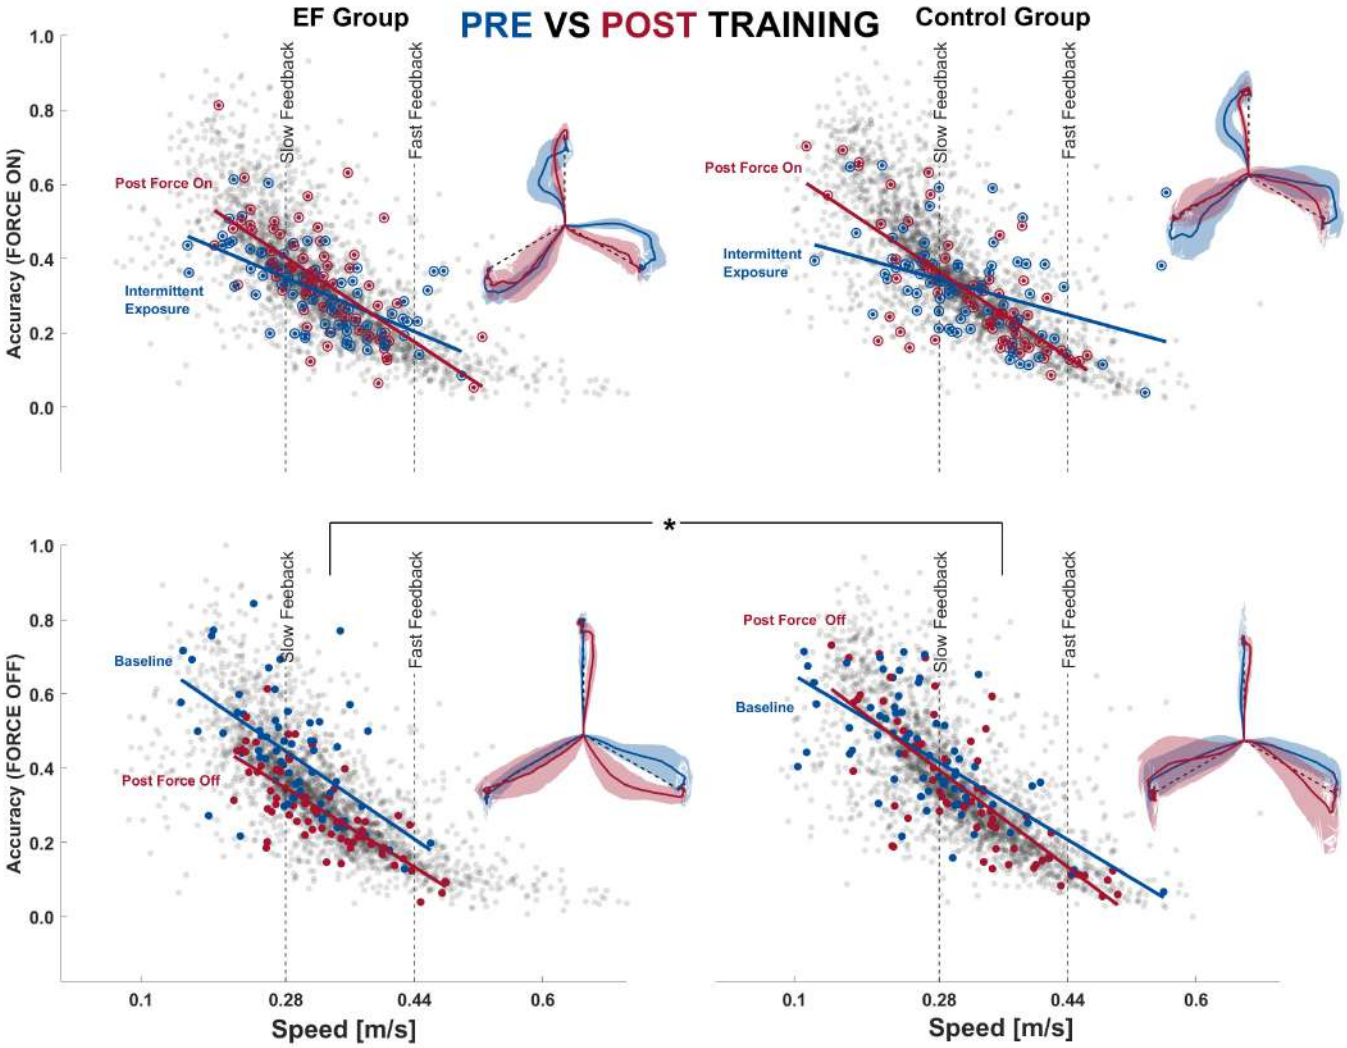

Fig. 4. Speed vs Accuracy trade-off plot shows that after training with the EF force, the EF group improved their reaching accuracy under the curl force disturbance and experienced higher after-effects when it was suddenly turned off. This figure shows the distribution of maximum error amplitude during launch relative to speed, comparing pre- and post- training for EF (left side) and Control (right) groups. The upper plots compare pre- and post-training under the curl force, while the lower plots show the same for no-force conditions. Each subplot includes trajectory plots illustrating movement deviations due to training. The x-axis represents speed, with vertical dashed lines marking the feedback range for slow and fast movements. The y-axis shows accuracy, scaled from 0 (the worst performance across all the trials for all the subjects) to 1 (the best), obtained as the inverse of error amplitude in a logarithmic scale. A horizontal black line with an asterisk marks statistical significance. Red and blue indicate pre- and post- training phases only and are not associated with movement direction.

between the elbow and body, further influencing movement patterns. These factors underscore the complexity introduced by individual-specific characteristics, such as arm configuration, force perception, and fatigue-induced adjustments. Recognizing and accounting for these influences is essential for accurately interpreting the results within the context of the experiment. The results obtained confirmed the main hypothesis, as shown in the previous sections. The EF force is effective, it induces a higher error by deviating the hand's trajectory when they are first interfaced, and then going on with the trials and familiarizing with the forces (conscious or not about the presence of a robot-generated perturbation) the subject starts to improve the performances and the error decreases. In Fig. 3 and the individual case in Fig. 2, we observed that the back-right movement shows a greater potential for learning, as indicated by a larger and faster reduction in error during the Training phase. Similarly, the forward movement also shows evidence of motor learning, and it exhibits the most significant discrepancy in learning rates between the two groups. This difference in learning can be attributed to the fact that anterior-posterior movements are more frequently performed in daily life, when we reach to grab objects on the table for example, making individuals more proficient at executing them and thus more resistant to perturbations. Additionally, the greater error observed in the back-left movement can be explained by the biomechanics of arm movement described by the stiffness ellipsoid: movements along the forearm's longitudinal axis tend to have

higher stiffness, while those perpendicular to it exhibit lower stiffness, making them more susceptible to the effects of perturbations [21].

Robot-assisted training offers the advantage of repeated, monitored practice over extended periods, progressively improving movement accuracy. Previous studies [22], [23] have demonstrated success in using robotics for rehabilitation, assessment, and training. Adaptive training serves as a promising addition to rehabilitation strategies. While conflicting methods exist for treating stroke and brain injuries, some advocating for assistance in error reduction in reaching movements and others for resistance, objective testing using robotic tools is still lacking. It remains unclear whether assistive or resistive forces are more effective, with this study focusing on the latter approach.

The significance of incorporating implicit learning through robot-assisted approaches is striking. This methodology enables individuals to acquire skills with reduced attention and motivation compared to explicit practice methods like pattern tracing. Notably, the concept of applying implicit learning techniques is now being explored in a preliminary manner within the context of post-stroke rehabilitation [24]. The process of implicit learning occurs unconsciously, without explicit awareness of what has been learned [25], and often does not demand full conscious attention. Moreover, the recall of implicitly acquired knowledge tends to be more automatic in nature [26]. Implicit learning is associated with distinct neural pathways [27], [23] that have evolved earlier than the brain regions involved in explicit learning [28]. To conclude, the personalized robotic training implemented in this study may provide an efficient way to induce motor learning that can be used as a guidance for rehabilitation, sport training or other general physical activities that involves motor control.

***Abstract*— To improve exoskeleton acceptability, there is increasing interest in soft actuators that operate safely near the human body. Dielectric elastomer actuators (DEAs) are particularly promising due to their silent operation and high energy density. In this study, we evaluate the stress and strain generation capabilities of the latest version of commercially available stacked dielectric elastomer actuators (SDEA-1550s) for rehabilitation robotics. This demand for soft, lightweight, and noiseless actuators is especially critical in pediatric applications, where current systems often lack a natural feel and suffer from low user acceptance. We investigated the pushing and pulling forces of SDEAs under two conditions: isometric contraction and free-standing. In isometric tests, peak forces reached 32.82 N and 28.75 N at 1200 V for compressive (pulling) force and tensile (pushing) force, respectively. In the free-standing setup at 800 V, the actuators achieved 1.61 mm of displacement in 0.038 seconds, with a peak strain rate of 4232.4 %/s, demonstrating rapid contraction. Notably, this study reports, for the first time, the capability of SDEAs to generate bidirectional force—both actively (pulling) and passively (pushing)—further differentiating their performance from other alternative actuators. These results highlight the enhanced stress and strain generation of SDEAs, reinforcing their potential as artificial skeletal muscles. Their integration into rehabilitation robotics—including biomimetic exoskeletons—aims to improve functionality and user experience, particularly in pediatric rehabilitation.**

Keywords— Rehabilitation robotics, Stacked dielectric elastomer actuators (SDEAs), Actuator performance, Artificial skeletal muscles

I. INTRODUCTION

Soft robotics represents a transformative advancement in rehabilitation robotics and exoskeleton design, enabling safer and more adaptive human-robot interactions [1]. The development of actuators that replicate natural muscle movements is critical for enhancing mobility and functionality in individuals with musculoskeletal impairments. Various types of soft actuators have gained attention in this context, including pneumatic actuators, hydraulic systems [2], flexible pumps [3,4], shape memory polymers [5], gel-based actuators [6,7], paper-based soft robots [9], and dielectric elastomer actuators (DEAs) [8-11].

Conventional actuators, such as servo motors and pneumatics, are often bulky, acoustically noisy, and heavy, which can hinder user comfort and compliance in orthotics and rehabilitation robotics. For better adoption of these systems, it is crucial to prioritize natural feel, which is characterized by lightweight, quiet operation, softness, and form factor resembling natural skeletal muscles. Accessibility also plays a key role in the development of such devices. Dielectric elastomer actuators (DEAs), which can be configured as artificial skeletal muscles [12], can potentially replace conventional actuators or augment their performance and natural feel in rehabilitation and assistive robotics. DEAs exhibit significant properties, including power efficiency, high cycle life, and low energy consumption. They provide a lightweight, soft, and silent alternative, enhancing the natural feel and overall user experience in rehabilitation robotics [13,14]. DEAs are mechanically compliant capacitors consisting of two stretchable electrodes sandwiching an elastic dielectric [15]. Upon applying DC voltage to the electrodes, electrostatic forces, through a phenomenon called Maxwell pressure, compress the dielectric, the elastomer, and thereby compress it longitudinally and expand its area [16,17]. DEAs typically require high voltages in the kilovolt range to generate sufficient electrostatic forces for effective actuation, presenting practical challenges. However, as capacitive devices, DEAs draw minimal current (under 10 mA), allowing for safe operation, below 20 mA per Underwriters Laboratories (UL) Safety Standard, despite their high voltage requirements [18]. Their performance is influenced by viscoelastic effects, where increasing strain and strain rate lead to higher internal stress, slowing response time and complicating precise control. [19]. Despite these drawbacks, there has been limited exploration of DEAs in rehabilitation

Table 1. Reported Mechanical Properties of CT-SDEA and SDEAs-1550 at 1200 V [22].

	CT_SDEA	SDEA-1550
Max Force (N)	10.01 ±0.2 N	25.84 ±1.5
Max Strain (%)	3.3 %	10.9 %
Shortening (mm)	1.3 ± 0.8	5.46 ± 0.48
Stress (Kpa)	35	111
Dimension (mm^3)	39 × 17 × 17	15 × 15 × 50
Weight (gr)	11.3	14

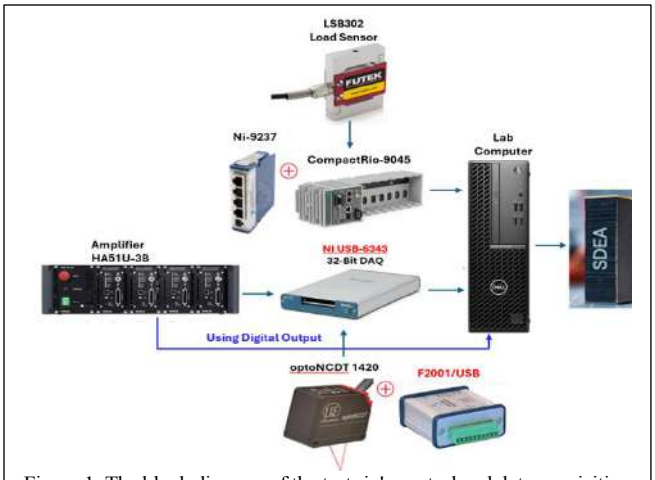

Figure 1. The block diagram of the test rig's control and data acquisition system is shown. NI MAX was utilized to manage the HV amplifier, which powered the SDEAs, and to capture force data through the NI 9237 module. Displacement measurements were directly recorded using a laser displacement sensor, with data acquisition handled via the Micro-Epsilon SensorTOOL software.

robotics, and research remains preliminary. Recently, the introduction of stacked dielectric elastomer actuators (SDEAs) has opened new opportunities for their application as "artificial skeletal muscles" in rehabilitation robots and powered exoskeletons.

Kovacs et al. [20] developed an SDEA configuration which closely mimics the properties of human skeletal muscles more effectively than other soft actuators. This design features multiple layers of thin DEAs stacked together, where each layer functions like a sarcomere in a myofibril. The original design of these tensile actuators was able to generate 32 N of isometric force and 15% strain while supporting an 11 N load. These outstanding performances led to the commercialization of SDEAs, making them the first commercially available DEAs [21]. We assessed the electromechanical characteristics of these commercially available SDEAs to determine their suitability for rehabilitation robotics, particularly in applications requiring numerous repetitive contractions to assist individuals with musculoskeletal impairments [22]. The earlier actuators demonstrated a high cycle life exceeding 50 million cycles, as reported by the manufacturer, making them well-suited for such applications. The earlier version exhibited a swift electromechanical delay of 21 ms and a strain rate of 660% per second, delivering a force of 21.74 N with a power-to-mass ratio of 426 W/kg [21]. Additionally, they achieved a longitudinal strain of 3.3% while consuming only 39 µA in steady-state operation. The combination of quick response times, minimal electromechanical delay, and high strain rates suggests their suitability for integration into closed-loop control systems. Furthermore, their robust force output, rapid response, high power-to-mass ratio, and low energy requirements underscore their potential for exoskeleton applications [20, 21]. These features position SDEA as an emerging viable option for creating artificial skeletal muscles, particularly in biomimetic rehabilitation robots.

Recently, SDEA manufacturing quality has improved substantially; thus, we assessed the latest commercial SDEAs (which we call SDEA-1550) and compared them with earlier versions from CTsystems (refer to Table 1). The SDEA-1550 actuator evaluated in this study is commercially available and manufactured by, Dätwyler Schweiz AG (Schattdorf, Switzerland) [23]. Our analysis revealed significant improvements in strain and stress performance, with stress values increasing by over 300%, to 111KPa, approaching levels comparable to human biceps. The data, collected for both single SDEA and 1x3 configurations, indicated enhanced responsiveness under high-voltage conditions. These advancements in muscle-like properties—such as longitudinal contraction, softness, and silent operation—further validate SDEAs as promising alternatives to biological muscles, highlighting their potential for next-generation rehabilitation robots [22].

Here, we shared the second round of these assessment results. Our experiments measured key performance indicators, including maximum pulling and pushing forces. In our testing setup, when the actuator is compressed, it exerts a pulling force on the attached force sensor, and when it expands, it exerts a pushing force. To clarify, we consistently refer to these as compressive (pulling) force and tensile (pushing) force throughout the manuscript. This manuscript presents the first evaluation of SDEA's capability to generate tensile force by leveraging its inherent elastic properties. Additionally, we evaluated the active and passive force generation under varying extension and compression levels using the Length-Tension analysis.

II. Method

A. Testing Setup

The performance of the SDEA-1550 was evaluated under two distinct conditions: isometric contraction and free-standing. A specially designed test rig, reported in [22] was utilized for this assessment, comprising the following components and is shown in (Fig. 1):

1) An aluminum mainframe, 2) A laser displacement sensor, 3) A load cell, 4) Precision translation stages, 5) High-Voltage (HV) fast amplifier, 6) National Instruments (NI) data acquisition (DAQ) boards

A laser displacement sensor (model ILD 142025 from Micro-Epsilon, Ortenburg, Germany) and F2001/USB, were used to measure the longitudinal contraction displacement of the actuators, providing high precision with a resolution of 1 µm to ensure accurate readings. These measurements were recorded using Micro-Epsilon's sensorTOOL software (version 1.12.0.1370).

A load cell (model LSB302 from FUTEK Advanced Sensor Technology, Inc., Irvine, CA, USA) was used to measure both active and passive forces, with a maximum capacity of 25 lb. The force data were obtained through an H-Bridge Input Module (NI 9237 from National Instruments, Austin, TX, USA), which was connected to a National Instruments compact RIO (cRIO-9045).

Three precision translation stages, each with a graduation of 10 µm and an axial load capacity of 102 N, are featured in the test setup. These stages allowed for precise positioning of the load cell, ensuring accurate alignment and load application (Fig. 2a).

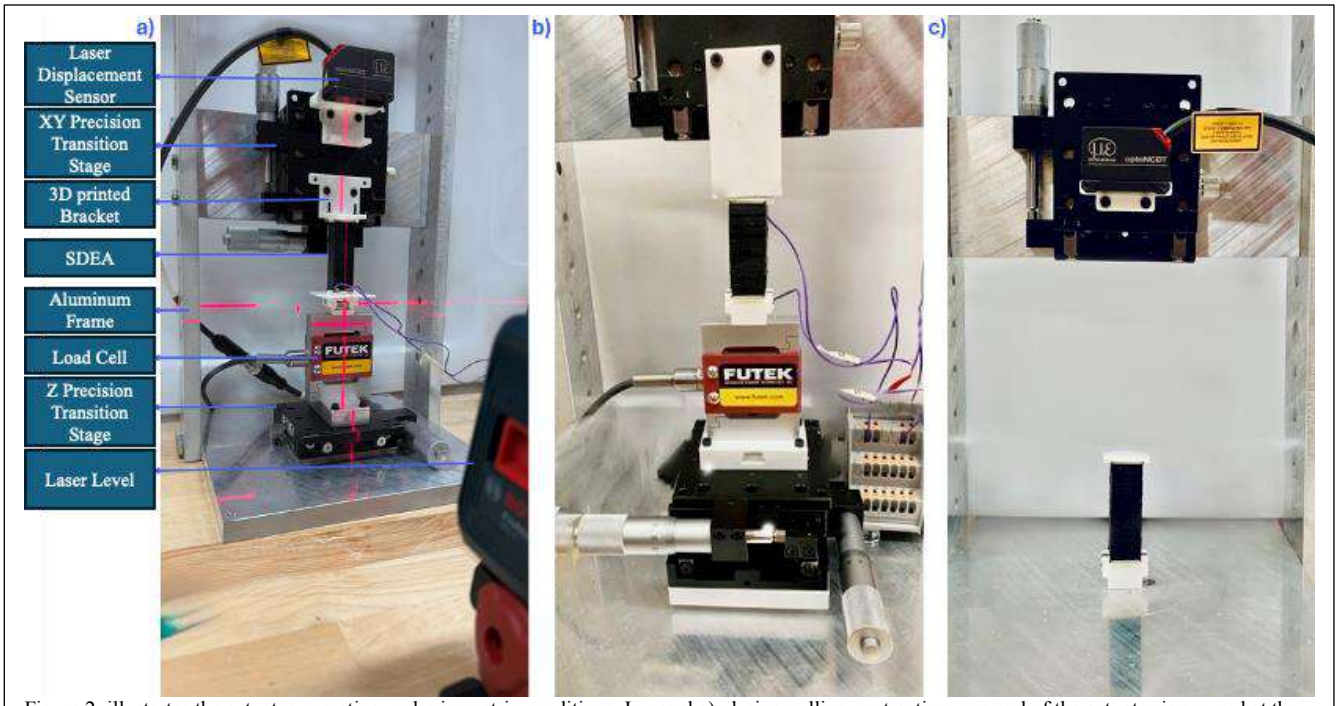

Figure 2. illustrates the actuator operating under isometric conditions. In panel a), during pulling contraction, one end of the actuator is secured at the bottom, and the other end is connected to a load cell. In panel b), for pushing contraction, the actuator's end is attached to a load cell, while the other end remains unanchored until voltage is applied. c) a free-standing configuration. An actuator is secured at the base and subjected to 1200 volts. The resulting contraction is then measured with the aid of a laser displacement sensor.

A High-Voltage (HV) fast amplifier (model HA51U-1.6P10-3 from hivolt.de, Hamburg, Germany) was employed to supply the necessary driving voltage to the CT-SDEAs, with a slew rate of 80 V/µs. The HV amplifier was controlled via an NI DAQ Data Acquisition board (NI USB-6343 from National Instruments, Austin, TX, USA).

NI MAX (version 2024 Q2) was used to generate control voltages ranging from 0.625 to 7.5 V, which were then amplified to a range of 100 to 1200 V by the HV amplifier, with a 1:160 amplification ratio.

The integration of these high-precision sensors and advanced data acquisition systems enabled a thorough assessment of the SDEAs' performance across various loading conditions, providing comprehensive insights into their operational capabilities and characteristics.

1) Isometric Condition

In this test, the length of the actuators was kept constant throughout the measurements. This testing setup was used to measure the blocked force for both compressive (pulling) and tensile (pushing) forces (Fig. 2a, b).

In our earlier research we measured the compressive force generation of the SDEA-1550 for 10 samples, (Fig. 3) [23]. For these measurements, the SDEAs were maintained at their rest length of 50 mm, under no compression or extension at the beginning of each trial. The SDEAs were mounted vertically, with one end fixed to a rigid frame and the other end attached to a load cell. Precise alignment was ensured using three precision translation stages: two for adjustments along the X and Y axes at the top and one for Z-axis adjustments at the base (Fig. 2a). Additionally, a Cross-Line Laser (Bosch GLL 2) was used to assist with precise vertical and horizontal alignment [22]. Forces generated at various activation voltages from 0V to 1200V were recorded by the load cell. To measure the tensile (pushing) force, the length of the activated actuator (the length after the application of voltage) was kept constant throughout the measurement. The activation voltage used was the same as that applied during the compressive (pulling) force measurements.

This setup ensured accurate measurement of the tensile force. The Y-axis translation stage was first adjusted to position the actuator neutrally, free from tension or compression. Upon applying voltage, the actuator compressed. Next, the load cell was lowered, using the translation stage until it touched the top endplate of the actuator without compressing it further. To ensure that no external force was applied during this process, the load cell output was continuously monitored while the upper endplate of the actuator made contact with the load cell. Upon releasing the voltage, the elastomer layers of the actuator attempted to return to their initial, non-compressed form, generating a substantial amount of passive/elastic force. This force was recorded by the load cell while blocking any movement. The peak compressive force generated by the SDEAs at activation voltages ranging from 23.15 N to 28.75 N was examined and reported [22].

Length-tension relationship: To assess the length-tension characteristics of the SDEA, we measured the force generation while the actuator was compressed and extended at various levels. The actuator was incrementally adjusted to different lengths, covering a range from 95.5% to 105% of the original length, to simulate both compression and extension. The passive (elastic) force was recorded at each length without applying any activation voltage. Note that as the actuator passive changes length, the elastic components (dielectric elastomers) want to return back to their original

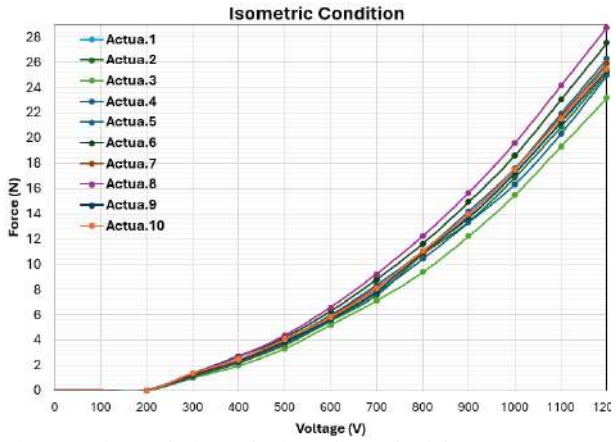

Figure 3. The graph shows the force that each of the 10 actuators can generate in isometric condition at voltages up to 1200 V [21].

forms. Subsequently, the active force was determined by applying voltage and subtracting the baseline passive force from the total generated force. This approach provided a comprehensive view of the SDEA-1550's ability to generate force under various compressive and tensile loads. This is crucial for applications where artificial muscles must replicate the force modulation required for varying load-bearing tasks, such as assisting ankle motion during gait [17,23].

2) Free-Standing condition (measuring strain-rate)

In the free-standing condition (Fig. 2c), the actuator was securely fixed in a vertical orientation by screwing its lower endplate to the base of the test rig's mainframe to maintain stability throughout the test. At the same time, the upper endplate was free to move. In our earlier research, we measured the displacement for each applied voltage in both single SDEA and 1x3 configurations using a laser displacement sensor [22]. The results showed that at 1200 V, displacements ranged from -6.15 mm to -4.4 mm, with an average displacement of -5.45 ± 0.47 mm for the single SDEA and 16.44 mm for the 1x3 configuration [22]. For the current study, we measure the time required to achieve maximum displacement (strain), and the strain rate (mm/s) at 1200 V to assess contraction speed. The strain rate is calculated using the recorded charge time and the measured maximum longitudinal strain. The laser displacement sensor positioned directly above the SDEAs, beaming on the upper endplate, to measure the displacement (Fig. 2c).

III. Results

Isometric condition: The compressive force generation measured in our previous study [22] and the measured tensile force at various voltages are shown in Fig. 4. The results demonstrate that both forces increased quadratically as the voltage rose from 0 to 1200 V, in agreement with the theoretical Maxwell pressure-voltage relationship, Equation (1). Notably, at 800 V, the SDEA-1550 generated a force comparable to the maximum force output of CT-SDEA at 1200 V, highlighting its improved force efficiency at lower voltages. At 1200 V, the maximum operating voltage (refer to Table 1), the highest recorded performance was achieved, with the tensile force reaching 32.824 N and the compressive force peaking at 28.75 N. This trend follows the theoretical Maxwell stress model, which predicts that force generation scales quadratically with applied voltage. Equation (1) describes this parabolic relationship between Maxwell pressure (P) and voltage (V), where ε and ε₀ represent the polymer's permittivity and vacuum permittivity, respectively, and d denotes the thickness of the dielectric material [22].

$$P = \varepsilon\varepsilon_0 \left(\frac{V}{d}\right)^2 \quad (1)$$

Strain-rate under free-standing conditions at 1200V: (Fig. 5a) presents displacement (mm) versus time (seconds) for five actuators, illustrating their rapid response characteristics under free-standing conditions. All actuators achieve 30% of their full displacement within approximately 0.038 seconds, demonstrating high responsiveness and rapid acceleration, which is crucial for applications requiring quick movements. Subsequently, the actuators reach 80% of their full displacement in around 1.48 seconds, highlighting their efficiency in achieving significant motion promptly. The displacement then progresses through 90% and 100% at a reduced rate, eventually reaching a steady state as internal resistance counteracts the applied force. Across all tested actuators, the final displacement values show minor variations, ranging between 4.95 mm and 5.15 mm. (Fig. 5b) depicts the strain rate (%/s) as a function of strain reported as a percentage of the resting length over time (%). The strain rate peaks at 20% displacement, reaching 8935 %/s, corresponding to the rapid initial phase observed in (Fig. 5a). Beyond 20%, the strain rate gradually decreases to a steady 3%/s at 100%, attributed to material resistance. This trend emphasizes the actuator's transition from rapid contraction to stable motion, which is essential for maintaining controlled, consistent movement across the full displacement range.

The Length-Tension curve (Fig. 6) shows the active and passive force generation capability of the SDEA under different levels of extension/compression. Although small, the more extended the SDEA, the less force it could generate. The SDEA showed a substantial passive force under compression and extension due to the elasticity of the dielectric layers, i.e., silicone elastomer (Fig. 6, grey trace). The passive force ranged (-14.9 N to 13.85 N) at 5%

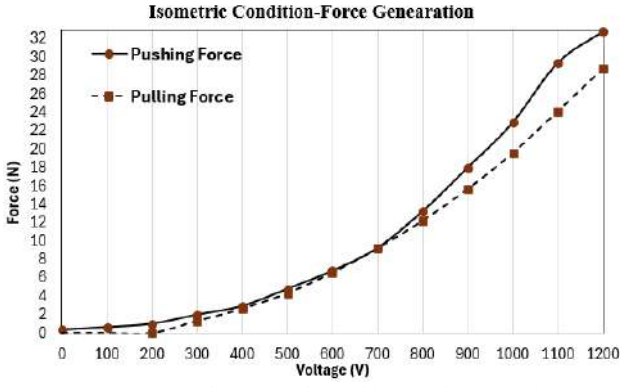

Figure 4. Isometric Condition, tensile (pushing), and compressive (pulling) force generation at voltages up to 1200 V.

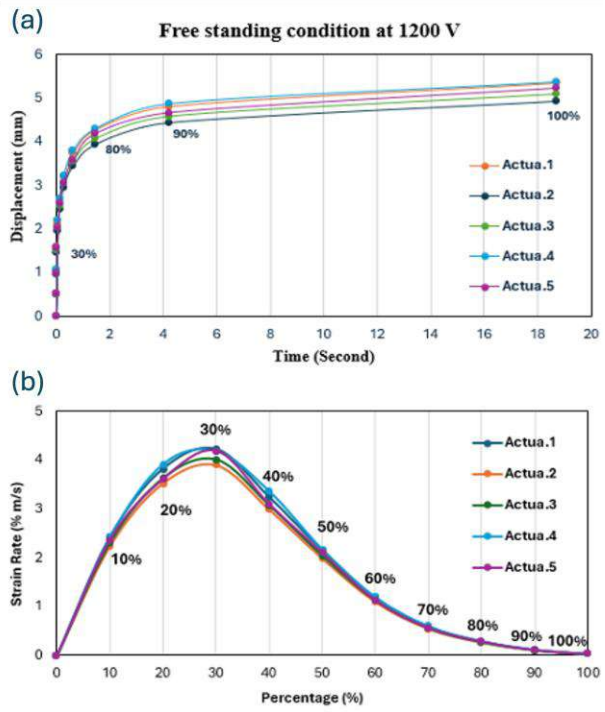

Figure 5. (a) Displacement over time, and (b) strain rate of the actuator as a function of displacement percentage under 1200 V.

compression and extension, respectively. along with the maximum total force (25.55 N)

IV. Discussion

The objective of this research was to assess the stress and strain generation capabilities of SDEA-1550 as a potential actuator for use in rehabilitation devices. Our tests, conducted under both free-standing and isometric conditions, highlighted the key performance metrics of SDEAs, including their ability to generate substantial tensile forces and their rapid response within the first 80% of displacement. These characteristics are particularly crucial for rehabilitation applications, such as lower-limb exoskeletons designed to enhance walking performance. Isometric testing demonstrated parabolic increases in both compressive and tensile forces as the voltage increased, with peak forces of 32.82 N and 28.75 N recorded at 1200 V, respectively. This strong force generation can be coupled to amplify joint moments and range of motion, making SDEAs well-suited for exoskeleton applications.

Additionally, SDEAs balance high stress, moderate strain, and rapid response, while maintaining long-term durability. Their commercial availability and exceptionally long cycle life (up to 70M cycles) provide them ideal for prosthetic limbs, rehabilitation robotics, and orthotic devices [20]. Furthermore, their muscle-like compliance and silent operation enhance user comfort, making them particularly suitable for exoskeletons and orthotic devices [12]. The layered composite structure enables them to withstand cyclic tensile loads while maintaining structural integrity, where applied voltage generates Maxwell stress, leading to contractive motion. Since the dielectric film only experiences compressive stress, tensile failure is prevented, enhancing fatigue resistance essential for long-term use. Compared to other soft actuators, such as hydraulically amplified self-healing electrostatic (HASEL) actuators and PVC gel actuators, SDEAs offer significant advantages. HASEL actuators provide high force and strain rates, but their extremely high voltage requirement (up to 40 kV) and snap-through behavior complicate integration into wearable rehabilitation devices. Additionally, their shorter cycle life (158k cycles) limits their long-term reliability. PVC gel actuators, while operating at lower voltages, exhibit moderate force and strain output but require bulky packaging, which reduces their practicality for compact rehabilitation applications. Their shorter lifespan (170k cycles) also poses limitations [12].

SDEAs demonstrate their suitability for rehabilitation robotics by providing biomimetic movement. The passive force, which varies with actuator length, can be effectively utilized in agonist-antagonist configurations, mimicking the elastic components of muscles. This feature, representing the elastic components in the Hill muscle model [22], is particularly beneficial when actuators work in parallel with muscles to augment their function, requiring performance that closely resembles natural muscle behavior. Furthermore, the minimal variation in active force generation across compressed and extended states highlights the reliability of SDEAs under varying load conditions. Leveraging their substantial force output to magnify displacement through mechanical linkages further enhances their versatility, making SDEAs ideal for a wide range of rehabilitation applications, including walking assistance [16], upper extremity prosthetics and orthotics [24,25], and even humanoid robots [26].

Our findings demonstrate that SDEAs can be a viable alternative to conventional actuators for wearable rehabilitation devices. We are currently applying SDEAs in the design of dielectric elastomer-powered ankle-foot orthoses (DE-AFOs) for children with cerebral palsy (CP), Fig. 7 [16]. These biomimetic exoskeletons aim to promote natural ankle motion by providing mechanical assistance during walking.

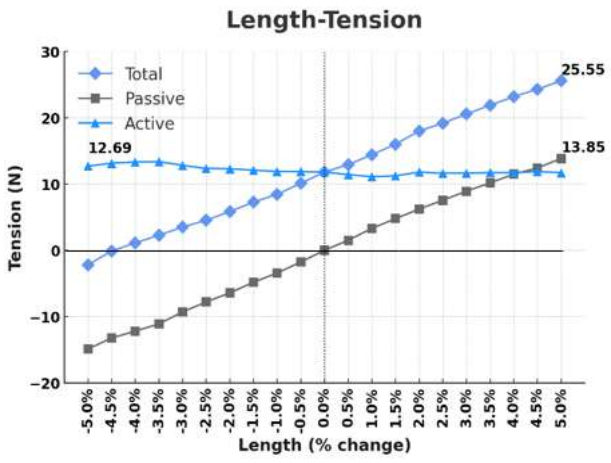

Figure 6. The Length-Tension curve illustration of the active and passive force generation of a representative SDEA during compression and extension. The 0.0% point represents the actuator's normal length, with positive values indicating extension and negative values indicating compression, emphasizing the role of material elasticity in force generation.

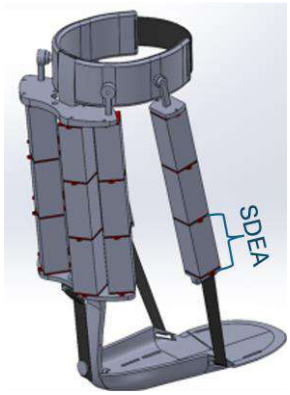

Figure 7. Our robotic ankle foot orthosis, DE-AFAFO, is powered by SDEA-based artificial muscles [16].

V. Conclusion

In conclusion, this study evaluated the tensile force generation, strain rate, and length-tension curve of commercially available SDEAs to determine their suitability for rehabilitation robotics. The SDEAs exhibited favorable characteristics, particularly in elastic (pushing) force generation, making them viable options for forming artificial muscles in robotic exoskeletons. Future work should focus on configuring SDEA-based artificial muscles, measuring their mechanical properties, and exploring control strategies for modulating the strain and stress of SDEAs and the resultant artificial muscles.

Markerless Motion Capture Enhances Clinical Assessments: Preliminary Validation with the Box and Blocks Test

Andria Farrens[1], Vicky Chan[2], Luis Garcia-Fernandez[1], Ziqiang "Joe" Zhu[3], Jun Min Kim[3], Matthew Karl Farrens[3] and Samuel T. King[3]

***Abstract*— Precision rehabilitation, therapy tailored to patient-specific impairments, is hindered by the low resolution of clinical assessments and the limited uptake of high resolution technological solutions that are too cumbersome for regular use. To address this, we developed C-MoRe, a phone-based system that applies computer vision to clinical assessments to produce quantitative metrics of upper extremity motor function. We tested C-MoRe in 7 chronic stroke participants performing the Box and Block Test (BBT), which scores the number of blocks participants can transfer over a divider in 1 minute. We used ML models to identify assessment and hand landmarks, and developed a custom algorithm to autoscore the assessment and quantify movement duration, amplitude, and velocity during grasping and transfer movements. Our algorithm had high fidelity in block counting (98.4% accuracy) and identifying task movement phases (ICC>0.99) compared to human raters. Movement velocity, grasp, and transfer duration were sensitive to functional differences between limbs, and grasp duration was significantly related to finger proprioception, a known predictor of therapy outcomes. Thus, C-MoRe can provide meaningful, quantitative measures of movement quality in BBT, and its simplicity may enable widespread use and the creation of large databases needed for predictive modeling.**

Keywords: computer vision, clinical assessments, stroke, proprioception, upper extremity

I. Introduction

One in four people will experience a stroke in their lifetime, and more than half of survivors are left with lasting motor impairments. Although there are numerous therapy options available, we have a limited understanding of the factors that mediate recovery. This lack of specificity, paired with the heterogeneous nature of stroke, has resulted in varied, sub-optimal (<50%) patient outcomes [1], [17].

Outcomes may be improved through tailored patient-specific rehabilitation, which can be achieved using machine learning (ML) and AI to create predictive models of how patients will respond to different therapy options. However, such modeling is limited by the relatively low resolution of commonly used clinical assessments that rate deficits as "absent, partial, or severe". Robots and motion capture technology can more accurately capture heterogeneity between patients via quantitative metrics of sensorimotor function (speed, smoothness, range of motion, strength). However, these tools have seen limited clinical adoption due to their high cost and the technical expertise and time required to use the systems [2].

[1]Mechanical Engineering Department, UC Irvine, California, USA farrensa@uci.edu, [2]Physical Therapy, UC Irvine, California, USA [3] Computer Science Department, UC Davis, California, USA

Advances in computer vision provide a solution to these issues, by offering a simple way to integrate kinematic analysis into existing clinical assessments without the need for a cumbersome marker set. Computer vision has been successfully used in the Fugl-Meyer Assessment and the Unified PD Rating Scale ([3], [14], and was found to increase assessment accuracy and consistency compared to assessment by clinicians alone. In this work, we incorporated computer vision in the Box and Block Task (BBT), a widely used assessment of upper extremity function in stroke, used for its ease of administration and functional relevance [18], [19]. Performance in this task is strongly linked to hand proprioception—the sense of position and movement—which is a predictor of responsiveness to robotic hand therapy [18].

In BBT, participants transfer as many blocks over a wooden divider as possible within one minute, and are scored by the total number of blocks successfully transferred. Kinematic analysis of BBT can provide greater detail regarding the source of patients' motor impairments. Previous research identified grasping and transfer duration, movement amplitude and speed as meaningful metrics of hand and shoulder function [4], [13]. Proprioception, which is believed to impair grasping ability, may be similarly quantifiable through kinematic assessment of block grasping. Previous groups report a high fidelity between markerless and standard motion capture analysis for these metrics, making them good candidates for computer-vision applications [8].

Given its relevance, other groups have incorporated sensors into the BBT assessment for clinical applications. However, these solutions all rely on specialized equipment, such as sensorized blocks [12], the Microsoft Kinect [16], virtual reality or a haptic robot [4], [5], which all require maintenance and costs that pose barriers to clinical uptake. Instead, our solution relies on widely available camera phones.

We present here the initial findings of our camera-vision based system for **C**linical **Mo**tor **Re**covery assessment (C-MoRe) tested in seven chronic stroke participants. We used an open-source, real-time hand-tracking model (MediaPipe Hand [6]), in combination with machine learning (ML), to develop an algorithm to autoscore the BBT assessment and perform kinematic analysis of hand movement. We hypothesized that 1) C-MoRe would be able to autoscore the BBT assessment with errors below the minimal clinically important difference (5 blocks), 2) that kinematic metrics (speed, movement amplitude) would be sensitive to hemiparetic effects of stroke, and 3) that grasping metrics would be associated with measures of finger proprioception.

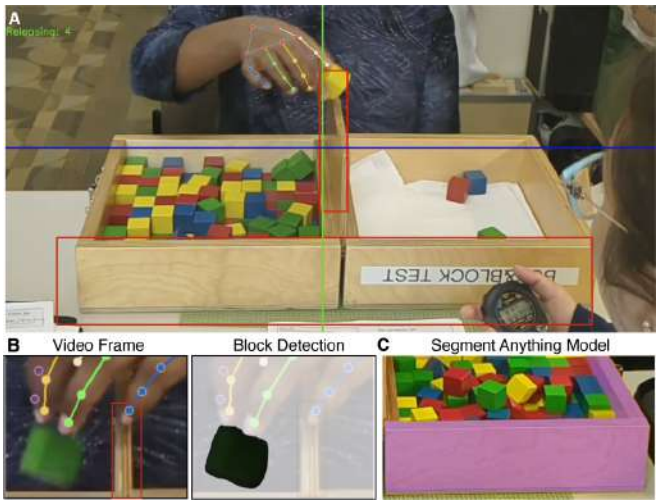

Fig. 1: A. Video frame showing ML annotations during BBT. The annotations show our hand landmark detection, box detection (red rectangles), task phase detection (green text) and task boundaries used for our scoring algorithm (blue and green lines). B: Preliminary block detection results, indicating future feasibility. C. Segment Anything Model identification of the front edge of the BBT box (pink highlight) used to convert pixels to meters

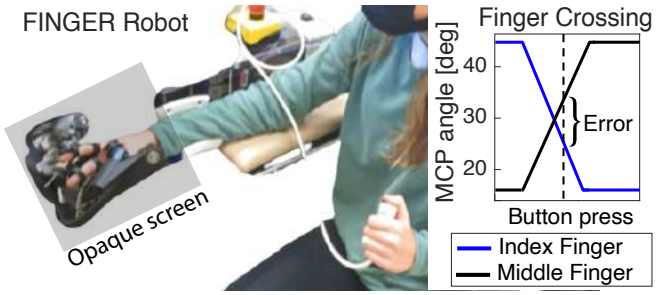

Fig. 2: Crisscross task on the FINGER robot. FINGER crosses the index and middle fingers of the affected hand in an alternating pattern with view of the hand blocked by an opaque screen. Participants must push a button at perceived finger crossing. Proprioception is quantified by the absolute error between MCP finger joints at button press.

II. Materials and Methods

A. Participants

Seven stroke survivors (59 ± 9.5 years, 2 female, 7 right-handed, 4 right-side impaired) with chronic stroke (mean: 34.9, range: [7.2, 95.2] months post stroke, 3 ischemic) were included in our study. Participants were recruited from the U.C. Irvine stroke survivor database, regional hospitals and stroke support groups. All visits took place at U.C. Irvine, and participants gave informed consent in accordance with the UCI Institutional Review Board.

The data was collected as part of a larger clinical trial on robotic hand therapy using the FINGER robot [18]. For this paper, we analyzed data from participants' 1-month post-therapy visit. During this visit, each participant performed BBT with their unaffected arm first, followed by their affected arm. Participants were instructed to transfer as many blocks as possible within one minute, crossing the center divider with their hand on every transfer. The center divider of the box was aligned to the center-line of the patient's torso and set at mid-torso height. The task was filmed on either a Pixel 7a (N=4) or an iPhone 13 mounted on a phone tripod for stability. The field of view was centered to the midline of the assessment box, and angled downward to include full view of the blocks (Fig. 1).

Following BBT performance, participants' proprioception was assessed using the Crisscross task on the FINGER robot (Fig. 2). In the crisscross task, the FINGER robot crossed the index and middle fingers of the affected hand in an alternating pattern with vision of the hand occluded. Participants were tasked with pushing a button when they felt their fingers were overlapped; performance was quantified as the absolute error between the metacarpal phalangeal (MCP) finger joints at button press. Average performance was measured across 20 crossings that had a movement amplitude of 30 deg and crossing speeds that varied randomly from trial-to-trial between 8-18 deg/s. Crisscross has a high degree of correlation to BBT, and is predictive of therapy outcomes following robotic therapy [9], [10], [18].

B. Experimental Protocol

C. Camera-Vision Markerless Motion Capture

Our goals were to automate the BBT assessment to autoscore the task, and to capture more fine-grained kinematic metrics that provide deeper insight into the individual's functional impairments. To acheive these goals, C-MoRe uses a commodity mobile device to capture videos of an individual performing BBT, and computer vision algorithms to detect the individual's hand, the box, and individual blocks on each frame of the video. By detecting and localizing these objects, we were able to use an algorithm to identify grasp, transfer and release phases of the task for autoscoring and kinematic analysis (Section II-D). As a general principle, we use off-the-shelf ML models as much as possible, reserving custom ML for tasks that do not have suitable off-the-shelf models necessary for our overall algorithm. We additionally favor deep learning ML to provide more flexibility in dealing with variations between different participants.

1) Hand Landmark Detection: Our first ML task was to detect and localize hands within the video using hand landmark detection [7] to infer transitions between distinct phases of picking up, transferring and releasing a block. We chose to use the hand landmark detection model from Media Pipe [6], which identifies hands in each frame, and then detects the wrist joint, all joints for all five fingers and all of the fingertips (Fig. 1).

The Media Pipe hand landmark detector worked well, but required a few adjustments to ensure accurate results. We found that for regular speed videos, rapid movements caused the hand to be blurred in the frames and the model

would struggle to accurately identify hand landmarks (at one point assigning a "finger" to the veins in the neck of the participant). Switching to capturing videos in "slow motion" (1/4 speed) removed the blurring and solved the problem.

We also found that we needed to crop the videos in post-processing so that the hands were large enough relative to the overall video for detection to work. To implement this in real-time, we plan to have a user interface that will instruct the therapist to align the assessment kit to a stenciled outline on the screen in order to standardize the camera field of view.

2) Box and Blocks Detection: Our second ML task was to detect and localize the BBT test kit within the video using object detection ML [20]. In particular, we detected the divider in between the two halves of the box and used this information to calculate when an individual transfers a block by virtue of their fingertips crossing the divider (Fig. 1). We also detected the front edge of the box, used for detection of when an individual attempts to grab a block. For this task, we used a pre-trained EfficientNet-lite0 object detector [15] and transfer learning to refine the detector to this specific task. To train our divider detection model, we labeled 152 frames from videos outside of our test set videos, and these labeled images served as training data for our custom model.

We also developed a custom object detection model to identify blocks during transfer. We have developed a model that can detect falling blocks in images (Fig. 1B) with a detection accuracy of 93%. However, at the time of this submission the model is still being refined and will be included in future manuscripts.

3) Converting Pixels to Meters: When processing video frames, all landmarks are recorded in pixel-space. However, to calculate speed and other meaningful metrics, as well as to standardize measurements between participants, pixels must be converted to meters. To do this, object within the video field of view that has a known fixed size must be identified, and can be used to calculate how to convert pixels to meter. We decided to use the front edge of the BBT tesk kit as all BBT sets are built to the same standardized dimensions.The challenge in performing this conversion is in localizing objects precisely enough for this calculation to be accurate. In our first version of this algorithm, we used the custom box object detector (Section II-C.2), and although it detected the front edge of the box accurately, the detected bounding box was too loose to support accurate transformations. Therefore, we chose to use the Segment Anything Model [11] to segment the image into different objects (Figure 1C). The output from this model is an annotation for each pixel about whether it is part of the same object. With this data, we use heuristics to identify the front edge of the box and an algorithm to calculate the number of pixels in the far right front edge of the box. We used the fact that the front edge of the box is 10.16 cm tall to effectively convert pixels to meters.

4) ML Training and Refinement: We focus our accuracy assessment on the end-to-end task of BBT automation, evaluating the entire system – ML, signal processing, and algorithms – as a whole (Section III). For the custom ML that we trained, we employed standard ML training best practices, including rigorous train/test separation, cross-validation during training, early stopping and model selection, and learning rate tuning to ensure the quality of each individual model. However, our quantitative measures focus on the system as a whole and the most clinically relevant measures for how we envision the system being used.

D. Signal processing

Currently, kinematic analysis is done offline by transforming frame-by-frame hand landmarks into continuous landmark signals measured across time. To define relevant features of the task workspace, we used the box detection ML to define the bounds of the center divider and the box, including the top, bottom and horizontal positions in the plane. Due to landmark detection errors and instances of spurious hands being detected, we created a signal preprocessing algorithm to reject outliers. We used a 1 second sliding window to detect local outliers due to signal dropout and a spline fill to address discontinuities. If the signal jumped outside of the reasonable workspace, defined by the borders of the box, the signal was removed from further processing. This occurred rarely (4 total instances), when the therapist's hand or the participant's other hand were misidentified in the video.

For kinematic analysis, we defined hand position as the average location across all the hand landmarks. Hand velocities were calculated by differentiating the hand position signal, and then filtering with a 4th order low-pass (Fc =1 Hz) butterworth filter using filtfilt in MATLAB. We defined finger "tips" and "touch" signals as the maximum and minimum values, respectively, across all distal finger landmarks (DIP joints, finger tips). The tips signal was used to identify all instances in which any finger tip crossed over the center divider, and the touch signal was used to identify grasping periods. All other analysis was based on the average hand position and velocity.

The algorithm first identified all potential crossing events and worked outward from each event. Potential crossing events were defined as the instance the "tips" signal exceeded the center dividers leading edge and height, until the "tips" re-crossed over the center divider. For crossing event detection, we reduced the leading edge and height of the divider by 0.5 cm to create a search buffer to enable detection of all potential crossing events (see vertical red box in Fig. 1).

We searched outwards from each potential crossing event to identify the time instances of transfer initiation, grasp initiation, and block release times. Transfer initiation was identified by searching backwards from the crossing event to identify the first local minimum ($<$15 cm/s) in vertical hand velocity. Release times were identified by searching forward from the transfer onset to the end of the potential crossing event for reversals in absolute hand velocity of 15 cm/s or greater. If multiple reversals were observed, and the crossing duration was normal ($<$2 s) we took the reversal closest to the crossing onset; for abnormally long crossings we selected the reversal closest to the end of the crossing.

To identify grasp initiation, we searched between the end of the previous crossing event to the instant of transfer initiation (search range) to identify all potential grasping periods. Potential grasping periods were defined from the instant the touch signal fell below the average position and velocity in the search range and persisted until the vertical displacement exceeded 4 cm. Within the grasp region, grasp initiation was defined as the first local minimum in vertical hand velocity prior to transfer initiation. If there were multiple potential grasp regions, then grasp attempts, transfer attempts and subsequent releases were identified for each region following the logic described above, and were counted toward attempted block transfers.

E. Automated Review

Potential crossing events in which the fingertips did not exceed the full height or leading edge of the divider were rejected as failed attempts, and not counted toward the number of block transfers. Crossings in which the finger "tips" did not cross within 0.1 cm of the divider top or leading edge or had velocity reversals prior to crossing onset were flagged for review by the proctoring assessor. All other events were considered as successful transfers and counted towards the total score.

F. Ground Truth Video Scoring

To create a set of ground truth metrics, the videos were hand scored by two of the authors and checked for consistency. We quantified the number of blocks successfully transferred, attempted grasps and attempted transfers. Successful transfers were counted only when participants fully transferred a block over the divider, such that their fingertips crossed the divider center line and the block fell on the other side of the divider. If participants transferred more than one block at a time, it was counted as a single block, consistent with clinical scoring. Grasp attempts were counted as each time a participant touched a block, and transfer attempts were counted each time the participant imposed a vertical velocity on a block.

To determine the duration of grasp and transfer phases of task performance, we identified the time instance of grasp initiation as the time instant the participant touched any block within the box, transfer initiation as the time instant of imposed vertical movement on the block, and block release as the time instant the block had an independent velocity or separation from the hand.

1) Kinematic Performance Metrics: Using the task events identified by both C-MoRe and the ground truth video scoring, we calculated participants' grasp duration as the difference between grasp initiation and transfer initiation, and transfer duration as the difference between transfer initiation time and block release. Using C-MoRe kinematics, we further defined the movement extent (sum of x and y displacement) and velocity (peak, avg) of the hand during the grasp phase and the transfer phase of movement.

G. Statistical Analysis

To validate our results, we quantified the percent accuracy and the maximum error in the number of blocks scored by C-MoRe compared to the ground truth scoring. For BBT, performance variation below 5 blocks is considered to be below minimal clinically important difference (MCID); as such, maximum errors must be below 5, and ideally, 0. To compare results between the ground truth and C-MoRe metrics, we calculated the interclass correlation between grasp, transfer, and release times, and performed a paired t-test between the calculated grasp and transfer durations calculated with C-MoRe compared to human-evaluators. Kinematics measured by C-MoRe were compared using t-tests to previously reported data in the literature [8], [13].

To determine the sensitivity of these metrics to the effects of stroke, we used paired t-tests to compare performance between the affected and unaffected hands. All participants suffered from upper-extremity hemiparesis, which should be observable as reduced performance in the affected limb. We further explored the relationship between our metrics and proprioception, because proprioception has been shown to explain 30% of the variability in BBT scores and is predictive patient outcomes following robotic rehabilitation of the hand [18]. To test the relationship between proprioception and performance in BBT, we performed an exploratory Spearman's correlational analysis between grasping and transfer phases of BBT and proprioception, and compared the performance of participants with impaired proprioception to non-impaired proprioception via Wilcoxon rank sum testing.

III. Results

A. Comparison to ground truth measures

Without review, C-MoRe had an average accuracy of 94.7%, with a maximum error of 7 blocks which exceeded our desire tolerance. However, with assessor review of automatically flagged trials, C-MoRe had an average accuracy of 98.4%, with a maximum error of 3 blocks, within our desired tolerance range (Tbl. I). Under these conditions C-MoRe performed suitably, with 100% accuracy in 11 of the 14 assessments.

C-MoRe and the ground truth task event times had an excellent agreement (all ICC$>$0.998). The mean estimation error was 146 $\pm$ 313 ms for grasp onset times, 128 $\pm$ 155 ms for transfer onset times, and 106 $\pm$ 107 ms for release times. In line with these results, there was no significant difference between estimation of grasp (difference mean $\pm$ std: 366 $\pm$ 1660 ms, p$>$0.42) or transfer durations (difference mean $\pm$ std: 174 $\pm$ 568 ms, p$>$0.27).

B. Kinematic Analysis

1) Comparison to standard motion capture: Hand movement extent had an average horizontal and vertical movement extent of 19.6 $\pm$ 7 cm, and 24 cm $\pm$ 8 cm respectively, and an average peak velocity of 137.35 $\pm$ 21.8 cm/s. Previous studies that used gold standard motion capture of the hand during the Box and Blocks assessment in stroke participants reported average movement ranges of 26 cm $\pm$

Subject	Side	Hand	PCE	R	F	Score	Raw	Final

TABLE I: Algorithm performance for participants' dominant/nondominant (D/N) affected/ unaffected (A/U) hands. Includes potential crossing events (PCE) detected, events rejected (R), and events flagged (F) for review. Ground truth scores (Score) are compared to the algorithms (raw) and (final) scores after review.

4 cm for horizontal movements and 21.6 $\pm$ 2 cm for vertical movements, and average peak vertical velocities of 150.7 $\pm$ 24.1 cm/s [13]. Using the reported standard deviations and two-sample t-tests, our results are not significantly different from reported values.

2) Sensitivity of selected metrics to effects of Stroke: To identify the sensitivity of our kinematic metrics to hemiparesis (unilateral weakness) secondary to stroke, we compared participants' movement extent and velocity between the affected and non-affected limbs (Fig. 3). Across participants, average velocity of the affected hand was significantly slower during both the transfer (mean difference $\pm$ std: 6.5 $\pm$ 10 cm/s, p<0.012) and grasp phases (mean difference $\pm$ std: 6.5 $\pm$ 10 cm/s, p<0.015) of the task, consistent with known effects of slowed movement speed with stroke. There was also a trend towards larger movement extent in the affected limb compared to the non-affected limb consistent with reduced movement efficiency, although these differences did not reach significance (mean difference $\pm$ std, grasping: 6.5 $\pm$ 10 cm, p<0.13; transfer: $\pm$ 19 cm, p<0.11). In line with these results, we observed increased grasp and transfer durations in the affected limb compared to the unaffected limb (mean difference $\pm$ std, grasp: 3 $\pm$ 4 s, p = 0.1, transfer, 0.7 $\pm$ .57 s p<0.007).

We further performed these comparisons at the individual level, to provide participants with feedback about the relative performance of their affected hand to their non-affected hand. In line with the known heterogeneity of stroke, not all participants exhibited deficits in the same categories. Two participants had significant deficits in movement efficiency but not speed, two had deficits only in speed, two had deficits in both movement efficiency and speed, and one had no comparative difference between sides (FRAP, Tbl. 1). The variability between subjects highlights the potential utility of such an assessment in identifying patient-specific deficits.

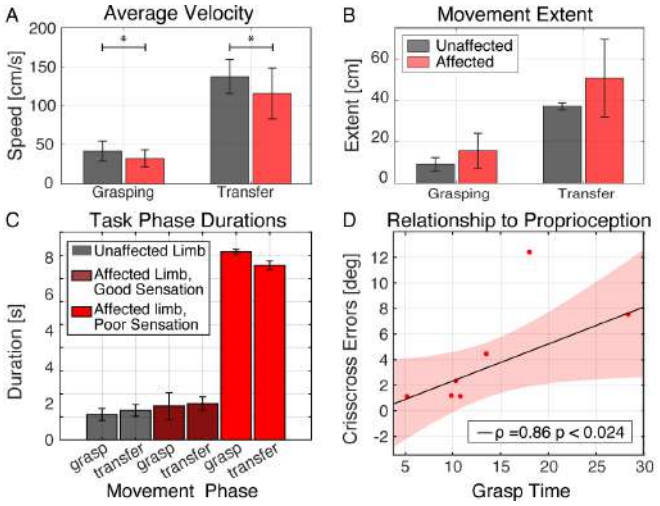

Fig. 3: Top: Hand kinematics during the grasp and transfer phases of movement. Velocity metrics (A) had the greatest sensitivity to effects of hemiparesis, while (B) differences in movement extent did not reach significance. (C) Comparison of grasp and transfer phases of movement for the unaffected limb and the affected limb, broken down by intact and impaired proprioception. (D) Correlation between grasp duration and finger proprioception

C. Relationship to Proprioception

Proprioception had no relationship to any kinematic measure nor transfer duration. However, grasp duration, which effectively combines the observed increases in movement extent and reduced velocity during grasping, showed a significant relationship to proprioception (Fig. 3, spearman's ρ = 0.86, p <0.024). The relationship between grasp duration and proprioception was stronger than its relationship to BBT Score (ρ = -0.56, p=0.21). Interestingly, individuals with poor proprioception tended to have grasp durations that were longer than their transfer durations, while individuals with intact proprioception showed the opposite trend (Wilcoxon rank sum test, p = 0.057). For the unaffected limb, which is assumed to have intact proprioception, all participants had average grasp durations that were shorter than their transfer duration. This suggests that the ratio of grasp duration to transfer duration may be a surrogate measure to identify proprioceptive deficits.

IV. Discussion

We have shown that C-MoRe, a phone-based system that uses computer vision to autoscore the Box and Block task, had an average accuracy of 94.7% and achieved an accuracy of 98.4% with assessor review of flagged trials. The algorithm primarily suffered from false positives due to block dropping and collisions, issues that will be fixed once block detection is fully implemented. Trial flagging was robust, and identified numerous instances that the human evaluators missed in which the participants fingers did not fully cross the divider. Consequently, we intend to add real-

time functionality to C-MoRe, to provide participants with auditory feedback each time their fingers cross the central divider to help prevent unintentional block tossing.

C-MoRe results had excellent agreement with ground truth task event times and produced kinematic metrics within expected ranges [8], [13]. Our kinematic metrics were sensitive to the effects of stroke, identifying group level differences in movement velocity between limbs, and subject-specific deficits in movement efficiency, velocity, and the relative duration of block grasping time to transfer time. We identified that grasp and transfer durations–which are not subject to any potential kinematic mis-estimation– were robust features of movement performance that were related to proprioception both at the group and individual level, providing a potential new avenue to identify proprioceptive deficits. The variability observed between subjects reflects known heterogeneity in stroke, and highlights the utility of such an assessment in more accurately quantifying patient-specific deficits.

Hand scoring took over an hour per video, and standard motion capture is similarly time intensive and requires specialized equipment. While other sensorized BBT solutions exist that capture similar features as C-MoRe, our system has the advantage that it only requires a commodity phone and no specialized equipment like [4], [5], [12], has higher accuracy compared to [16], and perfect fidelity to the standard assessment. As such, C-MoRe provides a rapid, simple method for quantitative assessment of movement in BBT.

Our kinematic analysis results are limited primarily by our sample size, and require additional test-retest reliability and direct comparison to gold standard motion capture metrics. In addition to validation, next steps will be to create a system that can process frames from the camera of a mobile device in real time, which will make the system easier for clinicians to adopt and employ in the field, and enable the opportunity to provide real time auditory feedback of block crossing.

V. Conclusion

Here we present C-MoRe, a phone-based system that implements computer vision during BBT for autoscoring and kinematic analysis. Our results show that we can effectively enhance the Box and Block clinical assessment of upper extremity motor function to produce sensitive, functionally meaningful measures of movement speed, extent and duration using only a camera phone and a tripod for stabilization, enabling potential widespread clinical uptake.

Reciprocal Learning of Intent Inferral with Augmented Visual Feedback for Stroke

Jingxi Xu*,[1], Ava Chen*,[2], Lauren Winterbottom[3], Joaquin Palacios[2], Preethika Chivukula[4], Dawn M. Nilsen[3,5], Joel Stein[3,5], and Matei Ciocarlie[2,5]

***Abstract*— Intent inferral, the process by which a robotic device predicts a user's intent from biosignals, offers an effective and intuitive way to control wearable robots. Classical intent inferral methods treat biosignal inputs as unidirectional ground truths for training machine learning models, where the internal state of the model is not directly observable by the user. In this work, we propose reciprocal learning, a bidirectional paradigm that facilitates human adaptation to an intent inferral classifier. Our paradigm consists of iterative, interwoven stages that alternate between updating machine learning models and guiding human adaptation with the use of augmented visual feedback. We demonstrate this paradigm in the context of controlling a robotic hand orthosis for stroke, where the device predicts *open*, *close*, and *relax* intents from electromyographic (EMG) signals and provides appropriate assistance. We use LED progress-bar displays to communicate to the user the predicted probabilities for *open* and *close* intents by the classifier. Our experiments with stroke subjects show reciprocal learning improving performance in a subset of subjects (two out of five) without negatively impacting performance on the others. We hypothesize that, during reciprocal learning, subjects can learn to reproduce more distinguishable muscle activation patterns and generate more separable biosignals.**

I. Introduction

Developing intuitive, user-driven methods for interfacing robotic devices with humans offers the potential to restore or enhance movement capabilities that are lost after neuromotor injuries such as stroke. Approaches that infer intent with the use of electromyography (EMG) and other biosignal data can encourage users to practice integrating the impaired limb in daily activities [1], which in turn can facilitate neuroplasticity to improve motor function [2].

Recent advances in machine learning (ML) can infer intent from EMG even when the strength of muscle activation is insufficient to move the limb [3], [4], [5]. However, neuromotor impairments after stroke include abnormal muscle coactivation and diminished capacity to generate consistent EMG patterns. Such abnormalities in biosignal generation increase with volitional effort when attempting to use the arm [6], [7], which in turn increases the challenge of intent inferral as a control method for robot-assisted movement.

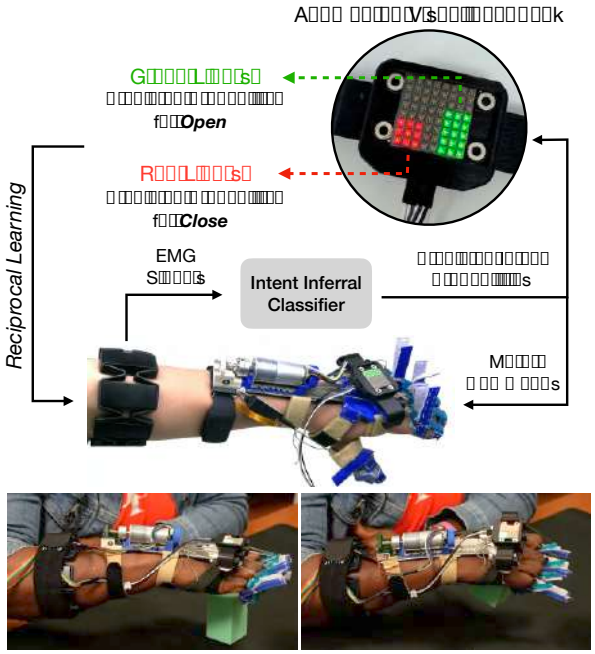

Fig. 1. **Reciprocal learning with robotic hand orthosis and augmented visual feedback.** Our hand orthosis assists stroke survivors in opening the hand when an *open* intent is detected from EMG signals, and allows the hand to close when it detects the *close* intent. Augmented feedback consists of LED display bars corresponding to the predicted probabilities of *open* and *close* from the intent classifier running on the orthosis. Subjects use visual feedback to adapt to the intent inferral model during reciprocal learning practice. The bottom row shows a stroke survivor using our device with augmented feedback for a functional pick-and-place task.

Typical intent inferral methods take in user intents as unidirectional ground truths, but wearable interfaces are inherently bidirectional systems. Humans modify their control inputs in response to sensory feedback of device behavior, such as whether the device moves according to expectations [8]. Device developers have sought to provide augmented feedback, or feedback in addition to intrinsic human sensing, to communicate information about biosignals that are not directly observable in order to aid human adaptation. Augmented feedback can compensate for reduced proprioception associated with sensory impairments after stroke [9], and when applied to EMG signals can offer insights into muscle coactivations [10]. Multiple groups [11], [12] have suggested augmented feedback of biosignals as a potential modality

to mediate co-adaptive learning and enable personalized control, such as human and device simultaneously adjusting control parameters in response to the other agent's behavior. However, co-adaptation in practical deployments such as physically assistive devices or rehabilitative interventions has yet to be realized for non-able-bodied users.

Our approach uses bidirectional intent inferral on a robotic device to dynamically encourage greater separability of control input patterns by stroke-impaired users, instead of solely relying on static thresholding of physiological or kinematic signals [13]. Furthermore, we can immediately deploy this approach for robot-assisted movement. We treat the human as a dynamic co-learner alongside the classifier algorithm, prompting each to update their understanding of the other's behavior. The combination of an adaptive classification algorithm and augmented feedback can increase the coherence of sensory input and action output, which in turn helps users develop greater automaticity when controlling the hand. In reciprocal learning, the user learns to generate better biosignals for ML models while practicing actively using the hand. In summary, our main contributions are as follows:

- We introduce a novel paradigm for training EMG-based intent inferral, consisting of interwoven sessions that alternate between updating ML models based on human biosignal generation and encouraging human exploration and adaptation to models with the use of augmented feedback.
- As far as we know, this bidirectional training system is a completely unexplored area in the context of upper-limb rehabilitation after stroke. We are the first to use augmented feedback to communicate the inner state of the learning model running on a wearable robotic orthosis as it assists hand movement.
- Our results demonstrate that reciprocal learning leads to better predictions for intent inferral on a subset of stroke subjects by aiding in the generation of more separable muscle activation patterns and biosignals.

II. Related Work

a) EMG Intent Inferral for Stroke: ML offers a data-driven approach to learn personalized human motor pattern classification. Many works have demonstrated robust EMG control of exoskeletons by healthy users and amputees [1], [11], [12]; however, the interpretation of biosignals from stroke-impaired users is a challenge. The majority of works on intent inferral for stroke use supervised [3], [14] or semi-supervised [4] learning approaches to train models on an initial dataset for later use during that same session, but these paradigms are vulnerable to severe shifts in distribution due to scarce data and time available for training. Recent works have sought to generalize intent inferral to enable few-shot transfer from data trained on a cohort of stroke survivors [15], [16], or have attempted to expand the data available from a single training session with a given stroke subject by use of synthetic data generation [17]. However, these methods expect muscle activation inputs to not substantially change as the user attempts to repeat movements. Impaired users who are unable to execute, and therefore are unable to observe, movements due to muscle weakness after stroke generate highly variable and inconsistent EMG patterns [14] that are prone to drift.

b) Interactive Learning with Augmented Feedback: Augmented feedback describes methods that provide the user with information on biosignals by sources outside the body. Visual augmented feedback, such as the use of computer displays or indication lights embedded on a device, has extensive support for improving rates of human motor adaptation beyond performing the task alone [18], and has long been deployed in EMG-based rehabilitation regimens for stroke [19]. Providing continuous, real-time concurrent feedback with human actions has widely shown benefit for stroke-impaired users to interactively learn mappings between different movement behaviors and resulting muscle activation patterns [20], [21]. In these works, augmented feedback is used to reinforce already-learned activation-movement mappings against fixed thresholds; instead, we use augmented feedback to train paretic users to practice movement capabilities that the user does not already possess.

Other research [11] combined augmented feedback with task-specific training to develop new control inputs. Seo et al. [22] altered flexor synergies in healthy subjects using EMG signal-guided conditioning on an isometric task. Silversmith et al. [23] used co-adaptation to enable a paralyzed subject to add additional control dimensions to a brain-computer interface. However, our reciprocal learning paradigm uniquely co-trains adaptation in the context of physical devices and movement. Simon et al. [24] developed a video-guided protocols to teach and recalibrate control of a myoelectric prosthesis, but relied on the user's ability to perform consistent muscle contractions and self-regulate force modulation with residual proprioception. To our knowledge, no previous works have tackled the challenge of mediating highly-variable intent signaling and adaptation between devices and users.

III. Reciprocal Learning Paradigm

The ultimate goal of this project is to develop algorithms that can infer discrete intent (one of {*open*, *relax*, *close*}) from EMG signals generated by stroke-impaired users attempting to move their hands, so that our robotic device can provide appropriate assistance. If the predicted intent is *open*, the robot extends the user's fingers to open the hand; if the predicted intent is *close*, the robot releases to allow the user to use their own strength to close the hand; if the predicted intent is *relax*, the robot simply maintains the previous state.

The classical way to train intent inferral algorithms is completely unidirectional. A researcher would issue cues to open, close, or relax the hand to a user wearing the device, then would record the real-time EMG signals and label the data using the provided cues as ground truth intent. In this unidirectional process, ML models learn personalized patterns through the labeled dataset and generate predictions. Although the user can observe the robot opening or closing,

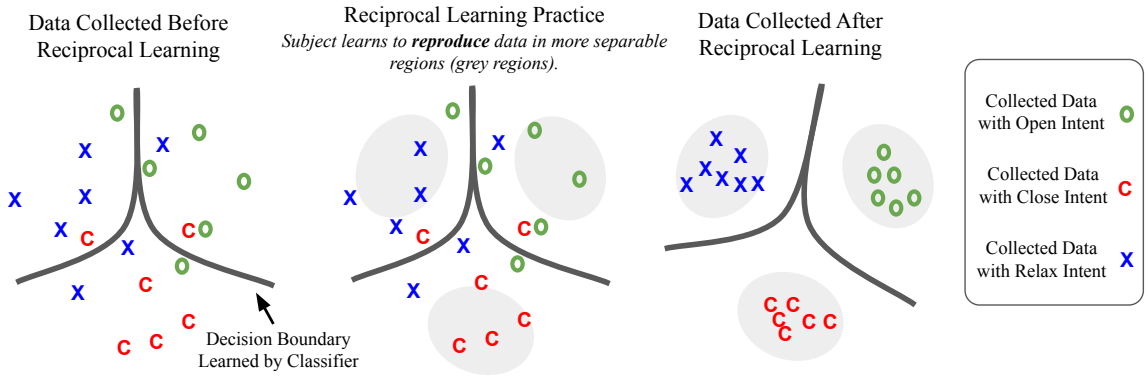

Fig. 2. **The goal of reciprocal learning is to guide the subject in generating more separable signals.** Before reciprocal learning practice, the collected data are more diverse for each intent, making it difficult for the classifier to learn a perfect decision boundary. During reciprocal learning practice, the subject adapts to the intent inferral classifier and learns to generate data in more separable regions. After reciprocal learning practice, we retrain the classifier using the newly generated more separable data. This figure is intended to illustrate the concept, and does not show EMG signals collected from real subjects; separability data from real stroke subjects will be shown in Fig. 4.

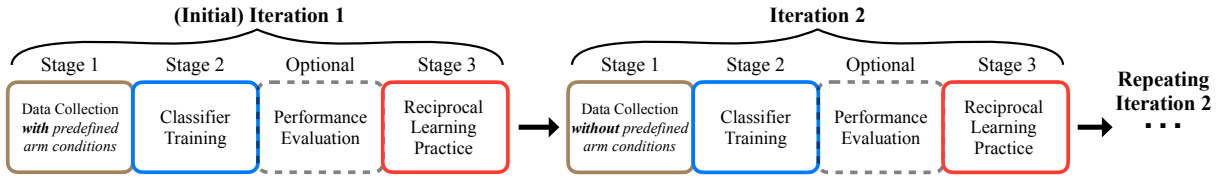

Fig. 3. **Reciprocal learning paradigm.** An iteration consists of data collection, classifier training, performance evaluation, and reciprocal learning practice.

they do not have knowledge about the underlying ML predictions or EMG signals that led to the robot taking action.

Our approach aims for a different bidirectional paradigm, dubbed reciprocal learning. We hypothesize that by providing insights about the internal state of the model in an intuitive and self-explanatory way, a user can adapt to the behavior of the classifier and reproduce more distinguishable control inputs. This idea is illustrated conceptually in Fig. 2.

Reciprocal learning is an iterative process and can have a potentially unlimited number of iterations (shown in Fig. 3). Each iteration consists of multiple stages, listed below:

- **Stage 1: Data Collection.** We collect a labeled dataset from a subject by providing verbal cues of *open*, *relax* and *close* while simultaneously recording EMG signals.
- **Stage 2: Classifier Training.** We train an intent inferral classifier using the collected dataset. This is where one direction of the learning happens—the ML model learns from the subject through the labeled dataset.
- **Optional: Performance Evaluation.** The purpose of this optional stage is to use any metric of our choice to track the performance of the trained intent inferral classifiers across iterations.
- **Stage 3: Reciprocal Learning Practice.** We run the learned intent inferral classifiers on the orthosis and provide the augmented visual feedback to communicate the inner state of the ML model that is not directly observable. The subject practices to generate distinguishable biosignals for *open* and *close* intents, using augmented feedback as guidance. This is where the opposite direction of learning happens—the subject explores and adapts to the ML model.
- **Repeat...** We continue to the next iteration, and collect a new batch of data from the subject who has supposedly learned to produce more distinguishable EMG signals.

IV. Methods and Implementation

Having described our general concept and approach, we now expand on the method and implementation of each stage.

A. Data Collection

In the data collection stage of each iteration, we collect a labeled dataset by providing verbal cues for subjects to open, close, and relax the hand. We simultaneously record the EMG signals and the given verbal cues as ground truth intent labels. The EMG armband (Myo, Thalmic Labs) has eight electrodes encircling the forearm. It streams filtered and rectified 8-channel surface EMG signals at 50Hz.

Note that the arm conditions under which the data is collected differ between the first iteration and the following iterations. A *condition* is a particular combination of hand position and whether the orthosis is actively providing assistance. In the initial iteration, the orthosis has no existing classifiers to run and thus no augmented visual feedback (see Sec. IV-C for details on the feedback mechanism) to provide. The subject has not done any reciprocal learning practice and thus has not found any muscle activations that consistently generate distinguishable EMG signals. As a result, we collect data from a diverse set of predefined arm conditions in the hope that this set provides enough diversity of muscle activation patterns such that one of them or interpolation between them is easily reproducible and separable.

The four different arm conditions of the initial iteration are as follows. (1) *Arm on table, motor off*: the assisted arm of the subject rests on the table, and the motor of the orthosis is disengaged, providing no physical assistance to the subject. (2) *Arm on table, motor on*: the assisted arm of the subject rests on the table, and the motor of the orthosis is engaged, allowing the device to provide active grasp assistance to the user. (3) *Arm off table, motor off*: the subject keeps their arm raised to shoulder level for the duration of data collection, and the motor is disengaged, providing no physical assistance to the subject. (4) *Arm off table, motor on*: the subject keeps their arm raised to shoulder level for the duration of data collection, and the motor of the orthosis is engaged, allowing the device to provide active hand-opening assistance.

For each condition, we collect two recordings, one for training and the other one held out for testing. A *recording* is defined to be a continuous and uninterrupted recorded sequence of EMG signals. For each recording, we instruct the subject to open and close their hand 3 times. Each verbal cue lasts for 5 seconds, with a *relax* cue between each *open* and *close* cue. As we have not yet trained a user orthosis controller, to collect data for motor-on conditions we manually command the orthosis to move approximately 1 second after the verbal cue.

In the data collection stage of the following iterations, there are no more predefined arm conditions. The orthosis runs the trained classifier, providing both active assistance and augmented visual feedback at a 5 Hz operational rate. The subject's goal is to reproduce the muscle activation patterns learned in the reciprocal learning practice of the previous iteration. We collect four recordings: two for training and the other two for testing.

B. Classifier Training

In each classifier training stage, we train a Linear Discriminant Analysis (LDA) classifier. We choose LDA because it is fast, trackable, and widely used in biomedical research [3], [4], [15], [17]. In the optional performance evaluation stage, we evaluate the performance of the classifiers both qualitatively and quantitatively (see Sec. VI for details).

The classifiers take in a single time step of an 8-channel, 50Hz EMG signal. We clip the signal to $[0, 1000]$ and then normalize it to $[-1, 1]$. Prediction on a single step is noisy, so during online inference we apply a median filter of window size 20 to the predicted probabilities of *relax*, *open*, and *close* over time. This median filter reduces unwanted oscillations in predictions when changing intents.

C. Reciprocal Learning Practice

Our augmented visual feedback consists of two progress-bar displays mounted on the dorsal side of the hand orthosis so that the subject can observe them comfortably during reciprocal learning, as shown in Fig. 1. The relative heights of the green and red LED bars correspond to the model's predicted probabilities for *open* and *close* intents, respectively.

In the reciprocal learning practice stage, we ask the subject to practice opening and closing their hands guided by the augmented visual feedback. We run the trained classifier on the device to provide appropriate assistance. In this stage, we instruct the subject to trigger different device states (*open* and *close*) by maximizing the respective green or red LED bars.

This is the exploration stage, where the subject adapts to the behavior of the device, and tries to discover and reinforce the muscle activation pattern that is easily reproducible and distinguishable. In this stage, the subject uses augmented visual feedback to learn to generate more separable EMG signals for each intent. This idea is conceptually illustrated in Fig. 2. Reciprocal learning practice essentially helps the subject locate the EMG subspace that is both reproducible and separable (i.e., far from the *decision boundary* learned by the classifier of the previous iteration). Then, in the next iteration, the subject can reproduce data in these more separable regions, leading to new retrained classifiers that can more accurately predict user intent.

V. Experimental Setup

We tested reciprocal learning in single-session experiments with five stroke subjects, and compared intent inferral accuracies from two iterations. Reciprocal learning supports multiple iterations; however, here we only complete two iterations due to session time constraints. We leave the study of reciprocal learning with more iterations as future work.

A. Subjects

We recruited stroke survivors who presented with chronic hemiparesis and moderate muscle tone defined as Modified Ashworth Scale (MAS) scores ≤ 2 in the upper extremity. Our subjects can fully close their hands but are unable to completely extend their fingers without assistance. The passive range of motion in the fingers is within functional limits. Testing was approved by the Columbia University Institutional Review Board (IRB-AAAS8104) and was performed in a clinical setting under the supervision of an occupational therapist. See Table I for details on subjects.

Our subjects have different degrees of hand impairment severity, as measured on the Fugl-Meyer scale for upper extremity (FM-UE). Subjects S1, S2, and S3 have no active finger extension (minimal observable movement) and lower corresponding FM-UE scores (27, 26, 26, respectively), whereas S4 and S5 have some residual active finger extension capacity (limited observable movement) and higher corresponding FM-UE scores (50, 47, respectively).

B. Hardware

Our hand orthosis [25], [26] is a robotic exotendon device with a forearm EMG armband and LED visual displays,

TABLE I
Subject information.

Subject ID	Age	Gender	FM-UE
S1	46	Male	27
S2	48	Male	26
S3	53	Female	26
S4	31	Male	50
S5	53	Male	47

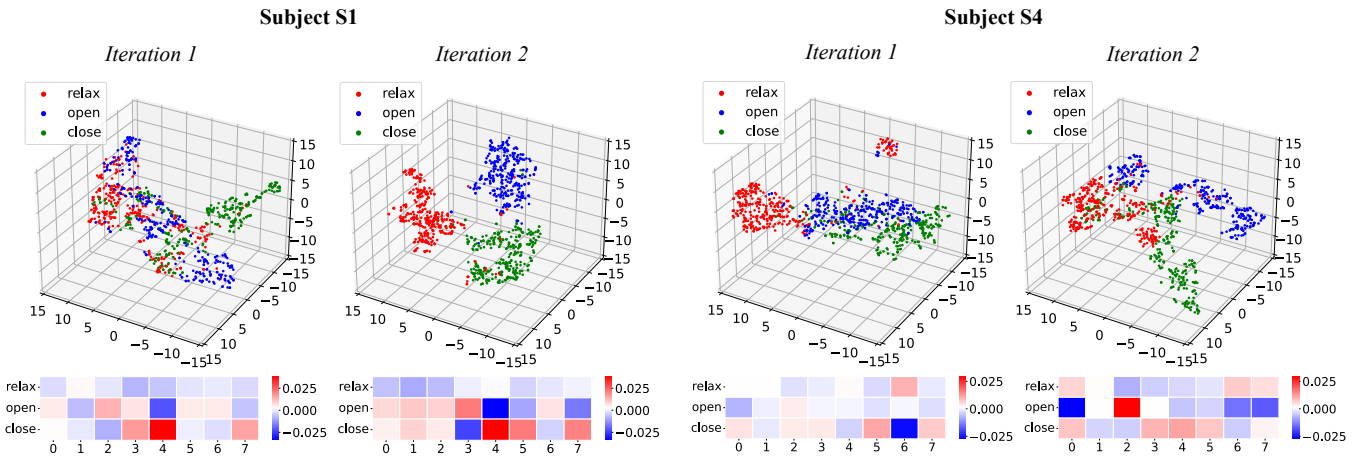

Fig. 4. **Reciprocal learning results on two stroke subjects. Top:** comparing data separability. After reciprocal learning, clusters associated with each intent become more easily separable. **Bottom:** LDA classifier weights visualization indicating a specific EMG electrode (0 through 7) is negatively (blue) or positively (red) associated with a specific intent. Reciprocal learning strengthens such associations, which helps separability.

TABLE II

MEAN INTENT INFERRAL ACCURACY.

Subject	S1	S2	S3	S4	S5
Iteration 1	0.61	0.69	**0.70**	0.86	**0.82**
Iteration 2	**0.88**	**0.71**	0.68	**0.94**	0.80

TABLE III

VARIANCE OF LDA WEIGHTS FOR THE OPEN INTENT.

Subject	S1	S2	S3	S4	S5
Iteration 1	7.8e/6	1.0e/4	8.8e/4	1.1e/4	1.0e/4
Iteration 2	**2.5e/4**	**4.6e/4**	**1.2e/3**	**2.8e/4**	**2.0e/4**

as shown in Fig. 1. The device assists hand opening by extending all digits simultaneously. It does not directly assist finger flexion and relies on human strength for hand closing.

When operating under user control, the device acts on streaming *open* and *close* predictions at approximately 5 Hz to move to preset hand poses. The user is able to countermand the device mid-motion by generating an opposing intent input. *Relax* predictions do not change device state.

VI. RESULTS AND DISCUSSION

A. Intent Inferral Accuracy

During the performance evaluation stage of each iteration, we use the test set to compute the classifier's per-timestep intent inferral accuracy against the ground truth labels. Table II reports the mean accuracies across samples. While the intent inferral accuracies for S2, S3, and S5 remain similar across the first two iterations, we observe an accuracy improvement for S1 and S4, from 0.61 to 0.88 and from 0.86 to 0.94, respectively. Augmented visual feedback during reciprocal learning practice may have helped S1 and S4 generate more consistent and distinguishable muscle activation patterns, creating more separable intent signals. As a result, the data collected after the first reciprocal learning practice become easier to classify. We note that S1 has more limited hand movement capacity compared to S4 (also reflected by their intent inferral accuracy). This suggests that whether reciprocal learning can improve intent inferral accuracy may not depend on stroke subjects' residual hand function.

One possibility for why reciprocal learning does not improve performance across all subjects is the randomness of exploration in the practice stage. Although the prescribed arm conditions during the data collection stage of the first iteration provide data variance, due to the variation of impairment across stroke subjects, it is not guaranteed that the initial dataset is diverse enough to contain reproducible and distinguishable muscle activation patterns for all intents. In addition, even though the initial dataset collected with predefined arm conditions contains many activation patterns, due to randomness of exploration, it is not guaranteed for a subject to successfully locate or reproduce a specific pattern.

While advancing the proposed paradigm to have a positive effect on most participants is obviously desirable and is the focus of our future work, we believe that an approach that improves performance on a subset of participants without hindering performance on the others can also have practical usefulness. Furthermore, a detailed study of the differences between cases showing successes versus more limited effects can suggest future areas of exploration.

B. Data Separability

We further investigate the data of subjects S1 and S4 to show how reciprocal learning may lead to biosignals with more discriminative information for classifying intent. We visualize 1000 randomly sampled 8D EMG signals for each intent before and after the reciprocal learning practice in 3D space using t-distributed stochastic neighbor embedding (t-SNE) [27], as shown in Fig. 4. Each data point is labeled using its ground truth label, which is only available during training. After reciprocal learning, the data clusters associated with each intent improve in separability, which could explain the increased classification accuracy and lend support to the hypothesis that reciprocal learning may help some subjects generate signals that are more easily interpretable by intent inferral algorithms.

We also visualize the LDA weights associated with each EMG electrode in Fig 4 to show the spatial distribution of predicted intents on the forearm. Positive values (red) mean that muscle activity under that particular electrode is positively associated with a specific intent, while negative values (blue) mean that muscle activity contributes negatively to that intent. We notice that after reciprocal learning practice, the weights (especially for the *open* intent) become more diverse, meaning that the positive weights are more positive, and the negative weights are more negative. In fact, the variance of the 8D weights for the *open* intent increases consistently for all subjects, as shown in Table III. These results suggest that subjects have stronger muscle activation patterns after reciprocal learning practice and explain improvements in intent inferral accuracy from another angle.

VII. Conclusion

We propose a novel bidirectional reciprocal learning paradigm that co-trains stroke-impaired users with intent inferral algorithms. We achieve reciprocal learning through augmented visual feedback in the form of LED progress-bar displays, which communicate the probabilities of the *open* and *close* intents predicted by the classifier. Our paradigm consists of iterative and interwoven stages of training the machine learning models and human exploration and adaptation to the classifiers. By using the augmented visual feedback of the classifier internal state as guidance, a subset of our stroke subjects learn to modulate muscle activation and generate more separable EMG signals, leading to better intent inferral performance, while the performance of the other subjects is not adversely affected. Future work includes conducting detailed studies of reciprocal learning involving multiple iterations, exploring the factors that influence a subject's ability to find consistent and reproducible muscle activation patterns during reciprocal learning practice, and finally to translate acquired skills across tasks and contexts of use.

Optimizing Locomotor Task Sets for Training a Biological Joint Moment Estimator

Jimin An[1], Changseob Song[1], Eni Halilaj[1] and Inseung Kang[1]

***Abstract*— Accurate estimation of a user's biological joint moment from wearable sensor data is vital for improving exoskeleton control during real-world locomotor tasks. However, most state-of-the-art methods rely on deep learning techniques that necessitate extensive in-lab data collection, posing challenges in acquiring sufficient data to develop robust models. To address this challenge, we introduce a locomotor task set optimization strategy designed to identify a minimal, yet representative, set of tasks that preserves model performance while significantly reducing the data collection burden. In this optimization, we performed a cluster analysis on the dimensionally reduced biomechanical features of various cyclic and non-cyclic tasks. We identified the minimal viable clusters (i.e., tasks) to train a neural network for estimating hip joint moments and evaluated its performance. Our cross-validation analysis across subjects showed that the optimized task set-based model achieved a root mean squared error of 0.29±0.06 Nm/kg. This performance was significantly better than using only cyclic tasks ($p<0.05$) and was comparable to using the full set of tasks. Our results demonstrate the ability to maintain model accuracy while significantly reducing the cost associated with data collection and model training. This highlights the potential for future exoskeleton designers to leverage this strategy to minimize the data requirements for deep learning-based models in wearable robot control.**

I. Introduction

Lower-limb exoskeletons have been shown to enhance human mobility, thereby improving quality of life [1]. These robotic systems can augment users and enhance gait performance, for example, by reducing energy expenditure in healthy individuals [2] and improving spatiotemporal gait metrics in patient populations [3]. Among different lower-limb exoskeletons, hip exoskeletons present a particularly compelling value proposition due to the critical role of the hip in generating substantial mechanical power during locomotion. Unlike the ankle joint, which benefits from an efficient muscle-tendon mechanism, the hip is mechanically less efficient, requiring greater muscle work (i.e., energy) to complete locomotor tasks [4].

Control strategies for robotic exoskeletons have significantly advanced over the past decade. Initially relying on heuristic, rule-based controllers utilizing onboard wearable sensors [5], [6], recent approaches now directly leverage the user's physiological state, such as biological joint moments, to control the exoskeleton more effectively [7]. Biological torque controllers directly estimate the user's biological joint moments and apply a reshaped, scaled envelope as the assistance profile [8]. This method leverages deep learning techniques with wearable sensing as model input and has demonstrated notable performance benefits [9]. The range of activities that can be assisted by exoskeletons has expanded significantly, progressing from simple continuous walking [10], [11] to dynamic transitions between locomotion modes [9], [12], and now including various non-cyclic movements [13], [14]. These advancements could enable more natural hip exoskeleton assistance during daily locomotor tasks.

However, a significant bottleneck of deep learning approaches is their data-intensive nature, requiring large datasets that comprehensively represent various activities, along with ground-truth joint moments obtained through motion capture. Studies have demonstrated that user-independent models typically require data from at least a dozen participants completing multiple tasks [15], with some relying on even larger groups and more diverse tasks [9]. While comprehensive datasets are essential for ensuring reliable model performance across various activities, the associated costs and resources are substantial. Furthermore, for patient populations, such data collection can be even more challenging due to physical limitations, time constraints, and logistical barriers. These challenges highlight the necessity for an automated solution that reduces the burden of data collection while not compromising model performance.

Few studies have verified that optimal model performance can be achieved with data from a reduced set of tasks [13], [14]. These studies employed an iterative forward task selection approach, incrementally adding tasks to the training dataset until further additions no longer improved model performance. While these results suggest that a full dataset is not always necessary during training, they do not clarify which tasks are most relevant and useful or explain why certain tasks are more effective in developing user-independent joint moment estimators. Without a deeper analysis beyond model performance, these approaches provide limited insight into the relationships between tasks and their biomechanical relevance. This gap emphasizes the need for a systematic approach to identify a minimal task set that ensures reliable model training and performance while reducing data collection requirements.

Given the similarities among human movement profiles across various locomotor tasks, collecting data with finely discretized task separation may not always be necessary. Instead, grouping tasks based on shared biomechanical features might be a better strategy for improving efficiency and

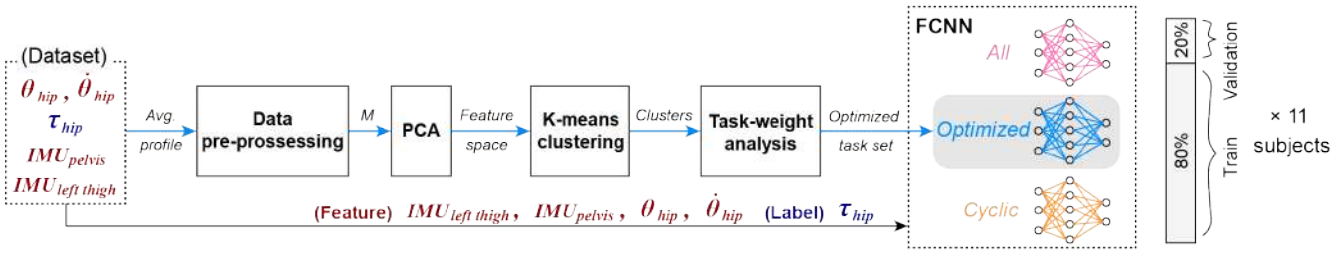

Fig. 1: Task Selection and Model Training. Average joint moment, angle, and velocity profiles were used for principal component analysis (PCA), k-means clustering, and task-weight analysis to determine a smaller optimized set of tasks that were representative of the full set. The time-series data for each training dataset condition (all tasks, optimized tasks, and cyclic tasks) were used for the fully connected neural network (FCNN) model training with leave-one-subject-out cross-fold validation.

applicability in various contexts. Prior studies have applied dimensionality reduction and clustering methods to biomechanical data analysis for applications such as locomotion phase classification [16], [17], kinematic pattern recognition [18], gait differentiation [19], and movement analysis [20], [21]. Building on prior literature, grouping tasks using a clustering approach based on shared biomechanical features offers a systematic solution for identifying redundant tasks that provide similar information. By selecting representative tasks from each cluster and training the model on these tasks, we can significantly reduce data collection efforts while preserving essential biomechanical patterns needed for accurate joint moment estimation.

In this work, we propose a strategy for optimizing locomotor task selection through clustering analysis. We hypothesized that a model trained on an optimized task set would achieve hip joint moment estimation comparable to a model trained on the full dataset. Our underlying rationale is that the latent space representation of these tasks likely exhibits significant overlap for certain tasks due to their shared biomechanical features. To test this hypothesis, we trained a neural network using three different datasets to evaluate the effectiveness of our task set reduction: 1) the full set of tasks, 2) an optimized reduced set of tasks, and 3) only cyclic tasks. The model estimated hip joint moments using sensor data commonly available for hip exoskeletons, such as encoders and inertial measurement units. Our study results contribute to the field by demonstrating that a biological torque controller for hip exoskeletons can be developed using data from fewer tasks, while also identifying key tasks for future data collection efforts.

II. Methods

A. Dataset and Data Pre-Processing

We used an open-source biomechanics dataset of 12 healthy young individuals (7 males, 5 females, age of 21.8±3.2 years, height of 176.7±8.6 cm, and weight of 76.9±14.4 kg) performing various locomotor tasks [22]. These tasks included 10 cyclic and 17 non-cyclic tasks. The dataset included kinematics (joint angles and velocities), kinetics (ground reaction forces, joint moments, and joint power), and wearable sensor data. For dimensionality reduction, we focused on unilateral hip joint angles, velocities, and moments in the sagittal plane. These features, combined with pelvis and thigh inertial measurement unit (IMU) data, were also used to train a user-independent model for hip moment estimation in exoskeletons.

We used principal component analysis (PCA) to reduce the dimension of our data. We constructed an input matrix, M, through a pre-processing pipeline (Fig. 1). The unilateral hip joint moment, angle, and velocity, pre-segmented and averaged by gait or movement cycle, were linearly interpolated to standardize their lengths while preserving overall patterns. These processed vectors were concatenated to represent the biomechanical features for each subject-task combination, and all such vectors were aggregated to form the matrix, M. During this process, seven non-cyclic tasks (meander, poses, push, obstacle walk, start stop, tug of war, and twister) were excluded due to their atypical movement profiles, which could not be segmented into uniform gait or movement cycles. The remaining tasks were categorized into eight cyclic and 12 non-cyclic tasks. We excluded data from one subject due to insufficient cyclic task trials, ensuring balanced task representation and minimizing potential biases in analyses.

B. PCA, Clustering, and Task Selection

By reducing high-dimensional biomechanical data, PCA [21] enhanced the interpretability of relationships among task datasets. We derived principal components and assessed their explained variance to determine the optimal number of components. This process balanced variance representation and component counts, ensuring an adequate representation of the data's variability for the clustering process.

We applied k-means clustering [17] to group tasks by biomechanical feature similarities in the PCA-derived feature space (Fig. 1). We first performed a silhouette score analysis to determine the number of clusters. The silhouette score measures both inter-cluster and intra-cluster distances, indicating how well-defined the clusters are [23]. The K (i.e., number of clusters) that yielded the highest silhouette score was selected as the optimal K.

Since each cluster contained different types of tasks, we developed a task-weight analysis to calculate, R, the representativeness of a task for a cluster using Eq. 1,

$$R = \frac{A}{B} \times \frac{A}{C} \times \frac{S}{11} \times w \quad (1)$$

where A is the number of a specific task's data points in a cluster, B is the total number of data points in that cluster, C is the total number of data points for that task across all clusters, and S is the number of unique subjects contributing task data in the cluster. w is a weight assigned to each task based on its popularity in the research field and the ease of collecting task data. Using Eq. 1, we accounted for the proportion of data, the diversity of subjects, and the difficulty associated with data collection in our task selection process. The representative tasks for each cluster identified through this analysis constituted our set of optimized tasks for model training.

C. Optimized Task Set Performance Validation

We implemented a fully connected neural network (FCNN) using PyTorch (Python v3.8) to predict a unilateral hip joint moment from IMU, joint angle, and joint velocity data. The network architecture was comprised of an input layer, three hidden layers, and an output layer. The input layer had a 14-dimensional feature vector corresponding to the input features (Fig. 1). Each hidden layer contained 50 nodes. We applied batch normalization after each linear transformation to enhance training stability and convergence speed. We used the rectified linear unit activation function followed by a dropout layer with a rate of 0.2. The output layer was a single node that returned the unilateral hip joint moment. The hyperparameters for each condition, including the learning rate (lr), dropout rate (dr), and batch size (bs), were sequentially tuned. The selected values are as follows: lr = 0.001, dr = 0.1, and bs = 128 for the all-task; lr = 0.001, dr = 0.1, and bs = 32 for the optimized-task; and lr = 0.001, dr = 0.4, and bs = 32 for the cyclic-task. Training proceeded for up to 100 epochs, with early stopping applied if the validation loss did not improve for 10 consecutive epochs to prevent overfitting and unnecessary computations.

To further address the data imbalance between cyclic and non-cyclic tasks, we applied bootstrapping. In our approach, for each training batch, we first separated the data into two groups: cyclic and non-cyclic tasks. We then computed the sample counts for each group. Recognizing that the minority group (typically the non-cyclic tasks) contained fewer samples, we applied bootstrapping to this group—repeatedly sampling with replacement—to match the sample size of the majority group. By doing so, we generated a balanced training set in which both cyclic and non-cyclic tasks were equally represented. This method ensures a balanced training set, reduces bias toward the majority class, and introduces variability that may enhance generalization.

We conducted leave-one-subject-out cross-validation for training and testing (Fig. 1). For each iteration, the entire dataset from one subject was left out, and the remaining data was filtered based on predefined task conditions (all tasks, optimized tasks, or cyclic tasks). The filtered data was then split into 80% training and 20% validation sets. After training, the left-out subject's data was used for testing. Model performance was evaluated using root mean squared error (RMSE) and the coefficient of determination (R^2). RMSE assessed the accuracy of the model's predicted hip joint moment values, while R^2 evaluated the model's ability to track the characteristic pattern of the hip joint moment profile. We computed the average RMSE and R^2 for each training condition across all cross-validation folds as the final metric of the model performance.

We performed statistical analyses to evaluate the differences among the three conditions. A one-way analysis of variance (ANOVA) was conducted to test for overall differences in RMSE and R^2 values across conditions with the significance level set to 0.05. If significant differences were identified, post-hoc pairwise comparisons with a Bonferroni correction were performed to determine which specific conditions differed.

III. Results

A. PCA and Clustering Results

The first three principal components accounted for 41.79%, 18.04%, and 10.21% of the variance, respectively (Fig. 2a). By projecting the original data onto these top three principal components, a three-dimensional representation of the biomechanical latent space of a total of 70.04% of explained variance was generated (Fig. 3a). This reduced-dimensional space served as the foundational coordinate system for our clustering analysis.

The optimal cluster number for our dataset was eight with a silhouette score of 0.38 (Fig. 2b). Using the clustering result (Fig. 3b) and task-weight analysis, the representativeness of each task, R, was computed (Table 1). The task with the highest R score in each cluster was selected as the representative task for the cluster. Among these eight tasks, three were cyclic tasks (normal walk, stairs up, and stairs down) and five were non-cyclic tasks (lunges, jump, cutting, sit to stand, and lift weight). These tasks were our training dataset for the optimized-task model. The other two conditions were trained with 1) all tasks, which included all 20 different tasks and 2) cyclic tasks, which included all eight cyclic tasks.

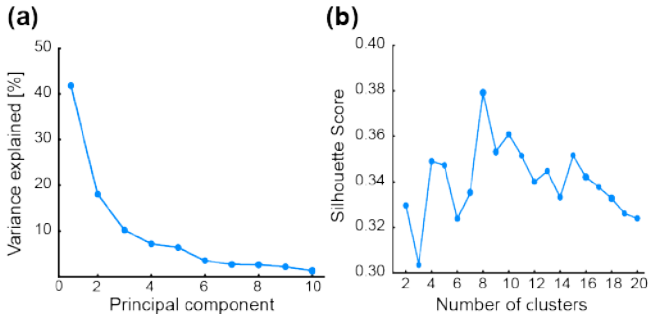

Fig. 2: PCA and K-means Clustering Parameter Selection. (a) We used the first three principal components since they explained over 70% of the variance. (b) The Silhouette method revealed that K = 8 yielded the best silhouette score, indicating it as the optimal number of clusters for our dataset.

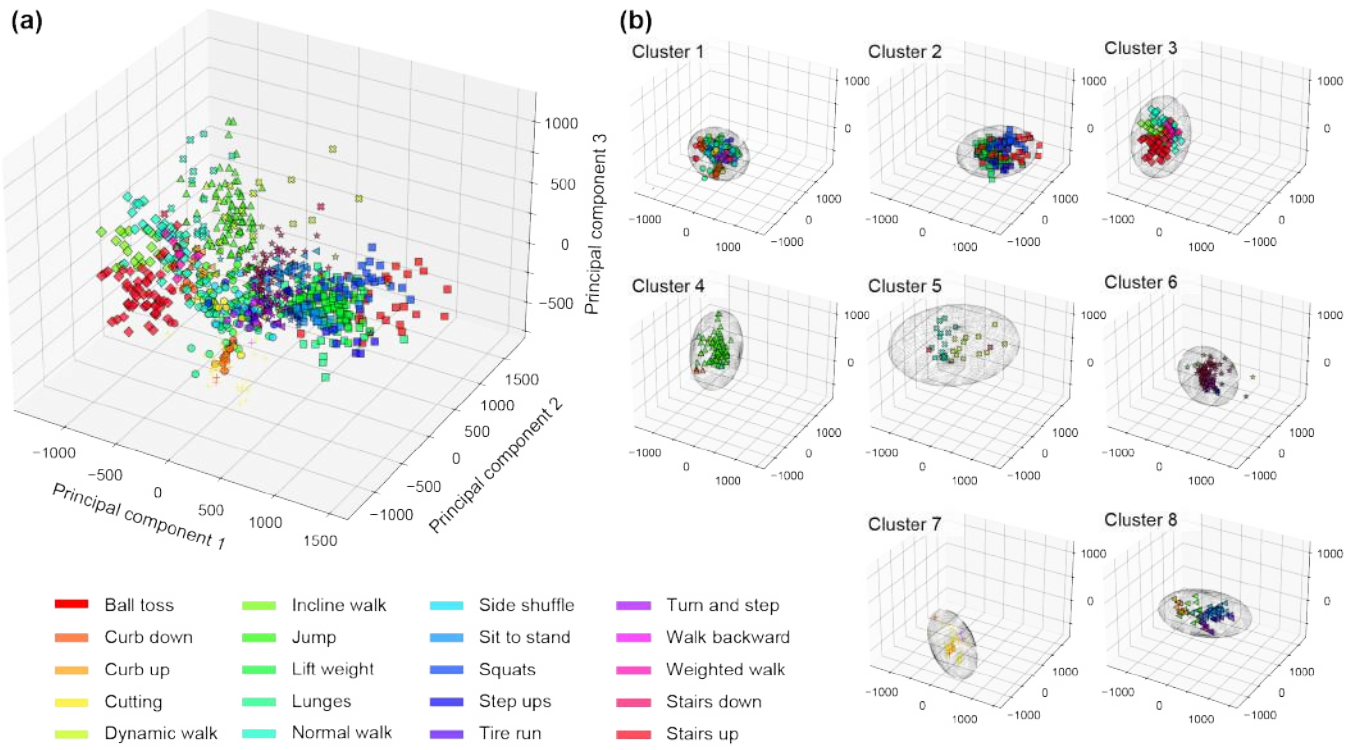

Fig. 3: PCA and K-means Clustering Results. (a) All biomechanical feature data represented in the reduced dimensions. Each task mode is colored differently and each cluster is marked in a different marker shape. (b) Separate plots for each cluster, with the ellipsoid representing the space of 99% confidence for each cluster.

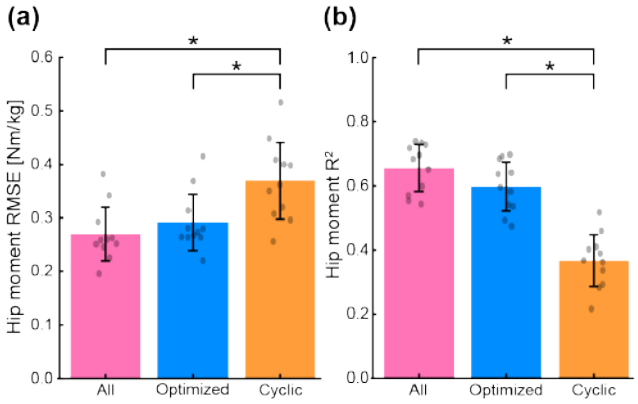

Fig. 4: Model Performance. (a) The all-task and optimized-task models outperformed the cyclic-task model, with significantly lower root mean squared errors (RMSEs). (b) Similarly, the optimized-task model showed higher R^2 compared to the cyclic task model, but similar performance compared to the all-task model. Gray dots represent values from 11 models per condition. * indicates a statistical difference from the cyclic tasks model ($p<0.05$).

B. Neural Network Performance

The optimized-task model performed better than the cyclic-task model and as well as the all-task model. The optimized model achieved an average RMSE of 0.29±0.06 Nm/kg and R^2 of 0.60±0.08 (Fig. 4). The all-task model had an average RMSE of 0.27±0.05 Nm/kg and R^2 of 0.66±0.08 . The cyclic-task model presented an average RMSE of 0.37±0.07 Nm/kg and R^2 of 0.37±0.08 . The

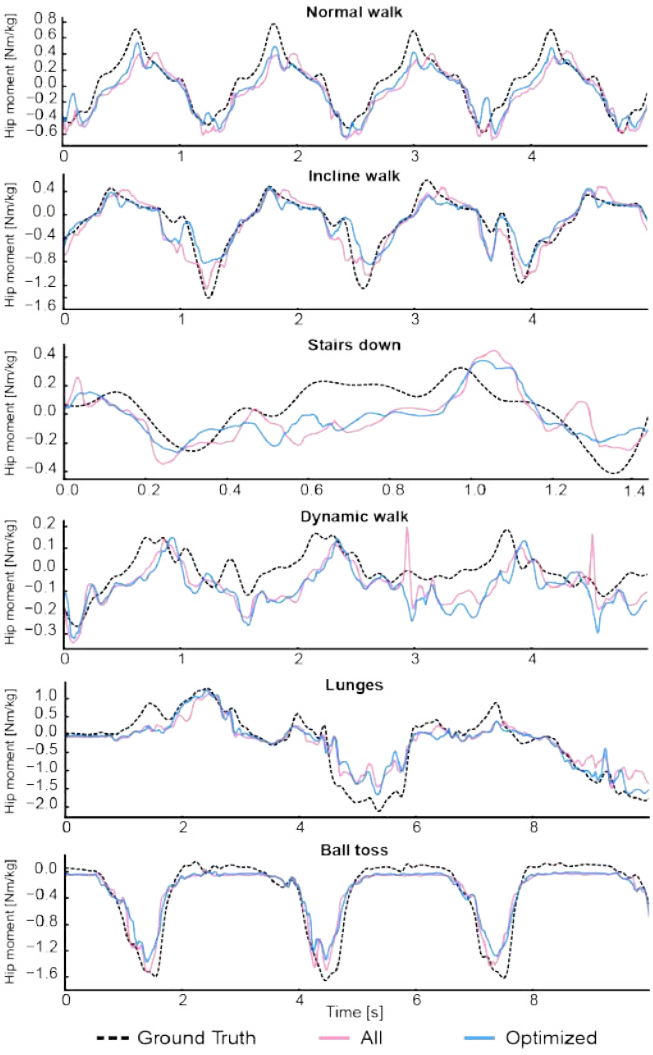

Fig. 5: Qualitative Performance Evaluation. Ground truth and estimated hip joint moments for the optimized-task (skyblue) and all-task (pink) models on four cyclic and two non-cyclic tasks using leave-out subject data with median RMSE performance. Ground truth is shown as a black dashed line. Both models follow the ground truth trend in similar performance.

models trained with all tasks and optimized tasks had lower RMSEs compared to the model trained with all cyclic tasks, by 26.52±6.48% and 20.40±6.70%, respectively ($p<0.05$). The optimized-task model was not different, by both RMSE and R^2, compared to the all-task model. The ground truth versus predicted hip joint moments of the optimized-task and all-task model are depicted for two cyclic and one non-cyclic tasks from both the included (normal walk, stairs down and lunges) and excluded task sets (incline walk, dynamic walk and ball toss), serving as representative examples of each task type (Fig. 5).

IV. Discussion

As hypothesized, the model trained on the optimized task set achieved comparable performance to the model trained on the entire dataset in hip joint moment estimation (Fig. 4). This finding validates the effectiveness of the task set optimization approach we used. Notably, the optimized-task model outperformed the cyclic-task model in RMSE and R^2 metrics, even though both sets contained the same number of tasks. This result highlighted the importance of including non-cyclic tasks in training data. It also presented the advantage of task optimization over relying solely on cyclic tasks for training a biological joint moment estimator.

The comparison of model predictions supports our argument that the optimized-task model performs comparably to the all-task model (Fig. 5). Both models were tested on a leave-out subject whose data showed median RMSE performance with the optimized task model. Despite its median performance, the model produced predictions nearly equivalent to those of the all-task model. Furthermore, when predictions were poorly executed, both models underperformed. This suggests that these difficulties are not stemming from the training tasks but from the limitation of using an FCNN and the inherent challenges of predicting non-cyclic tasks using only kinematic data. Overall, these results imply that developing a user-independent hip joint moment estimator is feasible with reduced task data. This approach could streamline future exoskeleton controller design by reducing data collection and training demands, facilitating the deployment of hip exoskeletons for daily activities.

Compared to a previous hip joint torque estimation using the same dataset, our optimized task model demonstrated comparable accuracy [22]. The study trained temporal convolutional networks (TCN) with kinematic sensor inputs (pelvis and thigh IMUs, hip angle, and velocity) and achieved an RMSE of 0.280 Nm/kg and an R^2 of 0.56 [22]. Using an FCNN, our model achieved similar performance, likely due to the exclusion of seven non-cyclic tasks with atypical movements. Although these excluded tasks were more challenging to predict accurately, the task set we included remains diverse compared to datasets limited to only treadmill or cyclic tasks. This comparison indicated the effectiveness of our task optimization and demonstrated that model performance is maintained even with fewer task data.

Furthermore, our approach of grouping tasks into clusters based on biomechanical features proved successful, offering a foundation for interpretable task relationships. The previous study applied a forward task selection algorithm and suggested that their ten tasks were sufficient to achieve optimal model performance [22]. Three of their tasks (sit-to-stand, normal walk, and jumping) overlapped with our optimized tasks. Their inclusion of some tasks that we excluded may have caused these distinct results. Nevertheless, this comparison highlighted the potential of our method to optimize task selection for model training through a more interpretable and biomechanics-grounded approach. From our clustering result, we can see that tasks were grouped with similarly performed tasks (Table 1). For instance, Cluster 3 predominantly included cyclic tasks focused on ascending movements (stairs up, incline walk, and normal walk), while Cluster 2 comprised non-cyclic and propulsive tasks (lift weight, lunges, and ball toss). These results demonstrated that our method provided a more intuitive understanding of task relationships compared to black box, performance-

driven approaches. Thus, our proposed approach was not only cost-efficient but also more interpretable, making it a practical alternative for task selection in model training.

While our study presented promising results, it has several limitations. First, compared to the previous studies that used more complex models like long short-term memory (LSTM) networks [24] or TCN [8], we opted for a simple FCNN. While the neural network architecture was intentionally kept simple to serve as a controlled variable in this study, a more complex model might better capture the intricate relationships between tasks within each cluster. Such models could also more effectively highlight the impact of task selection optimization. Future research could explore architectures like LSTM or TCN and fine-tune such models to investigate their potential advantages in this context. Second, the dataset used in this study exhibited an imbalanced number of trials for each task, which could influence the outcomes of the optimization process. Although a task-weight analysis formula was employed to mitigate these effects, ensuring an equal number of data points for each task in future datasets could further enhance the quality and reliability of the PCA and k-means clustering. Finally, this study used data only from healthy participants. Our approach relied on biomechanical profile similarities, which limits its effectiveness in individuals with significant differences, such as patient populations. Severe differences (e.g., crouch gait or stiff knee) may degrade the task optimization process and, consequently, model performance. Further research with more diverse subjects is needed to refine the approach for patient applications.

V. Conclusion

In this work, we presented a method to optimize task selection for a user-independent hip joint moment estimator. We identified the most representative tasks for model training by leveraging dimensionality reduction and clustering techniques on biomechanical features. The model trained on these optimized tasks achieved comparable performance to the model trained on the full dataset. These findings underscore the robustness of our approach and provide a pathway for future research on hip exoskeleton controller development with minimal training efforts.

***Abstract*—Direct electromyography (EMG)-controlled prostheses can allow people with amputation (PWA) to directly control their prosthetic ankle. This versatile control can assist with a variety of activities of daily life (ADL), including rising from and sitting down into a chair (i.e., sit-to-stand (S2S)). However, direct EMG control may be limited by a PWA's ability to activate their residual muscles. Physical therapy training with visual feedback may allow PWA to better utilize direct EMG-controlled prostheses. One PWA (transtibial) completed four training sessions with physical therapy guidance and visual feedback of their dorsiflexor and plantarflexor EMG during S2S tasks using a direct EMG-controlled prosthesis. They returned two weeks after the fourth training session and repeated S2S tasks without physical therapist guidance or visual feedback. We found that as the training progressed, residual EMG activation became more similar to the intact limb and was retained when feedback was removed. We also found that S2S movement was smoother (less jerk) during the retention session compared to the first training session. Our results demonstrate the potential of physical therapy with visual feedback to improve PWA's utilization of direct EMG-controlled ankle prostheses and performance in tasks related to ADL.**

I. Introduction

Powered ankle prostheses have been developed to mimic biological ankle muscles with the goal to improve function and mobility of people with lower-limb amputation (PWA) [1]. Most powered ankle prostheses utilize autonomous control, which is well-suited for cyclic tasks such as walking; however, these schemes do not allow PWA to directly control their device and typically require individual states and tasks to be pre-programmed [2]. Recently, researchers have developed methods to decode user intent and utilize neural signals to control powered ankle prostheses [2], [3], [4], [5], [6], [7], [8]. Neural control can allow for greater task versatility and is better suited to non-cyclic tasks than autonomous control [2]. One neural control strategy is direct electromyography (EMG) control, where signals from sensors placed on residual muscles are used to control the prosthesis directly and are proportional to the dynamics of the prosthesis [2]. Previous studies have demonstrated that PWA using direct EMG-controlled prostheses were able to adapt their prosthesis control to a wide range of tasks and improve balance during perturbations [3], [4].

While direct EMG control of powered ankle prostheses has shown promising results, it may be limited by a PWA's ability to activate their residual muscles. Different PWA exhibit varied activation patterns with their residual muscles, such as different levels of co-activation between the gastrocnemius (GAS) and tibialis anterior (TA) muscles and varied performance in generating desired activation patterns [9], [10]. While calibration methods can account for different levels of co-activation [11], there is still potential for PWA to improve their ability to generate desired, discrete activation patterns.

Feedback can be used to help PWA activate their residual muscles and control direct EMG prostheses. In Huang et al. [8], PWA using a direct EMG controlled prosthesis during walking were able to adapt their activation patterns and increase prosthetic push-off when visual feedback was given, but this adaptation was not retained when the visual feedback was removed. One research group developed a novel amputation surgery that maintains proprioceptive feedback from residual antagonistic muscles [4], [7]. PWA with the surgery exhibited less residual muscle co-activation and better utilized the EMG-controlled prosthesis during gait tasks such as walking on slopes, stairs, and obstacles compared to those without the surgery [4]. However, tying EMG-controlled prosthesis benefits to a surgical intervention may limit accessibility.

Alternatively, guided training may help PWA utilize direct EMG control [12], [13]. In a case study, one PWA completed a five-day training protocol with a direct EMG prosthesis that included tasks such as moving a rocker board, arm raises, forward reach, load transfer, and sit-to-stand (S2S) [12], changing their EMG activation strategy between the start and end of training [12]. Moreover, their performance in the load transfer task, requiring between limb synchronization, improved across training days [12]. This study demonstrated the potential for training with joint-level and whole-body movements to improve PWA's ability to utilize direct EMG prostheses for a range of tasks.

This study is funded by a National Institutes of Health Research Project grant (NIH: 5R01HD110519-02).

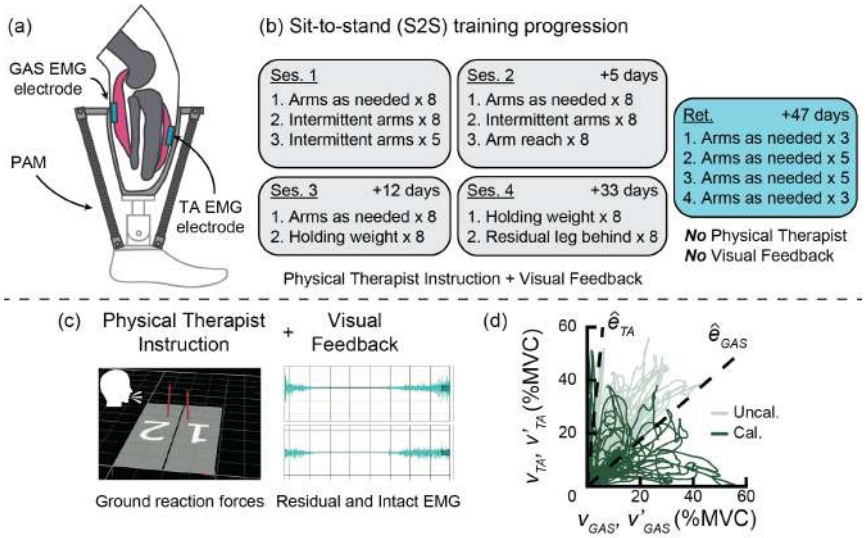

Fig. 1. (a) Diagram of the EMG-controlled powered prosthesis used. (b) Diagram of the sit-to-stand (S2S) training progression. For the first four sessions physical therapist instruction and visual feedback were given while the participant completed S2S trials. The difficulty of the S2S trials were varied to facilitate training. For the retention session, no physical therapist instruction or visual feedback were provided. The number of trials, cycles per trial, and days since the first session are indicated. This case study is a subset of a larger study and additional tasks were performed during sessions (Ses.) 1–4. In addition to S2S, the participant completed a joint-level visual feedback task during Ses. 1–2, squats during Ses. 1–4, arm raises during Ses. 2–4, rocker board during Ses. 3–4, stool stepping during Ses. 4, and stop and go walking during Ses. 4. (c) Physical therapist instruction and visual feedback given during sessions 1–4. (d) Uncalibrated (light green) GAS (v_{GAS}) and TA (v_{TA}) activation during the calibration task. Unit vectors ($\hat{e}_{GAS}$, $\hat{e}_{TA}$) that bound the uncalibrated control input space were used as a basis for the calibrated control signals (dark green, v'_{GAS}, v'_{TA}).

One important and ubiquitous activity of daily life (ADL) is sitting down and getting up from a chair [14], which can be challenging for PWA [15], [16]. Non-amputees activate the muscles surrounding the ankle during the S2S. For example, when rising from a chair the TA activates at the onset of movement contributing to forward motion of the body's center of mass while the GAS is activated later in ascension contributing to postural adjustments [17]. Given that passive prostheses cannot mimic these functions, PWA using these devices often compensate with their intact limb during S2S, exemplified by greater intact limb ground reaction forces and knee moments [16]. Direct EMG-controlled prostheses that can mimic the function of the muscles that surround a biological ankle have the potential to improve S2S performance through improved joint control for more symmetric joint motion. Therefore, the goal of the case study was to examine how a PWA controls a direct EMG prosthesis to perform S2S tasks and determine how guided physical therapy training with visual feedback could help the participant develop residual neural control activation that matches the intact limb and improve performance in the S2S. Moreover, we examined if the EMG activation strategies and task performance were retained after physical therapy instruction and visual feedback were removed.

II. Methods

One participant with unilateral, transtibial amputation (1 female, age: 29 years of age, height: 1.64 m, mass: 76.8 kg, time since amputation: 18 years, cause of amputation: cancer, K-level: 4 [19]) gave informed, written consent to participate in the study to the Institutional Review Board of North Carolina State University. This case study is a subset of a larger clinical study related to use of direct EMG-controlled prostheses for postural control and stability (NIH: 5R01HD110519-02).

A. Powered prosthesis

1) Design and sensing: The participant used a powered prosthesis with pneumatic artificial muscles (PAMs) (Fig. 1a) [3], [6]. The prosthesis has two PAMs in the front to control dorsiflexion and two PAMs in the back to control plantarflexion. Bipolar, low profile, neo-natal surface electrodes (Ambu Neuroline, Columbia, MD, USA) were placed on the residual TA and GAS muscles, inside the socket.

2) Signal processing and control: Residual muscle EMG (Ambu Neuroline 715, Ballerup, Denmark) were recorded in real-time at 1000 Hz (Motion Lab Systems MA-400, Lake Elsinore, CA, USA) and used as control inputs (v_{GAS}, v_{TA}) for the PAMs (dSPACE, Paderborn, Germany) [3]. In real-time, EMG were first high-pass filtered (100 Hz), then rectified, and finally low-pass filtered (2 Hz) using a custom Simulink model (Mathworks, Natick, MA, USA) [3]. Post-tuning and calibration, described below, the processed EMG signals (0-10 V) were sent to proportional pressure regulators (MAC 36 series valve and PPC36A pressure regulator, Wixom, MI, USA) to modulate PAM internal pressure (0 to 90 psi) [3].

3) Calibration and tuning: We calibrated control signals to lines of co-activation exhibited by the participant at the beginning of each session (Fig. 1d). To determine the co-activation, the participant completed a one minute visual feedback task in which they moved a cursor through a grid on

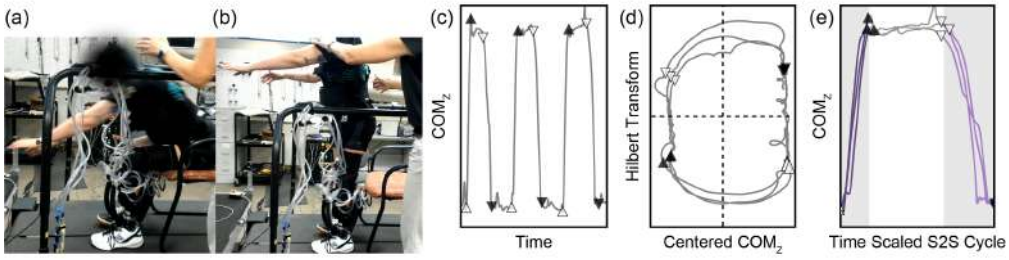

Fig. 2. Participant beginning (a) and (b) ending a S2S ascent. (c) Time series data from the vertical (i.e. "Z") component of the participant's CoM. Up and down pointing triangles indicate the beginning (open) and end (filled) of S2S ascent and descent periods, respectively. (d) These event locations were determined from the Hilbert transformed phase portrait of CoM_Z [18]. In this phase portrait (x-axis inverted), the first S2S cycle begins in the bottom right quadrant and proceeds counter-clockwise. (e) COM_Z data normalized to the time between ascent beginning and descent ending events. The shaded regions on the left and right depict the average ascent and descent sections of these cycles, respectively, and are highlighted in each cycle by purple.

a computer screen representing their control input space [9]. The processed, but not yet calibrated, control signals from the residual GAS and TA controlled horizontal and vertical cursor movement, respectively. As the cursor moved through the grid, the squares of the grid changed colors. The participant was asked to move the cursor as close to the x- and y-axes as possible, which corresponds to isolated activation from one muscle without activation from its antagonist. We determined the "natural" co-activation of the GAS and TA anterior muscles as the unit vectors of the lines that bound the participant's control input space ($\hat{e}_{GAS}$, $\hat{e}_{TA}$) (Fig. 1d). We calculated the calibrated control inputs (v'_{GAS}, v'_{TA}) using (1):

$$\begin{pmatrix} v'_{GAS} \\ v'_{TA} \end{pmatrix} = K^{-1} * \begin{pmatrix} v_{GAS} \\ v_{TA} \end{pmatrix} = \rceil \hat{e}_{GAS} \quad \hat{e}_{TA} \rceil^{-1} \begin{pmatrix} v_{GAS} \\ v_{TA} \end{pmatrix} \tag{1}$$

where K^{-1} is the inverse calibration matrix (Fig. 1d). We then manually set gains and baseline values that were multiplied and added, respectively, to v'_{GAS} and v'_{TA} [3], [6]. Gains were adjusted such that a maximum contraction during sitting for each muscle resulted in a 8–9 V signal which corresponds to 72–81 psi generated by the pressure regulators [3]. Adding constant offset values (2–3 V) established baseline prosthetic ankle stiffness.

B. Measurements and processing

1) EMG: Bilateral EMG were recorded from TA and GAS muscles at 1000 Hz. For analysis, EMG were demeaned, bandpass-filtered (fourth-order Butterworth , 10-350 Hz), rectified, and low-pass filtered (fourth-order Butterworth, 6 Hz).

2) Kinematics and kinetics: A 12-camera motion capture system (Vicon, Oxford, UK) recorded reflective motion capture markers placed on the anterior superior iliac spines, posterior superior iliac spines, and iliac crests at 100 Hz, while a dual-belt, force-measuring treadmill (Bertec, Columbus, OH, USA) measured ground reaction forces (GRFs) at 1000Hz. In analysis, marker data were low-pass filtered (7 Hz).

C. Protocol

First, a certified prosthetist fit and aligned the participant's socket to the pneumatic ankle prosthesis. Then on separate days, the participant completed four pre-training evaluation sessions, as part of the larger study. The participant completed postural control tasks using their own passive prosthesis and the pneumatic ankle prosthesis for two sessions each. After that, they completed five training sessions with a physical therapist using the pneumatic prosthesis on separate days at least 5 days apart. The training sessions consisted of joint-level and body-level tasks (e.g. joint-level visual feedback tasks, squats, stop and go walking) [9], [12], performing S2S tasks during each of the five sessions (Ses. 1–4 and Ret.; Fig. 1b).

1) S2S training protocol and feedback: The participant maximally contracted (MVC) the TA and GAS of both legs in sitting and standing three times each. We calibrated the control inputs and tuned the prosthesis controller gains based on the process described above. For the first four sessions, the participant completed S2S tasks with physical therapy guidance and visual feedback (Fig. 1b). They completed 5–8 S2S trials per task and 2–3 tasks per session. The physical therapist provided instructions regarding S2S performance and use of the prosthesis. For example, the physical therapist instructed the participant to bear weight symmetrically between the two limbs and contract the muscles in a smooth, controlled manner. The physical therapist progressed S2S difficulty. Variations of the S2S included utilizing the chair arm rests with one or two arms, not using the arm rests, reaching arms forward throughout the task, holding a 5 lb weight, and staggering the feet to target the residual limb (Fig. 1b). During these tasks, the participant was given visual feedback of GRFs and EMG from both legs (Fig. 1c). To determine if the participant retained any training benefits, she returned for a fifth session where she completed four S2S tasks without physical therapist guidance, visual feedback, and minimal arm rest use.

D. Data analysis and outcome measures

1) Determining S2S ascent and descent: To analyze the ascent and descent periods of the S2S independently, we sectioned the trials based on the body center of mass (CoM). We estimated CoM from marker data and a model of the pelvis in Visual3D (HAS-Motion, Kingston, Canada). To accommodate variations in S2S cycle duration and position extrema, CoM data was sectioned using a procedure similar to [20]. Briefly, this process created phase portraits for each trial and utilized

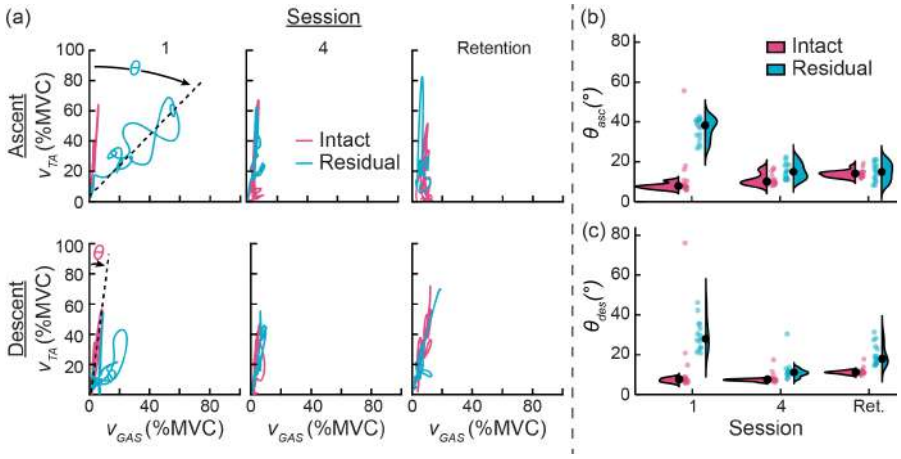

Fig. 3. (a) Representative S2S ascent (top) and descent (bottom) TA-GAS activation spaces, normalized to MVC, from the intact (red) and residual (blue) limbs during training session 1 (left), training session 4 (middle), and the retention session (right). The angle θ measures the amount of co-activation during the section. (b, c) θ of the intact (red) and residual (blue) limbs, their probability distributions, and medians (black symbol) for both ascent (b, θ_{asc}) and descent (c, θ_{des}) from all trials in each session.

the Hilbert transform method due to the data's non-sinusoidal nature [18]. The horizontal axis for each trial consisted of the CoM's vertical component, centered by its extrema, while the vertical axis was created from the imaginary portion from the Hilbert transform of the centered CoM position (Fig. 2c) [18]. Horizontal axis crossings from the resulting phase portraits occur at S2S superior and inferior midpoints (Fig. 2a,b) and vertical axis crossing midway through descent and ascent. Hence, the first passing of the phase angle across the phasal midpoints between axis crossings (i.e. 45, 135, 225, and 315°) approximate the beginning and ending of S2S ascent and descent (Fig. 2b-d). To avoid distortion from the Hilbert transform [21], data from the first and last 100 samples from a trial were not considered in this report.

2) EMG: EMG data were normalized to their respective MVCs (maximum value from sitting and standing MVC trials) and segmented into sections. To quantify the EMG activation strategy used during ascent and descent, we computed limb and ascent/descent-specific principal component analyses (PCA) (Fig. 3a). The angle of the PCA (θ) represents the relative contribution of the GAS and TA muscles where 0° signifies only TA activation and 90° signifies only GAS activation (Fig. 3a). PCA inputs were post-processed TA and GAS activity normalized to MVC. θ was acquired by calculating the cosine similarity between $[0, 1]^T$ and the first eigenvector of the covariance matrix.

3) CoM jerk: To quantify S2S performance, we computed CoM jerk because of the emphasis placed on task smoothness by the physical therapist and that smoother motion is a sign of improved control [22]. To account for differences in S2S duration and speed, we calculated the log transformation of normalized, integrated CoM [22]. To do this, we first took the third derivative of the CoM magnitude timeseries (2).

$$jerk = \left(\frac{\mathrm{d}^3 ||CoM||}{\mathrm{d}t^3} \right) \tag{2}$$

Next, data were sectioned into ascent and descent portions using the method described above. The squared jerk was integrated, multiplied by its duration (T) to the 5^{th}, and then divided by the square of its CoM magnitude amplitude (A). We log-normalized the result to get unit-less, log-normalized, integrated square jerk (NJ) (3).

$$NJ = \log_e \left(\frac{T^5}{A^2} \int jerk^2 dt \right) \tag{3}$$

For the CoM jerk, we analyzed data from the first trial in session 1, the first trial in session 4, and the second trial during the retention session (Fig. 1b). We chose to analyze data from the first trial on session 1 and 4 because those were the S2S tasks that were most similar between the first and last training days. We chose to analyze data from the second trial on the retention day as it was the first complete trial (trial 1 only had 3 repetitions).

EMG and COM jerk were analyzed descriptively given that the current study is a case study of one participant.

III. Results

On the first training day, in both the ascent and descent periods of S2S, the participant primarily activated their intact TA and displayed little co-activation (Fig. 3a). However, the residual muscles exhibited considerably more co-activation (Fig. 3a). During session 1, the median intact side θ_{asc} and θ_{des} were 7.84° and 7.68°, respectively (Fig. 3b-c). While, the median residual side θ_{asc} and θ_{des} were 38.29° and 28.01°, respectively (Fig. 3b-c). By session 4, the participant was able to activate their residual TA during S2S without GAS co-activation, better matching their intact limb strategy (Fig. 3a). The median intact θ_{asc} and θ_{des} from this session were 10.06° and 7.58°, respectively (Fig. 3b-c). Similarly, the median residual θ_{asc} and θ_{des} were 15.01° and 11.18°, respectively (Fig. 3b-c). The EMG activation pattern was retained two weeks following the final training session during S2S tasks

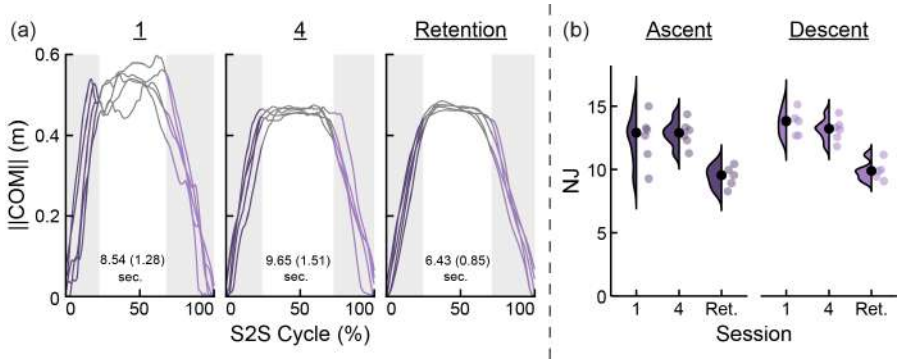

Fig. 4. (a) CoM Magnitudes of the S2S cycles analyzed during training session 1 (left), training session 4 (middle), and the retention session (right). The participant held a weight during session 4 S2S tasks. Shaded gray areas on the left and right show the average ascent and descent periods, while dark and light purple parts of the lines indicate these respective sections for each cycle. The average cycle time and trial standard deviation are displayed at the bottom of each plot. (b) Log scale normalized jerk (NJ; purple symbols), their probability distributions, and medians (black symbols) of the ascent (left) and descent (right) S2S sections.

without physical therapist instruction or visual feedback (Fig. 3a). During the retention session, the median θ_{asc} and θ_{des} of the intact limb were 14.10° and 11.28°, respectively (Fig. 3b-c). Similarly, the median θ_{asc} and θ_{des} of the residual limb were 14.92° and 17.90°, respectively (Fig. 3b-c).

CoM smoothness during the ascent of the S2S was almost equivalent during sessions 1 and 4, but the CoM smoothness improved relative to the training sessions on the retention day (Fig. 4a). Median NJ during ascent was 12.92, 12.91, and 9.54 during session 1, session 4, and the retention session, respectively (Fig. 4b). Similarly, during descent, the smoothness of the CoM was almost equivalent during sessions 1 and 4, but improved during the retention session (Fig. 4a). Median NJ during descent was 13.83, 13.24, and 9.89 during session 1, session 4, and the retention session, respectively (Fig. 4b).

IV. Discussion

Direct EMG control of powered prostheses allows people with limb amputation to directly control their prosthetic ankle, making it versatile to a wide range of tasks, but it can be limited by a participant's ability to activate their residual muscles. Our results indicate that guided physical therapy with visual feedback during training not only improves PWA's ability to control residual muscle activity, but also this ability is retained up to two weeks later without prior training aids. In the first training session, the participant displayed considerable co-activation between residual shank muscles but not intact muscles during both the ascent and descent S2S phases. In the final training and retention sessions, their intact and residual EMG co-activation patterns became more similar and were dominated by TA activation. This corresponds with non-amputee EMG activity during S2S. A study that measured EMG from eight lower limb and torso muscles of non-amputees found that the TA contributed 29% of the total activation during S2S ascent, while the GAS contributed 5% [23]. Furthermore, the training protocol seemed to affect S2S performance. Despite the increase in difficulty in S2S trials between session 1 and session 4 (holding 5 lb. weight in session 4), NJ was similar during S2S ascent and descent in session 4 compared to session 1. We also found that NJ decreased in the retention session compared to the other sessions. A reduction in NJ or an increase in "smoothness" of the movement implies that the participant was able to make a more controlled ascent and descent. The licensed physical therapist who conducted the training noted that the participant demonstrated improved ability to initiate the S2S task, attain and sustain postural stability in standing, and maintain control when descending onto the chair. Our result demonstrates the potential for direct EMG control to improve PWA's ability to stand up from a chair or sit down, an important ADL.

Our findings could have potential implications beyond S2S. Huang et al. found that without visual feedback, PWA using a direct EMG-controlled prosthesis walked with lower peak prosthetic power than with visual feedback [8]. Similarly, Song et al. found that PWA who had a novel surgery that provided proprioceptive feedback exhibited 187% greater peak prosthetic ankle power compared to the control group when both walked with a direct EMG-controlled prosthesis [4]. Their results suggest that without proprioceptive feedback, PWA were unable to fully capitalize on the EMG-controlled prosthesis. However, Stafford et al. reported that PWA walking with a direct EMG controlled prosthesis more than once a week helped maintain familiarity and improved EMG adaption [5]. Likewise, we found that even without physical therapist guidance and visual feedback, the control of residual EMG activation was retained in our participant at two weeks after training. Perhaps, training on a variety of tasks, progressing task difficulty, and utilizing visual feedback of muscle activation are key to the successful direct EMG-controlled prostheses use.

Our study had several limitations. First, this was a case study of one young, highly active participant who had never used EMG-controlled prostheses prior to the study. PWA's ability to activate residual muscles varies [10] and it is possible that the improvements observed throughout this case study represent larger changes than could be expected for other participants.

Second, we prioritized the physical therapy protocol and training flexibility over experimental control. The variation in the S2S tasks adds a potential confounding variable when comparing between sessions. Nevertheless, since the S2S tasks in session 4 were more challenging than in session 1, we speculate that we may have observed an improvement in NJ in session 4 compared to session 1 if the S2S tasks had been controlled. In future studies, we would like to examine the effects of the training protocol with a larger sample size and examine other important ADLs such as stop and go walking, turning, reaching, and rising up on toes. To evaluate independent effects of the EMG-controlled prosthesis and the training, we plan to recruit two groups of PWA: one group using their own passive prosthesis and the other using the EMG-controlled prosthesis.

V. Conclusion

One participant with lower limb amputation using a direct EMG-controlled prosthesis completed a 4-session training protocol with physical therapist instruction and visual feedback. As the training progressed, the participant was able to adapt their residual EMG activation so that it more closely matched their intact limb during S2S tasks. These residual EMG activation patterns were retained when physical therapy instruction and visual feedback were removed. Moreover, the participant improved S2S performance in the retention session compared to the first session. Our findings suggest that physical training that includes visual feedback, varies tasks to encourage use of the residual limb, and progresses in difficulty is a promising strategy to improve PWA's utilization of direct EMG-controlled prostheses.

Mantis shrimp-inspired quasi passive ankle-foot prosthesis*

Siavash Gitifar, Sy Nguyen, and Hwan Choi, *Member, IEEE.*

Abstract— **The biological ankle joint adjusts stiffness to adapt to changing walking speed and environments. However, commercial passive ankle-foot prostheses lack the ability to adjust stiffness, which causes gait issues. While powered prostheses can address these problems, they require large actuators, making them heavy, bulky, and energy insufficient. In this study, we introduce a quasi-passive, variable-stiffness ankle-foot prosthesis that employs unique characteristics of mantis shrimp's saddle spring. Mantis shrimps employ the saddle spring's energy storing and return mechanism to effectively punch their prey with their appendages. To integrate this saddle spring, we developed governing equations for parameterizing the geometry of the saddle spring. From the parameterization, the curvature and thickness of the saddle spring were optimized to match the biological ankle stiffness in normal walking speed. The moment arm of the saddle spring is then optimized to provide a range of biological ankle stiffness for slow to fast walking speeds. A theoretical model of the saddle spring is validated with experimental bench tests. The designed saddle spring can adjust dorsiflexion stiffness of the prosthesis from 8.63 to 18.43 Nm/° for a 100 kg user. The stiffness adjustment time from the lowest to highest stiffness is 0.3 sec. Our prosthesis shows a promising ability to provide prompt user-specific stiffness in daily living while maintaining compact, lightweight, and energy efficiency.**

I. Introduction

Approximately one million individuals in the United States are living with lower-limb amputations, and this number is expected to double by 2050 due to causes such as accidents and chronic illnesses, including obesity and diabetes [1]. The majority of lower-limb amputees utilize commercially available passive prostheses, generally manufactured with carbon-fiber, glass fiber, or other composite materials, which mimics spring-like behavior [2]. Although passive prostheses are affordable, lightweight, and compact, these designs impose significant limitations on the daily life of their users (e.g., uneven terrain or fast walking) [3]. Passive prostheses increase the risk of falls, decrease walking speed, and restrict users to a limited range of self-determined speeds, frequently leading to a walking speed that is half of a normal person's speed [4]. Moreover, the metabolic expenditure for users of passive prostheses is higher compared to able-bodied individuals [5], and activities such as ascending and descending stairs, as well as traversing the sloping surfaces, become considerably more difficult [6,7]. Prolonged usage of passive prostheses may result in side effects including backache, knee pain, and postural deformities, due to the asymmetrical gait cycle [8].

The issues faced by amputees mostly result from the lack of a functional lower limb, particularly the ankle joint. The biological ankle joint is essential for ensuring stability during the stance phase by adjusting the level of stiffness and facilitating moving forward during the push-off phase [9]. For example, ankle stiffness increases with an increase in walking speed. Biological ankle stiffness dynamically adjusts to diverse walking conditions, improving stability and efficiency over various terrains. On incline surfaces, such as ramps, increased ankle stiffness enhances control and facilitates propulsion by stabilizing the foot during push-off. Meanwhile, when traversing soft ground, stiffness generally reduces according to the terrain's instability, enabling the ankle to absorb and adjust to uneven forces [10,11]. The lack of joint stiffness adjustment capability in the passive prostheses considerably affects amputees' walking, daily activities, and overall quality of life [12].

Quasi-passive prosthesis, which use actuators to adjust stiffness, have been proposed as an alternate way to adapt different walking speeds and environments such as slop, soft ground, and stairs [13]. People with lower limb amputation can increase stability and reduce energy expenditure by using quasi-passive prosthesis that provides a suitable stiffness of the biological ankle joint while dynamically changing stiffness in response to walking demands [14]. These enhancements aim to improve amputees' quality of life by offering better control and reduced reliance on electrical power.

The variable stiffness prosthetic ankle-foot [15] uses an elastic cantilever beam to adjust stiffness by changing the slider's position. This design is compact and lightweight. However, it includes a rigid forefoot, limiting its ability to mimic the natural flexibility of the human foot, and requires continuous motor operation to adjust stiffness, resulting in a slow response. The Pro-Flex Pivot [16], with shear thickening fluid damper-spring system to vary stiffness through changing the damping ratio, also faces challenges with energy dissipation, and reducing efficiency in energy storage and return. The 2-degrees of freedom (DOF) Ankle foot prosthesis [17] uses two linear actuators to adjust stiffness. This design requires continuous motor operation, resulting in large battery demands. Quasi-passive variable stiffness prosthesis presented in [18] has multiple carbon fiber blades, and a locking mechanism uses solenoid as actuator. While lightweight, this quasi-passive variable stiffness mechanism is a high-profile design with discrete stiffness values, lacking the fine adjustment seen in a biological ankle.

This paper introduces a novel quasi-passive ankle-foot prosthesis inspired by the mantis shrimp, known for its rapid and powerful predatory strikes. The mantis shrimp utilizes a saddle-shaped elastic structure as a spring to store energy before striking, thereby amplifying the generated force [19,20]. Similarly, the proposed study employs a saddle-shaped elastic shell, named the "saddle spring", which functions as the prosthesis's spring element. This design addresses critical limitations of existing quasi-passive

prostheses by offering: (1) an adjustable stiffness with wider range to accommodate various walking speeds, sprinting, and running; (2) rapid stiffness adjustments within a single swing phase; and (3) an energy-efficient, self-locking mechanism that minimizes battery consumption. The paper presents the device's design, parameterization and optimization of the saddle spring, experimental testing, and an analysis of the results, demonstrating the effectiveness of the proposed approach.

II. Methods

A. Design of Mantis Shrimp-inspired Ankle-Foot Prosthesis (MSAFP)

The overall design of the ankle-foot prosthesis is shown in Fig. 1. The saddle spring is positioned between the upper and lower fixtures, which are capable of rotating around the central shaft that connects the adapter to the foot plate. The rotation of the upper fixture is driven by a worm-bevel gear system with a 60:1 ratio, powered by a DC motor (DCX 22 L, 10W, Maxon, Sachseln, Switzerland). The footplate is fabricated from Delrin, a strong and lightweight plastic material that offers sufficient mechanical strength while reducing overall weight compared to metal alternatives. This mechanism allows the saddle spring to rotate around the central shaft, enabling adjustments to the distance between the edge of the saddle spring and the central shaft. The distance between the saddle spring and hinge joint is defined as the moment arm, with the hinge joint functioning as the ankle joint.

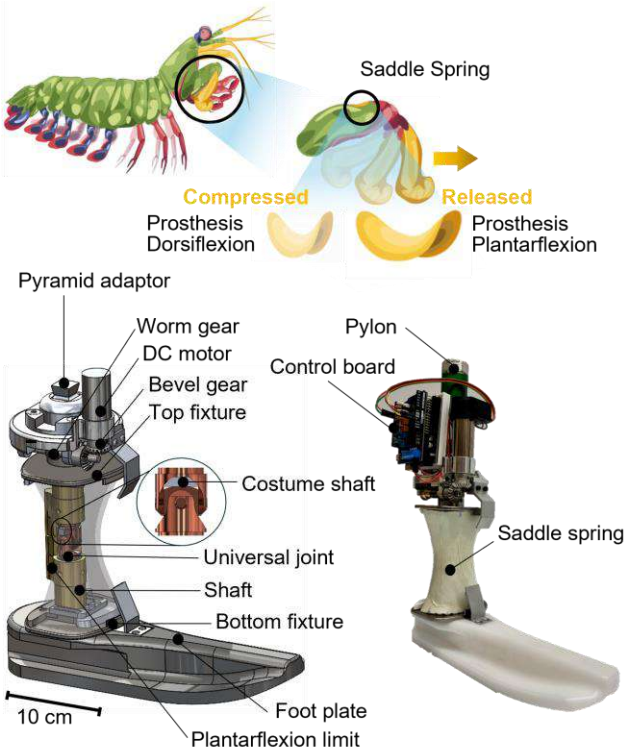

Fig. 1. Mantis Shrimp-inspire Ankle-Foot Prosthesis (MSAFP)

Utilizing the worm-bevel gear system, the proposed design can lock the saddle spring at the desired orientation and maintain stiffness without being affected by the induced torque on the transverse plane caused by the saddle spring's curvature, thereby enhancing energy efficiency. A custom-designed shaft pin was used to restrict the universal joint's degrees of freedom in the frontal plane, effectively converting it into a hinge joint in the sagittal plane. This design allows for future modifications to analyze the effects of inversion and eversion. The overall stiffness of the prosthesis adjusts as the saddle spring rotates. This hinge joint not only supports the user's load but also allows for bending to accommodate the saddle spring's movement. In addition, two stoppers are designed on the back side of the prosthesis in the sagittal plane to limit plantar flexion to a maximum of 5°, while dorsiflexion is constrained to 20° to ensure a controlled range of motion suitable for walking conditions [21]. These stoppers utilize rubber pants to prevent foot flapping and cancelling noise when two stoppers touch each other.

The prosthesis features an adjustable stiffness mechanism controlled by the rotation of the saddle spring. The design is compact and lightweight, with a height of 25 cm (including the DC motor) and a weight of 2 kg (excluding the battery), making it suitable for lower-limb amputees with varying residual limb lengths. The mechanism enables rapid stiffness adjustments, transitioning from minimum to maximum stiffness faster than the duration of the swing phase, ensuring quick responsiveness and adaptability.

B. Parameterization of saddle spring

The parameterization objective is to enable precise control over the saddle spring's curvature along the sagittal and transverse planes, which directly affects stiffness. Transforming the geometry to cylindrical coordinates allows direct curvature adjustments via defined parameters. The saddle spring's geometry is represented by Eq. 1.

$$\frac{x^2}{a} - \frac{y^2}{b} = z \tag{1}$$

Here, x, y, and z represent spatial coordinates, respectively, while a and b control the magnitudes of curvature along the sagittal and transverse planes, respectively. The level of stiffness of the saddle spring depends on its material properties and curvature on the sagittal plane [22]. To directly adjust curvature in different orientations, the Cartesian geometry is transformed into cylindrical coordinates, as shown in Eq. 2-4. This allows for targeted manipulation of moment arm via parameters in cylindrical terms.

$$x = c \cdot R \cdot cos(e\theta) \tag{2}$$

$$y = d \cdot R \cdot sin(f\theta) \tag{3}$$

$$R = \sqrt{z^2 + h} \tag{4}$$

Where R, θ, and z represent the radius, angle, and height in cylindrical coordinates. Parameters c and d scale the radius along the sagittal and transverse axes, respectively, while e and f adjust curvature orientation, and h controls flatness.

C. Stiffness calculation of saddle spring

The design optimization of the saddle spring aims to (1) minimize the height to accommodate different limb lengths and (2) achieve a stiffness range comparable to that of the biological ankle, which varies from 8.87 Nm/° to 14.91 Nm/° for a 100 kg prosthetic foot user [23]. This ensures the

prosthesis can deliver the required stiffness across different walking speeds.

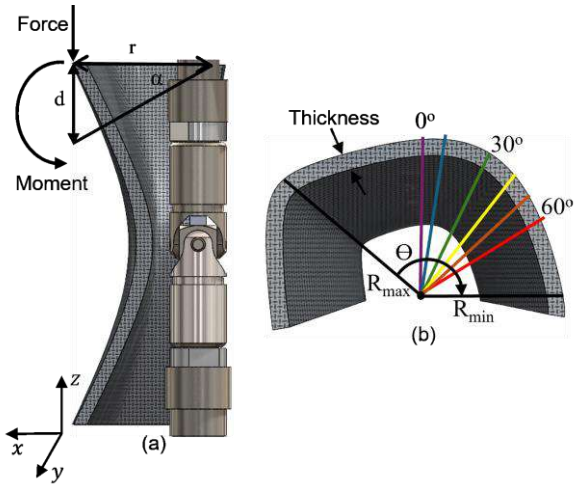

Fig. 2. Side and top view of saddle spring

Target stiffness is achieved by adjusting the moment arm and the saddle spring's thickness, as shown in Fig. 2 while maintaining identical curvatures in sagittal plane. Using the first-order shear deformation theory (FSDT) [24], we calculated stiffness values by integrating stress distributions over the thickness of saddle spring [25]. The saddle spring's radius of curvature along the sagittal (R_u) and transverse (R_h) planes are functions of the scaling parameters c and d. These equations are given as follows:

$$R_u = cR \tag{5}$$

$$R_h = dR \tag{6}$$

To model the saddle spring's stiffness properties, we calculate the extensional, coupling, and bending stiffness matrices A_{ij}, B_{ij}, and D_{ij}, which represent resistance to deformation under varying loads. These matrices are defined as follows:

$$A_{ij} = \int_{-t/2}^{t/2} Q_{ij}\left(1+\frac{f}{R_u}\right)\left(1+\frac{f}{R_h}\right)df \tag{7}$$

$$B_{ij} = \int_{-t/2}^{t/2} f\,Q_{ij}\left(1+\frac{f}{R_u}\right)\left(1+\frac{f}{R_h}\right)df \tag{8}$$

$$D_{ij} = \int_{-t/2}^{t/2} f^2\,Q_{ij}\left(1+\frac{f}{R_u}\right)\left(1+\frac{f}{R_h}\right)df \tag{9}$$

Here, the matrix A_{ij} integrates extensional stiffness across the spring thickness, the coupling matrix B_{ij} incorporates displacement fields and stiffness coefficients, and the bending matrix D_{ij} includes curvature effects. Where Q_{ij} is the transformed material stiffness coefficient for each layer, t is the shell thickness, and f is the displacement element in direction of thickness. The material stiffness coefficient Q_{ij} for each layer of saddle spring defines the material stiffness of each layer in terms of its elastic properties, allowing multi-layered material stiffness calculation, as shown in Eq. 10:

$$Q_{ij} = \begin{cases} \dfrac{E_s}{1-\nu_{st}\nu_{ts}} & i = j \\ \dfrac{\nu_{st}E_t}{1-\nu_{st}\nu_{ts}} & i \neq j \end{cases} \tag{10}$$

Where E_s and E_t are the young's modulus in sagittal and transverse plane, ν_{st} is Poisson's ratio. The subscripts i and j denote different layers in the system, referring to their respective load and stiffness components. Also, the sagittal and transverse planes are represented by the subscripts s and t, respectively. In Eqs. 11-13, S, V, and W are the global displacement components of both in-plane and out-of-plane components in the sagittal, transverse, and frontal plane, respectively.

$$S(u,h,f,t) = s(u,h,t) + f\phi_u(u,h,t) \tag{11}$$

$$V(u,h,f,t) = v(u,h,t) + f\phi_h(u,h,t) \tag{12}$$

$$W(u,h,f,t) = w(u,h,t) \tag{13}$$

The displacement field components s, v, and w are defined along the u-, h-, and thickness f -directions, respectively. The terms ϕ_u and ϕ_h represent the rotations of the saddle spring normal with respect to the u- and h-axes. Then, the corresponding normal, shear, and curvature strains are calculated for u-direction in Eqs. 14-16, respectively. The same method (Eq. 14-16) can be used to calculate the corresponding normal, shear, and curvature strains in other directions.

$$\varepsilon_u = \frac{\partial S}{\partial u} \tag{14}$$

$$\gamma_{uh} = \frac{\partial S}{\partial h} + \frac{\partial V}{\partial u} \tag{15}$$

$$k_u = -\frac{\partial^2 w}{\partial u^2} \tag{16}$$

ε_u, γ_{uh}, and k_u represent the corresponding normal, shear, and curvature strains in u-direction, respectively. s, v, and w defined along the u, h, and f-direction. To evaluate the spring's mechanical response, the strain energy U_S is calculated, combining force, moment, and shear across the entire geometry:

$$U_S = \tfrac{1}{2}\int_0^L \int_0^\pi \big(F_u\varepsilon_u + F_h\varepsilon_h + F_{uh}\gamma_{uh} + M_u k_u + M_h k_h + M_{uh}k_{uh} + Q_u\gamma_{uf} + Q_h\gamma_{hf}\big)(R_u)(R_h)\,dh\,du \tag{17}$$

In this equation, F, M, and Q are force, moment, and shear resultants, respectively, while ε, γ, and k represent the corresponding normal, shear, and curvature strains. Together, these terms represent stresses on the saddle spring. The stiffness matrix k is derived from applying the variational principle to the total strain energy U_S. L is the maximum height in sagittal plane. This matrix incorporates axial, bending, and shear forces, as follows:

$$k_{ij} = \int_0^L \int_0^\Pi \left(A_{ij}\frac{\partial U_S}{\partial u} + B_{ij}\frac{\partial^2 U_S}{\partial u^2} + D_{ij}\frac{\partial^3 U_S}{\partial u^3}\right) R_u R_h\,dh\,du \tag{18}$$

This matrix is assembled for the entire saddle spring domain and accounts for both classical and elastic boundary conditions through the inclusion of artificial springs, which simulate various boundary conditions by setting stiffness values to zero (free) or infinity (fixed). To address various

boundary conditions, each displacement function is expanded in a modified Fourier series:

$$u(u,h,t) = \sum_{m=0}^{M^*} \sum_{n=0}^{N^*} A_{mn}^{s} cos\left(\frac{m\Pi u}{L}\right) cos(nh) + \sum_{m=0}^{M^*} \sum_{n=0}^{N^*} a_{ln} p_l(u)\, cos(nh) \quad (19)$$

M^*, and N^* representing the highest orders of the terms in the series used to approximate the displacement functions in u, and h directions. The circumferential wave number is represented with n, and m in each direction. A_{mn}^{s} is the double Fourier cosine coefficient, a_{ln} represent the corresponding coefficients of the auxiliary function. The auxiliary function $p_l(u)$ is chosen to remove discontinuities at boundary points, ensuring continuity of displacement and its derivatives. Boundary conditions are simulated by adjusting artificial spring stiffness along the boundary. The governing equation system is transformed into an eigenvalue problem:

$$([k] - \omega^2[M])[G] = 0 \quad (20)$$

where $[k]$ and $[M]$ are the stiffness and mass matrices, ω is the natural frequency, and $[G]$ is the displacement vector. This equation is solved to obtain the eigenvalues and eigenvectors, representing the saddle spring's stiffness and modal characteristics. Finally, the overall stiffness matrix of the saddle spring in three-dimension coordinate, calculated based on the presented method in this section (Eq. 20). The entire stiffness of the prosthesis is calculated by converting the force-displacement stiffness of the saddle spring to geometry of the prosthesis (Eq. 20). Where M, r, and F are moment, moment arm, and vertical force, respectively. α , d, and r represent rotation angle, vertical displacement, and moment arm, respectively.

$$M = rF \quad (21)$$

$$\alpha = tan^{-1}\left(\frac{d}{r}\right) \quad (22)$$

D. Optimization of saddle spring

A nonlinear optimization identifies optimal values for thickness and height of saddle spring based on normal walking speed, then moment arm of the saddle spring, constrained to match biological ankle stiffness from slow to fast walking speed with using MATLAB's SQP algorithm [26]. The scaling factors of saddle spring's radius (parameters c, and d in Eqs. 5 and 6), and thickness of the saddle spring (t in Eq. 7) are selected as optimization variables. The objective function is formulated to minimize the discrepancy between the saddle spring's stiffness range to match the biological ankle. Specifically, it is defined as:

$$J = \sum_{i=1}^{N} \left| k_{Saddle\ spring,i} - k_{Target,i} \right| \quad (23)$$

$k_{Saddle\ spring,i}$, and $k_{Target,i}$ represent the computed stiffness of the saddle spring, and the biological ankle stiffness at the same speed, respectively. The curvature and thickness of the saddle spring is optimized based on the appropriate stiffness for normal walking speed. Then, the moment arm (r) optimized to cover the stiffness range needed for slow to fast walking speed. Thus, the cost function for optimization was set as the absolute difference between the stiffness of the saddle spring and the target stiffness of the human ankle. To determine the overall prosthetic stiffness in slow walking speed (mild stiffness) and fast walking speed (rigid stiffness).

As walking speed increases, biological ankle stiffness increases. Based on the saddle spring's parameterization and optimization (sections B and C), the saddle spring is designed to match stiffness at normal walking speed, with further adjustments of the moment arm, the mechanism covering the stiffness range from slow to fast walking speeds. The saddle spring's radius is constrained between 20 and 40 mm, with thickness ranging from 2-5 mm. Material properties of the glass fiber saddle spring are defined as 12700 Mpa, 2.48×10^{-9} ton/mm^3, and 0.22 for the young's modulus, density and Poisson's ratio, respectively [27].

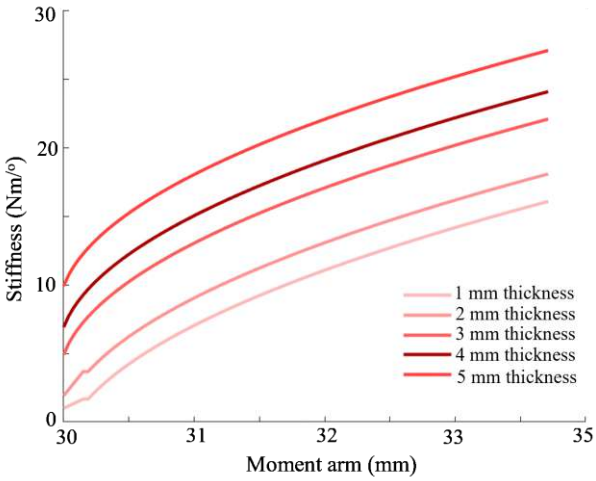

Fig. 3. Optimization of saddle spring

The stiffness-moment arm relationship for different thicknesses of the saddle spring, as shown in Fig. 3, highlights the impact of saddle spring's thickness on stiffness. Thinner saddle springs (1 mm and 2 mm) exhibit lower stiffness ranges. For instance, the 1 mm thickness provides a stiffness range of approximately 5 to 12 Nm/° across the moment arm range, while the 2 mm thickness achieves slightly higher values, ranging from about 7 to 15 Nm/°. Conversely, the 5 mm thickness yields the highest stiffness, ranging from 10 to 30 Nm/°. Therefore, the 4 mm thickness was chosen as the optimal configuration, offering a stiffness range of 8 to 25 Nm/°, which aligns well with the functional requirements of variable stiffness mechanisms, ensuring sufficient adaptability across different walking speeds.

E. Saddle spring bending test

The saddle spring is secured with two stoppers to prevent horizontal sliding, as shown in Fig. 4, replicating the boundary conditions of its fixtures in the prosthesis. A 30 mm diameter metal tip of the universal testing machine (313 tabletop dual column universal testing machine, TestResources, Shakopee, MN) was positioned on the top edge of the saddle spring to apply a vertical force of 1000 N at a constant rate of 100 N/s, ensuring compatibility with ISO 10328 [28]. The vertical force and displacement were calibrated before each test, with data recorded at 50 Hz. Static tests were conducted for different saddle spring orientations from 0° to 180° with 10° increments to evaluate the stiffness. Each test was repeated three times per orientation to assess stiffness changes, with experimental values collected based on the machine's measurements.

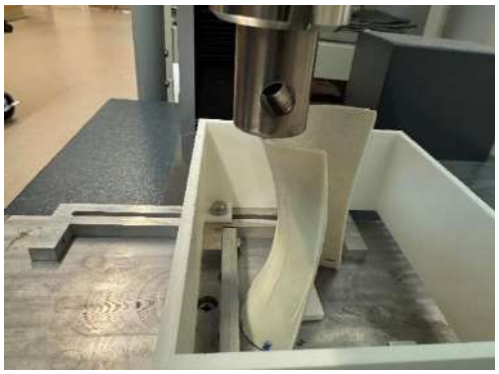

Fig. 4. Static bench test of experimental setup

III. Results

The saddle spring has variable stiffness at different orientations, with simulation results aligning closely with experimental data (Fig. 5). The stiffness of the saddle spring decreases as the moment arm shortens, making the system more compliant compared to configurations with a greater moment arm. From this analysis, the stiffness range of the designed saddle spring can be estimated to be from 8.63 to 18.46 Nm/° which meets the biological stiffness range [22].

Table 1 demonstrates that the saddle spring's stiffness decreases with increasing orientation angles, both in experimental and calculation results, indicating greater compliance at higher angles. The calculation closely matches experimental values, with root mean square error (RMSE) 1.2 to 3.89, suggesting that the model is fairly accurate across orientations. The lowest error occurs at 10° is 1.2, which indicates that the calculation performs best at mid-range orientations.

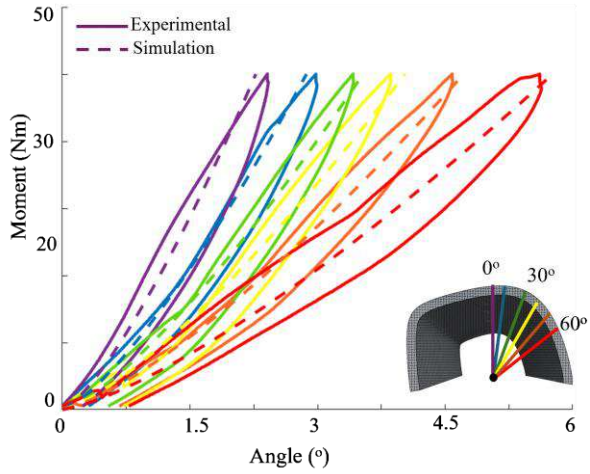

Fig. 5. Experiment and simulation stiffness. The color variation in the figure represents different orientations of the saddle spring, with the vertical purple line in the top view marking the origin (0°). Blue, green, yellow, orange, and red lines correspond to orientations of 10°, 30°, 40°, 50°, and 60°, respectively. Solid lines indicate experimental test results, while dashed lines represent simulation results for different saddle spring orientations.

MSAFP can adjust stiffness by rotating the saddle spring from 0° to 180° within 0.3 seconds. This speed is sufficient enough to change any level of stiffness within the swing phase duration that is approximately 0.4 seconds. This responsiveness enables real-time adaptation to gait changes.

TABLE 1 STIFFNESS ERROR BETWEEN CALCULATION AND EXPERIMENT

Saddle spring orientation	Stiffness (Nm/°)		
	Experiment	*Calculation*	*RMSE*
0°	18.46	19.62	1.69
10°	16.97	18.51	1.20
30°	14.47	13.86	1.60
40°	12.19	11.18	2.35
50°	9.63	9.05	2.78
60°	8.63	7.85	3.89

IV. Discussion

The MSAFP can adjust stiffness to accommodate a variety of walking speeds from slow to fast by altering the orientation of the saddle spring. This suggests that the prosthesis can deliver suitable stiffness for daily usage. The discrepancy between experimental and calculation occurs because the saddle spring is more balanced under load in the central region, whereas at the edges, slips occur during loading due to the uneven balance of the saddle spring (Fig. 5). Additionally, the edges are regions of high stress concentration, which can result in localized plastic deformation. Furthermore, the sharp edges of the saddle spring exacerbate stress distribution, contributing to the observed discrepancies.

The error between calculation and experimental values can come from manufacturing imperfections, such as uneven layer thickness or inconsistent material distribution across the saddle spring. Notably, fiber orientation, which has a significant impact on the quality of glass fiber, is designed based on the material stiffness coefficients (Q_{ij}) and elastic modulus [29,30]. Moreover, the discrepancy could stem from simplified material assumptions, such as linear elasticity, which fail to capture the complex responses observed during static tests. Also, the small slip during experiments leads to a higher experimental value compared to theoretical analysis. Furthermore, the universal testing machine may apply forces over a broader region of the saddle spring shell rather than targeting specific in theorical model.

In terms of energy storage and return in the saddle spring, the area of hysteresis increases as the saddle spring rotates from 0° to 60°. This is because the saddle spring's edge is more compliant than the center, resulting in more stored energy. Saddle spring is a specific type of hyperboloid shell. Previous studies [22] demonstrated that the curvature of hyperbolic paraboloid shells significantly influences their overall stiffness. Specifically, as the curvature decreases the stiffness of shell increases. In the MSAFP mechanism, the curvature on the sagittal plane of the saddle spring can be adjusted to reduce energy loss.

Future research will focus on refining the saddle spring design to better align with the biological ankle's stiffness profile over a wider range of walking, sprinting, and running speeds. For the current development, we optimized the thickness and moment arm of saddle spring to find the stiffness range for different walking speeds. Optimization of curvatures on the sagittal plane in addition to thickness and moment arm can be explored to maximize the range of stiffness and reduce the size of saddle spring and make it compact. Further optimizations using finite element analyses can also be

considered for the saddle spring's structural durability, as well as the hysteresis of energy storage and return.

In the MSAFP design, components such as the top fixture, bottom fixture, and bottom part support (which secures the bottom shaft to the footplate) are currently made of steel, with a combined mass of 0.573 kg. These components can be replaced with aluminum without compromising performance using finite element analyses. Employing aluminum can reduce the weight of MSAFP by approximately 0.2 kg, resulting in the total weight of the MSAFP, including the DC motor, of 1.8 kg.

V. Conclusion

Our MSAFP utilizes a novel saddle spring mechanism to adapt prosthetic foot stiffness across different walking speeds. The design is compact, fast respond, lightweight, and energy-efficient, with a responsive adjustment mechanism that operates within the swing phase duration. By consuming energy only during stiffness adjustments, the prosthesis minimizes power usage, enhancing its practicality for everyday use. Additionally, the mechanism is customizable to meet the unique needs of each prosthetic user and can accommodate running stiffness ranges, expanding its applicability.

Acknowledgment

The authors would like to thank Michael Carroll, Michael Varro, and Scott Anderson for their clinical advice on the prosthetic device design and saddle spring fabrication in this research project.

User Preferences and Information Gaps for AI-Assisted Selection of Engineered Devices for Home Rehabilitation after Stroke

Juan C. Perez-Ibarra, Luis Garcia-Fernandez, Andria J. Farrens, Miriam Bender, Jay J. Han, David J. Reinkensmeyer, *Senior Member, IEEE*

Abstract— **There has been a proliferation of engineered devices for movement rehabilitation, but their uptake remains sporadic. Using a mixed-methods approach with qualitative interviews and quantitative surveys, we asked nine post-stroke individuals to identify their information needs and to inform the design of an AI-powered decision support system to help select devices for home movement training after stroke. Key themes that emerged were: 1) difficulties finding information about device efficacy and motivational features and 2) openness to being helped by an AI chatbot. In a follow-up ranking exercise, participants indicated that the decision support system should provide information on the frequency of use required to get a benefit, ease of use, and the amount of expected benefit. They also highly rated potential features such as being able to provide personal information for customized recommendations, ask questions, and receive non-sales-driven guidance. In parallel, we analyzed 67 FDA-listed devices for movement rehabilitation. Of those with cost information, 43% were under $1,000, and 45% had insurance reimbursement. We emailed companies to get more data about motivational features and expected efficacy, but only 30% responded. These results confirm that post-stroke users have numerous devices available for home therapy but face substantial barriers to obtaining the information they want. Further, they are enthusiastic about using an AI chatbot to help find devices.**

I. Introduction

In 2021, more than 3 billion people worldwide were living with neurological conditions, representing about 43% of the world's population [1]. Stroke, in particular, remains one of the world's leading causes of long-term disability, with about 15 million people affected annually and half requiring long-term rehabilitation [2]. In response to the increasing demand for neurorehabilitation, the past three decades have seen a rapid increase in the development of neurorehabilitation technologies [3-4]. Innovations such as robotic therapy devices, sensor-based gaming systems, exoskeletons, brain-computer interfaces (BCIs), and functional electrical stimulation (FES) systems hold the promise of semi-automated therapy, increased user engagement, and more precise data for decision-making in treatment. Considering the case of rehabilitation robotics, the number of academic publications since 2001 has grown consistently due to the proliferation of both engineering and clinical studies [3-5]. The number of companies offering engineered rehabilitation devices also grew during this period. Despite this growth, clinical uptake of rehabilitation technology is sporadic. Key barriers include high costs, perceived complexity, and limited awareness of evidence-based benefits [6-8]. Both clinicians and patients struggle to find useful and trustworthy information that helps them select devices.

Our working hypothesis is that recent advances in AI could power a decision support system to help potential users of advanced rehabilitation technology make informed choices, reducing one barrier to uptake. In this paper, we report efforts toward gaining insight into how to develop such a system, focusing on two preliminary objectives of identifying user informational needs and gaps in available information. We have adopted a user-centric approach to ensure that the voices and needs of individuals with neurological impairments are central to the design and development of the proposed system. In this initial phase, we focus on post-stroke individuals as primary end-users, with the perspectives of other stakeholders, such as clinicians, planned for future studies. This paper describes the results of interviews followed by quantitative surveys of nine post-stroke individuals regarding the proposed system. In parallel, we sought to curate user-relevant information in a database of commercially available devices.

II. Methods

A. Interviews and surveys to gain insight into the informational needs and preferences of people post-stroke

Participants: We recruited nine individuals in the chronic phase of stroke from ongoing clinical trials of rehabilitation technologies at our institution; participant characteristics are shown in Table I.

Eight of the nine individuals participated in interviews (Group 1, see questions in Table II) and four in a pilot test of a survey comprised of a ranking exercise (Group 2, see Table III). All participants provided informed consent, and the Institutional Review Board of UC Irvine approved the study.

*This study was supported in part by the National Center for Research Resources and the National Center for Advancing Translational Sciences, National Institutes of Health (grant number 1UM1TR004927).

TABLE I. PARTICIPANT CHARACTERISTICS

ID	Gender	Age	Time post-stroke	Group 1	Group 2
SARS	Female	47	11 months	Yes	No
MASR	Male	68	10 months	Yes	No
RUPD	Male	62	2 years	Yes	No
LEDU	Male	61	13 months	Yes	No
CONK	Female	62	8 years	Yes	No
ZHAE	Male	46	8 months	Yes	Yes
BUIT	Female	60	13 years	Yes	Yes
SCHJ	Male	27	5 years	Yes	Yes
SIHR	Male	67	6 years	No	Yes

Interview Methods: Author A.F. conducted all interviews. Table II shows that the interview included questions about recovery, barriers to accessing and following rehabilitation advice, experiences using rehabilitation devices or apps, preferences for device recommendations, familiarity with artificial intelligence, and interest in AI-driven support systems. While not explicitly based on a single theoretical model, the questions were developed using a user-centered design approach, and they align with principles from the Technology Acceptance Model (TAM), particularly regarding perceived usefulness and ease of use [9-10]. Our analytical approach was guided by a constructivist paradigm, recognizing that individual experiences and social contexts shape attitudes. Therefore, we conducted an inductive thematic analysis, allowing themes to emerge organically from the data rather than being pre-defined. The analysis followed a summative content analysis approach, where we identified key themes based on the frequency and depth of participant responses. Two independent researchers developed a codebook (see the Results section) and coded the data separately, followed by consensus-building to refine the themes. Future studies will implement reliability assessments.

Survey Methods: We developed a quantitative survey based on the results of the interviews (Table III). The survey has two parts: ranking information preferences for a decision support system and ranking software feature preferences for the system. The same investigator who conducted the interviews briefly explained our intent of building a database and website to help stroke survivors compare and select rehabilitation devices. Participants were then presented with a list of nine potential types of information that such a website could provide about devices (e.g., ease of use, risks, and expected benefits; see Table III). They were asked to categorize each item into one of three levels of importance: most important (followed by ranking the top 3), medium importance, and lower importance. Following this, participants rated the importance of eight website features (e.g., personalized recommendations, chatbot functionality, accessibility on mobile devices) using a 10-point Likert scale, where 1 denoted "not important" and 10 "very important." A 3-point scale was used for ranking information priorities to simplify prioritization, while a 10-point scale allowed for finer granularity in assessing user preferences.

TABLE II. INTERVIEW QUESTIONS

1	What questions do you have regarding your recovery and rehabilitation?
2	How do you currently find information about your recovery? Internet, books, podcasts, primary care doctors, occupational therapists, friends/family, support groups?
3	What current barriers do you face regarding your recovery and finding resources to help?
4	Do you face barriers trying to follow the advice you've been given regarding your recovery (time, motivation, inability to perform suggested activities, conflicting advice)?
5	What have you done since your stroke that has been most helpful towards your recovery?
6	Have you used any devices or apps to help with your recovery? If yes, how did you learn about the device, how long did you use it, and what was your impression of its usability and usefulness?
7	Would you be interested in a customized system with a chatbot designed to answer your rehabilitation/stroke recovery questions?
8	What is your familiarity with AI/ChatGPT?
9	Would you be interested in device recommendations? If so, are you more interested in active devices (actuated gloves, home-based robotic tools, still devices), passive devices (weights, splints, hand exercisers, etc.), or computer or phone-based training apps?
10	Do you have any concerns about using high-tech devices (safety, useability, cost)?
11	What price range of devices would you want to have recommended?
12	Are you more interested in devices, recommendations on their use, or recommendations on general health/exercise?
13	What kind of information/vetting would you like to be provided with device recommendations (research articles, FDA approval, user reviews?)
14	Would you like the interface to be primarily optimized for computer or phone-based, or both?
15	What concerns do you have about the useability of such a system?

TABLE III. SURVEY QUESTIONS

Part 1. **Information the website should provide about the devices** (select three as most important, three as medium, and three lower)	
[ ]	Information about how easy each device is to use.
[ ]	Risks such as discomfort or pain
[ ]	How often and for how long do I need to use it to get a benefit?
[ ]	What amount of benefit can I expect?
[ ]	Information about what motivational features the device offers*
[ ]	Videos of people using the devices
[ ]	User reviews
[ ]	Information about scientific studies that support its effectiveness
[ ]	Return policy
Part 2. **How the website should help you find devices** (rate 1 to 10)	
[ ]	Ask me for personal information about my impairments and my goals so it can make personalized recommendations for what device would be best for me.
[ ]	Suggest devices in a way that's easy for me to compare them.
[ ]	Allow me to ask questions like a chatbot.
[ ]	Be accessible on my phone.
[ ]	Guide me through the selection process.
[ ]	Allow me to search without guiding me or asking me questions.
[ ]	Connect me with other people who are using a device I am interested in to help me make my decision.
[ ]	Connect me with a salesperson from the company that makes the device so I get more information.

* These could be things like progress tracking, social networks, gamification, goal setting with feedback, or motivational messages.

TABLE IV. FDA PRODUCT CODES RELEVANT TO OUR DATABASE

Code	Description
HCC	Device, Biofeedback
GZI	Stimulator, Neuromuscular, External Functional
ISD	Exerciser, Measuring
LXJ	Interactive Rehabilitation Exercise Devices
QKC	Interactive Rehabilitation Exercise Devices, Prescription Use
ION	Exerciser, Non-Measuring
PKS	Exerciser, Non-Measuring For Stroke Rehabilitation
BXB	Exerciser, Powered
JFA	Exerciser, Finger, Powered
QOL	EEG-Driven Upper Extremity Powered Exerciser
IPF	Stimulator, Muscle, Powered

B. Identifying informational gaps for a curated database of rehabilitation devices

We also developed a preliminary database of engineered rehabilitation devices suitable for home use. As part of this development effort, we sought to obtain information about each device related to the expressed needs and interests of the survey/interview participants.

Methods to develop the database: We conducted a structured search using online databases, manufacturer websites, and online marketplaces for rehabilitation devices. The search focused on FDA-approved devices suitable for home use and targeted those recovering from stroke. Devices were included if they addressed movement rehabilitation. The FDA classifies medical devices using a "product code." By searching the FDA's Product Code Classification database using keywords like "rehabilitation devices" and "stroke rehabilitation," we created a list of potential product codes to search for relevant devices (see Table IV). Then, we searched two FDA databases (the Establishment Registration & Device Listing database and the Premarket Notifications (510(k)s) database) using those product codes. We examined each device's online information to identify those that referenced or demonstrated applicability for stroke rehabilitation at home. We collected data on functionality, clinical validation, usability, and pricing if it was available.

Methods to obtain further information directly from manufacturers: Information available on websites was limited. We, therefore, contacted device manufacturers to supplement the website information and gain insights into areas of interest specific to end users. To do this, we sent a standardized email to solicit specific information identified as important by users in the interviews described above but often not available on product websites. We asked about:

- **Pricing and Return Policy:** We asked manufacturers to provide detailed pricing information for their devices, including whether they offered a return policy.
- **Ease of Use:** We asked about the device's ease of operation, specifically whether it required supervision, the level of independence users could achieve, and any reports of discomfort or pain. We inquired about the proportion of customers who used the device at home.
- **Usage Requirements:** We sought clarification on the recommended usage frequency and duration per week to achieve noticeable benefits. We also asked to share any supporting scientific studies validating their effectiveness.

TABLE V. PRELIMINARY DATABASE STRUCTURE

Field	Description
Name	The commercial name of the device
Manufacturer	The company that produces the device.
Website	Official website of the device or manufacturer.
Description	A summary of the device and intended use.
FDA Code	The classification code assigned by the FDA. Indicating the device category.
Year of Approval	The year the device received FDA approval.
Country	The country where the manufacturer is based.
Price	The retail price of the device, when available.
Price Per Year	Annual cost, applicable if the device is subscription-based or rented.
Insurance Coverage	Whether the device can be reimbursed or partially covered by insurance.
Return Policy	The availability of a return policy for the device.
Home Usability	An indication of whether the device can be used in a home-based setting.
Trained Body Parts	The specific body parts that the device targets (e.g., hand, arm, ankle, leg, torso).
Ease of Use	A summary of the ease of operation of the device.
Usage Requirements for Benefit	Recommended usage frequency and duration to achieve benefits. Expected size of benefits.
Clinical Evidence	Summaries of clinical studies.
Motivational Features	Does it contain features such as progress tracking, gamification, social networks, or feedback?

- **Motivational Features:** We asked companies to describe features to motivate users, such as progress tracking, gamification, social networks, or feedback.

We analyzed the replies from the companies for response rate and time, the replier's job title, answer format (i.e., whether companies answered by email or suggested a call or demo), and the presence of motivational features. We populated a database with the information obtained (Table V) for future use with the planned AI.

III. RESULTS

We asked individuals in the chronic phase post-stroke to identify their informational needs for selecting engineered devices to continue their rehabilitation at home. We also developed a preliminary database of FDA-approved, home-based rehabilitation devices and attempted to populate the database with answers to those informational needs.

A. Interview results

The eight participants interviewed reported facing challenges in their recovery, including time constraints (7/8), physical limitations (5/8), and transportation issues (4/8), highlighting the need for at-home therapy options. Participants expressed strong interest in a range of at-home rehabilitation tools. We briefly highlight several key themes related that emerged:

1. **Difficulties in finding reliable information:** They reported the use of a variety of sources for rehabilitation information, including the Internet, support groups, healthcare providers, books, and social media. However, 7/8 expressed difficulty finding reliable information.

TABLE VI. CODEBOOK: THEMATIC ANALYSIS OF USER INTERVIEWS

Theme	Code	Freq. (n/8)
Challenges in recovery	Time constraints	7/8
	Physical limitations	5/8
	Transportation issues	4/8
Difficulties in finding reliable information	Struggles to find trustworthy sources	7/8
	Difficulty assessing device efficacy	4/8
	Unclear treatment options	3/8
Desirable features in the devices	Motivation-enhancing features	7/8
	Community support	3/8
	Progress tracking	4/8
	Gamification	4/8
Openness to AI-based Chatbots	Low familiarity with AI chatbots	1/8
	Interest in AI chatbot for rehab support	7/8
	Preference for phone-based app	3/8
	Preference for computer-based access	3/8
Experience with home-based rehabilitation devices	Use of simple hand exercisers/stretchers	7/8
	Positive reception of engineered devices	4/8
	Use of fitness apps for tracking	2/8

2. **Desire to identify devices with motivational features:** Obtaining information about the motivational features of devices was mentioned as a key interest of participants (7/8). They mentioned community support (3/8), progress tracking (4/8), and gamification as desirable (4/8).
3. **Openness to AI Chatbots:** While familiarity with AI chatbots like ChatGPT was low (1/8), 7/8 patients expressed interest in using an AI chatbot for rehabilitation support, indicating a desire for accessible, interactive assistance in their recovery. Three participants preferred it on a phone-based app, while three on a computer.

Regarding home use of devices, participants used simple hand exercisers and stretchers (4/8) but viewed them as having mixed effectiveness (1/4). Mechatronic and sensor-based devices were well-received (4/8) despite some frustration (1/4) with technical difficulties. Some appreciated fitness apps like Garmin and Strava for tracking progress (2/8). Table VI provides the codebook for these analyses.

B. *Survey results*

Based on the interview themes, we created a survey that was conducted on four individuals. First, participants ranked the importance of eight types of device-related information. The most highly ranked attributes were the frequency of use required to achieve benefits (mean rating: 3.0), followed closely by information about ease of use (2.75) and the amount of benefit that can be expected (2.75) (Fig. 1a). Moderately important was information about risks such as discomfort or pain (2.25) and motivational features (2.25). Lower-ranked attributes were user reviews and scientific data on effectiveness (both 1.75), videos of people using the devices (1.5), and return policies (1.0). Second, participants rated the importance of eight potential features of a decision support system on a scale from 1 (least important) to 10 (most important). The highest-rated feature was the ability of the system to ask for personal information to make personalized recommendations (mean rating: 9.75, Fig 1b). Chatbot functionality and guidance through the selection process both received ratings of 9.5. Additional high-priority features included comparing suggested devices easily (9.25)

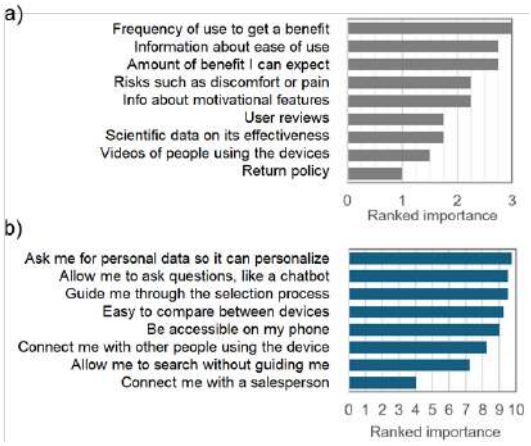

Figure 1. **Overview of survey results.** a) Participants ranked eight types of information about the devices using a 3-level scale: most (3), medium (2), and lower importance (1). Bars represent the mean rating for each category. b) Participants ranked the importance of eight potential features of the decision support system using a 10-point Likert scale, where 1 represented "not important" and 10 "very important." The graph shows the mean rating.

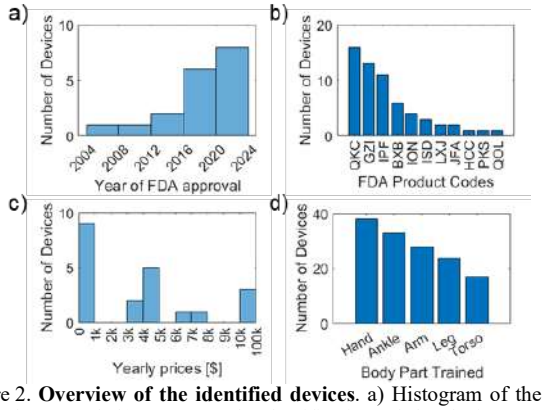

Figure 2. **Overview of the identified devices**. a) Histogram of the FDA's year of approval. b) FDA's code classification of the devices. c) Yearly expenses, including subscription, purchase, and leasing models. d) The body part targeted by the device (some devices target more than one part).

and mobile accessibility (9.0). Lower-rated features included the ability to search without guidance (7.25) and to connect with other users of the same device (8.25). The lowest-rated feature was connecting with a salesperson, with a 4.0 score.

C. *Database generation results*

From the FDA website, we identified 67 FDA-approved devices suitable for home use after stroke. Fig. 2 summarizes several observations about these devices. Notice that we could not obtain information for all 67 devices for each observation. Most devices for which we found approval dates were approved after 2016 (Fig. 2a). The most common FDA codes were 24% QKC (Interactive Rehabilitation Exercise Devices, Prescription Use), 19% GZI (Stimulator, Neuro-muscular), 16% IPF (Stimulator, Muscle, Powered), and 9% BXB (Exerciser, Powered), highlighting a focus on interactive and neuromuscular stimulation devices (Fig 2b). Device costs ranged from $60 to $70,000, with 43% under $1,000 (Fig. 2c) and about 13% offering subscription models. Only 45% of devices were covered by insurance, and 50% had a return policy. 94% had at least one supporting research paper, though the extent of validation varied widely. Most devices targeted the hand (57%) and ankle (49%), often as part of whole-arm and whole-leg training (Fig. 2d).

We sent emails to the 41 companies that manufactured the 67 devices requesting further information relevant to the specific interests of individuals post-stroke we identified in our surveys. 15 (37%) companies replied to our email inquiry, ten of them within 2 days and the rest within 8 days (no further companies responded over the next several weeks). Ten companies (67%) answered our questions via email, and 5 (33%) suggested a follow-up call instead. We set up meeting times with 2 of those 5 companies, bringing the total to 12 responding companies. All 12 companies provided information on the pricing and return policy, eight about ease of use, nine about usage requirements (e.g., recommended usage frequency and duration per week to achieve noticeable benefits), and 10 provided information about motivational features. From these, all 10 reported that their devices use progress tracking, five use goal-setting features, and eight provided feedback. Five reported gamifications on their devices, and 3 included social network tools. Regarding the roles of the individuals who replied to our inquiry, 33% of the responses were sent by C-suite executives (e.g., CEO, COO), 33% by sales representatives, 13.3% by clinical specialists, and the remaining 20% comprising managers, customer support staff, and automated replies.

IV. Discussion

We asked people post-stroke about their rehabilitation device information needs. We also attempted to catalog available devices for home rehabilitation after a stroke. Three key takeaways from this process are as follows. First, there is a large and growing array of engineered devices available for home rehabilitation movement therapy after stroke. Yet, users encounter significant barriers in identifying those that meet their needs. Second, users prioritize information about motivational features and dose-response efficacy, but reliable information is difficult to find. Third, users expressed openness to AI-powered chatbots as tools to guide them in the device selection process. We discuss these results now, followed by an analysis of limitations and future directions.

A. The current rehabilitation therapy device informational landscape is challenging to navigate

People post-stroke expressed difficulty finding relevant information about rehabilitation devices to continue home therapy. They told us that they used Internet searches, support groups, healthcare providers, books, and social media but felt that these sources were incomplete. When we attempted to collate devices for them, we also experienced significant barriers. With online searching, we were not confident that we were finding all the relevant devices, although we found some websites with more comprehensive listings of devices or companies (e.g., https://www.neurorehabdirectory.com/ or https://iisart.org/). AbleData, a comprehensive database, had been discontinued.

We thus turned to the general FDA medical device database but found it difficult to use. The process we eventually developed was an iterative process of finding FDA Product Codes related to the devices we were interested in, then searching several FDA databases for all the devices listed with those codes, then searching the devices' manufacturer's websites online to check if they were relevant for our database, then finding that some of those manufacturer's had more than one device, trying to locate those other devices in the FDA databases, all the while trying to expand the list of relevant codes and repeat this process. Even with this process, we are uncertain if we have found all relevant products. Nevertheless, we found 67 devices, which confirmed that a significant number of device options are now available for people post-stroke.

Finding specific information that people post-stroke want about these devices was even more difficult. Users highlighted, for example, that they desired information about motivational features (such as gamification, social support, and progress tracking) as well as ease-of-use features of devices. They also wanted information about potential outcomes and the effort required to achieve them. When we emailed companies to ask for this information, only 30% responded. Response content and level of detail varied, and there was no standardized way to compare features such as ease of use or expected dose response. These difficulties highlight the need for a concerted effort to collate information, coupled with an effort to define expectations, formats, and sources for information important to users.

B. People post-stroke see value in a personalized and guided search paradigm

In the interviews, people post-stroke expressed openness to "chatbots" to aid in decision-making. In the follow-up survey, when we asked them to rate specific potential design features, they highly rated features amenable to a chatbot approach, including being able to provide personal information to obtain customized recommendations, being able to ask questions, and being guided through the selection process. The only feature they rated as undesirable was being connected to a salesperson. This seems to suggest that the participants envision a chatbot as a way to get personalized information with reduced sales pressure or bias.

C. Limitations and Future Directions

The findings discussed above must be considered within the context of several limitations of this pilot study. The sample size was small (N=9), potentially limiting the observations' generalizability. However, prior studies suggest that a sample size of 6–12 participants is often sufficient for thematic saturation in qualitative research [11]. Consistent with this, while we did not formally assess thematic saturation, themes such as the difficulty in finding reliable device information and interest in AI-powered support were consistently reported across participants. Additionally, the study participants were residents of Orange County, California, an affluent and technology-oriented locale. This may account for the limited concern with pricing information and the openness to new technologies, including chatbots. Future work will expand the sample size and participant diversity to enhance the generalizability of the findings. A formal saturation analysis will also be conducted in future work to determine whether additional participants will introduce new insights.

The device search process remains a work in progress. Finding more devices or obtaining more responses from companies may alter the results. Future work will incorporate an early health technology assessment (eHTA) approach [12], including expert validation and direct user testing, to improve the database reliability.

We have begun developing an AI-powered decision support system that will integrate various features to guide people through selecting a device from the database, with a key component being a customized, retrieval-augmented, LLM-based chatbot. It will offer real-time, personalized guidance, addressing the need for accessible and customized device recommendations. While alternative methods such as static informational websites or clinician-guided consultations could also provide such information, a chatbot component allows users to ask specific questions and receive tailored responses dynamically, offering a scalable, low-cost, and 24/7 available interactive solution that aligns with the preferences of the study participants. This hybrid approach leverages the strengths of both structured information delivery and interactive AI-driven assistance.

We aim to leverage the potential of LLMs to process large amounts of information and to generate texts readable by populations of diverse backgrounds. The development of this system will require extensive feedback, not only from people with stroke to tune the way the chatbot interacts with them, but also from various stakeholders, including clinicians, scientists, industry, payors, and healthcare providers, to verify and be involved in vetting the collected information. An LLM has the potential to make information available in different languages and for individuals with different educational levels. In our next steps, we will refine the system's design, compare the chatbot's effectiveness with other approaches, and integrate additional stakeholder perspectives, including clinicians and caregivers, to ensure a well-rounded approach to rehabilitation technology selection.

Users highlighted the importance of motivational features in the devices they are looking for. This suggests that rehabilitation device companies could potentially increase the perceived value of their products by incorporating these features and highlighting them in detail. Likewise, users emphasized the importance of ease-of-use information. In the future, ease-of-use could be quantified and made publicly available using a standardized metric such as the System Usability Scale [13].

A third interest was for information about expected benefits and the amount of device use required to obtain that benefit. This is perhaps the most challenging information to provide, as the "dose-response" curve of movement training after stroke remains a debated topic and almost certainly depends on various patient baseline characteristics. Research data from clinical studies may be available for some devices. Those studies' main findings and results can be extracted and included in the information displayed. However, explanations of the relevance and implications of research data for predicting practical benefits to specific individuals are often written in technical language, which can be difficult for most people to understand. LLMs can be used to translate technical information into non-specialist language. Nevertheless, developing ways to measure and convey dose-response information should be a priority if companies seek to satisfy the consumers' interests.

V. Conclusion

This study describes our initial efforts to understand the rehabilitation therapeutic device informational needs of individuals post-stroke and their preferences for how an automated system might help meet those needs. The results confirm that people post-stroke have numerous engineered devices available to continue home rehabilitation therapy. However, they encounter substantial barriers to obtaining the information they want about these devices, particularly regarding motivational features and expected benefits. Finally, they are enthusiastic about the features an AI chatbot could provide in helping them find devices, including customizing to their individual needs, answering questions, and providing guidance.

Acknowledgment

We want to thank the individuals with stroke who participated in this study.

A home-based suite of sensors for monitoring and improving upper extremity proprioception after stroke

Guillem Cornella-Barba, Callen S. Zimmer, Shusuke Okita, and David J. Reinkensmeyer, *Senior Member, IEEE*

***Abstract*— Proprioception assessment and training are theoretically important in stroke rehabilitation because proprioception impairment contributes to reduced upper extremity (UE) function and is a promising predictor of the effectiveness of movement therapy. Currently, however, there are few tools available for home-based monitoring and training of proprioception. Here, we describe three tools that we are developing for UE proprioception rehabilitation that are suitable for home use. OpenPoint uses a webcam to automate UE proprioception assessment via a classic neurologic test: finger-to-finger pointing. Proprio gamifies proprioception training by embedding the finger-to-finger pointing test within a video game similar to GuitarHero. Diversify is an app on a smartwatch that provides feedback about the diversity of arm proprioceptive states associated with the variety of arm postures that an individual experiences throughout the day. We describe here the design of each system as well as preliminary testing results.**

I. INTRODUCTION

Over 50% of individuals who have had a stroke experience proprioception deficits in their upper extremities (UE) [1], [2]. These deficits are associated with reduced UE function [3], which makes sense in light of the crucial role proprioception plays in both the control [4] and learning of movement [5]. However, despite the functional importance and widespread nature of proprioception impairments, it has been reported that only 1% of rehabilitation clinicians are evaluating proprioception, as indicated by a recent survey of 431 clinicians [6]. If clinicians do assess it, they typically rely on coarse clinical scales.

Several studies have also suggested that proprioceptive impairment is one of the most powerful predictors of treatment response. For example, an analysis of data from the EXCITE trial of constraint-induced movement therapy (CIMT) found that, compared to people with intact proprioception, participants with impaired UE proprioception had a 20% probability of achieving a clinically meaningful outcome [7]. In our own work, proprioceptive deficits of the finger were the strongest predictor of the ability to benefit from an intensive course of robotic hand movement training [8]. Proprioception therefore can potentially play a crucial role in rehabilitation robotics and assistive technology, as tracking proprioceptive deficits could help tailor rehabilitation therapies and enhance assistive interventions.

Beyond assessing proprioception, retraining it is also of interest. In addition to stroke, there are other conditions that impair proprioception such as orthopedic injuries [9], spinal cord injury [10], Parkinson's disease [11], neuropathies [12], and genetic conditions [13]. Proprioception training is possible in a broad range of disease conditions [14]. Proprioceptive learning shows similar properties to motor learning, including training specificity, fast/slow learning dynamics, retention, and transfer [15]. Despite this, there are few technologies available to help with proprioceptive learning, particularly in the home environment.

The goal of the work described in this paper is to harness recent advances in computer vision and wearables to provide new tools to assess and retrain UE proprioception after stroke. We describe three novel technologies. OpenPoint [16] leverages computer vision for UE proprioceptive assessment. Proprio [17] is an innovative serious game that also leverages computer vision but for the purpose of gamifying finger proprioception training. Diversify [18] is a smartwatch application designed to sense forearm movement diversity.

II. METHODS

A. OpenPoint: A webcam-based proprioceptive assessment

The fundamental aim of the OpenPoint proprioception assessment is to automate the measurement of proprioceptive accuracy by returning the distance error between finger landmarks during a finger-to-finger pointing task using a webcam and hand tracking technology (Fig. 1). As described below, we have tested OpenPoint with sixteen post-stroke survivors and eighteen age-matched adults without neurologic impairments. The user is directed to hold their impaired hand (the "target hand") against their torso with the aid of a pillow or sling, if needed, as this is an attainable position for most individuals with stroke arm impairments, and it also puts the target hand out of view. The user then views a live video of themselves as a mirror image on the computer screen, and OpenPoint uses the MediaPipe library [19] to capture the keypoints on both hands, including the fingertips (Fig. 1).

*Development of this application was partly supported by the App Factory to Support Health and Function of People with Disabilities funded by a grant from the National Institute on Disability, Independent Living and Rehabilitation Research (NIDILRR) in the U.S. Department of Health and Human Services to the Shepherd Center (Grant #90DPHF0004). Also funded by NIH #R01HD062744; NIDILRR #90REGE0010; and NIDILRR RERC #90REGE0005.

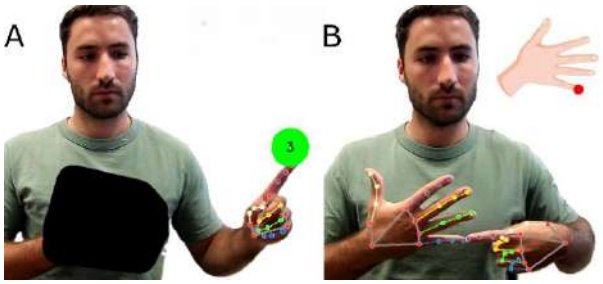

Figure 1. The OpenPoint proprioception assessment. A live video, obtained by a webcam, is shown to the user. (A): The user rests their impaired hand (the "target hand") on their torso. MediaPipe [19] tracks hand landmarks, and a polygon is used to obscure the target hand. The user raises their pointing finger to the green target. After a three-second countdown, the software displays a target on a cartoon fingertip. (B): After receiving the visual cue, the user points to the target fingertip. OpenPoint measures pointing error when movement stops. Note: the polygon is removed in B to show tracking but remains present during actual use of the system.

To obscure the hand, an opaque polygon is drawn over the target hand. To perform a pointing trial, the user raises their pointing index finger to a green start target. After a three-second countdown, a cartoon hand appears on the screen, highlighting a randomly chosen target finger. The user attempts to touch that finger by pointing to their target hand. OpenPoint detects when the pointing movement is complete and identifies the pointing error in the frontal plane, scaling it by measured hand size to convert it to centimeters. If a user is unable to extend the fingers of the target hand, OpenPoint allows for the target point to be set to the MCP or PIP joints.

To prove that OpenPoint is a valid way to test for proprioceptive impairment after stroke, sixteen people (54.0 ± 12.8 years, 11 male, 15 right-handed, 9 right-side impaired) in the chronic phase post-stroke (2381 ± 1499 days post stroke, 9 ischemic) performed 30 pointing movements to fingers on their hemiparetic hand [16]. Participants were grouped based on the severity of motor impairment using the Upper Extremity Fugl-Meyer (UEFM) score [20]: 3 had severe impairment (UEFM<30), 5 had moderate impairment (30≤UEFM<50), and 8 had mild impairment (UEFM≥50).

For comparison, a group of eighteen older users (62.3 ± 8.7 years, 6 male, 16 right-handed) with no neurological or visual deficits also performed the task. This group also performed several other testing conditions, one of them being pointing to a fake hand (a hand-shaped cardboard attached to a stick). This condition removed proprioceptive input from the target hand to test if OpenPoint's accuracy depends on it. We expected worse performance in unimpaired individuals due to the loss of proprioception from the target hand. We also tested OpenPoint's validity by examining whether its measured error correlated with finger proprioceptive error measured with a previously validated robotic proprioceptive assessment, the Crisscross assessment [21], where participants try to identify when their fingers pass each other as the robot moves them.

B. Proprio: a proprioceptive training game

The aim of Proprio is to gamify the finger-to-finger pointing task from OpenPoint, transforming it into a proprioceptive training tool. Proprio [17] is a rhythm-based game, inspired by GuitarHero, where players try to hit streaming notes to the beat of a song as the notes move over a visual target on the screen (Fig. 2).

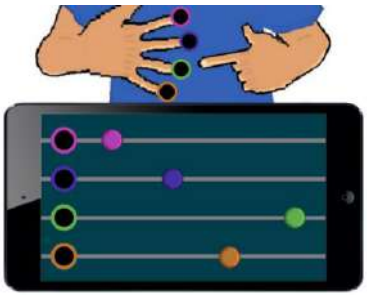

Figure 2. Proprio is a smart phone app available on the Apple Store that gamifies proprioceptive training. This figure shows the main gameplay scene on the phone. Players use the index finger of their pointing hand to touch the fingertips of their target hand, with each fingertip representing a different string. As notes move leftward across the screen, players try to point to the correct fingertip in time with the note. Successfully hitting a note on time earns the player a point https://apps.apple.com/us/app/proprio/id6630381452

Players use their pointing hand's index fingertip to touch the fingertips on their target hand as with OpenPoint. Each finger corresponds to a note travelling down a different string on a guitar. When the pointing distance error between fingertips falls below a certain threshold radius, the target note is considered a "hit," indicating good proprioceptive accuracy. For people post-stroke with limited finger extension, targets can be set at the PIP or MCP joints. Game difficulty can also be adjusted by choosing songs with varying note speeds. Players receive visual feedback based on their performance, aiming to hit as many correct notes as possible.

During Proprio's development, we conducted four rounds of user-centered testing: first, with 10 non-impaired young participants using the Windows beta version. Second, the same 16 post-stroke participants who had tested OpenPoint also tested the Windows game, and those same 16 also tested the beta iOS version later. In the fourth round, 10 additional impaired participants tested the finalized version, which is now available on the Apple Store (ID: 6630381452). Feedback from each round improved usability; we assessed usability using the System Usability Scale (SUS) [22].

As a pilot test of Proprio's effectiveness for proprioceptive learning, we invited the same 16 post-stroke participants that had previously used OpenPoint to play the game using both hands as the target for three 30-minute sessions: a baseline, 24 hours later, and one week later. The percentage of notes hit correctly for both target hands was normalized relative to the participant's score from the 3rd session to identify the gain in gameplay ability. We additionally used OpenPoint to assess proprioceptive accuracy by calculating each session's pointing error and normalizing it to the errors from the 1st session. OpenPoint requires a similar pointing ability as gameplay in Proprio, but the tasks are not identical, and so using OpenPoint allowed us to test generalizability of proprioceptive pointing ability to a related task.

C. Diversify: A wearable sensing app to encourage exploration of UE proprioceptive states

Due to spasticity and sensory-motor deficits, people with severe to moderate hemiparesis after stroke tend to adopt characteristic arm postures [23], and use their arm [24] and hand [25] less throughout the day. Challenge and new experiences are important for motor learning [26].

Figure 3. The Diversify app vibrates and provides visual feedback when the wearer moves their arm in a diverse and vigorous way in a one-minute epoch.

We hypothesized that movement stagnation limits recovery, and that Diversify, a smartwatch app (Fig. 3), will help people explore a more diverse set of arm postures in their daily life through wearable feedback, improving their "quality of movement experience" ("QOME") [27], [28]. From a proprioceptive training perspective, more diverse arm postures should cause a greater variety of proprioceptive input to the brain, helping maintain or expand proprioceptive representations in sensory areas under the "use-it-or-shrink-it" principle of somatosensory representations [29].

To provide a tool to test this hypothesis, we developed a new way to measure the variety of forearm posture that can be accessed from a smartwatch, the kurtosis of the forearm's tilt angle, which is calculated using its accelerometers [27]. Kurtosis is a widely recognized statistical metric used to assess the "peakedness" of distributions. Lower kurtosis values indicate greater movement diversity. Thus, our goal is to use kurtosis as the primary outcome measure for assessing the effectiveness of Diversify in promoting varied arm postures. In [27] we confirmed that people with greater impairment post-stroke exhibit lower forearm postural kurtosis throughout the day, and that different movement activities produce different values of kurtosis with seven unimpaired participants [18]. However, our hypothesis that promoting movement diversity feedback will enhance rehabilitation outcomes using wearables remains untested.

Providing real-time feedback of movement diversity is non-trivial because the computational demand of calculating kurtosis increases as the buffer sample size increases. Building upon the research presented in [30] we developed an innovative algorithm called "Rolling Sample Kurtosis" (RSK) [18]. We conducted an offline comparison of the execution speed of RSK to the speed of a conventional iterative kurtosis calculation, and to Python's SciPy kurtosis implementation. We chose a Samsung watch (Fig. 3) for implementing real-time RSK due to its low cost, API, and versatility. We attached the watch to the wrist of a custom-designed robot arm with three motors [18], which helped us simulate human-like movements with predetermined levels of movement diversity, and created an interface that notifies the wearer when they achieve diverse periods of movement.

III. RESULTS

A. OpenPoint: A webcam-based, proprioceptive assessment

OpenPoint quantifies finger-to-finger pointing skill. To determine if OpenPoint was sensitive to UE proprioceptive impairment after stroke, we compared proprioceptive pointing error between a group of people post-stroke (45±13 UEFM score) to an age-matched group as described more fully in [16].

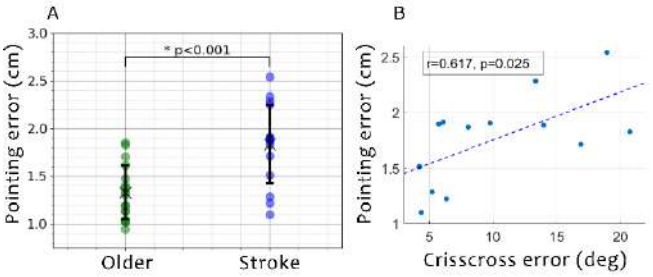

Figure. 4. Results from using the OpenPoint proprioception assessment to assess proprioceptive pointing error after stroke. (A): Pointing errors for older and stroke groups. The stroke group had significantly larger pointing errors ($p<0.001$). The error bars represent the standard deviation (SD) of the pointing errors. (B): The pointing error from the OpenPoint assessment had a moderate correlation with the angular error in finger proprioception measured by the Crisscross assessment. Adapted from [16].

We found a significant increase in pointing error after stroke (Fig. 4A, t-test, $p<0.001$). 53% of stroke survivors showed mean pointing errors exceeding two standard deviations from the older group. The pointing error in the OpenPoint assessment showed a moderate Pearson correlation with the finger proprioception error obtained through the robotic Crisscross assessment (Fig. 4B, $r=0.62$, $p=0.025$) after stroke, showing concurrent validity of the two proprioception assessments. For the unimpaired group, we also replaced their real hand with a fake hand, thereby removing proprioceptive input from the target hand. Pointing to the fake hand (2.97±1.25 cm) caused significantly higher errors compared to pointing to the real hand (1.33±0.28 cm). This verifies that OpenPoint accuracy depends on proprioceptive information from the target hand.

B. Proprio: a proprioceptive training game

Proprio gamifies finger-to-finger pointing. To determine if gameplay with Proprio improves proprioceptive accuracy, 16 individuals post-stroke played Proprio for 30 minutes in 3 sessions conducted in the laboratory. They switched which hand was the target and which was the pointing hand halfway through the session; 9/16 participants were able to do this. We also evaluated their UE proprioceptive ability using OpenPoint, allowing us to test the generalizability of any proprioceptive pointing ability gains achieved through practice with Proprio to a related but different pointing task (Fig. 5B).

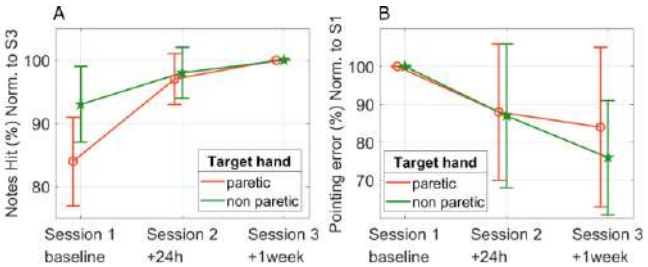

Figure 5. Results from testing the Proprio proprioceptive training game with 16 individuals poststroke. (A): The percentage of notes hit in each of the three sessions, normalized to percentage of notes hit in the 3rd session. The target hand is indicated by the orange line when it was the paretic hand, and by the green line when it was the non-paretic hand. (B): The pointing error across three sessions, measured with OpenPoint. We normalized each participant's error to that of the 1st session. Six participants with a more severe UE motor impairment were limited to using their paretic hand as the target, as they were unable to point with it. Consequently, only nine data samples were available for the non-paretic target hand.

Proprio's participants improved the quantity of notes they effectively hit with both hands throughout all the study, with the improvement from Session 1 to Session 2 being significant (Fig. 5A, $p<0.001$ when using the paretic hand as the target hand and $p=0.03$ for using the non-paretic hand as the target). Participants retained their skill from Session 2 to Session 3. Participants also reduced their proprioceptive pointing error (Fig. 5B), for both the paretic ($p=0.02$) and non-paretic ($p=0.01$) hands as measured with the OpenPoint assessment system from Session 1 to 3.

Ten individuals with stroke installed the Proprio app on their smartphone and used it at home for a week. They rated the usability of the app 76.5%±18% on the SUS, which can be described as "good" usability [31].

C. Diversify: A wearable sensing app to encourage exploration of UE proprioceptive states

Diversify is the smartwatch app we are developing to track forearm movement diversity. As we showed previously [27], individuals with more severe arm impairment after stroke exhibit significantly decreased forearm postural diversity, quantified with kurtosis (Fig. 6A). To allow real-time calculation of kurtosis on a smartwatch, we implemented the rolling-sample kurtosis algorithm on a Samsung smartwatch, as more fully described in [18]. The RSK algorithm greatly boosted computation speed across buffer sizes. For instance, it achieved a reduction in processing time that was approximately 200 times faster than the optimized SciPy kurtosis function for sample sizes under 3000, allowing execution in less than ten milliseconds [18]. We used a robotic arm to simulate a human arm trajectory and establish the ground truth of kurtosis. The results showed a strong correlation with the predicted kurtosis values derived from the watch tilt angles using RSK, with correlation coefficients of $r^2 = 0.99$, $p = 0.0001$ for slow motor speeds, and $r^2 = 0.86$, $p = 0.0078$ for faster speeds [18].

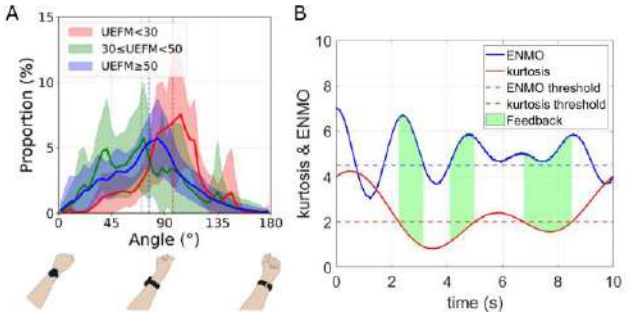

Figure 6. Results supporting the development of Diversify, a smartwatch app for providing wearable feedback on forearm postural diversity. (A): Results from 22 participants with chronic stroke who wore a 3-axis accelerometer on the wrist for one day, adapted from [27] under the (Creative Commons Attribution 4.0 International Public License). The orientation of the forearm relative to gravity and the distribution of the wrist accelerometer's tilt angle. The red, green, and blue lines represent the means of distribution for severely, moderately, and mildly impaired groups, as measured by the UEFM score. The severely impaired group (red) showed forearm postural "stagnation" with a more peaked distribution, quantified by a higher value of kurtosis. The shaded areas represent the confidence interval for each group. (B): Graph illustrating how the Diversify app works. When movement intensity (measured with ENMO [32]) exceeds a custom threshold, and movement diversity (measured with kurtosis) falls short of another threshold, the watch vibrates and provides visual feedback (Fig. 3)

We are using this information to design the Diversify app for Samsung smartwatches for daily use by individuals post-stroke. Initially, Diversify estimated forearm postural diversity for moving windows of 1 minute using RSK and then vibrated and provided an encouraging message if the kurtosis value in that window fell below an adjustable threshold, indicating high diversity. In pilot testing, however, we found it is possible to create low kurtosis values (i.e. high diversity) by holding the forearm statically in two disparate tilt states. Since we desire activity and diversity, we incorporated a conventional algorithm for movement vigor (ENMO, [32]) along with the diversity algorithm. The app now provides a vibration and congratulatory message when a one-minute epoch of movement is both vigorous and diverse (see Fig. 3 and Fig. 6B). We are preparing now to clinically test Diversify.

IV. DISCUSSION

These results represent steps toward designing home-based sensors for monitoring and improving upper extremity proprioception after stroke. OpenPoint automates the quantification of pointing errors for a finger-to-finger pointing test of proprioception ability using the MediaPipe computer vision library. We showed that pointing error measured with OpenPoint is increased after stroke, depends on proprioceptive input form the target hand, and is correlated with an independent, robotic measure of finger proprioception. Proprio automates game-based proprioceptive training. Our findings suggest that playing Proprio may help improve proprioception accuracy after stroke, as measured with OpenPoint, but further studies with larger populations and a broader range of proprioceptive outcome measures are needed to confirm its effectiveness. Finally, we presented pilot study data supporting the development of Diversify, a novel watch application that provides wearable feedback about the diversity of arm postural states achieved throughout the day. We found that more severely impaired individuals post-stroke show less forearm movement diversity throughout their day, and that is it possible to measure diversity with kurtosis in real-time using the RSK algorithm. We briefly discuss each approach including directions for future research.

A. OpenPoint

A review conducted recently [33] identified 1,346 methodologies for testing proprioception, with 42 studies specifically focusing on pointing to proprioceptive targets. In clinical practice, a common approach to assess UE proprioception involves instructing patients to close their eyes and attempt to touch their nose with a fingertip from various starting positions [34]. Another method involves asking patients to identify specific fingers by pointing [35]. We integrated similar methodologies into OpenPoint to assess pointing errors.

Despite being quick and equipment-free, clinical proprioception assessments face challenges such as poor resolution due to binary scoring, inconsistent results among assessors, lack of normative benchmarks, and limited sensitivity. Motion tracking systems [36] and robots [37], [38], [39] have been used to quantify proprioceptive, but their high costs and limited portability are barriers to clinical use. A few mobile phone-based applications have been developed for more practical and cost-effective proprioception

assessment [40], but they focus on joint angle reproduction and use the phone as an electronic goniometer.

Recent advancements in open-source, deep learning-based motion capture techniques like OpenPose [41] and MediaPipe [19] have improved human movement sensing without the need for body markers. We used MediaPipe Hands to develop OpenPoint, a smartphone-compatible hand-tracking application suitable for proprioceptive assessment.

One possible limitation is that, despite placing the target hand out of view, users could potentially "cheat" by looking down at their hand, introducing a confounding effect. To address this, we present visual stimuli on the screen, focusing attention on the display and away from the hand, but it would also be possible to use MediaPipe to try to detect "cheating".

We found that OpenPoint pointing errors increased when participants pointed to a fake hand; thus, the errors depend on the presence of proprioceptive signals from the target hand. OpenPoint also successfully detected increased proprioceptive pointing errors in individuals with chronic stroke. OpenPoint pointing error measured after stroke also moderately correlated with finger proprioception error measured with an independent, previously validated technique (Crisscross), suggesting concurrent validity. These findings support OpenPoint's potential for use in clinical settings for identifying UE proprioceptive deficits. Future work could also seek to automate other proprioception tests for different joints or limbs using computer vision.

B. Proprio

To our knowledge, there are few technologies for home-based training of UE proprioception, including a lack of smartphone-based approaches focused on proprioceptive training [42]. Our goal for Proprio was to design a gamified app to enhance engagement and adherence to training in at-home rehabilitation scenarios, aiding people post-stroke in retraining their UE proprioceptive skills.

In the pilot study described here, we found that the Proprio game is both learnable and retainable, supporting the idea that serious games could be effective for sensory rehabilitation. The reduction in pointing error measured with a separate assessment technique, i.e. OpenPoint, supports the hypothesis that training with Proprio enhances sensory-motor integration and precision [14], [15]. The iterative design process successfully addressed user requirements, as users found the system user-friendly and well-integrated. Although the system received a SUS rating above the standard usability benchmark, some users indicated a need for technical guidance, highlighting opportunities for further improvement. Future research will test whether extended use of Proprio at home improves UE proprioception using a wider variety of outcome measures and whether this improvement translates to improved UE use and function.

C. Diversify

Wearable sensors such as smartwatches and activity trackers are widely accessible and increasingly being used in physical rehabilitation [43], but they generally measure only the quantity of movement, like step counts or UE movements [44]. Quantifying the "quality of movement experience" (QOME), for example by describing the diversity or complexity of movement periods [27], might be valuable in neurologic rehabilitation, but this idea still needs to be tested. Considering the human somatosensory system, it is known that experiencing diverse physical activity sustains and expands cortical representations, while a lack of activity diminishes them [29].

We previously established a measure of forearm postural diversity based on kurtosis [27]. In a study with unimpaired individuals, we measured a diverse set of movement activity using the kurtosis of the wrist's tilt angle distribution [18]. Our findings indicate that various movement activities yield a broad spectrum of kurtosis values, suggesting that encouraging diverse movement could enhance UE movement diversity. The Diversify app may potentially encourage people to seek out vigorous and diverse movement activities.

To make Diversify possible, we developed a recursive algorithm (i.e. RSK) for real-time kurtosis calculation, reducing the kurtosis computation speed to a range suitable for a smartwatch [18]. Future research should investigate whether setting daily movement diversity goals and rewarding people with smartwatch feedback when they achieve periods of vigorous and diverse UE movement is effective at restoring proprioceptive ability and promoting UE use and function.

V. CONCLUSION

We presented three novel sensor systems for monitoring and improving UE proprioception after stroke. Each is potentially highly accessible since they depend only on webcams, smartphones, and smart watches. The three sensor systems could be used together to train and assess proprioception. We envision other proprioceptive assessments and games could also be implemented in a similar way with computer vision and smartwatches, expanding the toolset available to therapists and people post-stroke for engaging in proprioceptive training

A Customizable Fitting Protocol for the Body-Machine Interface

Fiona A. Neylon[1,2], Andrew Thompson[1,2], Rachel Kalvakota[2],
Corinne Fischer[2], Fabio Rizzoglio[1,2], Lee Miller[1,2], and Brenna D. Argall[1,2]

***Abstract*— In this work, we present a case study evaluation that compares two methods of fitting the Body-Machine Interface (BoMI) to an individual with cervical spinal cord injury for the purpose of operating a robotic arm in 6-D. A BoMI is a control interface created by recording body movements and mapping them to the controls of a device or machine, and has shown promise for individuals with motor impairments whose access to standard interfaces is otherwise limited. Results from this case study show a one-size-fits-all placement strategy is not a sufficient fitting method for an individual with severe upper extremity limitations. However, when a flexible fitting protocol informed by a clinical evaluation is applied, we see improvement in two key categories: (1) success in map fitting and (2) robot task results. Informed by the case study analyses, we develop a *novel* method to customize and fit the BoMI to users in a way that is analogous to how commonly used assistive technologies are fit clinically: the BoMI Customization Evaluation (BCE). This new method of customization is determined from a physical evaluation conducted by a clinician in conjunction with participant feedback and BoMI engineers. Deployment of this novel method within a full evaluation study is underway. The current work focuses on the evolution to this protocol.**

I. Introduction

Individuals living with cervical spinal cord injury (cSCI) depend on a variety of assistive technologies to perform activities of daily living (ADL). The commonly used powered wheelchair employs low-dimensional control (2-D) to achieve increased mobility [1]. The less commonly used robotic arm requires high-dimensional control (e.g., 6-D) to assist those with upper extremity limitations with feeding, picking-and-placing objects, or opening doors [2].

For those with cSCI, their assistive technologies (ATs) are not traditionally out-of-the-box ready. Users undergo fittings, calibrations, and customization options with clinicians. For a powered wheelchair, components of the chair such as seating interfaces, suspension mechanisms, and driving interfaces are written into a prescription [3]. For a sip/puff interface, the user undergoes a calibration protocol to construct a mapping from their respiration pressure signals to device controls. However, to the knowledge of the authors, an analogous prescriptive fitting protocol informed by clinical metrics does not exist for the Body-Machine Interface (BoMI).

We address this gap by designing the BoMI Customization Evaluation (BCE)—a prescriptive fitting protocol for the BoMI. A BoMI is a control interface created by recording body movements and mapping them to the controls of a device or machine. It has shown promise for individuals with motor impairments whose access to standard interfaces is otherwise limited [4]. We motivate the final BCE design through a case study evaluation of two BoMI fitting protocols, in which an individual with cSCI operates a robotic arm in 6-D. The contributions of this work are the following:

- A case study evaluation of two evolutions of BoMI fitting protocols to a person with cSCI for the purpose of robotic arm operation.
- The identification of a collection of considerations and guidelines when fitting wearable interfaces, such as the BoMI, to individuals with cSCI.
- A prescriptive fitting protocol for a BoMI to persons with upper-extremity mobility limitations: the BoMI Customization Evaluation (BCE).

In Section II, we present related background and describe the current gap in BoMI fitting protocol. We then present the evolution of our three approaches to fitting the BoMI in Section III. We setup our case study experimental protocol and evaluation metrics in Section IV and discuss the results in Section V. We summarize our takeaways and future work in Sections VI and VII.

II. Background & Related Work

For people both with and without injury, the use of interfaces to send a control signal to a device is a daily phenomenon; even pressing a button for an elevator is an example of a control interface. For those with cSCI and resultant upper and lower extremity impairments, the dependence on control interfaces is more significant. The interfaces accessible to them vary in operation, type, and issued signal depending on their injury level.

Common non-invasive interfaces used by cSCI individuals include joysticks, head arrays, sip/puffs (SNPs), and micro light switches (MLSs) [5]. The joystick, at most a 3-D interface, becomes limited or completely inaccessible to those with severe paralysis. Alternatives such as head arrays (2-D), SNPs (1-D), and MLSs (1-D) issue even lower dimensional signals. Moreover, when using traditional interfaces for higher-dimensional control, such as a robotic arm (6-D), there is a dimensionality mismatch between the issued signals and the device's control space.

One solution to this mismatch is the use of *modal control*—the partitioning of the control space into subsets, with *mode-switch* actions that change the operational mode of the interface in order to access the various subsets [6]. The added hurdle of mode switching can increase the mental and physical load on the user, and accordingly also the difficulty of simple ADL tasks [7].

[1]Northwestern University, Evanston, IL., USA
[2]Shirley Ryan AbilityLab, Chicago, IL., USA

A challenge when designing and fitting ATs to people with cSCI is how the same injury can manifest as very different movement capabilities [8], lending customization to be a desired feature. The aforementioned interfaces are commercially available in part due to their limited customization options. For the joystick, handle interfaces can be changed—for example to a T-bar for high cSCI individuals—but this modification reduces the input space from 3-D to 2-D. Moreover, any 1-D or 2-D interface requires significant mode switching when controlling high-dimensional devices—furthering the cognitive load.

The BoMI provides an alternative solution to address the dimensionality mismatch between ATs and their control interfaces, while maintaining the capability of customization to meet users where *they* are physically. The BoMI uses sensors to capture and translate body motions to control signals; common methods include capturing body kinematics via Inertial Measurement Units (IMUs) or cameras, and muscle signals via electromyography [4], [9], [10]. There is preliminary evidence that BoMIs are able to issue sufficiently high control signals to obviate the need for mode switching during robotic arm operation [11].

III. Body-Machine Interface Fitting

We present in this section an evolution of three BoMI fitting methods. In Method 1 (Sec. III-A), customization of the BoMI focuses on sensor placement and selection from a menu of vetted motion prompts. *Motion prompts* are body motions that are collected during calibration to obtain the parameters of the BoMI map, and which will be executed to operate the robotic arm. Method 2 (Sec. III-B) is a flexible approach, fitting the sensors and prompts based on the movement capabilities of the participant.

A case study comparison of these two methods then drives the development the third method. Method 3 (Sec. III-C) is a prescriptive approach which combines input from three parties—clinicians, BoMI engineers, and the user—in a collaborative effort to customize the BoMI.

Our target population is individuals with cSCI with a complete (ASIA A) lesion at C3-6 or an incomplete injury (ASIA B, C, or D) lesion in the cervical cord. These are individuals who have limitations in hand and manipulation ability, but also the potential to execute six distinct upper-body movements: that is, individuals who would benefit from the use of an assistive robotic arm, and would potentially be able to operate it without mode switching.

A. Method 1: Fixed Procedure

Method 1 fits a predetermined configuration of prompts and sensor placements to a user. As a default, the shoulder (up/down and forwards/backwards) and arm (elbow abduction/adduction) prompts are paired with empirically determined sensor placements limited to the shoulders (front/back) and arms (upper/fore). These default prompts are chosen as upper body joint motions that our target population are expected to be able to perform [12].

With the user in their seated rest position, we record a dataset as they execute the motion prompts. If the user is unable to reproduce a prompt, we replace it with a head prompt—defined as head up/down, left/right, up-right(UR)/down-left(DL), up-left(UL)/down-right(DR), or tilt right/left. These configurations are hypothesized to decrease the likelihood of generating an invalid map—a map wherein the user does not have access to all the required control dimensions.

B. Method 2: Flexible Procedure

Method 2 takes a flexible fitting approach to the BoMI that does not use a default configuration; instead, the configuration is defined via the range of motion (ROM) of the user. The user undergoes a clinical evaluation which assesses areas of the body to define the ROM. The results inform a fitting with the user, clinicians, and experimenters.

The user is asked to perform common upper extremity (UE) motions that they are expected to have access to based on the results of the ROM exam. Experimenters select six visually distinct movements—with visually appreciable motion and with limited similarity. Formally, these are motions in which extremities follow a rotation around orthogonal axes bisecting a common joint, which allow for conscious isolation between the six motions during execution. IMUs then are fit to the user's UEs with placements able to record the selected prompts.

C. Method 3: BoMI Customization Evaluation (BCE)

Method 3, the prescriptive approach, comprises two phases: (1) physical examination and (2) collaborative fitting.

Physical Examination. The first phase is comprised of a clinical evaluation protocol plus an evaluation framework that categorizes cervical and UE movements based on potential sensor placements. This evaluation framework ultimately facilitates the identification of viable sensor placements and the assessment of the movement quality at each placement.

Clinical Protocol. The clinical evaluation incorporates measurements of UE active range of motion (AROM) and utilizes a modified version of the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) [12] in an effort to provide insights into the users' residual motor abilities. The ISNCSCI provides an objective framework to quantify injury levels, thereby facilitating consistent comparisons among users. To enhance user comfort and minimize unnecessary procedures, modifications are made to the ISNCSCI, substituting the anal testing component with a self-report questionnaire [13]. This study targets individuals with injuries at or above the C8 level, so the sensory assessment concludes at T2, while the motor assessment is unaltered.

Movement Categorization. The movement scoring framework begins with a Manual Muscle Test (MMT) to the cervical and bilateral UE regions, reflective of any movement eligible for IMU placement. Unlike the MMT scale used in the ISNCSCI, the 5-point MMT scale used is a variation that is more sensitive to lower strength levels, which is relevant data when selecting optimal sensor placement [14]. This scale defines 0 as having no muscle contraction and 5 as normal muscle contraction with full motion in a gravity plane against maximum resistance. A score of 2 on the ISNCSCI

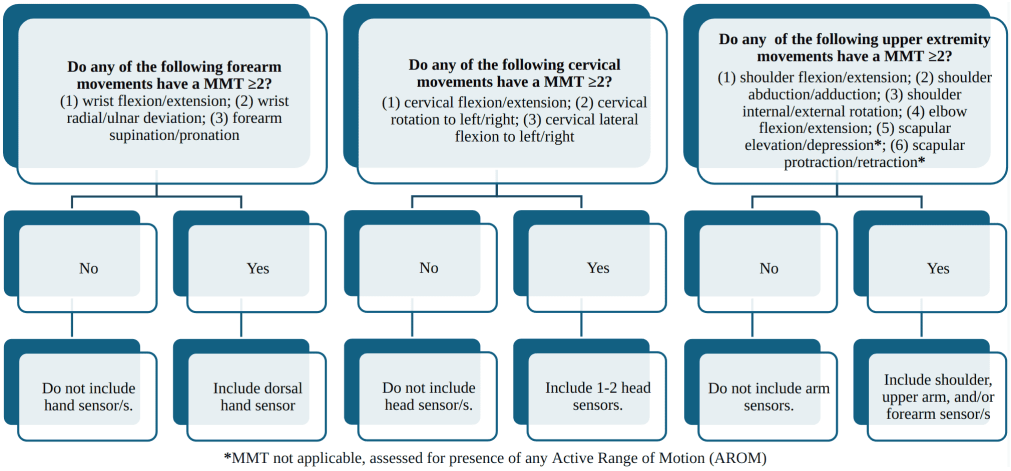

Fig. 1: Flowchart directing the sensor placement based on the movement score in each region.

MMT rubric requires full ROM in a gravity-eliminated plane, while a score of 2 on the updated scale only requires some motion. This provides a more nuanced scoring for someone who does not have full ROM, typical of our target population.

The MMT motions are divided into categories based on sensor placement, presented in Figure 1. For example, the eligibility of a hand sensor placement is determined by evaluating wrist flexion/extension, radial/ulnar deviation, and forearm supination/pronation. If the MMT score is 2 or greater for any movement in the sensor category, it qualifies as a valid sensor placement.

Collaborative Fitting. In the second phase, the clinician presents the list of valid sensor locations and the corresponding movements with above-threshold MMT scores. The BoMI developers choose six visually distinct movements: with appreciable motion and limited similarity (as in Section III-B). Experimenters ask the user to execute the prompts and visually inspect if appreciable motion is achieved on their body. The user then is asked if these prompts are comfortable and non-strenuous. If the user responds 'no', the prompt is either swapped out for an alternative high-scoring motion prompt in the same region, or the user may alter the execution of the motion to be within their comfort level. Once the motions are finalized, developers pre-assign each prompt to a specific robot control dimension.

IV. Experimental Protocol

Here we overview the experimental protocol for case study evaluations of BoMI fitting Methods 1 and 2, the results of which motivate the creation of the BCE.

A. Participant Profile

We compare Methods 1 and 2 with respect to BoMI fitting and operation by a 68 year-old male with a self-reported cSCI injury level at C2. The onset of injury was approximately 4 years ago after suffering from a spinal stroke post heart attack. Since his diagnosis, he uses a powered wheelchair daily controlled by a T-bar joystick, and self-assesses being 'comfortable' controlling his device. Participant also self-assesses experience controlling a wheelchair with a head array, but 'not experienced' controlling a robotic arm. The participant gave his informed, signed consent to participate in the experiment which was approved by the Northwestern University Institutional Review Board.

B. Hardware & Software

The experimental BoMI consists of 6 IMU sensors that capture body motions predefined according to the fitting procedure (Method 1 or 2). The 24-D quaternion signals issued from the IMUs ($\mathbf{q}_{[1\times 24]}$) are mapped via supervised learning to a 6-D robot end-effector control space ($\mathbf{v}_{[1\times 6]} = [\dot{x}, \dot{y}, \dot{z}, \dot{\phi}_x, \dot{\phi}_y, \dot{\phi}_z]$).

Specifically, a k-nearest neighbors classifier ($k = 50$) is used to predict the probability of each of the pre-selected prompts ($\Gamma^{[1\times 6]}$) given the user's movement as captured by the IMUs (Algorithm 1). The robot control dimension associated with the most likely prompt is selected for execution. The magnitude of the robot motion is determined from Principal Component Analysis (PCA) maps derived *a priori* for each of the 6 prompts from the calibration data ($\mathscr{D}$, described in Section IV-D); the first principal axis of the associated PCA map is used to determine the amplitude of the control signal for the selected control dimension.

The IMUs are the x-io Technologies x-IMU3 (Bristol, UK). The robotic arm is the 7-DoF UFactory xArm7 (Shenzhen, China) with associated ROS2 Humble packages. The experimental pipeline runs on a Lenovo ThinkStation P3 Tower (64GB RAM, 13th Gen Intel™ Core i9-1300 x32 processor) running Ubuntu 22.04. Hardware is commanded and data is logged using Open Robotics ROS2 Humble.

C. Data Collection

From fitting Method 1, we construct Configuration C_1 (Figure 2). Sensor placements are front of the shoulders (1/2), upper arms (3/4), and sides of the head (5/6). The prompts and map to robot controls for C_1 are: (1) Head R/L $\rightarrow x$, (2) R shoulder forwards/backwards $\rightarrow y$, (3) R shoulder up/down $\rightarrow z$, (4) L shoulder up/down $\rightarrow \phi_x$, (5) Head up/down $\rightarrow \phi_y$, and (6) L shoulder forwards/backwards $\rightarrow \phi_z$.

From Method 2, we construct configuration C_2 (Figure 2). Sensor placements for this configuration are front of the

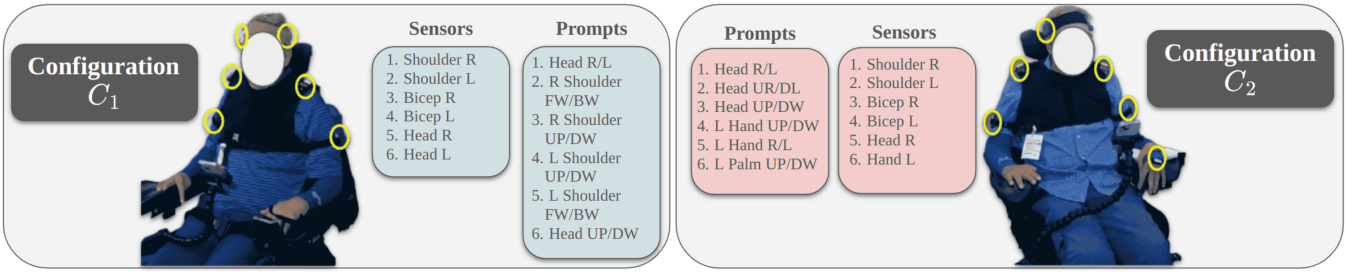

Fig. 2: Experimental setup showing the prompts and sensor placements for configuration 1 (C_1) and configuration 2 (C_2)

Algorithm 1 BoMI Mapping Using KNN and PCA

Input: 24-D quaternion input $\mathbf{q}^{[1\times 24]}$ and $\mathscr{D}$
Ouput: 6-D control signal $\mathbf{v}^{[1\times 6]}$
Step 1: Calibration (Offline)
for each motion prompt $\gamma_i \in \Gamma^{[1\times 6]}$ **do**
Derive PCA map $\mathbf{PCA}_i$ from $\mathscr{D}_i$
end for
Step 2: Motion Prediction (Run-time)
Use k-nearest neighbors (KNN, $k = 50$) to predict the probability vector

$$\mathbf{p} = \mathrm{KNN}(\mathbf{q}) \quad \text{where } \mathbf{p} \in [0,1]^{1\times 6}$$

Identify Highest Probability Index

$$i^* = \arg\max_i p_i$$

Step 3: Compute Velocity Vector (Run-time)
Reduce the 24-D signal to 1-D using the first principal axis of $\mathbf{PCA}_{i^*}$:

$$a = \mathbf{q} \cdot \mathbf{PCA}_{i^*,1}$$

Compute the final control signal:

i^*th position

shoulders (1/2), upper arms (3/4), side of the head (5), and top of the left hand (6). The prompts and map to robot controls for C_2 are: (1) Head R/L $\rightarrow x$, (2) Head UR/DL $\rightarrow y$, (3) head up/down $\rightarrow z$, (4) L hand up/down $\rightarrow \phi_x$, (5) L palm up/down $\rightarrow \phi_y$, and (6) L hand right/left $\rightarrow \phi_z$.

For this analysis, we focus on 4 study sessions: 3 sessions under C_1 ($C_1^{S_1}$, $C_1^{S_2}$, and $C_1^{S_3}$) and 1 session under C_2 ($C_2^{S_1}$), which define the divide between the two different fitting protocols. We focus on these sessions to highlight the immediate effects of changing to a BoMI configuration informed by a clinical evaluation. For the three C_1 sessions, each session occurred within 4 days of each other. The C_2 session occurred 16 days later. This is due to the presence of 3 *wash* sessions (defined in Section IV-E) that occurred under the C_1 fitting method, in which the C_1 map became unusable as a result of physiological changes in the participant—specifically, reduced ROM due to a gap in physical therapy.

D. Calibration

Each session begins with a calibration phase. The participant executes directed motion prompts to generate the dataset $\mathscr{D}$ for map computation. This is done in a cyclic fashion, where each prompt is executed in sequence 6 times. A sequential approach, in comparison to repeated iterations, is expected to better reflect the control signals the user issues during teleoperation, and also to mitigate the biased accumulation of IMU drift across the recording (sampling at 50Hz).

E. 6-D GUI Validation

Next, a 6-D GUI task is used to validate the map—ensuring that the participant has isolated control of each of the required dimensions (Figure 3a). The GUI is a circular figure divided into 6 equally spaced wedges with a different color arc located in the center of the wedge [15]. Each arc begins in a grey zone of the wedge which defines the *deadzone* of the control space that maps to the bodily rest position of the user. The colored arc moves in accordance to the magnitude of the velocity control signal issued by the user and returns to the *deadzone* when no signal is being issued.

To validate, the experimenter instructs the participant to execute a body prompt. If the correct arc displaces in the correct direction, the signal is considered valid. A valid map is defined as the user being able to issue intended and correct signals using the defined body motions in both the positive and negative directions for the required control dimensions, defined at a minimum to be 3-D translation. This is conducted for all 6 prompts in each direction (+/-), for 12 distinct movements total.

Wash Sessions. If instead a direction is considered invalid—incorrect or with no activation after repeated attempts—we *tare* the BoMI: the participant returns to their self-defined rest position, and we tare the IMU quaternions back to zero to eliminate any drift accumulation that might have caused poor GUI performance. We then revisit the invalid directions and ask the participant to repeat the motion.

If the map is deemed invalid—incorrect or no activation after repeated attempts in one or more of the required control dimensions—the most recent valid map (from prior sessions) is tested under the same protocol. If this map is valid, it is used, otherwise the calibration protocol is executed again. If the re-recorded map results in an invalid map, the session is a *wash* and concludes without progressing further.

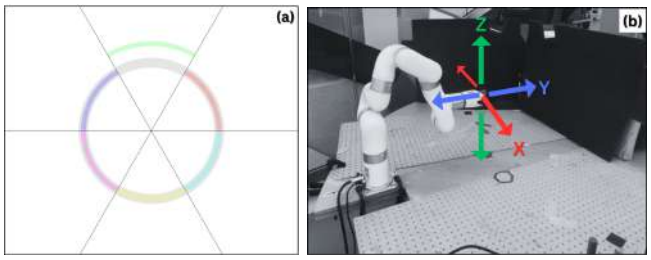

Fig. 3: Experimental setup where (a) shows the 6-D GUI validation task and (b) shows the 3-D Dimensional Freezing task.

F. 3-D Dimensional Freezing (DF)

The 3-D Dimensional Freezing (DF) task is a training task to teach users to command the robotic arm with the BoMI. For each translation dimension, the user practices how to independently move the robot end-effector in one dimension at a time in a center-out-reaching fashion (Figure 3a). During these reaches, the robot motion is restricted to only move in the training dimension, effectively filtering out all spurious BoMI commands and allowing only those that achieve motion in the intended robot dimension to pass through. We ask the participant to complete 3 reaches in a row for each robot control dimension.

G. Metrics

Expert Comparison. A common method used to evaluate reaching tasks is to define an 'expert' or desired trajectory and compare reaching trials [16]. To analyze the DF trials, we define an expert trajectory for each center-out reaching translation dimension. This expert trajectory is defined as a time series of end-effector positions as a result of a synthetic velocity control signal roll-out on the robot. For all trajectories, a moving window average ($N = 10$) is used to filter out mechanical noise from the profile of the end-effector positions, sampled at 100 Hz.

We use Dynamic Time Warping (DTW) to quantify the similarity between the participant trajectories and the expert trajectory. DTW lends itself to being useful for comparing time series profiles where events occur during a window of time—this algorithm has been used to compare trajectories [17]. We use the Fast Distance Dynamic Time Warping method from the DTAIDistance Python package [18].

Trajectory Characteristics. We also examine a number of *trajectory characteristics*. Three main characteristics we look for in a reach are, relative to the end-effector start position, (1) the presence of a departure path due to a positive velocity signal, (2) a turnaround, and (3) a return path due to a negative velocity signal. The presence of each indicate the user, at a rudimentary level, is able to not only access all areas of the control space for that dimension, but is also able to purposefully elicit the correct sequence of commands that would allow them to complete the task as asked.

We construct a scoring paradigm that looks for this sequence of events, or partial sequence at any point during the reach. We assign a score of 1 if the characteristic: (1) is present, (2) in the correct direction, and (3) occurs in the proper sequence of events (departure→turnaround→return).

TABLE I: Summary of trajectory characteristics.

	Characteristic	$C_1^{S_1} - C_1^{S_3}$	$C_2^{S_1}$
X Reaches	*Departure*	3.0 ± 0.0	3.0
	Turn around	3.0 ± 0.0	3.0
	Return	3.0 ± 0.0	3.0
Y Reaches	*Departure*	1.7 ± 1.2	3.0
	Turn around	1.3 ± 1.2	2.0
	Return	1.0 ± 0.8	2.0
Z Reaches	*Departure*	2.3 ± 0.9	3.0
	Turn around	2.0 ± 0.8	3.0
	Return	1.0 ± 0.8	3.0

The characteristic otherwise is assigned a score of 0.

Cross-talk. We finally look to the raw signals issued by the user during teleoperation. For every set of dimensional reaches and each timestep of each reach, we count the commands issued in every control dimension. This is to analyze *cross-talk*—in which unintended control dimensions are accessed due to prompt similarity.

With limited mobility, there are limited body sites to choose from for the motion prompts. When a single mobility site needs to be overloaded with multiple distinct motion prompts, the possibility of *cross-talk* is present. This introduces an optimization problem when fitting the BoMI, wherein we choose sites to maximize movement activation while minimizing crosstalk between prompts. An example of *cross-talk* would be if a third motion prompt combines two motion prompts off-axis (e.g., head up/down, left/right, and up-right/down-left). Within the latent space of the map, the user might have to pass through a region of one of the first two prompts before reaching the more defined and separated area of the third prompt, and within this region inadvertent commands would be issued.

Map & Experimental Metadata. In addition to robot task data, map and experimental metadata is considered to assess how reliable the fit is between days. We measure this by calculating (1) the percentage of wash sessions across all sessions, (2) the average number of calibration recordings per session, and (3) the number of modifications along with the intensity of the modification.

V. Results

We present the results of the metrics described in Section IV-G; this includes results from the 3-D DF task and metadata from the maps collected over the sessions.

A. Robot Task Results

Trajectory Characteristics. Table I summarizes the breakdown of the presence of each trajectory characteristic during each session. The end-effector trajectories for the corresponding reaches are shown in Figure 4.

Comparing the two fitting protocols, the y reaches improve by greater than 50% under C_2; notably, none of the characteristics are present in $C_1^{S_3}$. In z under C_1 the participant has difficulty obtaining a turn-around or return path; for these

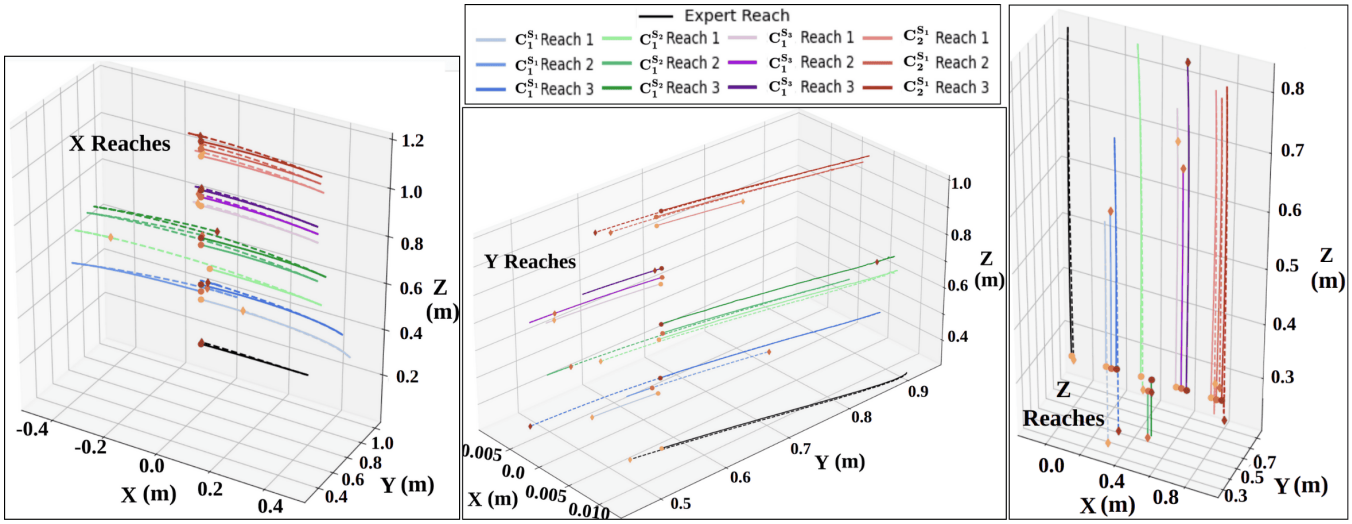

Fig. 4: Comparison of robot end-effector positions for $C_1^{S_1}$-$C_1^{S_3}$ and $C_2^{S_1}$. Reaches under C_1 are blue/green/purple, and under C_2 are red, with the expert trajectory in black. Motion prior to the first turnaround is presented as solid lines, and post turnaround as dashed lines. Start (yellow circle) and end (yellow diamond) positions indicated for each trajectory. Reaches are offset for visibility: by 0.03m within a single session, and by 0.2m between sessions.

two characteristics, there is greater than 130% increase with C_2. By contrast, for the x reaches (unchanged dimension), the presence of these characteristics is stable across all sessions and configurations.

Expert Comparison. In Figure 5, we see the mean DTW distance for each type of dimensional reach between C_1 and C_2. Comparing the two changed dimensions, y and z, there is an immediate ∼45% reduction in the DTW distance for each dimension (5.30 ± 1.02m to 2.84 ± 0.55m for y, and 8.93 ± 1.44m to 5.04 ± 0.21m for z) following the configuration change, $C_1^{S_3}$ and $C_2^{S_1}$.

While not statistically significant (Wilcoxon non-parametric statistical t-test), these reductions do indicate that the changes in configuration positively impacted robot operation performance. In the z dimension, performance under C_1 progressively erodes across sessions, while performance in the y dimension is consistently inferior to that under C_2. All sessions under C_1 furthermore display higher variability than C_2, in both dimensions y and z.

By contrast, for the unchanged x dimension, the DTW averages were comparatively similar between C_1 and C_2

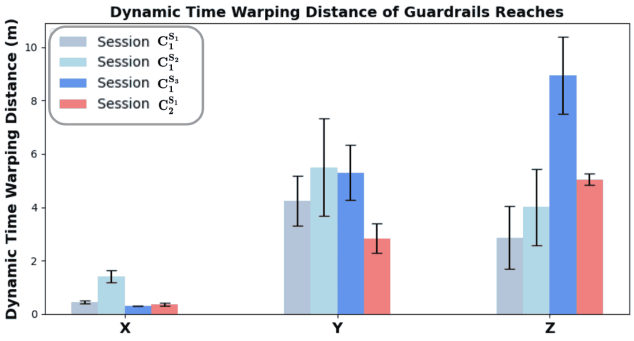

Fig. 5: Average DTW distance computed across reaches for $C_1^{S_1}$-$C_1^{S_3}$ and the $C_2^{S_1}$. The blue-toned bars indicate sessions under C_1 and the red-toned bars indicate sessions under C_2.

(0.31 ± 0.01m and 0.38 ± 0.06m, respectively), and are smaller overall. These results underline the suitability of the BoMI motion prompt affiliated with x dimension robot control, and also confirm that the change from C_1 to C_2 did not impact the operability of this motion prompt.

For C_2 we also see the average distance traversed is comparatively closer to the expert reach, in each of dimensions x (expert: 0.79m, C_2 : 0.97 ± 0.08m, C_1: 1.23 ± 0.32m), y (expert: 0.74m, C_2 : 0.45 ± 0.24m, C_1: 0.38 ± 0.25m), and z (expert: 1.15m, C_2 : 1.15 ± 0.08m C_1: 0.54 ± 0.34m).

Cross-talk. In Figure 6, we compare the commands issued under configurations $C_1^{S_3}$ and $C_2^{S_1}$. Specifically, for each intended control dimension, we tally the number of (positive/negative) commands issued all control dimensions.

We see for C_2, there is more *cross-talk*. This is not surprising with C_2 because the body prompt for y activation (head UR/DL) is a combination of the body prompts for x (head R/L) and z (head UP/DW). The user therefore likely needed to pass through a latent space region corresponding to x or z to reach y area. The body, specifically the upper body, is highly coupled which means that *cross-talk* (between prompts and, accordingly, control signals) is a natural feature of the BoMI that users need to learn how to manage.

We also, however, see more correct y and z signals issued under C2. These signals additionally are more balanced in the ratio of positive to negative signals, indicating reliable access to dimensions in both the positive and negative directions.

B. Map & Experimental Metadata

Our analysis so far has focused on 4 study sessions, to dive deep into the impact of the configuration change from $C_1 \rightarrow C_2$. We now zoom out for a moment, and examine metadata from all sessions with this participant, including *wash* sessions and continued sessions with C_2. The total number of sessions is 17: 8 under C_1 and 9 under C_2.

Wash Sessions. Looking at all of the maps recorded over all

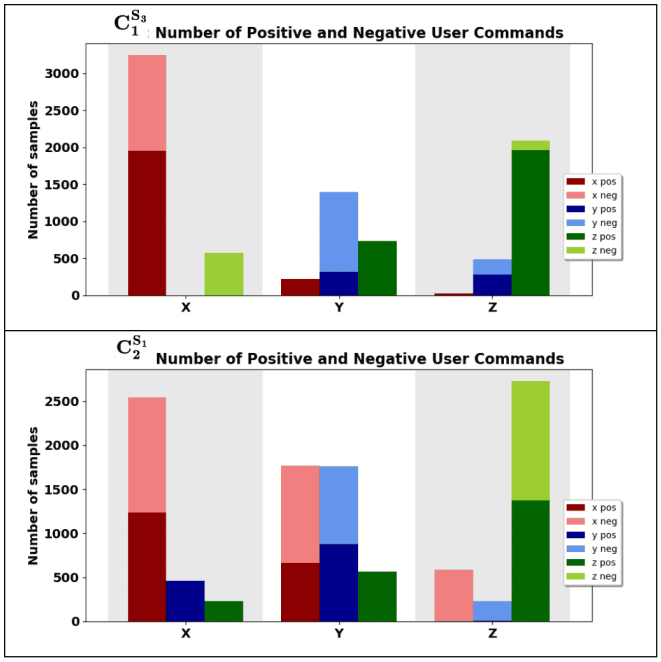

Fig. 6: Comparison of user signals commanded under C_1 and C_2. More *cross-talk* between dimensions is evident in $C_2^{S_1}$ than $C_1^{S_3}$, however the signals in y and z also are more correct and more balanced. (No crosstalk would have only a red bar in x, only a blue in y, and only a green in z.)

17 attempted sessions, for each configuration two metrics are calculated: (1) percentage of wash sessions of the attempted sessions and (2) average number of maps recorded per session. With C_1 we see 37.5% of the attempted sessions end in a *wash* protocol; for C_2 that number is 0.0%. The number of recorded maps per session is reduced from an average of 1.9 recordings per session to 1.1 recordings per session. Both of these metrics signal an informed approach to fitting the BoMI results in a more reliable mapping mechanism that is more robust to day-to-day variation. This not only eases the burden on experimenters and clinicians, but also on the user.

Moreover, while the evaluation of the BCE protocol is beyond the scope of this paper, we note that it has since been deployed in a total of 67 sessions across 8 participants, *none* of which has ended in a *wash* session.

Modifications. It is expected that unforeseen modifications will need to be made to the BoMI between users, as modifications made to ATs are not uncommon in the field [19]. Between C_1 and C_2, the physical and environmental modifications made in order to get the BoMI to work on a given day changed, including number and type.

Across all 17 sessions, we catalog 3 types of modifications: (1) removing wheelchair armrests, (2) providing limb support, and (3) restraining limbs. If the same type of modification is applied to both sides of the body, we count it as 2 modifications.

For C_1, 4 modifications were applied: (1/2) removing right/left armrest, and (3/4) restraining the right/left arm to wheelchair armrest. There was also a lack of consistency in whether a modification actually resulted in any appreciable difference in the map validity. In comparison, the only modification for C_2 during the 9 attempted sessions was the support of the left wrist to elevate the hand. This modification not only was less invasive compared with modifications made in C_1, but also was applied to every session as it positively impacted map validity.

VI. Discussion

For this work, we consider both the quantitative robot task data and the map metadata to provide insights into assessing the fit of each configuration (Section VI-A). We also compile our observations from this case study into guidelines for those working with wearable interfaces similar to the BoMI on individuals with cSCI (Section VI-B). Our on-going and future work will continue to evaluate the BCE, in a multi-session user study with the cSCI population.

A. Quantitative Results

This case study marks a milestone in the experimental development for properly fitting the BoMI. When trying to implement Method 1 on an AROM-restricted participant, the interface was unreliable and, at times, completely unusable. Once we took a flexible approach with Method 2, we not only saw *immediate* improvement in the day-to-day fitting and calibration process, but we also saw improvement in robot task performance. The inconsistencies and low yield of desired characteristics in the y and z dimensions in the DF task improved immediately in the first session with C_2.

It is suspected that motor learning of the interface was not the cause of this improved performance: in Figure 5, $C_1^{S_1} \rightarrow C_1^{S_3}$ in fact was moving farther away from the expert trajectory, prior to the switch to C_2. The lack of statistical significance in these results is hypothesized to be due to a small sample size ($N = 3$). Finally, the consistent trajectory characteristics across the x reaches indicated the x dimension was properly fitted from the beginning.

B. cSCI Wearable Considerations

The AT field expects modifications to fully meet the user. The reliability of these modifications requires an open dialog between clinicians, developers, and the user. The flexibility built into our mapping paradigm, taring protocol, and choice of hardware are vital to meeting these needs. The mapping paradigm has parameters, such as *deadzone* size, to algorithmically tune the sensitivity per participant. The taring protocol is the key to combating drift accumulation in the IMUs, which becomes even more vital when working with the relatively low-variance samples enacted by lower-ROM movements. The use of appropriate hardware and filtering methods enables the capture of these low-variance signals, in turn allowing for accurate mapping. These three components introduce robustness into a system that interfaces with a population with high physiological variability.

The need for stability in the user/device relationship is all the more pressing when any physical instability will manifest in the interface; because the stability of a wearable interface is tied to the stability of the user's body. Creating a system that is robust to instabilities results in a more learnable system by minimizing stochastic components of the user map. For example, our cSCI population requires

frequent pressure breaks and additional personal needs that cause changes in the position of the IMU and overall postural positioning. The user should be able to do these things, re-tare the interface, and resume operation as normal. Artifacts such as *cross-talk*, a present and unavoidable consequence of working with a population with limited sites for appropriate sensor placement, becomes more predictable and learnable to the user when the system is reliable and robust.

VII. Conclusions

The value of designing ATs that are inherently customizable lies in their ability to meet the diverse needs of individuals with varied motor abilities. Traditional interfaces to control ATs often fail to address the full spectrum of user needs due to their fixed design, which limits adaptability and accessibility. We have presented an evolution of protocols that fit a Body-Machine Interface (BoMI) to a person with cervical spinal cord injury (cSCI) for the purpose of 6-D robotic arm control. A case study comparison of the first two protocols has demonstrated the benefit of introducing flexibility into the fitting protocol, with improvements in the day-to-day fitting and calibration process as well as in robot task performance. We also have introduced the BoMI Customization Evaluation (BCE): a user-centric fitting approach that includes a clinical evaluation and combines input from three parties—clinicians, BoMI developers, and the user—in a collaborative effort to customize the BoMI to ensure that both the clinical and functional requirements of the technology are met. The evaluation of the BCE within a multi-session study with cSCI users is on-going, with promising preliminary results.

An Extensible Platform for Measurement and Modification of Muscle Engagement During Upper-Limb Robot-Facilitated Rehabilitation

Ajay Anand, Chad A. Berghoff*, Carson J. Wynn*, Evan Cole Falconer*, Gabriel Parra*, Jono Jenkens*, Caleb J. Thomson, W. Caden Hamrick, Jacob A. George, and Laura A. Hallock

***Abstract*—Populations with upper-limb neuromotor disabilities could greatly benefit from robot-mediated therapy, but the heterogeneity of these disorders, combined with unresolved questions around neuroplasticity mechanisms, hinders the standardized prescription of effective rehabilitation tasks and corresponding robot behaviors. Building on consensus that active neuromuscular engagement is vital for therapy, we introduce a novel, extensible rehabilitation robot platform to directly measure (and, ultimately, modify) user engagement at the muscle level. The system integrates surface electromyography to monitor muscle activation patterns during isometric tracking tasks in all 6 dimensions of hand exertion — beyond the planar constraints of most systems. Usability testing with 13 healthy and 2 post-stroke participants demonstrates the system's utility in analyzing motor behavior across varying poses, trajectories, and impairment levels. Preliminary results indicate that pose and task selection significantly impact activation patterns, highlighting the rehabilitative potential of systems that support motion along all axes and at multiple user poses and guiding our own planned augmentations of the platform (personalized controllers, additional sensing, etc.). To facilitate broader research into muscle activation–force relationships and address the scarcity of open-source upper-limb motor behavior data, we have released all collected data and analysis code as part of the OpenRobotRehab project on SimTK (`simtk.org/projects/openrobotrehab`) alongside this publication.**

***Index Terms*—rehabilitation robotics, human–robot interaction, biomechanics, surface electromyography (sEMG), user-centered design**

I. Introduction

Many patient populations, including individuals recovering from stroke or spinal cord injury, and those with cerebral palsy, multiple sclerosis, and other congenital or acquired neuromotor disorders, could benefit significantly from high-intensity motor therapy. In the context of a global shortage of therapists and caregivers [1], robot-mediated therapy is a promising method to rehabilitate such impairments [2]–[6]. However, the heterogeneity of individuals' motor behaviors and their evolution over time poses a significant challenge, and there remains no consensus on how rehabilitation robots should behave to optimize therapeutic outcomes — for example, when to provide assistance or resistance, and when to augment motion errors or correct them.

One rare point of consensus is that patients should be *actively engaged* in therapy, rather than passively moved by a device or therapist, which is key to inducing the neural plasticity that facilitates motor recovery [7]. While a number of rehabilitation robot control paradigms (detailed in section II below) have evolved to incentivize this engagement, they do not generally adapt to the muscle-level engagement actually observed in an individual user, and whether that engagement is healthy or pathological, nor do they leverage the full 6 dimensions (3 positional and 3 rotational) of possible effort at the hand. To address this gap, we propose a novel robotic rehabilitation system to directly measure and assess muscle-level engagement, and, ultimately, modify that engagement by prescribing personalized trajectories and robot behaviors across both positional and rotational axes. This paper presents the first steps toward the creation of this system. Specifically, our contributions include:

- development of a novel, extensible, proof-of-concept rehabilitation platform enabling muscle activation measurement (via surface electromyography, or sEMG), during isometric, force- and torque-based trajectory tracking tasks, robustly designed for future expansion (to include varied robot controllers and additional sensing modalities);
- a pilot, open-source data set, including all collected sensing and performance data, from 15 individuals (13 healthy and 2 post-stroke), at multiple poses, performing a variety of trajectory tracking tasks on this novel platform, enabling detailed examination of the relationship between applied 6D hand forces and torques and patterns of muscle engagement; and
- preliminary analyses of this force/torque–engagement relationship in this pilot cohort, as well as this cohort's subjective impressions of the system and protocol, motivating our planned augmentations of the system and highlighting the need for expanded research into the impacts of rehabilitation task selection on motor activation patterns.

The open-source data set noted above, as well as additional platform details and analysis code, has been made available as part of the OpenRobotRehab project on SimTK (`simtk.org/projects/openrobotrehab`).

II. Related Work & Context

Several control paradigms have evolved to motivate engagement during robot-mediated rehabilitation, including "assistance as needed" (AAN) [8], "intent-triggered" [8], and "dynamic difficulty adjustment" (DDA) [9] frameworks; however, these systems are all vulnerable to user laziness through their reliance on error signals and/or insufficiently comprehensive in their ability to adjust to individuals' diverse motor strategies and pathologies. Consequently, to date, no clinical trials of rehabilitation robots employing these paradigms have shown improvements in functional outcomes [10]–[13], for ambiguous reasons, illustrating the critical need for comprehensive, personalized models of individuals' neuromusculoskeletal engagement and how it changes under different robot control paradigms. Without such insights, we cannot systematically provide effective, engaging rehabilitation, nor can we quantify the efficacy of the control paradigms we already have.

Alongside these control schemes, muscle synergy analysis [14] has emerged as a promising approach to close this modeling gap by quantifying neuromotor behavior (and post-stroke impairment) and offering a window into how motor control is reorganized following neurological injury [15], [16]. Unlike traditional clinical assessments that primarily rely on kinematic performance or subjective scoring, synergy-based metrics capture the underlying coordination patterns of muscle activations, providing a more mechanistic understanding of motor deficits [17], [18]. However, while synergy-based assessments offer detailed neurophysiological insights, their direct integration into clinical rehabilitation — and particularly, into rehabilitation robotics — remains limited, and further validation and standardization is required to achieve widespread adoption of synergy-based paradigms in stroke rehabilitation protocols [17], [19].

To address this gap, we propose a novel sEMG-based rehabilitation paradigm that leverages these synergy analysis breakthroughs, including recent advancements demonstrating sEMG's potential in identifying muscle synergies to quantify post-stroke impairment [18]–[22]. Rather than employing the standard AAN-style assistance discussed above to enable users to complete specific tasks, we aim to prescribe tasks and robot behaviors to directly enhance user engagement and reduce pathological synergies at the neuromuscular level. Furthermore, because natural motion is not restricted to a single axis, we propose a system that can measure and rehabilitate motion along all 6 (positional and rotational) axes of hand action, a feature not prevalent in the planar rehabilitation systems that dominate the field of physical rehabilitation [23], [24] or in the anthropomorphic robots used for social rehabilitation [25].

The remainder of this paper presents the first steps toward such a system — one that enables this proposed engagement-centric control paradigm in all 6 dimensions — including hardware and software development of a (to begin, isometric) rehabilitation platform (section III); collection of pilot activation data from both healthy and impaired individuals completing a variety of multidimensional trajectory tracking tasks (section IV); preliminary analyses of those individuals' motor strategies and experiences using the platform (section V); and the resulting implications for future rehabilitation system design (section VI). While a full analysis of synergistic motor behavior is beyond the scope of this initial paper, we ultimately aim to perform such analyses on our collected data to inform future work on directly altering pathological synergies via robot intervention.

III. Rehabilitation Platform Design

In this section, we detail both hardware and software aspects of our proof-of-concept rehabilitation platform, as outlined in Figures 1 and 2, respectively. This section delineates both current capabilities and planned expansions (informed by the motor rehabilitation literature and our pilot data analysis in section V, as noted). Detailed system information, including firmware and software versions and configurations, can be found in the data release accompanying this paper.

A. Hardware

Our rehabilitation platform hardware consists of the following elements and associated capabilities:

1) Rehabilitation Robot: The core of our rehabilitation platform is an LBR iiwa 14 R820 7-degree-of-freedom cobot (KUKA AG, Augsburg, Germany), shown in Figure 1(f). The handle and force torque sensor (described below) through which the user interacts with the rehabilitation system are mounted to the cobot's end effector. This setup allows the robot to locate the interface at any point in space to accommodate different user poses and limb geometries. The robot currently serves as a static "jig" for isometric rehabilitation tasks, but will be augmented in future iterations of the system to move, and be moved, by the human user according to various robot control strategies (e.g., error correction or augmentation, resistance or assistance).

2) Force Torque Sensor & Handle: A SensONE 6-axis force torque sensor (Bota Systems AG, Zürich, Switzerland), shown in Figure 1(a), is used to measure the forces and torques applied to the end effector of the robot through a custom-built, ergonomic handle. In the future, additional handles will be designed to support varying user capabilities (e.g., under-wrist bracing for those unable to lift their arm, wrist attachments for those unable to grasp).

3) Surface EMG: Muscle activation data are collected from 8 key muscles of the arm — shown in Figure 1(e) — using two Trigno Quattro 4-channel sensor motes, controlled through a Trigno Base Station (Delsys, Inc., Natick, MA, USA), at 1000 Hz. Data are currently visualized and logged for motor pattern analysis via the software system described below; future iterations of the platform will use this data within the system control loop to adapt parameters of the game and robot behavior based on the user's muscle activations. We also aim to expand the platform to support additional sEMG channels and placements to enable even more comprehensive examination of muscle activation strategies in the arm and hand.

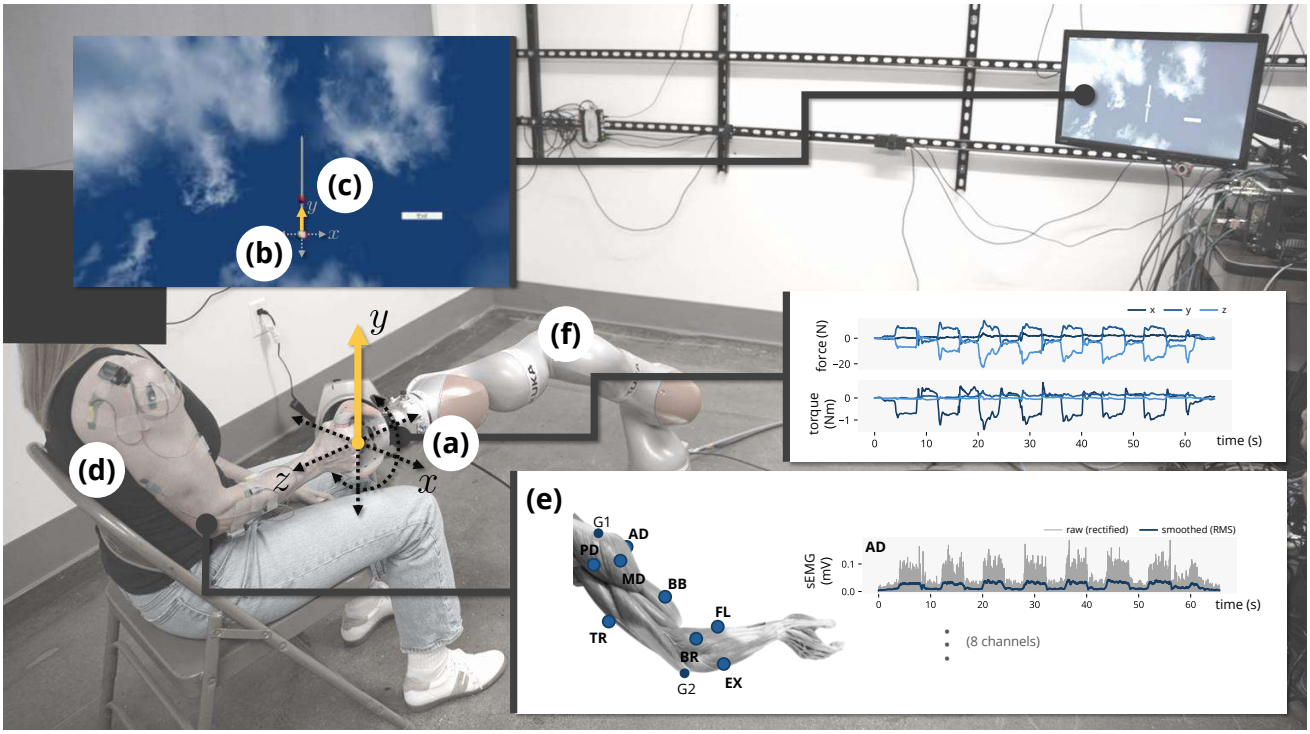

Fig. 1. Motor rehabilitation platform enabling measurement of muscle engagement during trajectory tracking tasks. Users exert forces and torques on load cell (a) through the attached handle, which are then mapped to x–y coordinates of on-screen avatar (b) to allow users to follow red target ball (c) through different trajectories, while surface electromyography (sEMG) electrodes (d) placed on key muscles of the arm (e) record muscle activations. The system currently supports isometric rehabilitation tasks at arbitrary poses — robot (f) remains static — but will be expanded in the future to support a variety of robot controllers. Surface EMG electrode placements: anterior deltoid (AD), middle deltoid (MD), posterior deltoid (PD), and biceps brachii (BB), grounded at the acromion (G1); triceps brachii (long head, TR), brachioradialis (BR), wrist flexors (FL), and wrist extensors (EX), grounded at the olecranon (G2).

B. Software

The hardware elements above, when networked together, enable the user to play a force-based trajectory tracking rehabilitation game while muscle activations are recorded for analysis. Details of this software and the platform's associated network architecture, as well as our plans for future expansion, are described below.

1) Rehabilitation Game: The platform's rehabilitation game, consisting of varied trajectory tracking tasks, is developed in Unity (Unity Software Inc., San Francisco, CA, USA). To play, users exert forces and torques on the above-described handle. These values are then linearly mapped to the (x, y) position of a small ball avatar (Figure 1(b)). Users are instructed to follow the position of a red target ball (Figure 1(c)) as it traverses a displayed trajectory. The specific mapping between 6-axis force/torque values and on-screen avatar positions, as well as the number of repetitions before the game ends, varies by trajectory and is documented in Table I, enabling examination of motor behavior under a wide variety of isometric exertions. Current trajectories and mappings are designed to span the space of forces and torques required during activities of daily living (ADLs), while the goal remains displayable on a 2D screen; future iterations of the system will use a virtual and/or augmented reality headset to display 3D trajectories, enabling even more complexity in game tasks (and, thus, motor behaviors).

2) Network Architecture: The rehabilitation game and hardware sensors are integrated across two desktop computers through a ROS2 network (Open Source Robotics Foundation, Inc., San Jose, CA, USA), as detailed in Figure 2. To enable integration with this network, sEMG data are routed through the Trigno Control Utility (TCU) (Delsys, Inc., Natick, MA, USA) to Motive 3.1 software and then through the associated NatNet SDK (NaturalPoint, Inc. DBA OptiTrack, Corvallis, OR, USA). To facilitate this data transfer, a Delsys Trigger Module is subordinated to an OptiTrack OptiHub controller, allowing recording start/stop signals to be passed down the system from the Motive software to the Trigno Quattro modules. All sensor data and game state information, as well as freeform typed investigator notes, are aggregated into a single time-synced recording ("rosbag") and stored locally, such that all sensor data streams can be accessed for analysis and full trial playback as desired.

Note that sensor data from, and control interfaces to, the rehabilitation robot have not yet been implemented; the current platform allows the end effector of the robot to be positioned at arbitrary locations using its associated pendant controller, but no robot data is collected or used in the current software system. In the future, we will leverage the robot's native ROS2 interfaces to both control robot behavior and log its associated kinematic and dynamic data.

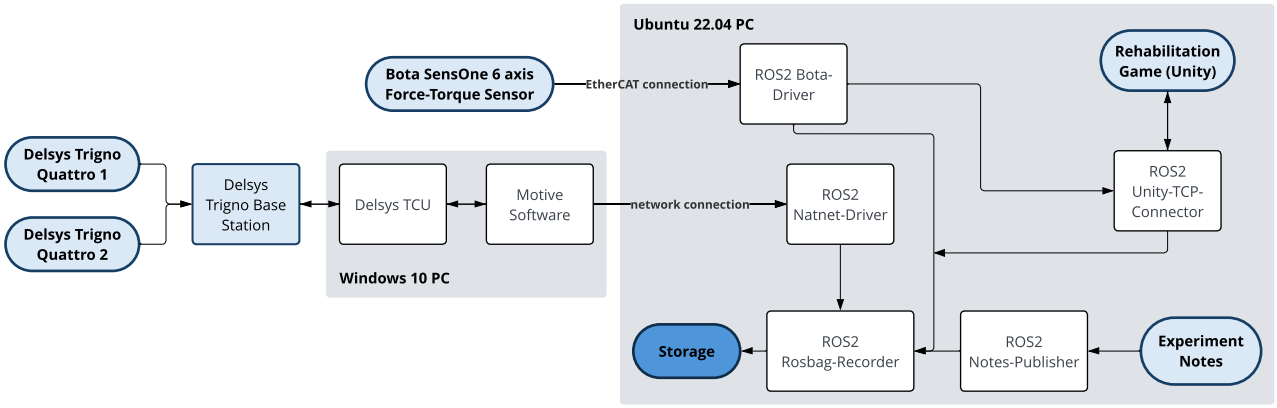

Fig. 2. Software architecture of motor rehabilitation platform. Delsys Trigno sEMG sensor motes, Bota SensOne force torque sensor, Unity rehabilitation game, and typed investigator input are networked via Delsys Trigno Control Utility (TCU), OptiTrack Motive software, and ROS2 network to enable time-synced streaming and storage of muscle activation, force/torque, and game state data, as well as typed investigator notes.

TABLE I
TRAJECTORY TRACKING TASKS & MAPPINGS

Goal Trajectory	Input	Output (Game)	Repetitions
x-axis	x-axis force	x coordinate	7
y-axis	y-axis force	y coordinate	7
z-axis	z-axis force	y coordinate	7
torque	z-axis torque	x coordinate	5
circle (CW[1])	(x, y)-axis force	(x, y) coordinate	3
circle (CCW[2])	(x, y)-axis force	(x, y) coordinate	3
spline 1 (CCW[2])	(x, y)-axis force	(x, y) coordinate	3
spline 2 (CW[1])	(x, y)-axis force	(x, y) coordinate	3

Screenshots of each trajectory are included with data release.

IV. PILOT DATA SET COLLECTION

To illustrate the capabilities of the above rehabilitation platform, assess users' subjective impressions of the system, and provide initial data with which to study variations in human motor strategies, data were collected from a pilot cohort of healthy and post-stroke participants as they performed various isometric trajectory tracking tasks in multiple poses.

Preliminary findings on observed muscle activation patterns and how they vary across individuals and rehabilitation tasks, as well as subjective participant feedback, follow in section V. In addition, to help alleviate the dearth of open-source data sets of this type, the complete data set, including raw and processed force torque and sEMG values, game performance data, and complete subject demographic information, has been released with this paper for further exploration by our own and other research groups.

A. Participant Demographics

Data were collected from 13 healthy individuals and 2 stroke survivors, for a total of 15 participants.[1] The 13 healthy individuals included 7 male individuals and 6 female, 9 right-handed individuals and 4 left-handed, of ages 29.5 ± 14.0 (mean $\pm$ standard deviation, min 20, max 70). Of the two stroke survivor participants, both in the chronic phase of pediatric stroke, the first was female, age 24, right-side hemiparetic, and reports being right-handed prior to her stroke. The second was male, age 34, left-side hemiparetic, and does not report handedness prior to neurological injury. Both stroke survivors exhibited mild spasticity (2 and 1, respectively, at the hand on the Modified Ashworth Scale [26]) and mild decreases in muscle strength (4/4 and 4+/4+, respectively, for flexion and extension of the wrist on the Manual Muscle Testing scale [27]).[2]

B. Study Procedures

The following section, alongside Figure 3, details the procedures used in pilot data set collection from the above participants.

1) Consent & Subjective Data Collection: After providing written informed consent on arrival, each participant completed an intake survey to obtain their baseline affect using the Self-Assessment Manikin (SAM) [28]. The SAM was also completed at the experiment midpoint and after all core experiments were completed, alongside Likert-scale [29] and free-response assessments of comfort, fatigue, motivation, and platform usefulness. Notes on participant feedback when conversing during experiments were also recorded by investigators for inclusion in subjective analysis.

2) Participant Sensorization: After completing the intake survey, participants were instrumented with 8 sEMG electrodes on key muscles of the arm, as described in section III and shown in Figure 1(d)–(e). For all healthy participants, the right arm was sensorized and subsequently used to play the rehabilitation games, allowing us to compare cohorts of dominant-hand users and lightly "impaired" non-dominant

[1]Two additional healthy participants also completed the study (male, left-handed, age 33 and male, right-handed, age 23), but their data was erroneously not recorded due to network issues, so their demographics are not included in the aggregate statistics above, nor is their partial sensor and performance data included in subsequent analyses or data release. As they performed the same experimental tasks, however, their feedback is included in the subjective platform impressions discussed in section V-F.

[2]For additional demographic data, broken down by subject, see the full open-source data release.

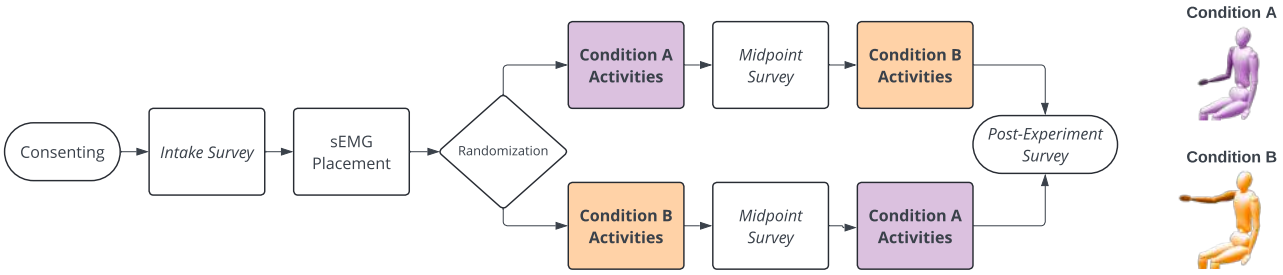

Fig. 3. Experimental flow during collection of pilot data set. Participants were consented and surveyed, then completed trajectory tracking tasks at two ADL-inspired poses (Conditions A and B) in randomized order before providing final survey feedback.

users. For post-stroke participants, the paretic arm was sensorized and tested, as it is the primary target for rehabilitation.[3]

Participants' skin was first cleaned and lightly abraded with alcohol wipes to remove dead skin, then electrodes adhered using Trigno adhesives (Delsys, Inc., Natick, MA, USA) and reinforced using transparent "transpore" surgical tape. Electrodes were precisely positioned using the protocol described in our supplemental data release, then manually adjusted by the investigator by real-time inspection of the signal traces to pick up data from the desired muscles with minimal noise.

3) Core Experimental Activities: Once instrumented with sEMG sensors, participants were seated comfortably upright, feet planted (as able), in a stationary, armless chair at the rehabilitation platform described in section III. The robot end effector was then moved to allow the participant to grasp the handle at one of two poses, illustrated in Figure 3: Condition A (right upper arm comfortably adducted (vertical), right elbow flexed $\sim 90°$ with forearm parallel to the floor) or Condition B (shoulder flexed forward slightly above horizontal and slightly externally rotated, elbow almost fully extended). These two poses were selected to span a workspace useful during activities of daily living, and their order was randomized per-participant, as shown in Figure 3, to avoid the confounding effects of fatigue when analyzing muscle activations across conditions.

Once posed, participants completed the 8 trajectory tracking tasks detailed in Table I. For each task, participants were first allowed to practice following the displayed trajectory as many times as desired, then verbally confirm that they were ready to begin the real trial, at which point data was collected for the listed number of trajectory repetitions. Participants were required to rest for at least 2 min between the first 3, the subsequent 3, and the final 2 tasks to avoid excessive fatigue, and were encouraged to request additional breaks as needed.

After completing all tasks in their first assigned condition, participants completed the midpoint survey, investigators reposed the robot to the second condition, and all tasks were repeated at this new pose using the same protocol. Participants then completed the post-experiment survey, were desensorized, and exited the study.

[3]Note that the second stroke survivor was the only participant for which we measured data from the left arm. This participant completed the same (non-mirrored) rehabilitation tasks, which means that some trajectory tracking tasks are not precisely equivalent in terms of required motor strategy. For our preliminary analyses in section V, we primarily treated this discrepancy as a source of noise, except where noted as impacting overall findings.

C. Data Post-Processing & Release

At study completion, data were cleaned and post-processed for release and further analysis. Trial data was first clipped to include the precise data between start and end timestamps of each rehabilitation task. Next, each channel of sEMG data (pre-rectified by the software pipeline) was smoothed with a 400-sample RMS filter. To remove artifacts caused by (reasonably rare) bumped wires and non-isometric motions, the mean value of each channel, for each subject across all activities and conditions, was calculated, and any data points more than 4 standard deviations greater than this mean were saturated at this value. Each sEMG signal was then normalized to the maximum value of this outlier-reduced signal (in practice, this saturating value), again calculated per-subject across all activities and conditions.[4]

These processed data (alongside raw rectified sEMG signals) have been released for open-source analysis with this paper and are used in our preliminary analyses below.

V. Preliminary Analyses of Task-Dependent Muscle Engagement

Ultimately, we aim to augment the rehabilitation platform described in section III to prescribe poses, trajectories, and robot behaviors to induce desired patterns of muscle engagement in individual device users. In this section, we leverage the data set above to gain preliminary insights on how altering poses and trajectories generates changes in motor behavior, and how these changes vary across impairment levels. We also briefly discuss participants' subjective impressions of our system and suggested enhancements. These analyses not only inform our plans for future system development, but suggest promising directions for further study of upper-limb motor behavior by the wider rehabilitation community.

The analyses below constitute only a small fraction of those enabled by the collected data set. We outline our own plans for its future exploration in section V-E, and encourage other

[4]Note that we normalized to this maximum value because in the context of multi-joint motions, the more standard maximum voluntary contraction (MVC) value becomes poorly defined, as well as potentially hazardous to test in certain impaired populations.

teams to perform their own to support their own rehabilitation system development.

A. Muscle Activation Metric: Area Under the Curve

For our initial analyses comparing muscle activations across poses, trajectory tracking tasks, and impairment levels, we used the area under the curve (AUC) of each processed sEMG signal trace, normalized by trace length, as an aggregate measure of a given muscle's level of activation over the length of the trial. In the future, we aim to employ richer analysis methods to describe the time-dependent and synergistic aspects of the observed data, as discussed in section V-E below.

B. Pose-Dependent Engagement

To explore the relationship between kinematic pose and muscle activation pattern, we examined the AUC-quantified level of activation for each muscle, aggregated across all participants, for each experimental condition (i.e., pose), for each of the trajectory tracking tasks. In general, we found that for the same trajectory, Condition B (arm lifted) elicited an increase in activation of the shoulder muscles (PD, AD, and MD), but had inconsistent impact on arm and wrist muscles, as is expected from the active arm gravity compensation required by that pose. Figure 4 shows illustrative data from the y-axis task, in which this relationship is demonstrated. This trajectory-independent finding suggests that in future rehabilitation systems, the body pose during each activity can be employed as a variable to directly modulate muscle activations toward rehabilitatively desirable patterns.

C. Trajectory-Dependent Engagement

We explored the relationship between task trajectory and muscle activation in an analogous manner, again aggregating AUC-quantified activations for each muscle across all participants and observing relative levels of activation during each activity. Given the wide variety of muscle exertions required to generate each trajectory's varied, time-dependent forces and torques, a plethora of different patterns can be observed; for this first exploratory study, we present a single exemplar result, shown in Figure 5, that illustrates the manner in which different types of trajectories reliably induce changes in specific muscle activations. Even this simple result, which only scratches the surface of the rich patterning observed, supports the idea that prescribed motions can be strategically designed to target specific muscle groups, further enabling the development of more individualized robotic rehabilitation therapies.

D. Engagement Across Impairment Levels

Both healthy and (mildly impaired) post-stroke participants were sufficiently able to complete all trajectory tracking tasks[5] to generate associated muscle activations, confirming the feasibility of system usage by those with motor impairment. Using

[5]Qualitatively, our post-stroke and healthy participants performed comparably well; a full quantitative analysis of tracking performance (described in section V-E as future work) is beyond the scope of this paper.

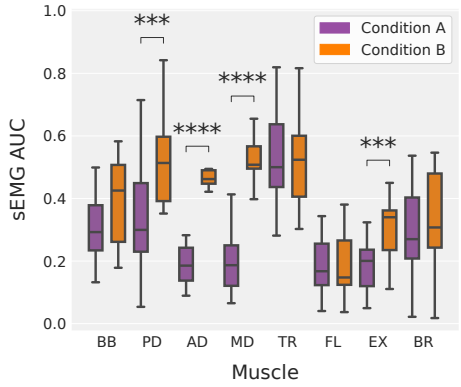

Fig. 4. Cumulative activations of each of the 8 arm muscles (calculated as area under the sEMG curve (AUC), as detailed in section V-A), aggregated across all participants, during the y-axis trajectory tracking task across both tested pose conditions (shown in Figure 3). Adjusting from Condition A (arm low) to Condition B (arm high) caused a largely consistent increase in activation of the muscles required to lift the arm (PD, AD, and MD), across this and all other trajectories, suggesting that pose can be used to selectively modulate muscle activations for rehabilitative purposes. In the activity shown, PD, AD, and MD all showed statistically significant differences across conditions (as calculated via Wilcoxon signed-rank statistical test, reported as $*p < 0.05$, $**p < 0.01$, $***p < 0.001$, $****p < 0.0001$). An addition statistical difference was observed in EX, but was not observed consistently across other unreported trajectories. Statistical annotations displayed via [30].

the same AUC-quantified activation from previous analyses, post-stroke and healthy participants (including left-handed participants using their right hand) exhibited similar motor strategies, as illustrated during the y-axis activity[6] in Figure 6. The one exception is that one stroke survivor exhibited almost no activation of the brachioradialis (BR), which may be the result of nonuse by the participant or of sensor malfunction.[7] Despite this similarity, however, investigators qualitatively observed characteristic compensatory motions in both post-stroke participants (as well as in our age-70 left-handed participant), including various rotations of the torso and lifting and flexing of the shoulder and elbow. This discrepancy suggests the need for more sophisticated sensing (including motion capture and/or inertial measurement sensing to capture joint angles and torso pose) and analyses (discussed below in section V-E) to describe these pathologies, at least in the mildly impaired individuals tested, as well as additional data collection from post-stroke individuals to enable non-anecdotal findings.

E. Future Isometric Analyses

The data collected during this study, though limited to isometric exertions, constitute a novel archive with which to study patterns of motor behavior across individuals as they engage with the end effector of rehabilitation robots. The

[6]Note that while this task is right/left symmetric and thus the data presented are directly comparable for both stroke survivors, this is not true for other task plots included with data release; analyses of these supplementary plots must account for this discrepancy.

[7]Erratic behavior of this electrode was observed by investigators during the trial in our otherwise-reliable sEMG system, and it is unclear whether this was the result of true motor behavior or sensor failure, a question we will explore during expanded future data collection.

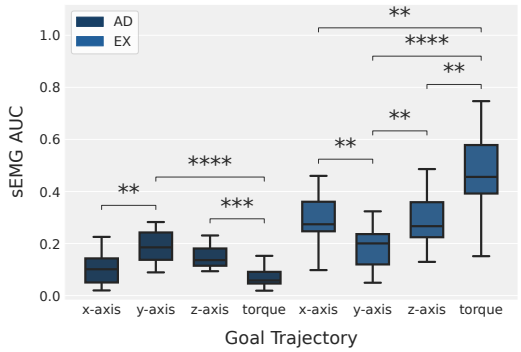

Fig. 5. Cumulative activations of the AD and EX arm muscles, aggregated across all participants, during the 4 single-axis trajectory tracking tasks in pose Condition A. The choice of trajectory — x-axis, y-axis, z-axis, or (z-axis) torque — substantially influenced the activation of both the shoulder flexor (AD) and the wrist extensor (EX). Specifically, movements typically associated with the AD, such as forward and upward motions at the shoulder (y- and z-axis tasks), demonstrated significantly increased activation patterns when compared with x-axis force and z-axis torque (as calculated via Kruskal-Wallis statistical test, reported as $^*p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, $^{****}p < 0.0001$). Similarly, tasks requiring twisting movements at the wrist (here, the torque task) showed significantly increased EX activation compared with the non-twisting x-, y-, and z-axis tasks. Significant differences were also observed, to a lesser degree, among EX activations in the non-twisting tasks. These observed patterns provide evidence that force- and torque-requiring trajectories can be combined to independently modulate desired muscle activations. Statistical annotations displayed via [30].

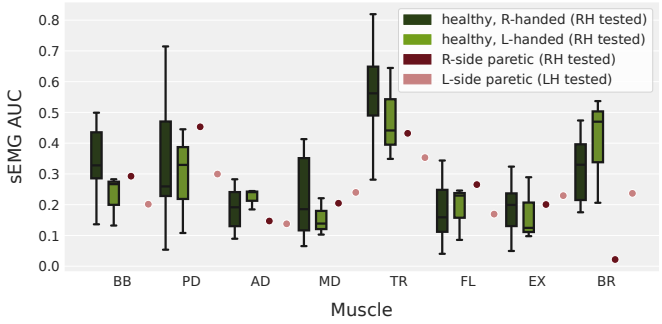

Fig. 6. Cumulative activations of each of the 8 arm muscles, during the y-axis trajectory tracking task in pose Condition A, for aggregated healthy right-handed and left handed participants (all completing the tasks with the right arm) and for individual post-stroke participants (completing the tasks with their paretic arm). Both healthy and post-stroke participants effectively completed the tasks, confirming the feasibility of system usage in the target population. Aside from consistent nonuse of the brachioradialis (BR) by one stroke survivor (which may also be the result of technical malfunction), post-stroke participants exhibited similar motor behavior to that of healthy individuals as evaluated by this metric, despite qualitative observation of compensatory motions, suggesting the need for more sophisticated temporal analyses and/or additional sensing to describe these pathological movements.

preliminary analyses above examine only a single aspect of this patterning, leveraging the same aggregate AUC measure of muscle activation to begin elucidating which muscles are activated under what circumstances, and neglect many aspects of these signals (including time- and co-dependence) that are key to fully understanding both healthy and pathological motion. In the future, we aim to employ tools like statistical parametric mapping [31] and synergy analysis [18] to assess and describe the observed motor behavior in its full temporal richness.

In addition, the analyses above compare muscle activation levels regardless of task performance: while participants largely followed each assigned trajectory, they varied in both how much they deviated from the assigned path and the extent to which they exerted forces and torques in "null" dimensions that did not impact cursor movement for a given task.[8] Future analyses will probe these relationships more deeply by explicitly relating activations to observed forces (through both data-driven methods and physiology-based modeling systems [32]) and examining the relationship between displayed and executed trajectories.

F. Subjective Impressions of the Platform

Both quantitative and qualitative analysis of subject feedback showed a largely positive impression of the system, which participants described as "fun" to use and largely "responsive" to their desired motions. Several participants provided concrete feedback on system improvements, which we will implement in the next version of the platform and should be considered in the development of future rehabilitation systems generally (including the need for a more comfortable and supportive chair, and for a larger screen to capture a wider field of view, reducing visual distractions and enhancing focus). Participants also emphasized the importance of maintaining cognitive engagement through interactive and engaging activities. One participant noted that their engagement in the activity contributed to lower levels of habitual pain, underscoring the potential therapeutic benefits of enhanced engagement beyond the motor neuroplasticity we explicitly target with this system.

Unsurprisingly, due to the additional gravity compensation required, participants found pose Condition B significantly more fatiguing, as measured by Likert scale feedback at the midpoint survey after all tasks at a single experimental condition had been completed.[9] This statistical finding was further supported by subjective remarks, with multiple participants reporting that Condition B was more challenging. Notably, one participant remarked that while Condition B was more difficult compared with Condition A, its difficulty was comparable to that of a traditional rehabilitation therapy session, indicating that the protocol overall was not prohibitively fatiguing for those with only mild impairment. To allow those with more severe motor impairment to use the platform in the future, we aim to incorporate gravity compensation systems through wrist-supporting end effectors and supportive robot controllers.

[8] An example of the latter can be seen in the force torque traces in Figure 1: accomplishing the displayed y-axis task required force only in the y direction (upward and downward), but this participant also exerted substantial force along the z axis (in and out) that was disregarded by the game but is definitionally reflected in the observed muscle activation.

[9] Of the 17 participants who completed the study, 8 were randomized to perform tasks at pose Condition A first, while 9 performed Condition B first. A Wilcoxon rank-sum statistical test indicated that Condition B was statistically more fatiguing than Condition A ($p = 0.05$). No significant differences were found across the intake, mid-point, and post-experiment surveys on the valence, arousal, and dominance scales of the Self-Assessment Manikin (SAM) or the Likert scale used to assess participant comfort.

VI. Conclusions & Future Work

The neurorehabilitation field is still contending with many foundational questions around neuroplasticity, rehabilitation task prescription, and device control. There is thus a great need for improved tools to explore large cohorts of patients in standardized, replicable, extensible, and clinically interpretable ways, and to do so during natural, multidimensional motion. This paper presents our first step toward such a tool: a modular, robust framework to enable wide ranging, controller-agnostic study of these questions and precise quantification of motor behavior across all isometric dimensions of the end effector workspace. We look forward to expanding this system's capabilities in all the ways detailed throughout this paper in order to address these questions — and, ultimately, provide more effective neuromotor therapy — and invite the wider rehabilitation and neuromechanics communities to leverage our data to do the same.

***Abstract*— Transcutaneous spinal cord stimulation (tSCS) is a promising neuromodulation strategy with the potential to enhance locomotor rehabilitation for individuals with spinal cord injury. To maximize the effectiveness of this technique, it is crucial to select the optimal stimulation amplitude during a rehabilitation session. But, current tuning methods are time-consuming and subjective, relying on trial-and-error, clinician observations, and participant feedback. To improve this process, there is a need to define quantitative relationships between stimulation amplitude and measurable biomechanical metrics. In this study, we present a case series that includes two participants with motor-incomplete spinal cord injury walking with tSCS programmed to provide different stimulation amplitudes. We measured spatiotemporal parameters, electromyography, and inverse kinematics during overground walking with tSCS. Our results indicate that gait speed, stride length, and electromyography outcomes (e.g., muscle co-activation) systematically change with stimulation amplitude. This research is valuable in advancing our understanding of how stimulation amplitude relates to walking biomechanics. In the future, this knowledge will be used to design real-time, adaptive tSCS tuning methods for use in rehabilitation.**

Keywords—transcutaneous spinal cord stimulation, spinal cord injury, walking, biomechanics, neuromodulation

I. Introduction

Spinal cord injury (SCI) is a heterogenous condition, wherein spinal cord damage can impact both efferent and afferent nervous signals. This injury can result in partial or complete loss of motor, sensory, and autonomic function [1]. A common effect of SCI is reduced mobility, which in turn can lead to secondary health complications such as loss of bone density, and impaired cardiovascular function that may further impact quality of life [1], [2].

The majority of people with SCI (67%) have incomplete injuries [3], which indicates some capacity for recovery. However, impacted functions and symptoms vary greatly between individuals and across level and severity of injury. Prior research indicates that walking is a high priority for people with SCI, particularly for individuals with incomplete SCI [4], [5], [6], [7]. Thus, restoring walking is a valuable rehabilitation target for people with incomplete SCI.

Standard approaches for functional rehabilitation of walking include a variety of activity-based therapies such as bodyweight-supported treadmill training, functional electrical stimulation, and locomotor training [8]. However, rehabilitation outcomes for individuals with incomplete SCI are mixed, and many do not achieve their functional goals [9], [10].

One emergent technology that has the potential to improve rehabilitation outcomes for individuals with SCI is transcutaneous spinal cord stimulation (tSCS) [11]. tSCS is a neuromodulation technique that delivers pulsed electrical stimulation via surface electrodes placed on the skin over the spinous processes. Unlike surgically implanted epidural spinal stimulators, tSCS is non-invasive, which makes it accessible, customizable, and easy to use during outpatient rehabilitation.

Transcutaneous spinal cord stimulation can be combined with activity-based therapies, such as overground walking, bodyweight-supported treadmill training, and exoskeleton walking [12], [13]. Previous research demonstrated that adding tSCS to locomotor rehabilitation can improve walking function compared to locomotor rehabilitation alone, and improvements are sustained for at least several months after stimulation [14]. It is thought that the electrical stimulation delivered by tSCS increases the excitability of the primary afferent fibers in the spinal cord. This enables neural signals that may still propagate along residual spinal cord tracts to facilitate voluntary control of lower extremities [12]. tSCS is also hypothesized to contribute to activity-based neural plasticity, which may promote recovery within a rehabilitation session and over a broader recovery timeframe [12], [15].

Presently, tSCS implementation in rehabilitation research is still both novel and experimental. A clinician could spend significant time during a session "tuning" the tSCS stimulation for an individual participant. While frequency and waveform properties (e.g., pulse width) are often held constant based on objective values derived from prior experiments [16], the amplitude of stimulation is often tuned subjectively. Clinicians may evaluate the participant's range of motion, walking speed, and/or voluntary movement at different stimulation amplitudes before deciding on a final amplitude [14]. Further, once a stimulation amplitude is set, it is often held constant for the duration of the session.

Funding for this study was provided by Wings for Life.

However, neuromotor recovery, particularly under the influence of neuromodulation, can be nonlinear and dynamic. Therefore, shifting away from conventional fixed-amplitude stimulation towards personalized, adaptive amplitude modulation may improve functional outcomes.

One significant barrier to designing adaptive tSCS tuning paradigms is that there are currently no quantitative metrics that define "optimal" stimulation. Publications typically only report the final stimulation amplitude for a training session and do not specify any changes made to amplitude during the session, which makes it difficult to define the tuning process [13]. Trial-and-error visual observation of locomotion at different stimulation amplitudes is inherently subjective and requires an experienced clinician. Clinicians also rely on qualitative participant feedback about how different amplitudes feel for stimulation tuning. This process can take a significant portion of each session to optimize just once, let alone multiple times per session. Therefore, to successfully implement adaptive tSCS algorithms, there is a need to understand the relationship between stimulation amplitude and measurable biomechanical or physiological signals.

The goal of this study was to determine how spatiotemporal gait parameters, electromyography, and gait kinematics systematically vary as a function of tSCS amplitude during overground walking. In this paper, we present a case series with two adult participants with motor-incomplete cervical SCI walking overground using a sweep of tSCS amplitudes. In the future, this knowledge can be used to refine protocols for tSCS-mediated locomotor rehabilitation programs, improving treatment efficiency. This work is a crucial first step towards the development of real-time adaptive tSCS tuning algorithms for locomotor rehabilitation that can maximize functional walking recovery for adults with motor-incomplete SCI.

II. Methods

A. Participants

Two participants with chronic (>1 year) motor-incomplete SCI were recruited for this study. Participant 1 (P1; female, 59 years old) has spinal cord injury level C5-6 with American Spinal Injury Association Impairment Scale (AIS, [17]) grade D, 15 years post-injury. P1 uses a powered wheelchair as her primary means of mobility in the community, and uses no mobility aids at home. Participant 2 (P2; male, 49 years old) has spinal cord injury level C6 with AIS grade C, 18 years post-injury. P2 uses a manual wheelchair as his primary means of mobility. Participants gave informed written consent to participate in this protocol, which was approved by the University of Washington Institutional Review Board (Study #00003070).

B. Experimental Protocol

We used the experimental SpineX SCONE device to deliver tSCS (SpineX, Northridge, CA). We placed electrodes on the T11-12 and L1-L2 spinous processes, with ground electrodes placed bilaterally over the anterior iliac crests [14]. Stimulation was delivered via 30 Hz biphasic rectangular 1 ms pulses, with a 10 kHz carrier frequency [11]. At the beginning of each session, a trained physical therapist assessed the participant and determined their 'preferred' stimulation amplitude based on visually observed changes in voluntary movements.

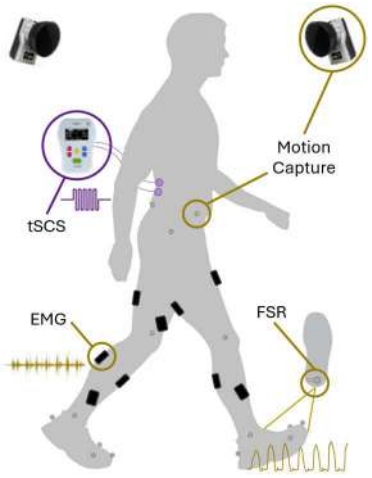

Figure 1. Summary of experimental setup. We applied transcutaneous spinal cord stimulation (tSCS) over a participant's lumbar spine. We measured muscle activity using electromyography (EMG), foot contacts using force-sensitive resistors (FSR), and kinematics using motion capture.

Each participant completed a single experimental session. Participants were asked to perform overground walking passes across a 9m walkway at a variety of stimulation amplitudes. Participants wore a safety harness that provided no bodyweight support. P2 completed his session using a two-wheeled walker as a mobility aid. Participants walked at their self-selected walking speed for all trials.

The number of trials and the stimulation amplitudes we tested varied between participants to accommodate for stamina and different participant needs. P1 completed 35 walking trials and P2 completed six (one pass per trial). We selected stimulation amplitudes for each participant above and below their clinician-preferred value. We also repeated some stimulation amplitudes to examine changes across a single session. Participants started and ended the session walking with no stimulation (0 mA) as a baseline. The stimulation amplitude protocol for each participant is shown in Table 1.

TABLE I. Stimulation Amplitude Conditions

Stimulation amplitude (# of trials)	
Participant 1	***Participant 2***
0 mA (4)	0 mA (1)
80 mA (2)	120 mA (1)
100 mA (2)	140 mA (1)
120 mA (2)	160 mA (1)

C. Data Collection

We collected lower-limb motion data using a 12-camera optical motion capture system (Qualisys AB, Gothenburg, SE). Thirty-nine (39) markers were placed on the lower limbs according to the modified Helen-Hayes model. We measured muscle activity using electromyography (EMG) (Delsys Inc,

Natick, MA). We collected EMG data bilaterally from six muscles: tibialis anterior (TA), medial gastrocnemius (MG), soleus (SOL), biceps femoris (BF), rectus femoris (RF), and vastus medialis (VM). EMG sensors were placed in accordance with SENIAM guidelines [18]. We captured foot strikes using four force-sensitive resistors (FSR) (Delsys Inc, Natick, MA) placed on the plantar surface of each foot. We captured motion capture data at 120 Hz for P1, 100 Hz for P2 and EMG and FSR data at 2000 Hz. All data were synchronously collected using Qualisys Track Manager (QTM; v2019.3).

D. Data Processing and Analysis

We labeled motion capture marker trajectories in QTM using a combination of Automatic Identification of Markers (AIM) models and manual labeling. We exported labeled trajectories and performed inverse kinematics analysis via OpenSim (Stanford, CA) using the Gait 2392 model scaled to each participant. We then exported these trajectories to MATLAB (Mathworks, Natick, MA) and used the FSR data from the mid-heel to perform stride segmentation. We averaged the kinematic trajectories across strides within a stimulation condition. All subsequent analyses were conducted using MATLAB.

For each trial, we calculated average gait speed by measuring the distance traveled by the sacral marker (as an approximation of center of mass) divided by the total trial time. We performed linear regression and calculated Pearson's correlation coefficient (r) for gait speed vs. stimulation amplitude and gait speed vs. trial. We calculated stride length as the distance traveled by the heel marker from 0-100% of the gait cycle for each leg per stride.

For the EMG data, we applied an ACSR filter [19] to remove stimulation artifact with window size of 300 ms at 50% window overlap. Due to limited quiet standing data, training data for the filter was selected as 0.4 seconds of quiet EMG data for each trial. After stimulation artifact removal, EMG data were bandpass filtered (2nd order Butterworth 20-450 Hz), rectified, and lowpass filtered (2nd order Butterworth 5 Hz). We segmented the filtered EMG data by stride using the FSR signal, and calculated the area under the curve (AUC) for each stride. We performed linear regression between the AUC and stimulation amplitude for each muscle.

We also analyzed the joint-probability density (JPD) for the TA and SOL agonist-antagonist muscles to evaluate changes in co-activation across stimulation amplitudes [20]. We performed JPD analyses using all strides from all trials at each stimulation amplitude. We normalized the filtered EMG signals by the 99th percentile of the peak EMG amplitude for each muscle. We then created the JPD by creating a 2-dimensional histogram between the amplitude of the TA and the amplitude of the SOL. We divided the data into four quadrants (Q1-Q4) with the designation between quadrants set at 20% of the maximum amplitude of each muscle. The total number of data points in Q2 and Q4 represent alternation between TA and SOL activation; the total number of data points in Q1 represents co-activation of TA and SOL. We calculated the percentage of data points in Q2 and Q4 as well as the percentage of data points in Q1 for each stimulation amplitude. We repeated these analyses for both legs.

III. RESULTS

The clinician-preferred stimulation amplitude was 140 mA for P1 and 120 mA for P2, determined through a combination of clinical observation and conversation.

A. Spatiotemporal Parameters

For P1, we observed a negative correlation between gait speed and trial number (r = -0.6) (Fig. 2), with a linear regression R^2 = 0.36. Gait speed did not strongly correlate with stimulation amplitude for P1 (r = -0.02, R^2 = 0.0). For P2, the correlation between gait speed and trial number was r = -0.37 (R^2 = 0.13), and between gait speed and stimulation amplitude was r = 0.77 (R^2 = 0.59).

We compared average gait speed between the repeated stimulation conditions for each participant (Fig. 3). For P1, we found that, on average, gait speed decreased by 11.8% (0.4%) [mean (SD)] from first to second repetition for no stimulation, 100, 120, and 140 mA conditions. We observed only a 0.5% decrease in gait speed between repetitions for the 160 mA condition. For P2, there was a 32% decrease in gait speed from the first to second repetition of the no stimulation condition, and there was a 2% *increase* in gait speed for the 120 mA condition.

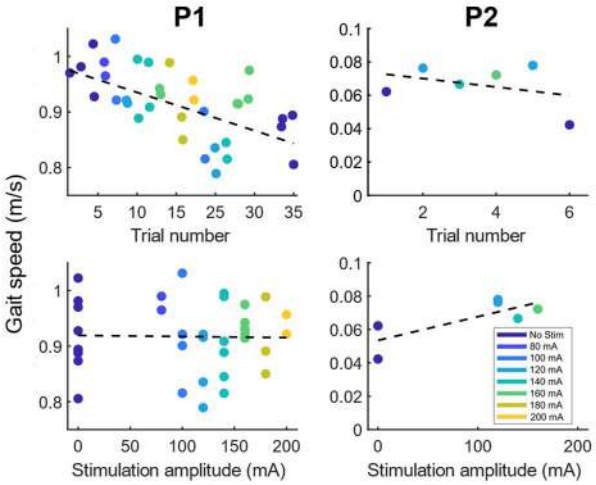

Figure 2. Gait speed across session and stimulation amplitudes. Each data point represents the mean gait speed for one walking pass. Different colors correspond to different stimulation amplitudes. The dashed black line shows a linear regression model for each plot. Please note the different y-axes used to best visualize the data.

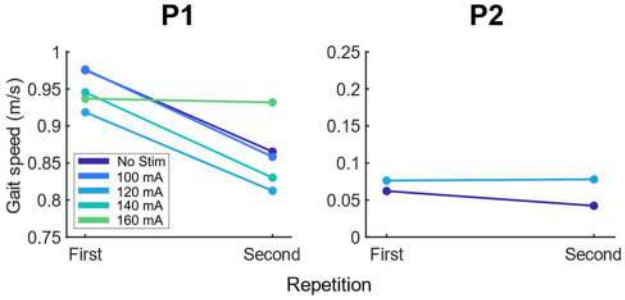

Figure 3. Comparison of gait speed between first and second repetitions of stimulation amplitude conditions. The colored lines depict different repeated stimulation amplitude conditions. Each data point shows the average gait speed calculated across all trials for that condition. Please note the different y-axes used to best visualize the data.

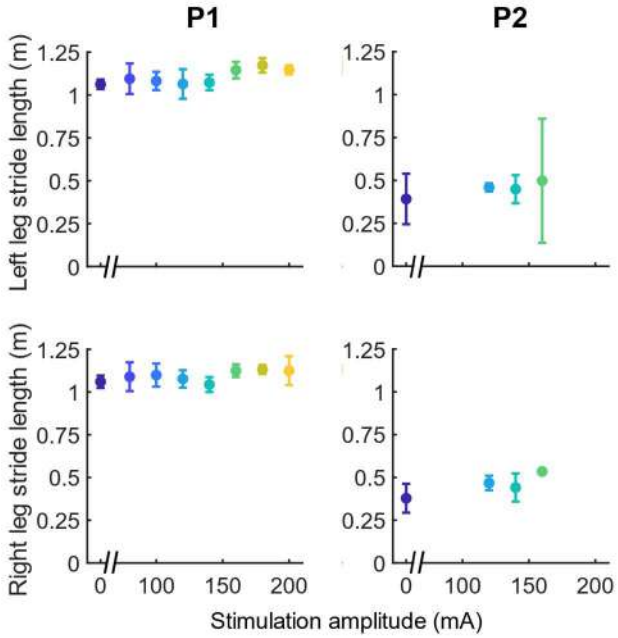

Figure 4. Stride length as a function of stimulation amplitude. Data for P1 (left column) and P2 (right column) are shown for both left (top row) and right (bottom row) legs. Each data point indicates the average stride length calculated over all strides collected for a given amplitude condition. The error bars indicate the 95% confidence interval.

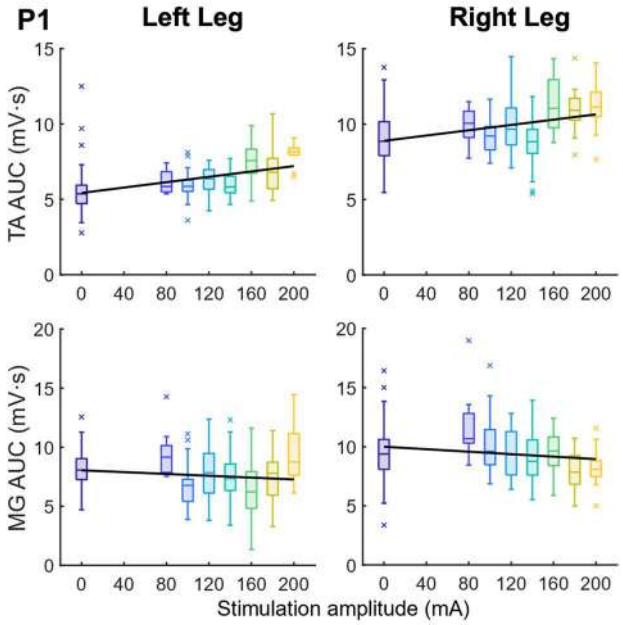

Figure 5. EMG area under the curve (AUC) across stimulation amplitudes for Participant 1. Tibialis anterior (TA, top) and medial gastrocnemius (MG, bottom) AUC distributions for left and right legs as a function of stimulation amplitude. Each boxplot shows the distribution across all strides collected for a given amplitude condition. The solid black lines show the linear regression models fit to the data.

For P1, we observed a longer mean stride length for both left and right legs at higher stimulation amplitudes (>160 mA) compared to no stimulation (Fig 4). For 160, 180, and 200 mA conditions, P1's average stride length (across both legs) increased by 0.08 (0.02) m (7.6% change) compared to no stimulation. For the 80, 100, 120, and 140 mA conditions, P1's average stride length (across both legs) increased by 0.01 (0.01) m (1.5% change) compared to no stimulation. We observed a similar trend for P2, whose average stride length (across both legs) increased by 0.09 (0.04) m (23% change) compared to no stimulation for 100, 120, and 140 mA conditions.

B. Electromyography (EMG)

The muscles with the highest positive and negative correlations between EMG area under the curve (AUC) and stimulation amplitude for P1 were for the tibialis anterior (TA) and medial gastrocnemius (MG), respectively (Fig. 5). The TA had $R^2 = 0.18$, $r = 0.43$ for the left leg and $R^2 = 0.10$, $r = 0.32$ for the right leg. The MG had $R^2 = 0.01$, $r = -0.11$ for the left leg, and $R^2 = 0.02$, $r = -0.16$ for the right leg. All other muscles for P1 had correlations $|r| < 0.12$.

A representative joint probability density (JPD) plot for P1's 180 mA condition is shown in Figure 6. For this analysis, more points in quadrant Q1 indicates increased co-activation of the muscles, while more points in quadrants Q2 and Q4 indicates less co-activation of the agonist-antagonist (TA-SOL) pair. We found that for P1, the lowest-co-activation (i.e., the largest percentage of points in Q2 and Q4) occurred during the 180 mA condition (74.6%).

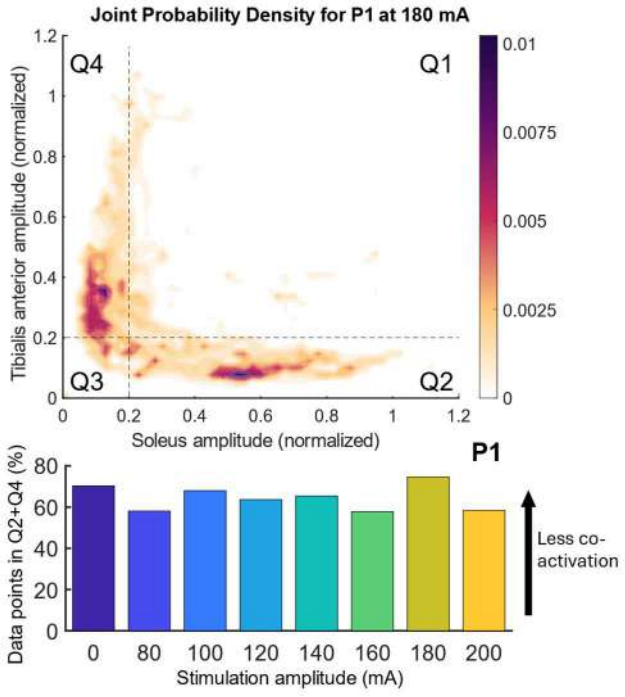

Figure 6. Joint probability density (JPD) between agonist-antagonist muscle pair (tibialis anterior and soleus) for Participant 1. *Top:* A representative JPD is shown for P1 during the 180 mA condition. A higher percentage of points in quadrants Q2 and Q4 (*i.e.,* the plot is more 'L-shaped') indicate less co-activation. *Bottom:* The percent of data points in Q2 and Q4 across all stimulation conditions for P1.

For P2, we did not examine linear regressions for EMG AUC or generate JPD plots due to the small number of strides and conditions that P2 completed.

C. *Inverse Kinematics*

Overall, inverse kinematics at the ankle, knee, and hip did not appear to meaningfully change at different stimulation amplitudes for either participant (Fig. 7).

IV. Discussion

Here, we document our preliminary findings on how walking biomechanics vary as a function of transcutaneous spinal cord stimulation (tSCS) amplitude for two individuals with motor-incomplete cervical spinal cord injury (SCI). While both participants were able to complete walking passes at different stimulation amplitudes above and below the clinician-preferred value, Participant 1 (P1) completed significantly more conditions (35 trials at 8 different amplitudes) than Participant 2 (P2) (6 trials at 4 different amplitudes). In this study, we observed relationships between spatiotemporal gait parameters, muscle activity and stimulation amplitude, but did not observe noticeable changes in kinematics when tSCS amplitude was varied.

We observed that gait speed had a slight positive correlation with increasing stimulation amplitude for P2, but were surprised that P1 did not have a similar trend, as prior studies have shown that participants with SCI are able to walk faster with tSCS than without [14]. However, when we examined the relationship between gait speed and trial number (i.e., time) for P1, we found a moderate negative correlation (Fig. 2). We found a similar relationship for P2, albeit less striking. This overall trend suggests that fatigue may be playing a dominant role in the participants' choice of walking speed. When examining Figure 2, we noticed that walking trials 28-31 (160 mA, green) for P1 do not appear to follow this overall downward trend. In fact, when we examined how gait speed compared between repeated amplitude conditions, we saw that P1's gait speed was essentially unchanged for the 160 mA condition, while it decreased by 11.8% (on average) for all other amplitudes (Fig 3.). We observed a similar phenomenon in P2, whose gait speed decreased by 31% in the repeated no stimulation condition, but actually increased slightly (2%) in the repeated 120 mA condition. This suggests that there may exist some optimal stimulation amplitude that can counteract the effects of fatigue.

We observed increased stride length at sufficiently high stimulation amplitudes (Fig. 4), which agrees with prior studies that have also reported this phenomenon [13], [14]. Because P1 completed more conditions across a wider range of amplitudes, we can see that there appears to be a 'threshold' of stimulation amplitude required before observable changes in stride length may occur. For P1, it appears this threshold is

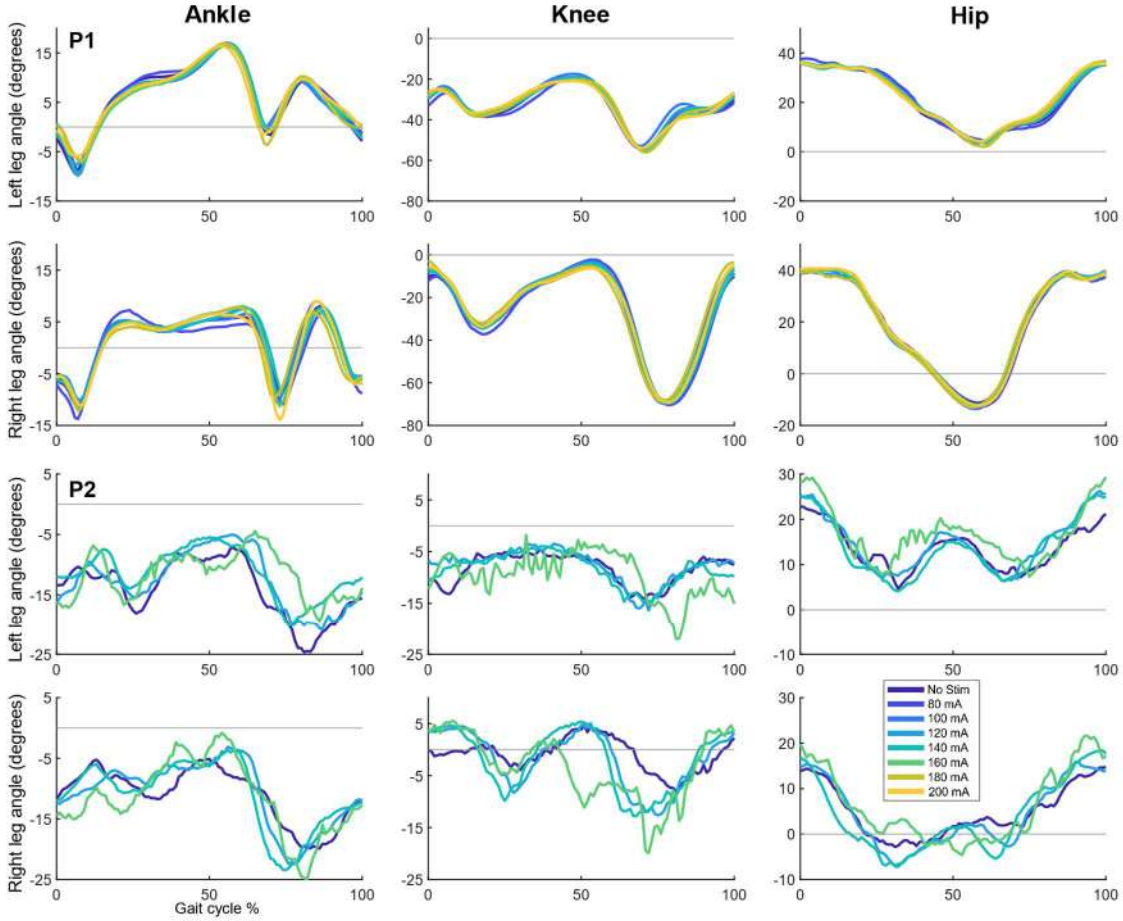

Figure 7: Mean inverse kinematics trajectories. Mean ankle, knee, and hip angle traces across stimulation amplitudes for P1 (5-18 strides per condition) and P2 (2-6 strides per condition). Grey lines indicate zero degrees for each plot.

around 140 mA. For P2, we saw the same increase in stride length for all amplitudes conditions tested. Because we could not continue to increase stimulation for either participant, we do not yet know if there exists a higher amplitude for which stride length would decrease again.

Our analysis of EMG data for P1 indicates that different muscles respond differently to changes in stimulation amplitude. We observed an overall increase in TA activity (but an overall decrease in MG activity) with increasing stimulation amplitude. However, in the absence of clinical data that describe the muscles' strength, tone, or spasticity, we cannot definitively conclude that these results correspond to "improved" or "worsened" biomechanics. The joint probability densities between the TA and SOL (Fig. 6) indicate that for certain stimulation amplitudes (i.e., 180 mA), P1 displayed more normative agonist-antagonist coordination compared to the other stimulation conditions.

We did not observe noticeable changes in overall gait kinematics between stimulation conditions (Fig. 7). It has previously been shown that adults with SCI have higher kinematic variability during overground walking compared to nondisabled adults [21]. This may have contributed to less distinction between kinematic joint angle outcomes across stimulation amplitudes. We have not yet quantified the role that fatigue may have played on kinematics.

Our results highlight the challenges inherent in determining an individual's "optimal" stimulation amplitude. For example, if the objective was to maximize walking speed or increase stamina, the optimal amplitude for P1 may be 160 mA. Alternatively, if the goal was to maximize stride length or minimize muscle co-activation, 180 mA provides better results for P1. Furthermore, we cannot discount the clinician-preferred amplitude of 140 mA for P1, which was determined through holistic observation and conversations with the participant about their qualitative experience of ease of walking at different stimulation amplitudes. In the future, having easy-to-obtain quantitative outcome measures that can supplement clinical expertise could accelerate the tuning process and provide clinicians with additional data to support their decision-making.

This case series was limited by its small sample size and small number of trials per participant. In the future, we seek to expand this protocol to more individuals with SCI across multiple sessions to determine population trends and further elucidate the multi-dimensional factors that underlie choosing the optimal stimulation amplitude. With this knowledge, we plan to design real-time adaptive tuning algorithms for tSCS that can enhance locomotor rehabilitation for adults with SCI.

Development of multimodal EEG-EMG human machine interface for hand-wrist rehabilitation: A preliminary study

Minki Kim, SeongHyeon Jo, Hyeonseung Cho, Seungmin Ye, Yeongtae Kim, Hyung-Soon Park *

Abstract— **Patients with neurological disorders, such as stroke, often undergo upper limb motor impairments, severely limiting their ability to perform activities of daily living (ADL). Wearable robots have been developed to provide intensive and precise repetitive training for upper limb rehabilitation. Effective rehabilitation requires aligning robotic assistance with patient movement intention to promote brain plasticity. Additionally, robotic assistance must accommodate the complex, coordinated upper limb motions required for ADL tasks, including not only isolated hand movements but also integrated hand and wrist actions. This paper presents a multimodal human-machine interface (HMI) for integrated hand-wrist rehabilitation using both EEG and EMG signals. A three-degrees-of-freedom (3-DOF) soft wearable robot, combining a robotic hand glove and forearm skin brace, was designed to assist coordinated hand and wrist movements during reaching and grasping. EEG signals classified rest and grasp states using a Riemannian geometry approach, while EMG signals from three forearm muscles detected reaching onset to trigger the wrist adjustment. Preliminary tests with four healthy participants demonstrated 85% accuracy in EEG-based classification and sufficient EMG amplitude for motion onset detection. Future studies will expand participant testing to improve system robustness and evaluate its effectiveness for stroke rehabilitation.**

I. INTRODUCTION

Stroke, a common neurological disorder caused by blocked or ruptured brain blood vessels, often results in upper limb motor impairments, affecting up to two-thirds of post-stroke patients [1]. The motor function disabilities lead to spasticity and flexion in the hand, wrist, and forearm, which significantly limit their ability to perform essential activities of daily living (ADL) tasks, thereby reducing the quality of life [2]. To address these deficits, robot-assisted rehabilitation therapy has emerged as a promising approach, offering high-intensive repetitive training [3]. This approach facilitates task-oriented training by incorporating repetitive, goal-oriented tasks that enhance upper limb function in stroke patients while reducing the workload of physical therapists [4], [5]. In recent decades, wearable robotic systems have evolved from rigid exoskeletons [6], [7] to soft wearable robots [8], [9], [10], [11], which are lightweight, portable, and fabricated soft materials, making them more suitable for long-term use in intensive rehabilitation tasks. In this work, we propose a soft wearable robot designed for grasping assistance, aimed at task-oriented stroke rehabilitation.

To effectively support upper limb rehabilitation of post-stroke, robotic assistance should account for the coordinated and complex movements of the hand, wrist, and forearm. Many existing assistive robots, however, focus on isolated rehabilitation of either the hand or the wrist [12]. Most wearable robotic systems designed for ADL-oriented training target hand movements alone, as they are directly associated with task completion [13]. Nevertheless, the biomechanical interdependence of the hand and wrist—where hand muscle tendons traverse the wrist to control finger movements—makes wrist posture critical to finger range of motion (RoM) and stiffness [14]. Consequently, many hand rehabilitation robots require additional passive wrist support or therapist intervention to address spasticity-related forearm postures. To facilitate natural movement in ADL tasks, robotic systems should assist both the hand and wrist in coordination. Although some robots have attempted simultaneous hand-wrist support [6], [7], [15], achieving compactness while restoring both functions remains a challenge. Thus, our wearable robot is designed to assist both the hand and wrist during object grasping.

Active participation in rehabilitation is essential for promoting natural, intuitive movements and inducing brain plasticity [16]. Passive repetitive tasks, even with robot assistance, may aid in restoring motor function but do not guarantee recovery of the damaged neural systems in stroke patients. Emerging evidence suggests that closed-loop rehabilitation systems, based on the Hebbian rule, effectively enhance brain plasticity and require patient-initiated movement intent to actuate robotic systems [17]. Developing human-machine interfaces (HMI) that facilitate active participation is therefore essential for effective rehabilitation, a concept applied to this work as well.

For decoding motor intention, electromyography (EMG) and electroencephalography (EEG) are widely employed in upper limb rehabilitation HMIs [18], [19]. EEG-based brain-machine interfaces (BMI) classify motor intentions to execute motion, while EMG detects direct muscle activation during arm movement. However, EEG suffers from low signal-to-noise ratio (SNR) and non-stationarity, whereas EMG signals exhibit high inter-individual variability and degradation in patients with severe spasticity. To overcome these issues, multimodal EEG-EMG HMIs combine both modalities [19], [20], [21], but most merge EEG and EMG

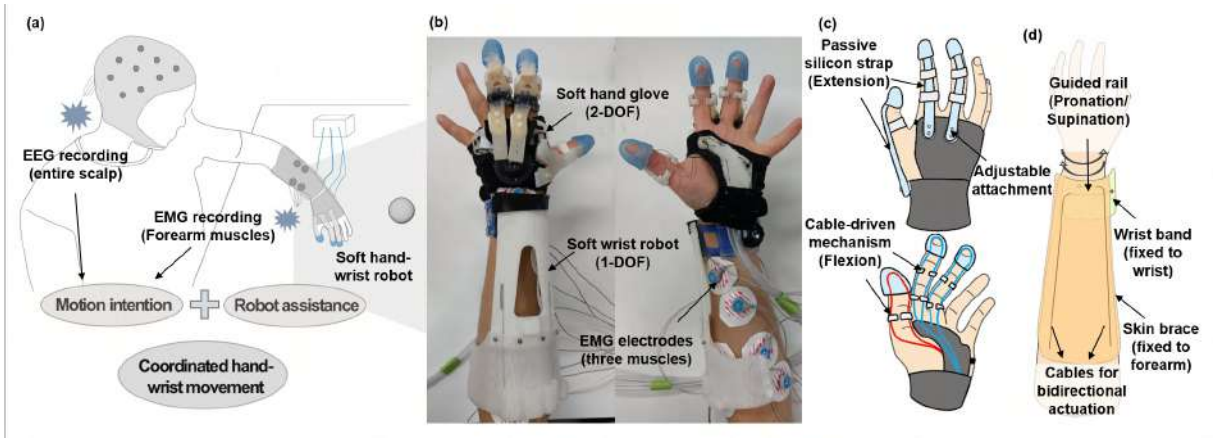

Fig. 1. Schematic of the multimodal EEG-EMG human machine interface for hand-wrist rehabilitation. (a) Conceptual overview of the proposed system, (b) Dorsal and palmar views of 3-DOF soft wearable hand-wrist robot integrated with EMG electrodes, (c) Soft hand glove mechanism demonstrating finger/thumb flexion-extension, (d) Soft wrist robot enabling bidirectional actuation for wrist pronation-supination.

into a single classification, overlooking the sequential coordination needed for grasping. In particular, effective grasping necessitates forearm-wrist adjustment before hand closure, which many existing systems difficult to accommodate [22], [23]. This study proposes a sequential multimodal EEG-EMG HMI system, where EMG detects reaching intent to induce preemptive wrist adjustment, followed by EEG-based grasp/rest classification, ensuring natural movement transitions for robotic stroke rehabilitation.

This study aims to develop a multimodal HMI that utilizes EEG and EMG data for coordinated hand-wrist rehabilitation using a wearable robot (Fig. 1 (a)). The proposed motion intention recognition algorithm facilitates smooth transitions from rest to grasp. EEG signals were recorded from 19 sponge electrodes placed across the entire scalp to classify grasp and rest states. EMG signals, collected from three forearm muscles, detected reaching intent to adjust wrist posture before grasping. The hand-wrist wearable robot (Fig. 1 (b)), integrating a soft hand glove and forearm skin brace, provides independent assistance for finger/thumb flexion-extension and wrist pronation-supination, forming a three-degrees-of-freedom (3-DOF) system. EEG and EMG data were collected from four healthy subjects performing a grasping task with the wearable robot. The feasibility of the system is evaluated for its potential application in stroke rehabilitation beyond this preliminary study.

II. Materials and Methods

A. Soft wearable hand-wrist assistive robot

For hand movement assistance, a modified version of the high-DOF soft-robotic glove originally developed in [11], [24] was utilized to suit the specific requirements of this study. The original glove was designed for versatile in-hand manipulation to support activities of daily living (ADL) for patients with neurological disorders. Its actuation mechanism employed a bioinspired design: active cable-driven exotendons routed along the palmar side facilitated flexion, while passive elastic exotendons on the dorsal side maintained extended postures.

To enhance wearability and focus on grasping assistance, we simplified both the actuation mechanism and the structural design of the glove. The original glove assisted individual finger movements, but in this study, the soft hand glove design was simplified to involve only the thumb, index, and middle fingers, which play primary roles in various grasping postures. This decision improved wearability by reducing system weight and bulk while retaining effective functional grasping of various objects, including spheres, cylinders, and thin plates. The two cables routed on the index and middle fingers were bundled and connected to a single actuator so that two fingers could make flexion or extension simultaneously. Consequently, the number of actuating motors was reduced from eight to two (2-DOF): one motor drives the extension of two fingers, and the other facilitates thumb extension, as highlighted in Fig. 1 (c). Additionally, two passive elastic tendons for the thumb enable both extension and opposition movements, supporting natural grasping postures.

The soft wearable wrist robot employed for wrist motion assistance is based on the low-profile forearm skin brace developed in [25]. This wrist robot comprises a wristband and cuff that rotate relative to each other along a guided rail to achieve wrist pronation and supination. The guided rail and the associated cables were designed to mimic the pronation and supination, which result from the rotation of the radius bone around the ulna. A single motor is required to drive two cables aligned with the guided rail, enabling bidirectional rotation of the wrist motion (Fig. 1 (d)).

The soft hand glove and soft wrist robot were simply integrated without structural interference, allowing independent motion of the hand and wrist. As the wristband of the skin brace and the glove's proximal portion do not overlap, wrist pronation/supination and finger flexion/extension can be actuated freely. Both components shared a cable-driven mechanism, enabling simultaneous assistance during reach-

- Soft wrist robot (Fig. 1 (d)): Assists wrist supination/pronation (1-DOF) for wrist adjustment before grasping.
- Soft hand-wrist wearable robot (Fig. 1 (b)): Integrate both components (3-DOF) for coordinated hand-wrist assistance.

B. EEG-EMG signals acquisition and processing

EEG and EMG data were independently collected through the same acquisition module (Mindd Scan, Ybrain). For the EEG measurement, 20 electrodes, including a reference channel, were positioned in accordance with the international 10-20 system. The EEG signals were sampled at 500 Hz and preprocessed using a 60 Hz notch filter to remove noise, a high-pass filter with a cutoff frequency of 2 Hz, and a low-pass filter with a cutoff frequency of 50 Hz. For EMG measurement, signals were sampled at 1000 Hz using a bipolar electrode configuration. Commercial electrodes (Monitoring Electrode, 3M) were attached in pairs to the forearm skin over targeted muscles. As illustrated in Figure 2, eight electrodes were used: two as references placed on non-muscular regions and six arranged in three pairs to acquire surface EMG (sEMG) signals from three muscles in the forearm. The recorded EMG signals were processed using a fifth-order bandpass Butterworth filter with cutoff frequencies of 1 Hz and 60 Hz.

After preprocessing, the Ledoit-Wolf Shrinkage method was applied to calculate the covariance of EEG signals collected from 19 channels. The EEG data were then mapped onto the Riemannian manifold and expressed T in tangent space using the following equation for further analysis, where C_r refers to the mean covariance matrix, while C_i is the estimated covariance matrix for each trial. A linear discriminant analysis (LDA) algorithm was implemented to classify the subject's intention as either the rest or the grasp based on these features (Fig. 2 (a)).

$$T = \log(C_r^{\frac{-1}{2}} C_i C_r^{\frac{-1}{2}}) \tag{1}$$

For EMG signals, the root mean square (RMS) value was computed from the difference signals of paired electrodes using a 200 ms sliding window with a 50% overlap. The extracted RMS amplitude was directly used as a feature to determine threshold values (Fig. 2 (b)), triggering the soft wearable robot's actuation for wrist adjustment during reaching. This multimodal system was configured to distinguish between grasp and rest intentions using EEG data, and to sequentially assist grasping after facilitating reaching by utilizing distinct EMG signals observed during the reaching phase prior to grasping an object (Fig. 2 (c) and 2 (d)).

C. Experimental protocol

A pilot experiment was conducted to collect EEG and EMG data for developing the motion intention algorithm and validating the multimodal EEG-EMG HMI system (Figure 3). The study was approved by the Institutional Review Boards of KAIST (KH2024-227), and all participants provided written informed consent. Four healthy participants were recruited, with EEG and EMG sensors placed at designated positions (Figure 3 (c)). EEG channel impedances were adjusted below 50 kΩ using saline-soaked sponge electrodes. EMG electrodes were positioned on the extensor carpi radialis (wrist movement), flexor pollicis longus (thumb flexion), and flexor digitorum profundus (finger flexion) in a bipolar configuration, with reference electrodes on the wrist.

Subjects wore the hand-wrist robot and followed visual cues displayed on a computer (Fig. 3 (a)), including 'Grasp,' 'Rest,' and a preparatory '+' signal. Each trial began with a 2s '+' cue, followed by a 5s 'Grasp' phase, another 2s '+',

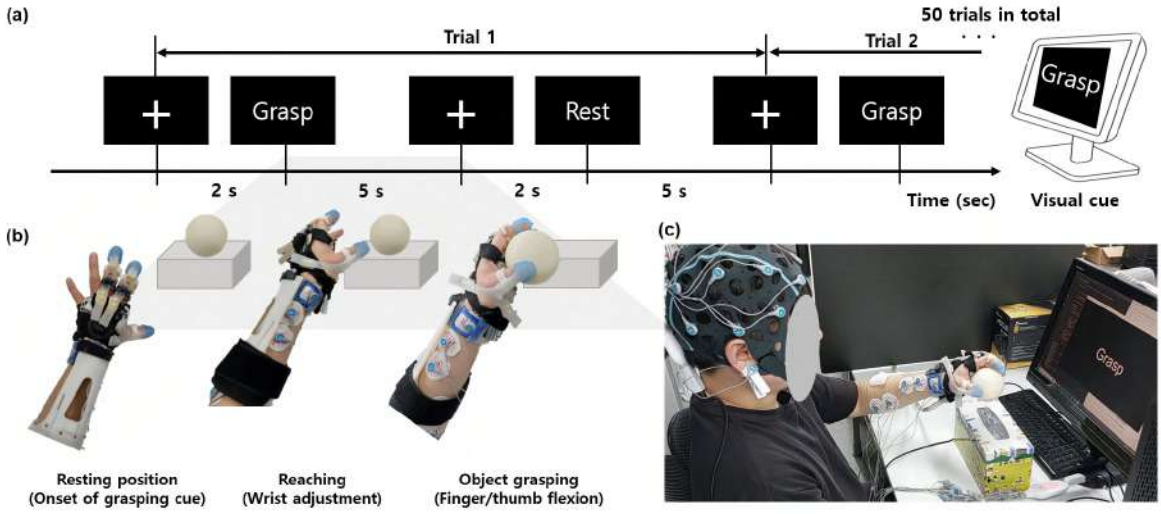

Fig. 3. Experimental protocol for data collection. (a) Visual cues presented to guide subject movement, (b) Sequential snapshots of hand-wrist movements during the grasp phase, from rest to reaching and grasping, (c) Experimental setup with EEG and EMG sensors worn by a subject using the wearable robot.

and a 5s 'Rest' phase. During grasping, subjects reached for and grasped a spherical object at a set height, then released it upon the 'Rest' cue, returning to the initial posture with their hands open and wrists neutral on a table (Fig. 3 (b)). Each session included 50 trials, with a 3-minute break after 25 trials to reduce fatigue.

III. RESULT

Following data collection from the four subjects, offline analyses were conducted to evaluate the proposed multimodal EEG-EMG motion intention detection system. Figure 4 presents the EEG-based classification results for grasp and rest states. The Receiver Operating Characteristic (ROC) curve achieved an Area Under the Curve (AUC) of 0.93 (Fig. 4 (a)). The confusion matrix (Fig. 4 (b)) indicates 338 correct predictions, yielding an accuracy of 84.5%, precision of 83.9%, and a recall of 85.5%. Pseudo-real-time validation using a 500 ms time window demonstrated stable classification performance (Fig. 4 (c)), where the blue line represents predicted classes (1: Grasp, 0: Rest) and red dots indicate true labels. Figure 5 illustrates EMG activity from hand-wrist muscles during grasp and rest states collected from the four subjects. The RMS amplitudes of flexor pollicis longus, flexor digitorum profundus, and extensor carpi radialis were averaged across sessions, highlighting distinct activation patterns for wrist and finger movements during grasping cue.

IV. DISCUSSION

This study presents a multimodal EEG-EMG-based motion intention recognition system integrated with a 3-DOF soft wearable hand-wrist robot. Unlike conventional EEG-EMG HMIs that fuse both modalities into a single decision model, our system integrates EEG and EMG independently to recognize distinct phases of the grasping task. EEG classified grasp and rest states for grasping the object, while EMG detected reaching onset, allowing for preemptive wrist adjustment before grasping. This sequential approach promotes natural movement transitions, as hand and wrist movements are inherently interconnected [14]. Given their biomechanical interdependence, proper wrist orientation is essential for optimizing distal hand RoM and executing stable grasps. Since stroke patients often exhibit inwardly flexed elbow, wrist, and clenched fists [26], this HMI system extends rehabilitation support beyond the isolated hand function to

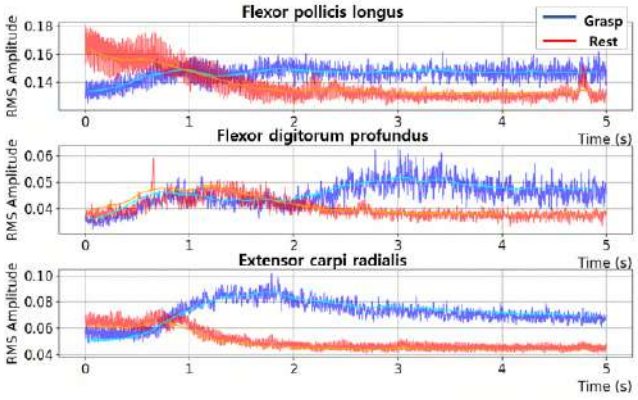

Fig. 5. Measured EMG activity during grasp and rest states. RMS amplitudes overlaid on rectified raw EMG signals for three muscles: (top) flexor pollicis longus, (middle) flexor digitorum profundus, (bottom) extensor carpi radialis.

facilitate coordinated upper limb recovery.

The EEG binary classification algorithm was developed by transformation from Euclidean space to Riemannian space using signals recorded from 19 channels. While prior studies often employ fewer channels focused on the motor cortex for motor intention or execution, we opted for full-scalp coverage to enhance robustness across individuals, particularly for future applications in stroke patients with varying neural activation patterns. Our EEG-based motion intention recognition demonstrated comparable classification performance, with an AUC of 0.93 and an accuracy of 84.5% according to the confusion matrix. Though this study primarily presents offline validation results as a preliminary investigation, a pseudo-real-time test was conducted to bridge the transition from offline to real-time implementation. By randomly selecting the grasp/rest task sessions from the offline pilot dataset, we generated a pseudo-real-time environment and achieved over 80% accuracy when classifying every 0.5 seconds (Fig. 4 (c)). This result aligns with existing literature, where EEG-based motor intention detection using pre-recorded real-time test sets reported accuracies of 87% [27], and multi-class motor imagery classification studies achieved 84% accuracy [28]. These findings suggest that our algorithm is viable for real-time application, as its classification performance is comparable to prior studies [29].

EMG signals were analyzed independently from EEG-based grasp/rest classification to detect the reaching phase, enabling preemptive wrist posture adjustments. As shown in Fig. 5, wrist extensor activation peaked 1–2 seconds after the grasp cue, while finger flexors exhibited an initial response alongside wrist extensors, followed by a second, greater activation around 3 seconds before declining. This activation pattern marks the reaching phase, allowing for wrist supination assistance before grasping by setting subject-specific activation thresholds. We employed 6 bipolar EMG signals to enhance detection reliability across diverse activation patterns, ensuring robust classification across individuals despite the relatively large number of channels. Notably, the thumb flexor (flexor pollicis longus) lacked a distinct peak during grasping but exhibited an initial peak during the rest cue, gradually decreasing over time. This suggests redundancy in reaching detection, and such redundant channels may be excluded in further studies while maintaining detection robustness in stroke patients.

The soft hand-wrist robot was designed with lightweight, compactness, and adjustability in mind to enhance wearability. By assisting only two fingers, the design reduces weight to under 250g, while a simplified cable routing guide minimizes its footprint on the palmar side, preserving thumb RoM and enabling quick donning/doffing. Although excluding the ring and little fingers may reduce grip strength [30], this wearable robot prioritizes functional grasping over maximizing grip force. As the thumb, index, and middle fingers play dominant roles in various grasping tasks, the soft glove supports various hand postures beyond power grasp, such as lateral pinch and precision grip, facilitating diverse ADL tasks. To accommodate varying hand sizes and levels of spasticity, passive elastic exotendons feature adjustable attachment points for personalized anchoring on the dorsal hand. The wrist robot, equipped with a BOA lacing system and soft silicone materials, provides a secure, customizable fit for different wrist and forearm dimensions. These design considerations contribute to comfortable, long-term rehabilitation with reduced physical and mental fatigue.

Overall, the proposed multimodal EEG-EMG HMI system offers advantages for stroke rehabilitation. Its soft and lightweight design supports long-term use while enabling coordinated hand-wrist-forearm assistance, promoting natural movement patterns. Unlike conventional robots focused solely on hand grasping, this system adjusts wrist posture during reaching to cover a broader range of upper limb motion, addressing post-stroke impairments like inwardly flexed elbows, wrists, and clenched fists. The motion intention recognition model effectively integrates EEG for grasp/rest classification and EMG for reaching detection, allowing wrist pronation before grasping. This multimodal approach enhances functional grasping compared to single-modality systems.

However, the system also has limitations. First, the current model was only validated on a small sample of healthy participants. Stroke patients show high variability in EMG due to muscle weakness and spasticity, requiring individual calibration processes to detect reaching accordingly. The EEG classification algorithm must also be adjusted to accommodate weaker motor-related EEG responses in stroke patients. Second, the wearable robot only supports pronation-supination, lacking flexion-extension, which is important for natural reaching. Third, the system lacks object and hand posture recognition, limiting adaptability to different grasping tasks, despite the soft glove can support various grasping postures like lateral pinch, or tripod grip. Integrating a vision-based object recognition system [31] could enhance adaptive grasping postures.

Future work will expand testing to stroke patients and refine the motion intention algorithm based on patient-specific neural and muscular responses. The vision-based

object detection system may further improve grasping adaptability. The system will be evaluated for its impact on motor function recovery and neuroplasticity through task-oriented rehabilitation for mild to moderate stroke patients.

V. ACKNOWLEDGMENT

The authors thank YBrain for providing the EEG and EMG acquisition module used in this study.

Design and Evaluation of a Solar-Powered Modular Robotic Object Maneuvering Assistance System

S. M. Mizanoor Rahman, *Member, IEEE*

***Abstract*—We present the design and evaluation of a solar-powered robotic object maneuvering (reaching, grasping and manipulating) system for assistance to sick, weak, and disabled people. The system is 0.78m long and 0.4kg heavy. The structure is made of lightweight PLA material. The front side of the system (device) acts as an end-effector, which is made of a 2-parallel jaw gripper actuated by a servomotor via a spur gear mechanism. Additional components can be attached to the inner sides of the jaws to help the gripper adjust its gripping strategies with objects of different shapes, sizes and surface textures. The back side of the device includes a rectangular groove that holds electronics circuit components such as the Arduino board, wires, batteries, etc. A solar panel is placed on the groove, which can harvest solar energy and charge the batteries to power the electronics circuit. A rotary potentiometer placed on the handle is connected to the Arduino board, which is used as a haptic input knob to control the servomotor for opening and closing the jaw-type gripper. We present the CAD model and the proof-of-concept physical prototype of the system. We experimentally evaluate the prototype for its performance (technical specifications) and human-robot interactions using healthy subjects. The results show that the system can assist humans maneuvering objects of different shapes and surface textures and produce satisfactory human-robot interactions. The proposed system can assist sick, weak and disabled people in maneuvering objects in their daily activities, facilitate people needing upper arm rehabilitation and thus significantly improve their quality of life (QoL) even in remote areas where electricity is scarce or unavailable.**

I. INTRODUCTION

Accident, age, sickness, etc. can reduce the abilities of human upper arms for object maneuvering (reaching, grasping and manipulating) in their daily activities [1]. Consequently, they depend on others for their daily activities, which imposes burdens on family members and/or caregivers. They also need assistive technologies to assist them in maneuvering objects for their daily activities. Considering this need, researchers proposed numerous object maneuvering assistance devices to assist people in this situation [1]-[4]. However, some existing devices are purely or mainly mechanical devices [1]-[3]. We believe that suitable robotic (mechatronic) devices used for maneuvering assistance and rehabilitation support may be more convenient, useful, user-friendly and effective [4]. The literature shows several robotics-based maneuvering devices, but their designs are complex in nature, and they are expensive for users with limited financial abilities [5]-[6].

Therefore, robotic devices that are inexpensive and that are easy to use and control are still in demand. The shape, size and weight of the devices are very important for effective, ergonomic and satisfactory performance of the devices. Researchers emphasized anthropomorphic or human-like appearance and design of robotic object maneuvering assistance devices [7]-[8]. They argued that robotic assistance devices for object maneuvering that use human-like design and/or working principles may be robust and dexterous like humans [8]. The literature shows that large sizes of the devices are inconvenient for use, and heavy weights of the devices can create fatigue in users, which may reduce usability of the devices and hinder their long-time use [9]. Modularity in the design may help mitigate this problem partly [9]. However, modular design of robotic object maneuvering assistance devices has not received much attention yet.

Supplying power to robotic object maneuvering assistance devices is a challenging task, and it becomes extremely challenging to operate assistive devices in remote areas that either lack electricity or electricity is scarce there [10]. Use of large batteries to power the devices increases size, weight and cost of the devices. Therefore, it is realized that application of solar energy to power robotic object maneuvering assistance devices may be more reasonable, economic, ergonomic and convenient for the users [10]. However, solar energy cannot be used directly to operate robotic assistance devices for object maneuvering. Appropriate methods and strategies of harvesting and storing solar energy as well as converting solar energy to useful electric power are required to operate robotic assistance devices for object maneuvering powered by solar energy [10]. Innovative design considerations for the robotic assistance devices are also required for this purpose [9]. However, the literature does not show significant attention towards developing robotic object maneuvering assistance devices powered by solar or renewable energy [10].

A comprehensive evaluation scheme should be developed and applied to evaluate robotic object maneuvering assistance devices to ensure that they meet technical performance requirements (technical specifications) and gain target user satisfaction [11]. We need novel evaluation schemes that are comprehensive in the nature and that address the evaluations from multifarious aspects such as evaluation of key performance indicators (KPI), assessment of interactions between the devices and their users, etc. A few performance evaluation schemes have been proposed in the literature for

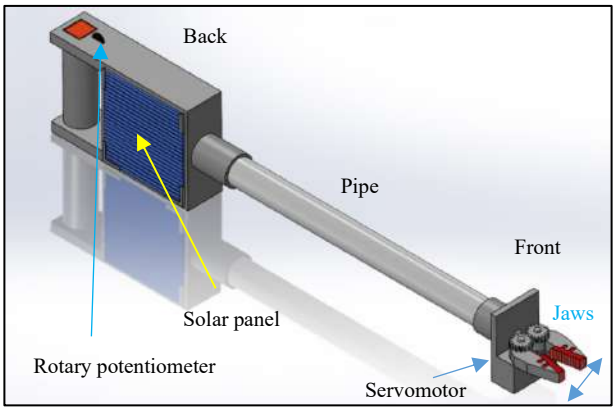
S. M. M. Rahman is with the Mechanical Engineering Program at The Pennsylvania State University, 120 Ridge View Drive, Dunmore, PA 18512, USA (e-mail: mrahman@psu.edu; Tel.: +1-570-963-2588).

robotic object maneuvering assistance devices [11]-[12]. However, these evaluation schemes do not seem to be comprehensive for holistic evaluations of the devices.

Considering the above background and motivation, the objective of this paper is to propose a simple, lightweight, easy to use, low-cost, anthropomorphic, solar-powered and modular object maneuvering assistance robotic device for sick, weak and disabled people and for people needing upper arm rehabilitation support. We here present the innovative electro-mechanical design of such an assistance device, describe its prototype and present the evaluation results for the prototype device after evaluating the device following a novel, innovative and comprehensive evaluation scheme.

II. Design of the Robotic Object Maneuvering Assistance Device

We developed a 3-dimensionl CAD model of the solar-powered robotic object maneuvering (reaching, grasping and lifting) assistance device, as shown in Fig.1. As shown in the figure, the front side of the device includes an end-effector for grasping objects. The end-effector is designed with a 2-parallel jaw-type gripping mechanism that can be used to grip objects by the end-effector of the device. The two jaws are attached to 2 spur gears. One gear is the driver, the other gear is the driven. The axis of the driver gear is colinearly aligned with the shaft of a servomotor, which can actuate the gear mechanism. When the servomotor rotates, it rotates the gears that creates linear inward and outward motions of the jaws, which help grasp an object by the device for its maneuvering [3]. The inward and outward movement directions of the jaws can be controlled through controlling the direction of rotation of the servomotor via a rotary potentiometer placed at the other end of the device [4]. The linear speeds of the jaws are proportional to the rotational speeds of the servomotor, if we ignore nonlinearities in the mechanism [3], [9].



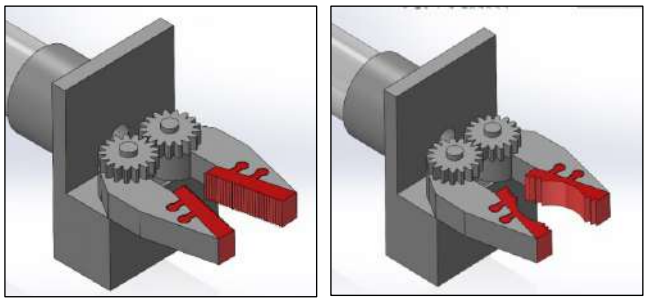


Fig.1 Design of the solar-powered robotic object maneuvering assistance device.

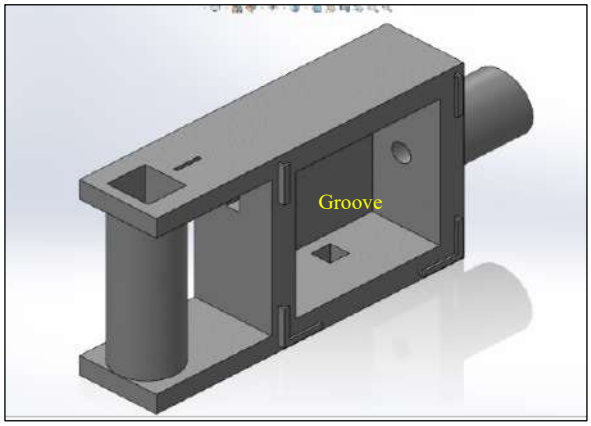
Gripping arrangements and strategies at the inner sides of the jaws can be adjusted by attaching two different gripping attachments or modules (the red components at the front of the device as shown in Fig. 1). This is shown using enlarged views in Fig.2. The attachments can change the surface roughness of the inner sides of the jaws. Such changes of surface roughness can facilitate grasping of objects with different shapes, sizes and surface textures. It can happen because the changes in surface roughness of the inner jaws can change the grip force requirements for maneuvering objects of different shapes, sizes and textures with the device [9]. The arrangement in Fig. 2 (a) can be used when grasping rectangular objects with smooth surfaces. The arrangement in Fig. 2 (b) can be used when grasping circular objects with smooth surfaces. These attachments (modules) can be attached and detached conveniently considering the target objects to be grasped and maneuvered, which adds modularity to the design [9]. The attachments can be removed (detached) for grasping rectangular or circular objects with rough or not-so-smooth surfaces.

(a) (b)

Fig.2 Adjustable modular gripping mechanisms. Attachments at the inner surface of the jaws for gripping (a) rectangular objects with smooth surfaces, and (b) circular objects with smooth surfaces.

As the back side of the device shows in Fig. 1, we used a rotary potentiometer (the black half-circular component) as a haptic input knob of the system. The rotary potentiometer is connected to an Arduino board. There is a groove at the back side of the device (it is covered with the blue solar panel in Fig.1). The inner view of the groove is shown separately in Fig.3. As Fig.3 shows, the groove can accommodate the Arduino board and other necessary electronic and electric components such as batteries, wires, etc. The solar panel is placed on the groove that acts as the lid of the groove. The solar panel can be used to harvest solar energy in remote areas where electricity is scarce or not available [10]. Required number of small batteries can be connected to the solar panel to store the harvested solar energy, and then the electronics



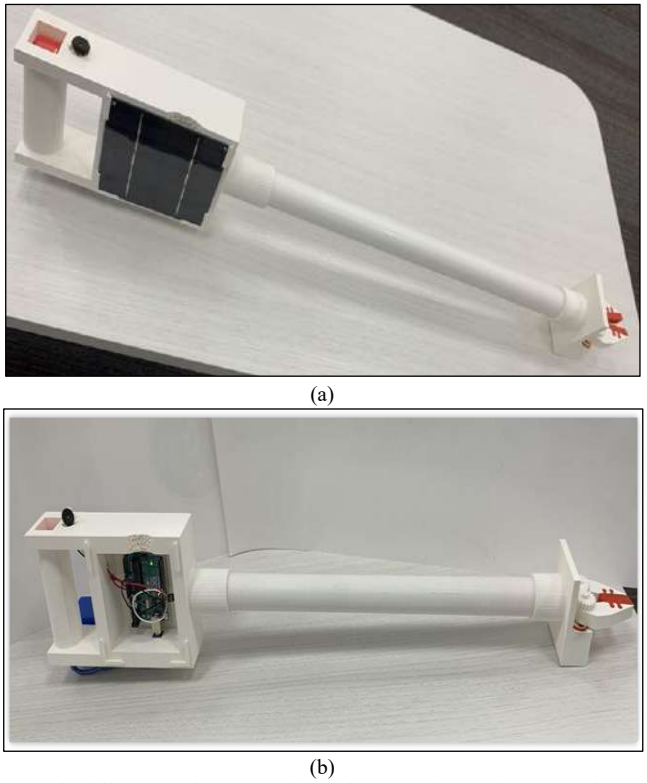


Fig.3 The groove at the back side of the device to contain electronic and electric circuit components.

can be powered by the batteries [10]. The front and back sides of the device are rigidly connected via a pipe-like structure. The servomotor placed at the front of the device is also connected to the Arduino board using a wire (placed inside the pipe), and the servomotor can also be powered by the batteries placed inside the groove at the back of the device.

The design uses lightweight PLA material to 3D print the structure of the device as Figs.1-3 show [9]. The device was 0.78m long, which could make it feasible to grasp different objects from a distant location [1]. The weight of the device was designed to be approximately 0.4kg [9].

III. Development of the Proof-of-Concept Device

We developed a physical prototype of the design demonstrated in Fig.1. Fig.4(a) shows the assembled view of the physically developed robotic reaching and grasping assistance device, where the electronics circuit is covered with the solar panel. Fig. 4(b) exposes the electronics circuit of the fully assembled device. A battery holder could be accommodated inside the groove, or it could be attached to the structure of the device. The batteries could be charged with the solar energy harvested using the solar panel to supply power to the electronics circuit. PLA plastic material was used to 3D-print the structure of the device to make it lightweight (less than a pound) [9].

(a)

(b)

Fig.4 The fully assembled views of the robotic reaching and grasping device: (a) with a solar panel covering the electronics circuit, (b) without the solar panel exposing the electronics circuit.

Fig. 5 shows the mechatronics design of the solar-powered reaching and grasping device [10]. The solar panel was connected to a battery via a charge/solar controller, and then it was connected to an Arduino and shield board, which was used to control the electronics of the device. The solar panel was used to harvest solar energy and to store the energy in the battery to power the electronics. We connected the rotary potentiometer (analog input) to a 3.3V input port (analog) and the ground terminal of the Arduino board. We connected the servomotor (placed at the end-effector) to a 3-pin extension wire, and then we connected it to the 5V port (digital output) and the ground terminal of the Arduino board. The force and position sensors used for experimental purposes could be connected to the Arduino board as well. The Arduino board was connected to a computer with the Arduino IDE. Note that the Arduino board could be powered using either the power from electric line or the battery power. We used the Arduino IDE to develop code in C++ to control the electronics circuit.

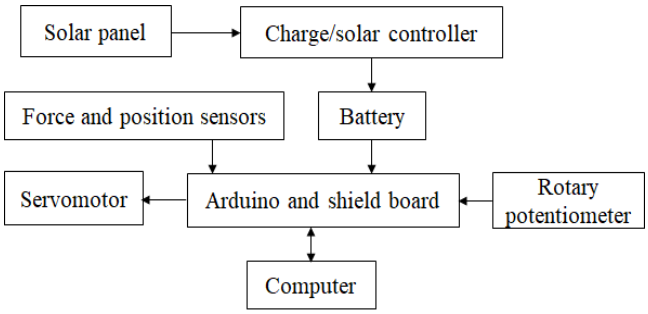

Fig.5 The mechatronics design of the solar-powered robotic reaching and grasping assistance device.

IV. Performance Evaluation of the Device

A. Experiments

The literature shows that different researchers emphasized different criteria when evaluating object maneuvering assistance and rehabilitation robotic devices [11]-[17]. We here accumulated the evaluation approaches of technical performance specifications and of human-robot interactions based on a comprehensive set of criteria [18]. We conducted a series of experiments of the physical reaching and grasping robotic device to evaluate its performance and interactions based on the evaluation scheme and tried to justify the design and applications of the device, as follows.

(1) Experiment 1: Solar Energy Harvest Test

We exposed the solar panel to the direction of the sun in a sunny day from 11am to 2pm to harvest solar energy and charge the battery. The charge of the battery was measured using a digital multimeter. The amount of charge obtained in the battery was a measure of the harvested solar energy assuming no loss of energy occurred in the conversion or harvesting process [10]. We charged two batteries separately and connected them in series to power the circuit depending on the total power requirement of the circuit.

(2) Experiment 2: Input-Output Displacement Relationships

As Fig. 6 shows, a human subject opened and closed the jaws of the gripper (end-effector) by rotating the rotary potentiometer attached onto the back side of the device

counterclockwise using the thumb finger of the right hand. A horizontal ultrasonic sensor was used at a distant position to measure the opening lengths of the jaws of the gripper (termed as output displacements) for approximately 90 degrees, 180 degrees, 270 degrees and 360 degrees of counterclockwise rotations of the rotary potentiometer (termed as input displacements) separately [1], [3]. We also used a stopwatch to separately measure the time the human subject took to complete 90 degrees, 180 degrees, 270 degrees and 360 degrees of rotations of the rotary potentiometer. Those times were termed as input times. We used another stopwatch to measure the duration of time starting from when the subject started to rotate the rotary potentiometer to when the jaws of the end effector ended the linear displacement. This time was termed as the output time. The difference between the input and output times was considered as the time delay between the input displacement and the output displacement. We determined the time delay of the system for 90 degrees, 180 degrees, 270 degrees and 360 degrees of rotations of the rotary potentiometer separately [4].

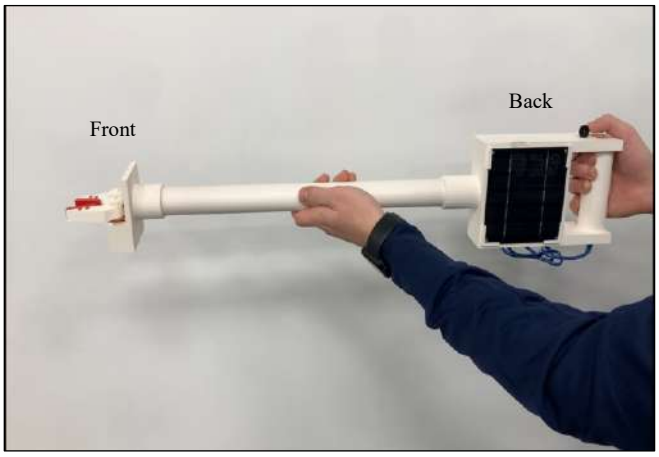

Fig.6 A subject opens and closes the jaws of the gripper (end-effector) by rotating the rotary potentiometer counterclockwise using the thumb finger of the right hand. It is a two-handed or one-handed (dominant hand) operation.

(3) Experiment 3: Input-Output Force Relationships

A foil strain gauge type force sensor was pasted on the rotary potentiometer. The force sensor was used to measure the tangential force applied by the human subject to rotate the potentiometer counterclockwise to operate the device (input force). Another foil strain gauge type force sensor was pasted on the inner side of a jaw of the end effector to measure the grip force (output force) to grasp and lift an object using the device. In an experiment, a human subject rotated the rotary potentiometer 360 degrees counterclockwise to grasp and lift 4 different types of objects using the device such as a rectangular object with a smooth surface, a rectangular object with a rough surface, a circular object with a smooth surface and a circular object with a rough surface separately. We adjusted the gripping mechanism for the objects considering the shapes and surface textures (roughness) of the objects by attaching and detaching additional attachments inside the jaws as introduced in Fig.2. The input and output forces for each object were recorded and analyzed separately [18].

(4) Experiment 4: User Study

A human subject rotated the rotary potentiometer 360 degrees counterclockwise to grasp and lift 4 different types of objects using the device such as a rectangular object with a smooth surface, a rectangular object with a rough surface, a circular object with a smooth surface and a circular object with a rough surface separately. Same as the above, we adjusted the gripping mechanism for the objects considering the shapes and surface textures (roughness) of the objects by attaching and detaching additional attachments inside the jaws as introduced in Fig.2. We recorded whether the subject was able to grasp and lift each object using the device successfully to calculate the success rate for each type of object [18].

At the end of the experiment, the subject completed a set of questionnaires to evaluate human-robot interactions (HRI) based on his/her interactions with the device for grasping and lifting objects [13], [18]. We developed the questionnaires reflecting relevant HRI criteria and the subject evaluated each of the HRI criteria using a 7-point Likert scale, 1 being the least favorable HRI and 7 being the most favorable HRI [18]. The physical HRI (pHRI) criteria were anthropomorphism (whether the use of the device resembled object maneuvering using a biological human hand in terms of configuration and biomechanics of the hand) [7], haptically perceived heaviness of the device where the least heaviness would be the best [9], symbiosis (how the human subject and the device depended on each other for the object maneuvering operation) [18], adaptability (how the human felt when using the same device to grasp objects of different types) [15], coordination (how the human users coordinated and balanced the input-output relationships especially the force and position relationships) [17], ease of use (how easy the human felt when maneuvering the objects using the assistance device) [18], naturalness (how the human user felt when maneuvering objects using the device compared to when maneuvering the same objects without using the device, i.e., using the biological hand only) [1], and intuitiveness (whether the human user was intuitive in using the device for potential future maneuvering of objects) for grasping and lifting objects using the device [14]. The cognitive HRI (cHRI) criterion was the user trust in the device for its application, which was also evaluated using the above-mentioned Likert scale [16], [18], [19].

Another measure of cHRI was the cognitive workload of the subject for grasping and lifting each object. The subject completed the NASA-TLX to report cognitive workload [20]. In total, 10 subjects participated in this user study separately. The subjects received instructions on experiment procedures. The ethical standards for human subject tests were maintained following the IRB principles.

B. Experiment Results

(1) Experiment 1 (Solar Energy Harvest Test) Results

Table I shows voltages contained in a rechargeable battery for different time periods. The voltages were produced by the solar panel, which were to be used to power the device for its operations. The results thus prove the potential of the device for its applications in remote areas that lack electricity or where electricity is scarce [10].

Table I: Solar Energy Harvest Test Results

Time periods (trials)	Solar panel voltage (V)	Battery voltage (V)
11:00am-11:30am	4.16	3.32
11:31am-12:00pm	4.28	3.44
12:01pm-12:30pm	4.36	3.52
12:31pm-1:00pm	4.47	3.61
1:01pm 1:30pm	4.62	3.74

(2) Experiment 2 (Input-Output Displacement Relationships) Results

Table II shows the input-output displacement relationships results (the mean displacements with standard deviations in parentheses). The opening and closing lengths of the jaws (at the front side of the device) for different angles of rotations of the rotary potentiometer (at the back of the device) showed that it was possible for the users (subjects) to successfully open and close the jaws of the end-effector. The jaws were actuated by the servomotor which was haptically controlled via the rotary potentiometer [4]. The results thus proved the potentiality of the grasping and lifting device for its intended use by handicapped, sick, weak and disabled people for assistance in reaching, grasping and lifting objects in their daily household activities [1]-[4].

The time delays in the operations of the device (difference between input and output times) were also small as Table III shows, which proved efficient and synchronized operations of the device between the input (rotation of the rotary potentiometer) and the output (linear movements of the jaws of the end-effector) [3]. However, the time delays could be further reduced by providing trainings to the users, improving the quality of the rotary potentiometer and reducing nonlinearities in the mechanisms of the end-effector (e.g., reducing backlash of the gear pair, reducing friction, etc.) [9].

Table II: Input-Output Displacement Relationships Results

Output displacements (mm)	Input displacements (degrees)			
	90	180	270	360
	12.72 (0.13)	25.86 (0.33)	38.18 (0.74)	51.44 (1.09)

Table III: Time delays in the operations of the device

Time (s)	Input displacements (degrees)			
	90	180	270	360
Input	0.51 (0.03)	0.96 (0.04)	1.48 (0.06)	1.92 (0.08)
Output	0.78 (0.04)	1.28 (0.07)	1.93 (0.05)	2.21 (0.03)

(3) Experiment 3 (Input-Output Force Relationships) Results

Table IV shows the input-output force relationships results. The results show that the device was able to amplify the input forces significantly, which were sufficient to grasp and lift objects of different shapes and surface features. The results also show that the device needed to apply slightly larger magnitude of forces to maneuver circular and smooth surface objects than rectangular and rough surface objects [4].

Table IV: Input-Output Force Relationships Results

Mean measured forces (N)	Test conditions (objects)			
	Rectangular-smooth	Rectangular-rough	Circular-smooth	Circular-rough
Input force	0.11 (0.02)	0.10 (0.015)	0.12 (0.01)	0.11 (0.03)
Output force	2.96 (0.07)	2.88 (0.03)	3.19 (0.05)	3.08 (0.04)

(4) Experiment 4 (User Study) Results

Table V shows the success rates for grasping different types of objects [18]. The results reveal that the device was capable of maneuvering objects successfully. Fig.7 shows the HRI evaluation results for the device [13]. The results show high level of effectiveness in HRI for maneuvering objects using the device. As the HRI results show, the subjects haptically perceived the device as a less heavy or lightweight device for the targeted applications. Low heaviness of the device should not generate high fatigue in users if they use the device for long duration, which can make the device suitable for old, disabled and weak persons [9]. We conducted analysis of variance (ANOVA) for the results in Fig. 7, which showed that variations in HRI scores between subjects were statistically non-significant (p= 3.79, p>0.05). Such statistical results indicate that the results were consistent even though we used a small number of subjects [18].

Table VI shows that the operations of the device did not create high level of cognitive workload in the users, which proved user-friendliness of the device [20]. The results in Table VI show that the shape and surface roughness slightly impacted the cognitive workload of the users. We see that the circular objects with smooth surfaces created slightly higher cognitive workloads in users compared to rectangular objects with rough surfaces [20]. The ANOVA results showed that the cognitive workload percentages between objects were statistically significant (p = 0.0018, p<0.05), but the cognitive workload percentages between subjects were not statistically significant (p = 5.13, p>0.05). Such statistical results indicate

Table V: Success rate (%) for grasping different types of objects using the device

Test conditions (objects)			
Rectangular-smooth	Rectangular-rough	Circular-smooth	Circular-rough
100%	100%	100%	100%

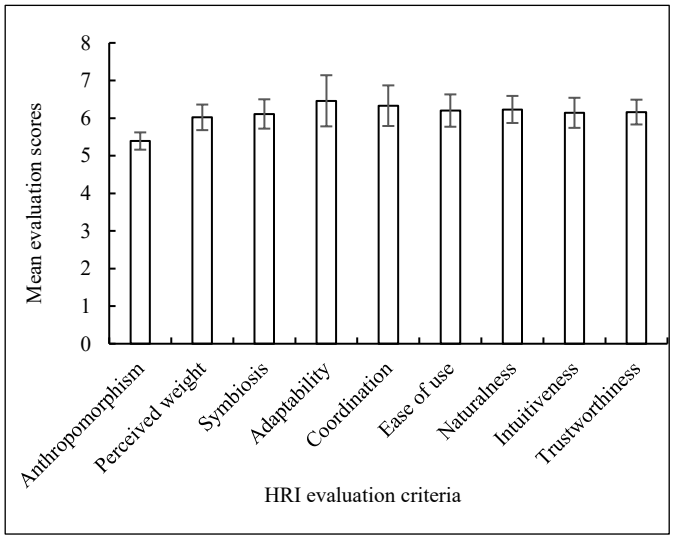

Fig.7 HRI evaluation results for grasping and lifting objects using the device.

Table VI: Total cognitive workload (%) of users for grasping and lifting different types of objects using the device

Test conditions (objects)			
Rectangular-smooth	Rectangular-rough	Circular-smooth	Circular-rough
24.61 (2.38)	22.42 (2.63)	28.24 (2.89)	26.58 (1.76)

that the results were consistent even though we used a small number of subjects [18]. The statistical results also proved that shapes and surface conditions of objects can impact the cognitive workload of human users when maneuvering objects using the robotic assistance device [20].

V. Conclusions and Future Research Directions

We presented the design and prototype evaluation of a novel robotic object maneuvering assistance system powered by solar energy for assisting sick, weak and disabled people. The evaluation results showed that the system was able to satisfy the technical requirements in object maneuvering operations. The results also showed that the system was able to produce satisfactory and effective human-robot interactions. The design of the system included a novel adjustable gripping mechanism, which added modularity to the design. The system was designed to be powered with solar energy, which made it suitable for use in remote areas lacking electricity. Similar robotic assistance devices are not so common in the literature. Thus, the proposed design is important, and it advances the state-of-the-art contributions in this research area. We propose to use the device as a personal assistance tool to improve the quality of life (QoL) of people with sickness, weaknesses, and disabilities needing upper arm rehabilitation support.

In the future, we will reduce the weight and size of the device. We will examine the effectiveness of the force input using a force sensor instead of the position input of the potentiometer to control the motor. We will maximize the energy efficiency (the time required to fully charge the battery and the maximum duration the device can be operated with a fully charged battery). We will apply a PID control of the opening and closing motions of the grippers so the objects can be grasped with more accurate opening lengths of the jaws. An RGB-D camera will be attached to the end-effector, which will be used to implement a Convolutional Neural Networks (CNN) algorithm to enhance accuracy in detecting and grasping arbitrary objects. A suitable collision avoidance strategy based on an intelligent motion control algorithm will be proposed to avoid collisions while grasping objects. We will conduct a clinical study using many sick and disabled patients to verify and validate the results for sick and disabled people and to confirm the generality of the results.

Research Ethics Statement:

The author applied responsible conduct of research (RCR) and followed relevant IRB principles with human subjects. Informed consent was received from the subjects.

A Novel Elastic Model for Exoskeleton-User Coupling Interfaces

Christian Mele[1], David Choi[2], Katja Mombaur[3] and James Tung[4]

***Abstract*— Current research on physical human-robot interactions (pHRI) in wearable assistive robots, such as lower-limb exoskeletons, primarily focuses on improving net force estimates at each interface to improve robot controller performance. Consequently, estimating force distribution along physical interfaces of wearable robots, crucial for user safety and comfort, has been largely overlooked. We propose a novel computational model that uses interface geometry and strapping tension as inputs, and predicts the static pressure field generated during the user donning process by treating the supporting surface as an elastic foundation. Accuracy of the proposed computational method was validated by comparing the estimated static pressure field of a commercially available interface to experimental data. While measured pressure magnitudes were significantly lower than model prediction, likely due to a combination of assumptions and limitations associated with model design, similar loading patterns were observed. Identifying regions of high pressure from simulation and similar patterns allow for reliable scaling to reduce inaccuracies, and may be used to inform design. Further refinements of the proposed model will provide a valuable tool for developing more comfortable and safer interfaces for wearable robots.**

I. Introduction

The coupling interface is the location, or surface(s), at which forces and torques are transmitted from the device to user [1]–[4]. The coupling interface is critical for functional performance of exoskeleton (exo) devices in transmitting controlled forces from actuators, or stored energy from passive components, to the user. User safety is directly tied to the coupling interface by joining the user to the device for assistance, support, and preventing of user-device separation, as well as the potential complications and risks from improper or ineffective coupling [1]–[8].

The H3 exoskeleton (Technaid, Spain), pictured in Figure 1, left, is a 6-DoF assistive lower-limb exoskeleton with coupling interfaces typical to assistive wearable exoskeletons [1], [2]. While there exists a range of interface designs for coupling the user to the exo, most comprise of a soft convex hull interface, rigid surface, and a "strap" or hook-and-loop system that fixes and holds the user in position [1], [2], [9]. An example coupling interface is shown in Figure 1, right.

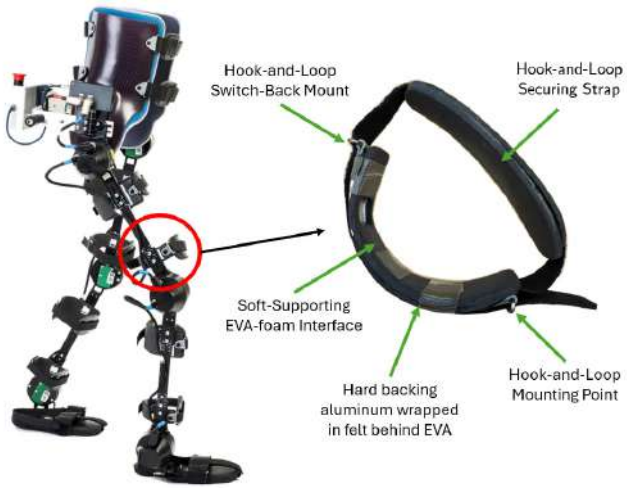

Fig. 1. The H3 Exoskeleton, (Technaid, Spain) alongside the lower thigh coupling interface as seen from a top-down view. Points of interest critical to the function of the device, and user comfort are highlighted. This interface is characterized by the convex hull shape and soft supporting interface overlaid a rigid hard-backed surface. It has a hook-and-loop strap for securing.

The coupling interface directly influences compliant and restrictive motion at the interface. Excessive or improperly designed pressures and misalignments caused by them can lead to musculoskeletal and/or skin injuries [1]–[4], [6]–[8], [10]. The risk of pressure injuries, such as ulcers and bruising, increases with large and/or prolonged applied normal and shear forces to the skin, and has been shown to occur during exo use [1], [3], [4], [10], [11].

Research on physical human robot interaction (pHRI), specifically interface pressure and coupling interface design for exos is centered on sensorisation and linear modeling approaches [1], [2], [9], [12]. Sensor-based approaches often use single value readings as metrics associated with coupling interface effects, complicated by a lack of user variable control or consideration, which makes tying sensor-based findings to design features of the coupling interface challenging [1]. Model-based approaches have focused primarily on force and torque vectors necessary for rigid-body dynamics and control [1], [2], [12]–[14]. Compliant single linear spring elements have been utilised, but are currently incapable of correlating predicted results to coupling interface design. Recent advancements examine how initial donning pressures influence kinetics; however, these have not yet impacted coupling interface design for exoskeletons [15], [16].

Elastic foundations, which have been implemented in robotics and assistive devices to model complex geometric interactions between biomechanical interfaces [17]–[20],

may be useful in relating coupling interface geometry to pressure fields. The objective of this paper is to describe a proposed algorithm implementing elastic foundations for modeling static donning pressures of the exo coupling interface for evaluation and design. The algorithm and the formulation of the supporting elastic foundation interfaces are described, then validated against experimental evaluation of a mannequin and an isolated H3 exo coupling interface.

II. The Coupling Model Algorithm

A. Model Overview

The methods presented are a framework for utilization and analysis with an elastic foundation model that may be applied to exoskeleton coupling interfaces to determine initial donning indentation depth and pressure distributions prior to interface fabrication. A flow chart of the algorithm used that highlights the implementation of the elastic foundation model in localizing pressures can be seen in Figure 2.

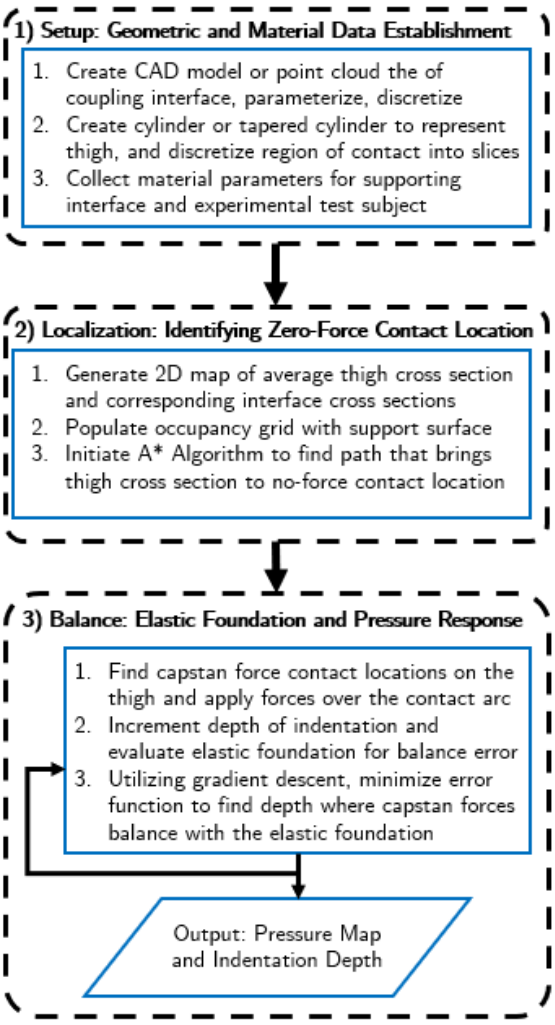

Fig. 2. Flowchart highlighting the three distinct phases of the algorithm to determine coupling surface interactions.

The H3 Exoskeleton was selected as the testing interface. An example of the coupling interface is shown in Figure 1, right. It is a rigid metal supporting surface with an ethylene-vinyl acetate (EVA) foam soft supporting surface. This algorithm is designed to be applied to coupling interfaces with similar mechanical composition.

B. Interface Surface Mechanical Properties

Elastic foundation models implement constants informed by material properties. ISO 3386-1:1986 [21] for cellular flexible materials in compression was selected to inform compression testing evaluation. The H3 Exoskeleton uses a generic non-labeled ethylene vinyl acetate (EVA) closed cell foam as a supporting interface, and was sampled for evaluation.

Two 50mmx50mm samples with the same thickness as the H3 supporting EVA surface (5 mm) was evaluated in compression up to 100N in quasi static loading conditions [22]. Young's modulus was found (0.7629 MPa) from the initial linear elastic region [22]. The plateau region of EVA foam was not able to be characterized due to hardware limitations. Figure 3, showcases the experimental setup, and stress-strain. The Poisson's ratio is assumed negligible for open-cell foams from collapse under compression [22].

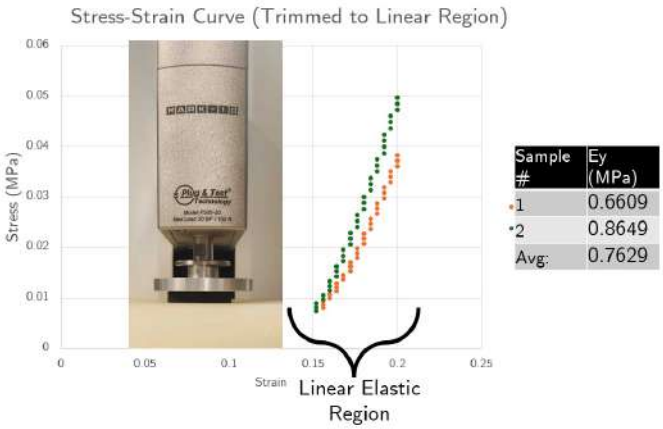

Fig. 3. Material testing setup and linear elastic compression region for the EVA foam used by the H3 exoskeleton on the coupling interface. Region of no-load strain was removed to highlight the linear elastic region.

A mannequin limb was used in the experimental evaluation to reduce the number of compliant interfaces that must be simulated. The mannequin thigh, as such, was assumed and treated as rigid, and was not characterized.

C. Defining Interface and Indenter Geometry

Interface geometry can be broken into stacked slices that represents the coupling interface in the cross-sectional transverse plane. These slices are treated as uncoupled to limit interface interactions to 2 dimensions. The thickness of the selected slices can vary; however, for simple interfaces, such as the H3 interfaces with no variation with height (Figure 1), then the driving factor for slice thickness should be height variation along the length of user limb.

Coupling interface geometry for the H3 exoskeleton was found by reconstructing the interface in SolidWorks. With

a CAD model, the surface may be cut and the transverse outer edge converted into a point cloud using DXF files. The point cloud is then converted into an equivalent high-dimensional spline and points are interpolated to achieve a minimum segment length between points (1 mm). Figure 4 highlights the example curvature.

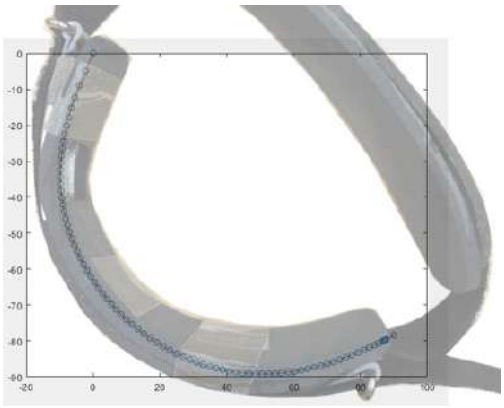

Fig. 4. Equivalent spline for the H3 coupling interface. Interfaces with variation in curvature along interface height require additional splines.

The indenting surface represents the user's limb, in this case a mannequin. The CAD mannequin was sliced along the center of the contact region and the same process was followed as the interface to retrieve a point cloud thigh cross section. To simplify the process, an assumed cylinder or tapered cylinder may be chosen if no particular user cross section can be used.

D. Identifying Zero-Force Contact of Body Segment

Initial no force contact locations are the points or curves where two bodies may be adjacent in contact without applied force [23]. The initial zero-force contact location determines where indentation and pressure begins for elastic foundations. Considering exoskeleton donning is difficult to perform, known initial configurations may be hard to find, and selecting a random location for initial contact may not be representative of the use case.

A heuristic method for initial contact configuration is proposed to determine initial zero-force contact. When aiding someone into the device, it is assumed the objective is to situate the user securely within the convex hull. In the case of the H3 Exoskeleton where no clear goal location can be identified, the furthest outside points of the surface are selected, seen in Figure 5, left.

Using these assumptions, an A-star path algorithm is proposed. With the center of the simulated limb cross section as the control point, the objective is to find the location/position closest to the objective goal within the convex hull. Each thigh slice is stored in cylindrical coordinates and referenced to prevent overlap. A visualization of an example trajectory path and grid configuration can be seen in Figure 5.

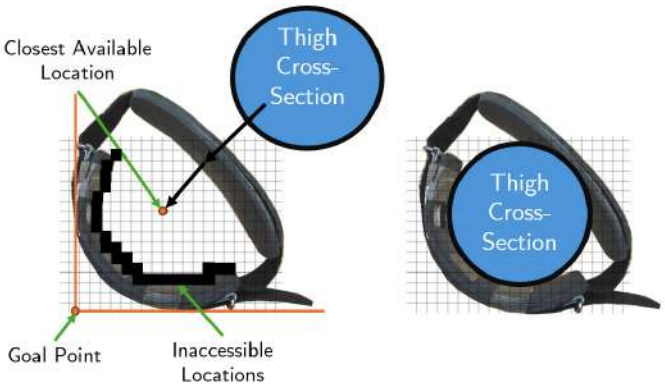

Fig. 5. Visualization of the A* algorithm as it has been applied to the H3 exoskeleton. Without a clear inflection point, the most extreme outer points have been defined as the goal for zero force contact.

E. Estimating Net Strapping Force

The hook-and-loop strap on the coupling interface provides securing forces that act as input forces for the elastic foundation reaction. During donning, a range of applied tensions is expected at different coupling interfaces, and between donning sessions. Evaluating a range of strapping tensions is necessary to systematically evaluate coupling interface performance.

For interfaces with a securing soft surface that wraps around the user's limb, like hook-and-loop straps, a generalized capstan clamping approach may be used [24]. Capstan forces relate tension in a rope-like material to a change in curvature. The governing equations for capstan forces are shown in eq. 1, and visualized in Figure 6, left. T is the tension in the rope, $d\Theta$ is a slice of the curvature, and dN is the force normal to the surface curvature.

$$dN = T * d\Theta \tag{1}$$

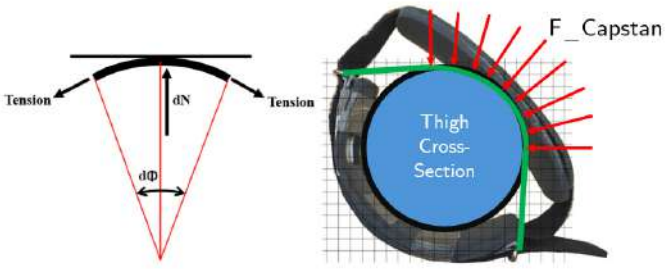

Fig. 6. Visualization of capstan forces applied to the thigh.

Capstan force values may be found within the local coordinate system by "wrapping" curvature from the loop mount location to the simulated thigh, around the surface, and to the terminal loop. The length of the curvature arc on the thigh is determined by locating the tangent line between the strap mounting locations and simulated thigh cross section. An example of the strap securing configuration in simulation can be found in Figure 6, right. Strapping tension varies along the

contacting surface, influenced by the relative friction between the two surfaces. A coefficient of $mu = 0.15$ was selected, from frictional properties between Nylon - the surface of the mannequin thigh [25].

F. Elastic Foundation Formulation

Elastic foundations are simplified representations of complex contact mechanics problems into analogous spring and shear layer representations [17]–[20]. Two elastic foundations, Winkler and Pasternak, were implemented with the assumption that only the EVA foam interface was compliant.

The Winkler foundation is the simplest elastic foundation approximation. The pressure-displacement relationship is defined in eq. 2, where k, the foundation modulus, is analogous to the spring constant and p, is the applied force. Figure 7 illustrates the Winkler foundation.

$$p\left(x,y\right) = kw\left(x,y\right) \tag{2}$$

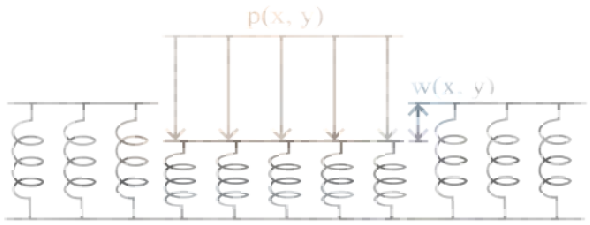

Fig. 7. Example of a Winkler foundation with discrete uncoupled springs.

The Pasternak foundation has a shear layer over top of the springs that allows for forces to be transmitted transversely and deform adjacent springs. The load-deflection relationship for the Pasternak foundation is given by eq. 3, where G is a modified shear modulus, visualized in Figure 8.

$$p\left(x,y\right) = kw\left(x,y\right) - G\nabla^2 w\left(x,y\right) \tag{3}$$

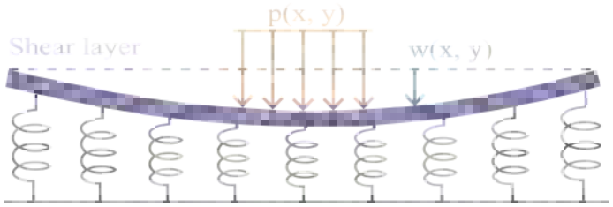

Fig. 8. Example of a Pasternak Foundation

The two constants k and G are typically calculated as a function of the foundation's material properties [17]. The relationships are as follows in eq. 4 and eq. 5:

$$k = \frac{E_{Young}}{(H * (1 - v^2))} \tag{4}$$

$$G_{foundation} = \frac{G_{shear} * H_{Hetenyi}}{6} \tag{5}$$

Where:

- H - Width of the supporting interface
- $H_{Hetenyi}$ - The depth of the shear layer [17].
- v - Poisson's ratio - zero for EVA foam

Using the depth of indentation in the two principal global coordinate directions as control variables (X,Y), an optimization approach may be implemented to find the relative position of the limb cross section to satisfy the goal condition minimizing error in eq. 6:

$$\min_{\delta} \quad \left(P - \sum_{n=-a}^{a} p_i \Delta x\right)^2 \tag{6}$$

Where P denotes the total applied force from capstan forces and p denotes the reaction of the elastic foundation for any individual cell summed over the contact region. Only compressive interactions are observed, and it is assumed that no friction or sticking is present at the interface. For the Pasternak foundation, an additional constraint must be solved for the point of separation on surfaces.

When the elastic foundation is mapped to the support interface, each segment of the spline is assigned an elastic element normal to the rigid backing. Elastic foundation resistance is determined first in the local coordinate system using cylindrical coordinates and relative indentation depth.

Depth of indentation is determined by overlapping indenter point clouds, with the supporting interface cells. Indentation depth is found by the normal of the relative slope between points, as seen in Figure 9. If multiple particles fall underneath a contact arc, depth of contact is averaged for that cell. All forces are then summed and used in eq. 6.

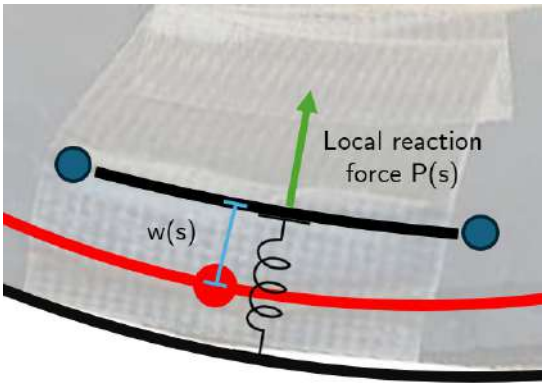

Fig. 9. Visualization of the particle calculation underneath.

The user thigh is then shifted based on a gradient descent approach scaled to the error from an initial small guess, with a small learning rate ($\gamma = 0.05$) to avoid large oscillations or overshooting. The final position and elastic foundation force vectors are used to determine pressure normal to the interface that balances the applied capstan forces.

G. Validation of Algorithm

To validate the relative accuracy and effectiveness of this algorithm in predicting interface pressure, a single isolated

coupling interface from the H3 Exoskeleton (Figure 1, right) and a mannequin leg, is shown in Figure 10. Testing was performed upright to avoid introducing gravitational forces. Regions of contact and orientation were marked and measured for replication in simulation.

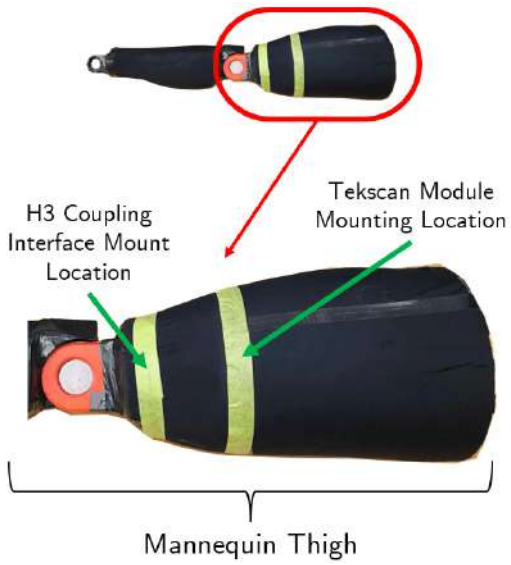

Fig. 10. Mannequin leg utilised for experimental evaluation. Made of rigid PLA, with 3D geometry drawn from scanning. Locations of sensor mounting and strap mounting are marked with green tape.

The pressure sensor used, Tekscan-MDL 9811E, comprises of 96 individual FSRs over a 203.2 by 76.2 mm area. The sensor was secured to the mannequin to avoid crimping and/or creasing, within the marked region of contact, seen in Figure 10 and Figure 11, and calibrated for zero load. A comparison of peak, average, and general trends in pressure will be analyzed, with details in subsequent sections.

A range of applied tension force values was evaluated using a handheld load cell. Three tests ranging from 30 to 50 Newtons was evaluated, tested, and collected with the Tekscan sensors. The experimental setup in Figure 11 shows 3 angles to indicate relative positions relative to the mannequin, sensor, and H3 coupling interface.

Fig. 11. Experimental setup of mannequin, H3 coupling interface and Tekscan sensor. The strap was held in place between tests to keep the cross-sectional area consistent between uses.

III. Results

Results include experimental and simulated pressure maps. Data is presented within the surface frame respective to the Tekscan (for experimental results). The Tekscan was limited to mounting to the thigh without crimping or folding excessively due to the securing hook-and-loop strap during donning. The pressure map generated from simulation is oriented to the surface of the coupling interface.

A. Experimental Pressure Values and Relationships

Peak and average pressures were evaluated over active Tekscan cells covered by the coupling interface. The pressure maps taken from the Tekscan sensor were averaged over a labeled collection period. An example of the collection, and processing can be seen in Figure 12.

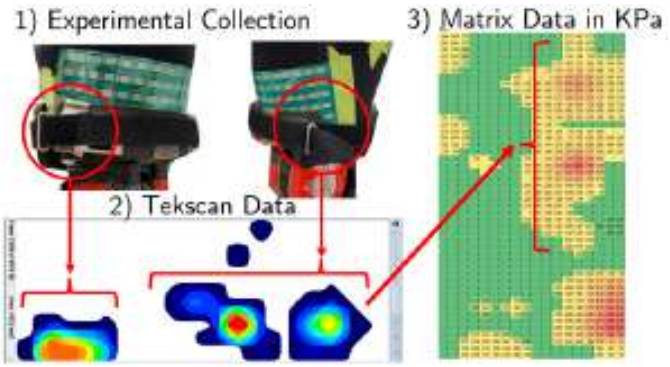

Fig. 12. Experimental setup and collection. Corresponding resulting Tekscan measurement for 50N pull test (maximum load), and the processed average data for the load in a matrix format for analysis.

Values for analysis from the Tekscan data include average observed pressure, peak pressures, and total active area. Table I contains the values for each of the three tests.

TABLE I
EXPERIMENTAL DATA COLLECTED FROM THE TEKSCAN MDL SENSOR

Test–Pull (Newtons)	Peak Pressure (KPa)	Average Pressure (Kpa)	Total active area/ Number of cells
27-29	76.58	14.99	27.7%
39-41	70.34	12.3	39.1%
48-52	82.34	12.36	62.5%

Notably, average pressure remain relatively stationary with increasing applied force, while surface area increases. Peak pressure does rise in the final test with a large increase in surface area. Surface area changes dominate the pattern of applied tension over this small sample size.

B. Simulated Elastic Foundation Pressures

Table II, contains the Winkler pressure information, and Table III contains the Pasternak pressure information. Each method of defining the coupling interface remained relatively similar, with small differences in pressure, where the Pasternak foundation had increased contact depth. The Winkler

spring for normal indentation depth was the primary driving constant in pressure during simulation. Raised points at the edges generated the most pressure at the edges of the convex hull, primarily due to a mismatch in overlapping curvature.

TABLE II

SIMULATED WINKLER FOUNDATION PRESSURES.

Test–Pull Newtons	Peak Pressure (KPa)	Average Pressure (Kpa)	Total active area/ Number of cells
28	295.35	115.19	47.66%
40	350.03	143.02	53.13%
50	395.28	168.47	55.47%

TABLE III

SIMULATED PASTERNAK FOUNDATION PRESSURES.

Test–Pull Newtons	Peak Pressure (KPa)	Average Pressure (Kpa)	Total active area/ Number of cells
28	295.23	112.47	48.44%
40	350.40	138.54	54.69%
50	395.27	165.51	56.25%

An example of an overlapping contact arc may be seen below in Figure 13 for a balanced Capstan - Elastic Foundation equilibrium. This point cloud informs the elastic foundation response using cylindrical coordinate overlap.

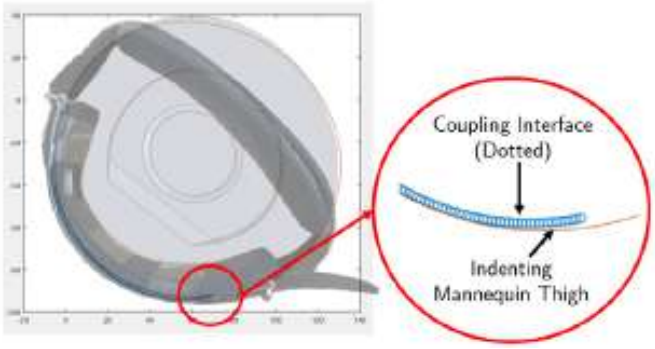

Fig. 13. Point cloud representation of overlapping support surface and thigh indenter equilibrium. The blue dotted surface represents the coupling interface, while the orange outline visualizes the contact of the thigh.

C. Comparison

Measured Tekscan peak and average pressure magnitudes were significantly lower than both Pasternak and Winkler model predictions across all three test-pull conditions. Measured total active area was also smaller than predicted model results, except at the highest pull condition. Trends in average active area were similar with increasing pull magnitude. Trends in measured average pressure, which were observed to decrease with increased pull magnitude, did not correspond to predicted model results. Discrepancies in model performance will be addressed in the next section.

A graph comparing the pattern of pressure loading along the surface is shown in Figure 14. As a result of treating the thigh cross section as an extruded cylinder at the point of contact, each simulated cell is treated as in contact with the interface at the coupling point along the length of the thigh. The lack of a vertical pressure gradient is explained by the assumption of no variation in the vertical contact direction.

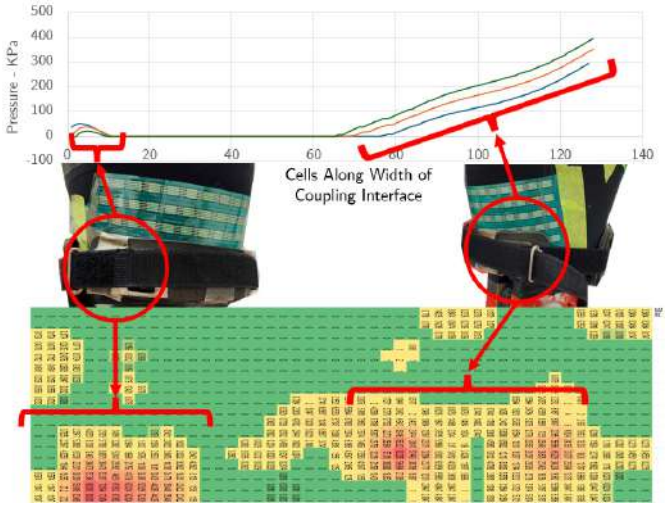

Fig. 14. Visual comparison of the simulated pressure map from the algorithm (top) and the Tekscan heatmap (bottom) pressure locations (red indicates high load). The top graphic showcases the low (28N), middle (40N) and high (50N), strap tension conditions. The active area of the Tekscan is 62.5% while the experimental predicted area is 56.25%. Brackets highlight pressure regions and their respective area on the experimental setup.

IV. DISCUSSION

This paper proposes a novel computational model utilizing interface geometry and strapping tension to predict the support surface static pressure field generated by elastic foundations during the donning process. Accuracy of the proposed computational method was validated by comparing measured and simulated pressure fields. While measured pressure magnitudes were significantly lower than model predictions, likely due to model assumptions, similar patterns in pressure magnitude and spatial distribution were observed.

A. Performance and application

Contact between a user and the robotic coupling interface is a complex system. Factors such as friction, shearing, relative geometric positions and configurations alter the conditions and define modes of contact. With increasing strapping tension, experimental peak and average pressures follow a similar pattern, decreasing in magnitude before increasing at the final strapping tension, while total active area increases with applied tension.

Discrepancies in pressure-area behavior is potentially attributable to unmeasured shear and friction forces shifting or rotating the coupling interface on the thigh. Once shifting is initiated, the configuration of contact, and relative depth of contact may shift as a combination of rotational and translational forces. Shifting may cross regions of larger

peak pressure before settling into an area with increased contact, but not necessarily increased pressure. Regions of peak pressure on the Tekscan are correlated with raised surfaces on the mannequin thigh and outer edges of the H3 interface overlapping, seen in Figure 14, highlighted in red. Differences in location and magnitude of pressure between experimental and simulation results may be influenced by the placement of the Tekscan sensor on the mannequin, while simulation evaluates the coupling interface surface, resulting in a mismatch of surface normal slope.

Simulation of the coupling interface yielded pressure magnitudes higher than measured results. While not ideal, loading patterns appear similar when examining overlapping regions of contact at raised surfaces, and the location of regions of no contact. In Figure 12, the regions of no contact are represented similarly in the simulated data with two distinct regions of peaking pressure. The major distinction between the two is the relatively small peak force on the left of Fig. 14, mismatching the experimental values in the same region. Discontinuation in force on the right of Fig. 14 (bottom) was not modeled, likely due to the simplifications made for the interface curves and the prevention of sliding or bunching of material. Pressure magnitudes in the current iteration of this model are not useful for design (i.e., exact values), but are typically difficult to use when designing for a wide user population. Relative ratios of peak and gradient pressures are more informative of mechanical interaction, and may be used to inform design. Additional limitations exist in the inability to model frictional and shear pressures, major factors in skin injury and static-dynamic interaction that limit the applicability of this model currently.

The Pasternak and Winkler foundation performed relatively similarly, attributable to the contact depth being shallow, and the curvature of the thigh and the supporting interface being relatively similar. Hence, the contributions of the Pasternak shear layer are relatively small compared to the Winkler foundation in this contact configuration.

B. Experimental Study Limitations

Limitations in experimental validation may contribute to the differences observed in evaluation. Due to limitations of the Tekscan MDL sensor, placing it directly on the coupling interface was not possible without damaging the sensor. By measuring on the user's thigh, it is harder to match geometric features with heightened normal pressure, both due to the potential for mismatched surface curvature and positioning. In the experimental setup, the coupling interface was removed from the exoskeleton frame. When tension was applied through the strap, rotational motion occurred which may have displaced the strap relative to the Tekscan. While the test mannequin possessed similar geometry to an actual user's thigh, the material was rigid, not compliant. Future validation should include a compliant cross-section to better represent user application of this model.

C. Model Limitations

Implementing hyper-elastic material models over linear elastic constants may improve soft material responses [17]. Currently moment forces, frictional/tangential shear effects, and time-dependent (viscous) components are not accounted for in the foundation. Frictional forces may allow additional surfaces that contribute very little in this current iteration (i.e., with little indentation depth) to contribute to resisting motion. Considering measured average pressure stagnated despite an increasing applied tension may be attributed to friction, and including these contribution via modeling represents a promising approach for improvement.

Material properties primarily influence elastic foundation equations, and can be changed by utilizing more accurate and improved material testing methods. EVA and other open-cell foams have a plateau region of loading that was not accounted for [17]. Including neo-Hookean governing models [17], [22], may potentially explain the experimental pressure to increasing area relationship. Additionally, reactions with respect to the mannequin are relatively simple due to rigid assumptions, but contact with users will include compliant interaction that is currently not accounted for.

Interface and indenter geometry is defined by the desired complexity of the simulation. In the current implementation, a simplified approach is examined. Concessions were made in simplifying the mannequin thigh to a single average curve. Future works utilizing scanning techniques, or curves from CAD models as opposed to approximations, are warranted to investigate the influence of higher geometrical accuracy.

Localization required the most heuristic assumptions to be made on how a coupling interface may come into contact with a user donning the device. It was assumed that, with a visual goal target, a clinician would move the limb towards that goal/point. A clear inflection point such as a "U" hull, or in the case of this simulation the points closest to the outermost surface edges in the global coordinate space. Limitations of this approach are pronounced when considering how some configurations that would be achieved in practice, may only be achieved by applying pressure to move past regions of high friction, or elastic resistance that would be avoided in purely zero-force localization.

Capstan forces rely heavily on the curvature of the wrapping surface, highlighting the influence relative surface-indenter orientation has on the model. Changing initial orientation of the thigh cross section and supporting surface will alter where tangency is, the applied forces, and what geometry of the thigh intersects with the coupling interface. Improvements in the approach to how the elastic foundation is optimized may still be made. Shifting, or jumping, over regions of peak pressure with smaller contact areas, into configurations that rely more heavily on friction to balance with larger surface areas may be the cause of the pressure-area relationship found in experimentation. Using global optimization techniques to search for minima past the first equilibrium may locate more accurate contact configurations.

V. Conclusion and Future Work

Assistive lower-limb exoskeletons provide assistance and rehabilitation in gait, posture and balance to those affected by mobility impairments. The coupling interface is a critical component of an exoskeleton's functionality and, until recently, has not been the focus of design and research in exoskeleton development. Initial pressures and coupling interface composition directly influence the kinetics and kinematics of exoskeleton-user interactions [1], [15], [16], and excessive pressures, and steep pressure gradients, can influence the formation of skin injuries [1], [10], [11]. This knowledge of exoskeleton interaction, and skin injury, highlights the need for an increased focus on the coupling interfaces between user and device in exoskeleton research.

The algorithm presented herein models the initial donning pressure and deformation map for a coupling interface. Using this algorithm, initial pressure, risky areas and an evaluation of trends in coupling interactions may be identified. With future work and improvements to the model the goal becomes applying this model in the evaluation and optimization of novel interface designs for exoskeletons.

Utilizing interface and user-subject geometry coupled with compliant elastic foundations, this algorithm determines static pressure field interactions during donning. After localizing the subjects in 3D space for no-force contact locations, capstan forces are applied to determine initial securing conditions which balance with the elastic foundation. This generates a pressure field that describes general patterns of pressure and areas of contact for exo donning.

As a preliminary algorithm, future work is needed to improve the applicability of this algorithm to alternative coupling interface designs, dynamic loading conditions and expanded out to include the entire exoskeleton. With additional contributions, the goal would be to create an environment where adjustments to interface geometric design, placement location, and materials would be controlled for idealized interactions in exoskeletons.

***Abstract*—Gait impairments impact mobility and quality of life, necessitating intelligent rehabilitation devices that utilize dynamic models to improve the human-machine interaction and provide effective assistance. This study presents a data-driven model that integrates Koopman operator linear estimations with fused surface electromyography (sEMG) and ultrasound (US) imaging for estimating volitional ankle torque throughout the gait cycle. The Koopman operator estimates the nonlinear, phase-dependent dynamics of ankle motion, while the fusion of sEMG and US signals enhances muscle activation predictions by combining electrical and morphological insights. This framework demonstrates the potential to improve state and volitional torque estimation accuracy, laying the groundwork for individualized exoskeleton assistance and enhanced gait rehabilitation strategies.**

I. Introduction

Gait impairments precipitated from neurological disorders or injuries present profound challenges for mobility, independence, and quality of life [1], [2]. For many with these impairments, regaining the ability to walk independently, minimizing gait abnormalities, and increasing walking speed and endurance are primary goals [3]. As such, the use of devices that emphasize muscle activation while aiding in movement completion is highly encouraged.

Exoskeletons are one such type of wearable device that have emerged as promising tools to support individuals with various types of gait impairments [4], [5], [6], [7], [8]. In this paper, we specifically focus on those that impact the critical role that the ankle plays in walking. Ankle "push-off" during the late stance phase and prolonged foot lift during the swing phase are both vital features of a energy efficient gait cycle that are often heavily impacted by neurological impairments [9], [10], [11]. Ankle exoskeletons capable of assisting with plantarflexion and dorsiflexion are therefore especially useful in gait rehabilitation.

An exoskeleton with a model of the user's volitional capabilities can estimate how much joint torque needs to be compensated to complete the gait cycle. Accurate modeling of voluntary ankle torque is challenging due to the nonlinear, phase-dependent dynamics of walking. The application of Koopman operator theory (KOT) offers a modeling solution to the complexities of gait. KOT transforms nonlinear dynamics into a higher-dimensional space, enabling a linear approximation of gait across stance and swing phases [12], [13]. Such linearization techniques simplify the computational demands of real-time control and improve the scalability of predictive models in response to dynamic changes in human gait. Theoretically, a Koopman operator is infinite-dimensional and can linearly describe the evolution of the system's observables. Therefore, to compute a practical estimation, we use extended dynamic mode decomposition (EDMD), which approximates a finite-dimensional Koopman operator using data-driven methods.

To enhance the EDMD model's ability to predict volitional torque, this study incorporates real-time muscle activation signals derived from multi-modal sources: ultrasound (US) imaging and surface electromyography (sEMG). Torque contributions during walking are dynamic, influenced by complex physiological factors such as muscle fatigue, activation levels, and coordination with other joint movements [14], [15]. Traditionally, sEMG has been the primary modality for estimating muscle activation by recording electrical activity in muscle fibers, but it has notable limitations, including susceptibility to noise and difficulty in accessing deep muscle layers [16]. Ultrasound imaging, conversely, provides a direct visualization of muscle morphology, offering higher spatial resolution and the ability to capture mechanical aspects of muscle contractions which are correlated with force generation [17], [18], albeit at a lower sampling frequency.

By combining sEMG and US imaging data, this study leverages the complementary strengths of these two modalities. Ultrasound-derived echogenicity can assess deeper muscles (e.g., the soleus) and has shown potential to monitor changes in muscle architecture that reflect activation and fatigue levels [17], [18]. When fused with sEMG signals,

which provide a high-frequency electrical assessment of superficial muscle activity, the combined data allow for a more comprehensive and robust estimation of muscle activation states. This integration improves the fidelity of volitional torque estimates, which is particularly critical for gait assistance applications where accurate prediction of user intent is essential for seamless interaction with the exoskeleton. Furthermore, by employing a sequential multirate observer, this framework mitigates the mismatch in sampling rates between the low-sampled US signals and high-sampled sEMG signals, providing continuous and accurate volitional torque estimates suitable for real-time control applications.

The primary contribution of this study is an a Koopman operator linear estimation of gait dynamics utilizing fused US and sEMG muscle activation signals. The proposed data-driven model of ankle dynamics and muscle activation data aims to lay the groundwork for individualized optimal assistance, fostering natural gait patterns and reducing unnecessary dependency on robotic support.

II. Problem Formulation

A. Ankle Joint Dynamics

During a gait cycle, ankle movement can be modeled as continuous dynamics within the swing and stance phases, with a discrete transition event between the two phases [19]. Therefore, these dynamics, modeled as a switched system to account for the transition, is expressed as

$$\begin{bmatrix} J^P\ddot{\theta} + f^P(\theta,\dot{\theta}) \\ J^D\ddot{\theta} + f^D(\theta,\dot{\theta}) \end{bmatrix} = \begin{cases} \tau^P + \tau^m + \tau^{ext} & t \in t_{st} \\ \tau^D + \tau^m, & t \in t_{sw} \end{cases} \quad (1)$$

where $\zeta = P, D$ represents the ankle dynamics driven by ankle plantarflexors during the stance phase, timed as $t_{st} \coloneqq [T_{start}, t_{stance}]$, and ankle dorsiflexors during the swing phase, timed as $t_{sw} \coloneqq [t_{swing}, T_{end}]$, respectively. $J^\zeta \in \mathbb{R}^+$ is the unknown inertia term of the foot along the dorsiflexion and plantarflexion axis of rotation, and θ, $\dot{\theta}$, and $\ddot{\theta} \in \mathbb{R}$ denote the angular position, angular velocity, and angular acceleration, respectively. $f^\zeta(\theta,\dot{\theta})$ is composed of the musculoskeletal viscosity torque term, musculoskeletal elasticity, and the gravitational term acting on the ankle. The explicit definitions of these functions can be obtained from [20], [21]. τ^{ext} is the external plantarflexion torque caused by the ground reaction forces.

The torque driven by the exoskeleton motor is given as

$$\tau^m(t) \quad = \quad K_m i(t), \quad (2)$$

where $K_m \in \mathbb{R}^+$ is a constant motor gain and $i(t) \in \mathbb{R}$ is the controlled current. The volitional ankle torque is described by

$$\tau^\zeta \quad = \quad r^\zeta(\theta) F_m \eta_1^\zeta(\theta) \eta_2^\zeta(\dot{\theta}) a^\zeta, \quad (3)$$

where $r^\zeta(\theta) \in \mathbb{R}^+$ represents the gait phase-specific moment arm for the muscle tendon force, which is a function of the joint position. The explicit functional form is described in [22]. The moment arm is a continuously differentiable, positive, and bounded function with a bounded first-order time derivative. $F_m \in \mathbb{R}^+$ represents the constant maximum isometric muscle contraction force at the equilibrium position. Variables $\eta_1^\zeta(\theta)$, $\eta_2^\zeta(\dot{\theta})$ denote the force-length and force-velocity fascicle terms [23], and both are continuously differentiable, non-zero, positive, and bounded functions.

For each phase t_{st} and t_{sw}, we can rewrite the system dynamics in (1) by selecting $\theta_1 = \theta$ and $\theta_2 = \dot{\theta}$.The equivalent state space representation for can be formulated as

$$\dot{x} = \begin{cases} f^P(x) + g^P(x,u^P), & \forall\ t \in t_{st} \\ f^D(x) + g^D(x,u^D), & \forall\ t \in t_{sw} \end{cases} \quad (4)$$

where $\dot{x} = \begin{bmatrix} \dot{\theta}_1 & \dot{\theta}_2 & \dot{a}^\zeta \end{bmatrix}^T$, $f^\zeta(x) \in \mathbb{R}^3$ are the system dynamics, and $g^\zeta(x,u^\zeta) \in \mathbb{R}^3$ are the actuation dynamics.

We can define an indicator function σ_k based on the gait phase time intervals for the stance and swing phases as

$$\sigma_k = \begin{cases} 0, & \forall\ t \in t_{st} \\ 1, & \forall\ t \in t_{sw} \end{cases}, \quad (5)$$

where the phase indicator σ_k takes the value 0 for the stance phase and 1 for the swing phase.

Using a zero order hold, these dynamics can then be discretized as

$$\begin{aligned} x_{k+1} \quad = \quad & (1-\sigma_k)\left(f^P(x_k) + g^P(x_k, u_k^P)\right) \\ & +\sigma_k\left(f^D(x_k) + g^D(x_k, u_k^D)\right) \end{aligned} \quad (6)$$

B. Muscle Activation and Ultrasound Echogenicity

Now discretized, the variable $a_k^\zeta \in [0,\ 1]$ from (3), which denotes the muscle activation level can be described by

$$a_k^\zeta = \delta^\zeta Y_k^{\zeta,emg} + (1-\delta^\zeta) Y_k^{\zeta,us} + v_k^\zeta \quad (7)$$

where $Y_k^{\zeta,\,emg}, Y_k^{\zeta,\,us} \in \mathbb{R}$ are the normalized measurements from the sEMG linear envelope and US imaging-derived echogenicity described in [24]. $\delta \in [0,\ 1]$ is a weighting variable, and v_k^ζ is a net additive white Gaussian noise signal. Echogenicity measurements from US images are defined by our previous work [18] , which has detailed methods for estimating real-time muscle activation during walking. At sampling instant k, echogenicity is calculated as

$$echo_k = \frac{1}{N_A N_L} \sum_{x=1}^{N_A} \sum_{y=1}^{N_L} I_k(x_{pos},\, y_{pos}), \quad (8)$$

where $N_A, N_L \in \mathbb{R}^+$ represent the number of pixels along axial and lateral directions of the region of interest, respectively. The term $I_k(x_{pos},\, y_{pos}) \in \mathbb{R}$ represents the US intensity information at the pixel location $(x_{pos},\, y_{pos})$ on the

image at sampling instant k from the logarithmically compressed imaging signals after the beamforming procedure.

C. Koopman Operator Framework

We consider the dynamics in (6) where the controlled state $x_k \in \mathcal{X}$ and input $u_k \in \mathcal{U}$ are sampled to form a finite set, $\mathcal{N}_c$. The Koopman operator acts on a function space $\mathcal{F}$ of mapping from $\mathcal{X}$ into $\mathbb{R}$, referred to as observables. The Koopman operator, $\mathcal{K}$, is an infinite-dimensional linear operator that models the time-based evolution of a composite function $\Lambda(x_k) \in \mathbb{R}$, which act as the $Koopman\ observables$, forward in time. Koopman operators are parameterized by x_k, u_kas follows:

$$\mathcal{K}\Lambda(x_k) \quad = \quad \Lambda(f(x_k, u_k)), \qquad \Lambda \in \mathcal{F} \tag{9}$$

where $\mathcal{K}$ maps observables $\Lambda(x_k)$ to the original state space dynamics in (6). A subspace is Koopman-invariant if

$$\mathcal{K}\Lambda \quad \in \quad \mathcal{F}, \quad \forall \Lambda \in \mathcal{F},\ \forall u \in \mathcal{U} \tag{10}$$

A dictionary of observables, $\chi : \mathcal{X} \to \mathbb{R}^{\mathcal{N}}$ is Koopman-invariant if its elements span a Koopman-invariant subspace. Since evaluation of the dictionary often involves "lifting" of the original state vector to a higher dimensional space, $\chi(x_k)$, the new state is commonly referred to as the lifted state. $\chi(x_k)$ is composed of the original states or nonlinear functions of the state that are $Lipschitz$ continuous. The extension to non-autonomous systems has been researched extensively recently, see [25], [26], [27]. For a non-autonomous system, the equivalent to (9) is given as

$$\mathcal{K}(\Lambda(x_k, u_k)) \quad = \quad \Lambda(f(x_k, u_k),\ h(x_k, u_k))\ \forall \Lambda \in \mathcal{F} \tag{11}$$

While this operator accurately describes a nonlinear system through an infinite-dimensional linear system, it is practically infeasible to implement. For practical feasibility, the infinite-dimensional operator, $\mathcal{K}$, is approximated using a finite dimensional operator, defined as $\tilde{\mathcal{K}}$, which is usually calculated using Extended Dynamic Mode Decomposition (EDMD) [25].

To derive the Koopman operators for each phase, we collect time-series data snapshots of the state data as $\{x_k\}_{k=1}^{M}$ where x_k represents the state at time step k, and control input data as $\{u_k^{\zeta}\}_{k=1}^{M}$, where u_k^{ζ} represents the control input at time step k during the stance and swing phases. We define the Koopman observable in lifted space, $\Psi_k(x, u^{\zeta}) \in \mathbb{R}^W$, to set up an EDMD problem. We can predict the linear evolution of the Koopman observable vector using

$$\Psi_{k+1}(x, u^{\zeta}) \quad = \quad \tilde{\mathcal{K}}\Psi_k(x, u^{\zeta}), \tag{12}$$

where $\tilde{\mathcal{K}}$ is the finite-dimensional Koopman operator approximation which maps the lifted-state observables forward in time. Using the state and control time-series snapshots, we populate the lifted-space data matrices with $M \in \mathbb{N}$ samples as

$$\begin{array}{rl} \mathcal{D}^{\zeta}{}_k & = [\Psi(x_1, u_1) \quad \Psi(x_2, u_2) \quad \cdots \quad \Psi(x_{M\circledast 1}, u_{M\circledast 1})] \\ \mathcal{D}^{\zeta}{}_{k+1} & = [\Psi(x_2, u_2) \quad \Psi(x_3, u_3) \quad \cdots \quad \Psi(x_M, u_M)] \end{array} \tag{13}$$

where $\mathcal{D}^{\zeta}{}_k,\ \mathcal{D}^{\zeta}{}_{k+1} \in \mathbb{R}^{W \times M}\ \forall\, k = 1, \ldots, M$, are the collected observable block snapshots from kinematic state measurements for each gait phase. The Koopman observable data matrix dynamically evolves as

$$\mathcal{D}^{\zeta}{}_{k+1} = \tilde{\mathcal{K}^{\zeta}}\mathcal{D}^{\zeta}{}_k, \tag{14}$$

where $\mathcal{D}^{\zeta}{}_k = \Psi_k(x, u^{\zeta}) = \begin{bmatrix}\Psi_x(x_k) & \Psi_u(u_k)\end{bmatrix}^T$. To obtain the control state and control flow maps in the lifted space, the approximated Koopman operator$\tilde{\mathcal{K}}$ can be further subdivided as

$$\tilde{\mathcal{K}^{\zeta}} = \begin{bmatrix}\tilde{\mathcal{K}}_{xx} & \tilde{\mathcal{K}}_{xu} \\ \tilde{\mathcal{K}}_{ux} & \tilde{\mathcal{K}}_{uu}\end{bmatrix}, \tag{15}$$

where $\tilde{\mathcal{K}}_{xx}$ represents the influence of the state observables, $\Psi_x(x_k)$, on the future state observables, and $\tilde{\mathcal{K}}_{xu}$ represents the influence of the control observables, $\Psi_u(u_k)$, on the future state observables. The terms $\tilde{\mathcal{K}}_{ux}, \tilde{\mathcal{K}}_{uu}$ in (15) refer to mappings that evolve the observations on control, which are ignored here. To determine the Koopman operator for each phase, $\zeta = \{P - stance\ phase,\ D - swing\ phase\}$, we set up a least-squares regression problem minimizing the error between the observed next step data, $\mathcal{D}_{k+1}$, and the prediction from $\tilde{\mathcal{K}^{\zeta}}\mathcal{D}_k$. The problem is formulated as

$$\begin{aligned} \tilde{\mathcal{K}^{\zeta}} \quad = \quad & \arg\min_{\tilde{\mathcal{K}}} \sum_{k=0}^{M\circledast 1} \left\| \begin{bmatrix}\Psi_x(x_{k+1}) \\ \Psi_u(u_{k+1})\end{bmatrix} \right. \\ & \left. - \begin{bmatrix}\tilde{\mathcal{K}}^{\zeta}_{xx} & \tilde{\mathcal{K}}^{\zeta}_{xu} \\ \tilde{\mathcal{K}}^{\zeta}_{ux} & \tilde{\mathcal{K}}^{\zeta}_{uu}\end{bmatrix} \begin{bmatrix}\Psi_x(x_k) \\ \Psi_u(u_k)\end{bmatrix} \right\|^2. \end{aligned}$$

The least-squares solution for $\tilde{\mathcal{K}}$ is given as

$$\tilde{\mathcal{K}^{\zeta}} = FG\ , \tag{16}$$

where

$$\begin{aligned} F &= \frac{1}{M}\sum_{k=0}^{M\circledast 1} \mathcal{D}_{k+1}\mathcal{D}_k^T, \\ G &= \frac{1}{M}\sum_{k=0}^{M\circledast 1} \mathcal{D}_k\mathcal{D}_k^T, \end{aligned} \tag{17}$$

where Moore-Penrose pseudoinverse G is utilized. Using the indicator function in (5) and the phase-based Koopman operator, the ankle motion dynamics during a complete gait cycle can then be represented as

$$\begin{aligned} \begin{bmatrix}\Psi_x(x_{k+1})\end{bmatrix} \quad = \quad & (1-\sigma_k)\begin{bmatrix}\tilde{\mathcal{K}}^P_{xx} & \tilde{\mathcal{K}}^P_{xu}\end{bmatrix}\begin{bmatrix}\Psi_k(x, u^P)\end{bmatrix} \\ & +\sigma_k\begin{bmatrix}\tilde{\mathcal{K}}^D_{xx} & \tilde{\mathcal{K}}^D_{xu}\end{bmatrix}\begin{bmatrix}\Psi_k(x, u^D)\end{bmatrix}. \end{aligned} \tag{18}$$

To obtain the prediction dynamics for the original state in (4), we compute the flow map between lifted-space observables $\Psi_k(x, u)$ and original state dynamics x_k. To recover x_k, we can describe the mapping between K$\Psi_k(x, u)$ and

x_k as $x_k = C\Psi_k(x,u)$, where $C \in \mathbb{R}^{3\times P}$ is obtained by solving the following least-squares problem:

$$\arg\min_{C} \quad \sum_{k=0}^{M\infty 1} \frac{1}{2}||C\Psi_k(x,u) - x_k||^2. \tag{19}$$

By solving (19) and substituting $\Psi_k(x,u) = C^{\infty 1}x_k$ into the lifted-space flow map (12), we obtain the linear prediction model for phase-based ankle motion dynamics during a complete gait cycle as

$$x_{k+1} = \tilde{A}^{\zeta}x_k + \tilde{B^{\zeta}}u_k^{\zeta}, \tag{20}$$

where

$$\tilde{A}^{\zeta} \quad = \quad C\tilde{\mathcal{K}}_{xx}^{\zeta}C^{\infty 1};\ \tilde{B}^{\zeta} = C\tilde{\mathcal{K}}_{xu}^{\zeta}C^{\infty 1}. \tag{21}$$

Using the indicator function, σ_k, the combined state dynamics can be written as

$$\begin{aligned} x_{k+1} \quad &= \quad (1-\sigma_k)\left(A^P x_k + B^P u_k^P\right) \\ &\quad +\sigma_k\left(A^D x_k + B^D u_k^D\right), \end{aligned} \tag{22}$$

where $x_k \in \mathbb{R}^3$ is the original state vector as described in (6), A^P, $A^D \in \mathbb{R}^{3\times 3}$,$B_1$, $B_2 \in \mathbb{R}^{6\times 2}$ are the Koopman operator-based linear state space mappings, and u_k^P, $u_k^D \in \mathbb{R}$ are the control inputs for assisting ankle plantarflexion and dorsiflexion during a gait cycle.

III. Experimentation Validation of the Proposed Koopman Approach

A. Experimental procedure

This treadmill walking study was conducted with approval from the Institutional Review Board (IRB) at NC State University (IRB #20602). A 24-year-old able-bodied female participant (height: 168 cm) without neuromuscular disabilities or walking difficulties was recruited. She walked at 0.5 m/s on a treadmill (Bertec, Columbus, OH, USA) outfitted with load cells measuring ground reaction forces (GRF) at 1000 Hz while wearing a bidirectional, cable-driven ankle exoskeleton. The walking speed was intentionally chosen to approximate the reduced walking speeds commonly observed in individuals undergoing rehabilitation for neuromuscular disorders. This selection aimed to create gait conditions more representative of clinical populations while maintaining experimental control.

The ankle exoskeleton was not closed-loop controlled; it provided pre-determined sinusoidal torques synchronized to the participant's gait cycle, matched to the GRF period at the specified walking speed. Two sEMG sensors (DELSYS, Natick, MA, USA) were placed on the medial gastrocnemius and tibialis anterior to record muscle electrical signals at 1000 Hz. Offline processing included filtering, rectifying, and normalizing the signals to create the sEMG linear envelope.

An ultrasound probe (L7.0SC Prodigy Probe, S-Sharp, Taipei, Taiwan) was affixed to the participant's shank above the tibialis anterior to capture US images at 992 Hz. Offline, echogenicity from the US images was calculated and normalized to derive muscle activation. Twenty reflective markers for motion capture (Vicon Motion System Ltd., Los Angeles, CA, USA) were placed on the pelvis and lower limbs to measure kinematic data, including ankle angle and torque. Fig. 1 shows the placement of the US, sEMG sensors, and motion capture markers during the experimental procedure.

Fig. 1. Sensor set-up for the treadmill walking experiments. (A) sEMG sensors are placed on the plantarflexors (medial gastrocnemius) and dorsiflexors (tibialis anterior) and an US probe is placed on the dorsiflexors only. (B) After wearing the cable-driven ankle exoskeleton, the motion capture markers are placed on the lower limbs.

The participant walked for 30 seconds with exoskeleton assistance. Data acquisition, including sEMG, US imaging, GRF, and exoskeleton motor output, was implemented in Matlab's Simulink Real-Time environment (R2019b, MathWorks, Natick, MA, USA) on a Speedgoat target machine (Bern, Switzerland). Motion capture and GRF data were collected separately at 100 Hz and time-synchronized offline. From the recorded data, 23 seconds representing 12 complete gait cycles were extracted for analysis.

Seeing as the lowest sampling rate for the data collected for offline processing was 100 Hz, all data was downsampled to that frequency. This was done to avoid interpolating the data to the higher frequency since the lower sampling frequency more closely reflects the rate of real-time processing. As well, US data was only collected from the dorsiflexors, therefore δ^P from (7) was set to 1, which made the muscle activation measurement for plantarflexion entirely based on the sEMG sensor data from the medial gastrocnemius. δ^D was chosen at values of $1.00, 0.90, 0.80, ..., 0.00$ in different model iterations to evaluate the benefit of increasing the weight of the echogenicity measurements on the model accuracy.

B. Ankle Exoskeleton

The ankle exoskeleton is comprised of an actuation module, a push-pull cable, and an end-effector unit. All components required for the exoskeleton are portable, except for the power supply. The actuation module consists of a brushless EC motor (EC 90 flat, Maxon, Switzerland), a servo controller (ESCON 50/8, Maxon, Sachseln, Switzerland), a threaded ball screw and ball nut (Thomson Linear, Radford, VA, USA), a linear magnetic shaft encoder (LinACE InAxis,

TABLE I
RMSE VALUES FOR THE VALIDATED STATES, ESTIMATED USING EDMD MODEL

δ^D	1.00	0.90	0.80	0.70	0.60	0.50	0.40	0.30	0.20	0.10	0.00
q	0.228	0.242	0.214	0.202	0.201	0.236	0.226	0.234	0.253	0.241	0.238
$\dot{q}$	0.146	0.146	0.145	0.145	0.144	0.144	0.143	0.144	0.146	0.146	0.146

RLS, Ljubljana, Slovenia), and a microcontroller with PWM functionality (Arduino Uno, Torino, Italy). The motor sits upright at the hip, within 3D printed housing. When the motor rotates, the ball nut, connected to the push-pull cable, moves upwards or downwards, pushing and pulling the ankle to produce plantarflexion and dorsiflexion. The magnetic shaft encoder measures the movement of the ball nut – an analog for the ankle joint angle. The maximum motor torque is 1.56 Nm. The device has a total mass of 3 kg, with most of that centered at the hip-worn actuation module. The actuation module was secured to the participant using a standard utility belt.

IV. KOOPMAN PREDICTION RESULTS

The Koopman operator framework was used to model (6) for the entire experimental cycle. The first 5 seconds were designated as training data, after which the remaining time was used for validation. A root-mean-squared-error (RMSE) value was calculated for each of the validated states. This modeling process was performed for 11 datasets. Each dataset differed only in the a^D value, calculated using different sensor fusion weights δ^D. The RMSE values for validated states q and $\dot{q}$ are shown in Table I. Underlined values represent the sEMG sensor fusion weight (δ^D) that produced the best possible RMSE for the evaluated state. Among all the EDMD modeled states, the best average performance for q was demonstrated when $\delta^D = 0.60$ (shown in Fig. 2) and the worst performance was demonstrated when$\delta^D = 0.20$ (shown in Fig. 3). RMSE values for $\dot{q}$ had relatively low variance.

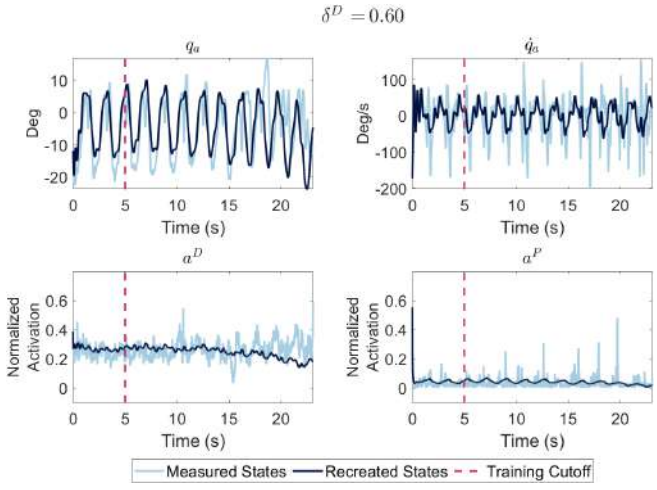

Fig. 2. The measured and recreated states from the EDMD model in the dataset with the best q RMSE value.

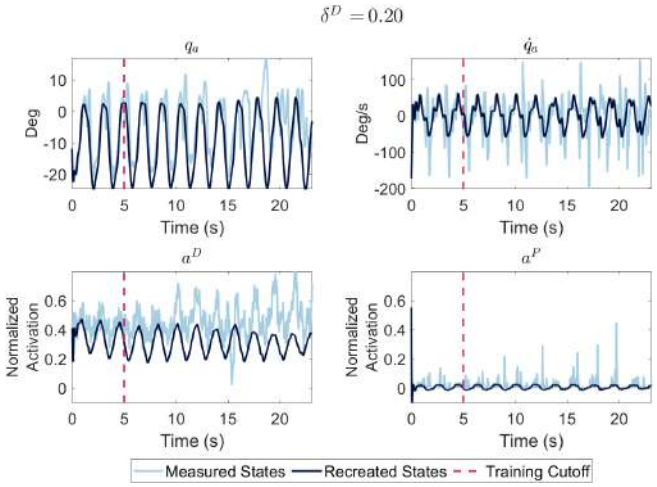

Fig. 3. The measured and recreated states from the EDMD model in the dataset with the worst q RMSE value.

V. DISCUSSION

The results demonstrate that the proposed Koopman operator framework, combined with fused US and sEMG signals, effectively models the nonlinear, phase-dependent dynamics of ankle motion during gait. By leveraging the complementary strengths of US and sEMG, the framework achieved accurate estimations of muscle activation, particularly for the dorsiflexors, with peak performance observed at a sensor fusion weight of $\delta^D = 0.60$. This configuration yielded the lowest RMSE for q. Notably, models relying exclusively on sEMG ($\delta^D = 1.00$) or US imaging ($\delta^D = 0.00$) demonstrated higher RMSE values, highlighting the limitations of single-modality approaches in comprehensively estimating muscle activation dynamics. However, the differences in RMSE across various δ^D values were relatively small, suggesting that the fusion framework is robust across a range of weight configurations.

The results indicate that while the model accurately captures overall gait trends, it struggles to reproduce high peaks and extreme values in the validated states. Highly transient periods or abrupt state changes during, for instance, peak force production, may not captured by basis functions since they represent particularly high frequency data or may be filtered out and smoothed during sensor processing. Introducing higher-order polynomial or expanding the set of Koopman observables could improve the model's ability to track extreme values.

A key limitation of this study is that experiments were conducted on a single young, able-bodied participant. While this approach allowed for a controlled comparison of the

EDMD model across various sensor fusion weights, it does not account for inter-individual variability that may be particularly common among populations with neuromuscular impairments, who remain the ultimate intended clinical population. It is well established that neurological impairment often alter muscle activation patterns, gait kinematics, and torque production, which may impact the performance of any model. Additionally, muscle fatigue and compensatory strategies that are more prevalent in clinical populations were not accounted for in this study. For improved generalizability, our future work will be trained on a wider dataset with participants of varying levels of ability and increased variability in peak torque production.

The immediate next step in this research is to perform the same analysis for sensor weights in combined US and sEMG measurements for modeling plantarflexor muscle activation. To strengthen the findings, future work should include statistical analyses to quantify the significance of performance differences across δ^{ζ} values and conduct sensitivity analyses to evaluate the framework's robustness under varying gait speeds or load conditions. Additionally, assessing the real-time feasibility and computational efficiency of the Koopman-based model would demonstrate its applicability for exoskeleton control. Overall, the integration of Koopman operator theory with fused US and sEMG data presents a promising avenue for individualized gait modeling, offering enhanced accuracy and adaptability for potential exoskeleton applications.

Do Motor Skills Learned in Isometric Training Generalize to Unpracticed Workspaces?

Arturo Ramirez[1,2*], Naveed Reza Aghamohammadi[1,2] , Courtney Celian[1]
Adriana Cancrini[1,2], Bruno Borghi[1], James L. Patton[1,2*]

***Abstract*— Previous studies have looked at the potential for using visual feedback from isometric forces to illicit movement learning without actually moving. We investigate the potential of isometric movement training further by investigating the generalization of motor skills learned through isometric training to unconstrained movement. Using the Barret Upper-Extremity Robotic Trainer as both a position control device and a force clamp, participants engaged in an isometric reaching task with simulated movement arm dynamics feedback. The simulated movement was displayed on an augmented reality display that occludes the arm to increase immersion and belief of movement. We studied planar-targeted reaching in the presence and absence of a velocity-dependent curl field and evaluated if skills acquired in isometric reaching using robotic constraints transfer effectively to free-reaching tasks in an unpracticed and practiced workspace. Our results demonstrated an ability to transfer motor skills in the practiced workspace which supports previous findings in literature; however, motor skills in an unpracticed workspace showed increase performance in the presence of the curl field but no signs of an after effect in the absence of the field. This finding shows promise of generalization of isometric movement training in unpracticed workspaces, and further studies are needed.**

I. Introduction

The amount and type of rehabilitation an individual receives after a stroke can significantly impact their recovery and functional gains. Patients benefit from repetitive physical and mental exercises, such as mental rehearsal, progressive resistance force training, and repetitive motion therapy [1], [2]. Error augmentation has also shown promise as a therapeutic approach, where task errors are intentionally amplified, requiring participants to make greater corrections rather than receiving assistance [3]–[6]. However, many stroke survivors experience severe weakness or spasticity, making it difficult to perform the recommended therapeutic activities or generate sufficient volitional movement to benefit from error augmentation [1]. This difficulty increases their risk of long-term disabilities, including "learned non-use," reduced mobility, and persistent spasticity [7]. Ensuring that individuals with varying levels of movement ability can participate in repetitive exercises is essential for optimizing recovery outcomes. For patients with greater impairments, force-modulated training and constraint-induced movement therapy have proven effective in mitigating learned non-use [1], [2], [8], [9]. Isometric movement training has emerged as a potential solution to address these rehabilitation challenges, though its effectiveness in transferring training benefits to real-world movements remains under explored.

Understanding how skills learned in constrained environments transfer to free movement is critical for determining the viability of isometric training as a therapeutic approach. Previous work by Melendez-Calderon et al. (2017) demonstrated that dynamic motor skills acquired through isometric training could transfer to free-reaching movements [10]. In their study, participants performed isometric tasks within a single workspace using a simulated environment where an avatar represented arm movements based on force output, enabling training in velocity-dependent force fields. The participants exhibited positive transfer effects, suggesting that isometric learning can induce sensorimotor adaptations applicable to unrestricted movement conditions.

Building upon this research, the present study employs a similar isometric reaching protocol while introducing tests in a second, unpracticed workspace. Investigating generalization to unpracticed workspaces is essential for establishing isometric reaching as a viable rehabilitation approach. Since isometric training is inherently confined to a single workspace, its effectiveness depends on whether the acquired skills can transfer to new movement contexts required for daily function. We hypothesize that dynamic motor skills learned through isometric training will transfer within the practiced workspace and, critically, will also generalize to the unpracticed workspace, reinforcing the potential of isometric training for real-world rehabilitation.

II. Methods

A. Participants

Four healthy adults (two males, two females) aged 25–55, with no prior experience in isometric training, were recruited. All participants were right-handed, and their data and informed consent were collected in accordance with the Declaration of Helsinki and Northwestern University's Institutional Review Board (STU00220740).

B. Experimental Setup

Our experiment utilizes a robotic arm, an augmented reality display, and an arm simulation. The robotic arm used is the Barrett Upper Extremity Robotic Trainer (Burt®) [11] (Fig. 1) from Barrett Technologies. The Burt® is a 3-DOF robotic manipulator that provides real-time end-effector

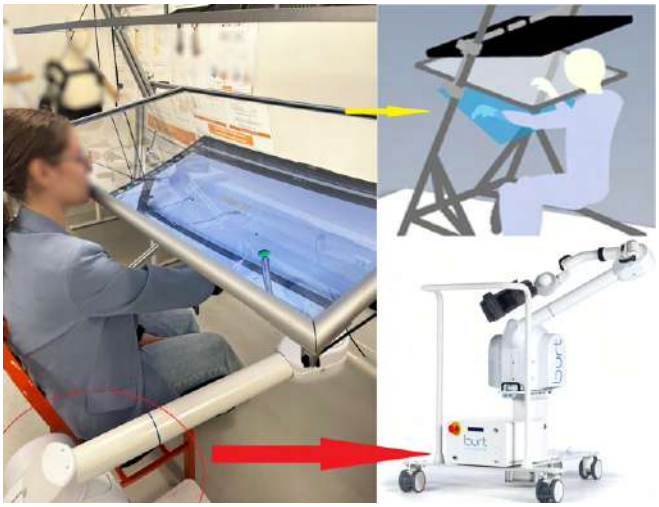

Fig. 1. Example of the experimental setup used for data collection. The yellow arrow indicates the LookinGlass augmented reality display, while the red arrow highlights the Burt® robotic arm

tracking, haptic feedback, and force generation, which are used to generate perturbations and maintain a force clamp during isometric training. A key feature of the Burt® is its full back-drivability, ensuring user safety.

The augmented reality display is the Looking Glass, which consists of an angled display and a semi-silvered screen. Unlike systems that require head tracking, the Looking Glass eliminates latency and the need for additional devices attached to the user [3], [12]–[16] (Fig. 1).

We developed the virtual arm simulation using Unity software, which provides visual feedback in real time to the participant. A virtual cursor (0.3 cm in diameter) was aligned with the end effector of the Burt® to ensure accurate spatial feedback.

C. Force Clamp

To perform isometric training,the participant's hand is clamped in place using the robot handle which applies forces to maintain the hand at a desired location. These forces are generated by a virtual spring with resting length of zero, whose origin is located at the starting position of the workspace. The equation governing the spng force is as follows.

$$F_{\text{spring}} = -F \cdot \hat{F} = -\rho \cdot k \cdot \begin{bmatrix} \sin(\phi)\cos(\theta) \\ \sin(\phi)\sin(\theta) \\ \cos(\phi) \end{bmatrix} \tag{1}$$

Where:

$$\rho = \|r\|, \quad \theta = \tan^{-1}\left(\frac{r_y}{r_x}\right), \quad \phi = \cos^{-1}\left(\frac{r_z}{\|r\|}\right) \tag{2}$$

$$r = RobotPosition - SpringOrigin \tag{3}$$

An additional damping force is applied to the user to mitigate the spring's oscillatory behavior and ensure stable positioning.

$$\mathbf{F}_{\text{applied}} = \mathbf{F}_{\text{spring}} + c \cdot (\mathbf{v} \cdot \hat{\mathbf{F}}) \tag{4}$$

Where c is the damping coefficient (dampeningCoeff), and $\mathbf{v} \cdot \hat{\mathbf{F}}$ represents the velocity component aligned with the direction of the spring force

Since the Burt® robot lacks a force sensor, the force clamp serves as a proxy for measuring user-applied forces. It is assumed that the force exerted by the robot to hold the user in place is equal and opposite to the force applied by the user:

$$\mathbf{F}_{\text{ext}} = -\mathbf{F}_{\text{applied}} \tag{5}$$

D. Isometric Framework

The virtual arm simulation is modeled using the dynamic equation below. This experiment involves a planar reaching task, where the arm is represented as a two-link, two-degree-of-freedom system with revolute joints at the shoulder and elbow. The mass,length and moment of inertia were determined for an average person of 1.75 m in height and 70 kg in weight [17].

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + G(q) = J(q)^T * (\mathbf{F}_{Vf} + \mathbf{F}_{ext}) + \tau_{fb} \tag{6}$$

Where:

$M(q)$ is the mass matrix.
$C(q,\dot{q})$ is the Coriolis and centripetal matrix.
$G(q)$ is the gravitational torque vector.
$J(q)^T$ is the transpose of the Jacobian.
$\mathbf{F}_{Vf}$ is the virtual force applied to the end effector.
$\mathbf{F}_{ext}$ is the external force applied by the user.
τ_{fb} is the feedback torque.

In the presence of a curl field, the virtual force is given by:

$$\mathbf{F}_{Vf} = \mathbf{F}_{curl} = \dot{\mathbf{X}} \cdot \begin{bmatrix} 0 & 25 \\ -25 & 0 \end{bmatrix} \tag{7}$$

Feedback torque is determined using an equilibrium point controller in the joint domain. The desired joint angles are calculated based on the minimum jerk trajectory from starting point to target as the ideal path and transformed to joint angles using inverse kinematics. The controller is defined as:

$$\tau_{fb} = \lambda \left(K_p(q - q_{\text{desired}}) + K_d(\dot{q} - \dot{q}_{\text{desired}})\right) \tag{8}$$

The scaling factor λ is velocity-dependent to prevent high feedbacks at low velocities:

$$\lambda = \begin{cases} 1, & |\dot{x}| \geq 0.8\,\text{m/s} \\ \frac{|\dot{x}|}{0.8}, & |\dot{x}| < 0.8\,\text{m/s} \end{cases} \tag{9}$$

Joint stiffness K_p is torque-dependent derived from empirical data gathered from published work [18]:

$$K_p = \begin{bmatrix} 10.8 + 3.18|\tau_{\text{Fext1}}| & 2.83 + 2.15|\tau_{\text{Fext2}}| \\ 2.51 + 2.34|\tau_{\text{Fext2}}| & 8.67 + 6.18|\tau_{\text{Fext2}}| \end{bmatrix} \tag{10}$$

Joint damping K_d is proportional to K_p and inversely related to joint velocity magnitude [10], [19]:

$$K_d = \frac{0.42}{\sqrt{\dot{q}^T(\dot{q}+1)}} K_p \tag{11}$$

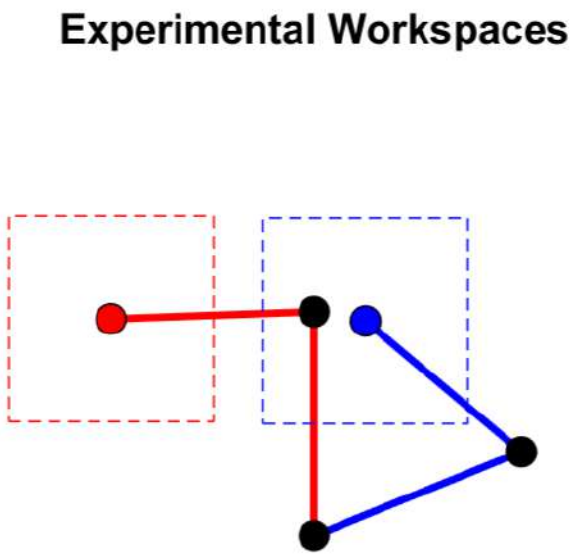

Fig. 2. Visual representation of the two workspaces. The blue workspace is the practiced workspace centered at elbow angle 118° and shoulder angle 22°. The red is the unpracticed workspace centered at elbow angle 92° and shoulder angle 90°

This feedback model incorporates torque-dependent joint stiffness and damping, ensuring realistic responses during isometric tasks. The velocity-dependent scaling factor λ prevents feedback from driving the simulation when minimal input is provided by the user.

E. Protocol

The experiment consisted of 445 trials of 15 cm center-out reaches (4 cm targets) across 15 phases in two workspaces as seen in Fig.2. The practiced workspace had three target directions (90°, 210°, 330°) and additional catch trials in unpracticed directions to take into consideration generalization within the workspace (30°, 150°, 270°). The unpracticed workspace featured only the three practiced directions. Table 1 summarizes the phases with "c" for catch trials, "*" denoting key analysis phases, yellow highlighting the unpracticed workspace, and blue highlighting phases in the isometric condition.

Participants received 150-second rest periods every 75 trials to minimize fatigue. During each reach, they received continuous feedback on their movement speed via a color-coded cursor system: - **Yellow**: Movement time below 550 ms (too fast). - **Green**: Movement time between 550 ms and 850 ms (ideal). - **Red**: Movement time over 850 ms (too slow).

If participants reached the target within the ideal time window (550–850 ms), they received a **positive reinforcement** in the form of a green explosion visual effect and a rewarding auditory cue. If they missed the ideal time, a **negative auditory cue** was provided as feedback. The color feedback and positive reinforcement were implemented to enhance extrinsic motivation, promoting learning and encouraging proper reaching during trials [20].

F. Data Collection and Analysis

The position and velocity of the robotic end effector and the arm cursor were recorded for each trial. During isometric conditions, since the robotic end effector remains stationary, the position and velocity of the arm cursor were used to analyze trajectories and error metrics. The primary error metric was the maximum perpendicular distance, defined as the maximum deviation of the arm cursor from the ideal straight-line path between the starting point and the target for each trial:

$$d = \pm \frac{ax_1 + by_1 + c}{\sqrt{a^2 + b^2}} \tag{12}$$

where a, b, and c represent the coefficients of the line equation, and (x_1, y_1) represents the arm cursor's position.

To compare phases, the Kolmogorov-Smirnov test was used first to assess data normality. If both datasets were normally distributed, a paired t-test was conducted. For non-normal datasets, a non-parametric Wilcoxon signed-rank test was performed. A significance level of $\alpha = 0.05$ was applied for all comparisons, and p-values were reported to indicate the statistical outcomes.

III. Results

We hypothesized that skills learned in isometric training will transfer to unconstrained reaching tasks in the practiced workspace and will also show generalizability to the unpracticed workspace. We consider transfer of learning to be an increase in performance in unconstrained reaching while under the effects of a velocity-dependent curl field and a decrease in performance in the null condition after training. The maximum perpendicular error of each subject at every phase were plotted as shown in Fig. 3. Trend lines were then computed to determine if individual subjects were responding similarly to the protocol. In the isometric training phases (phases 8-10) there is a clear downward trend that

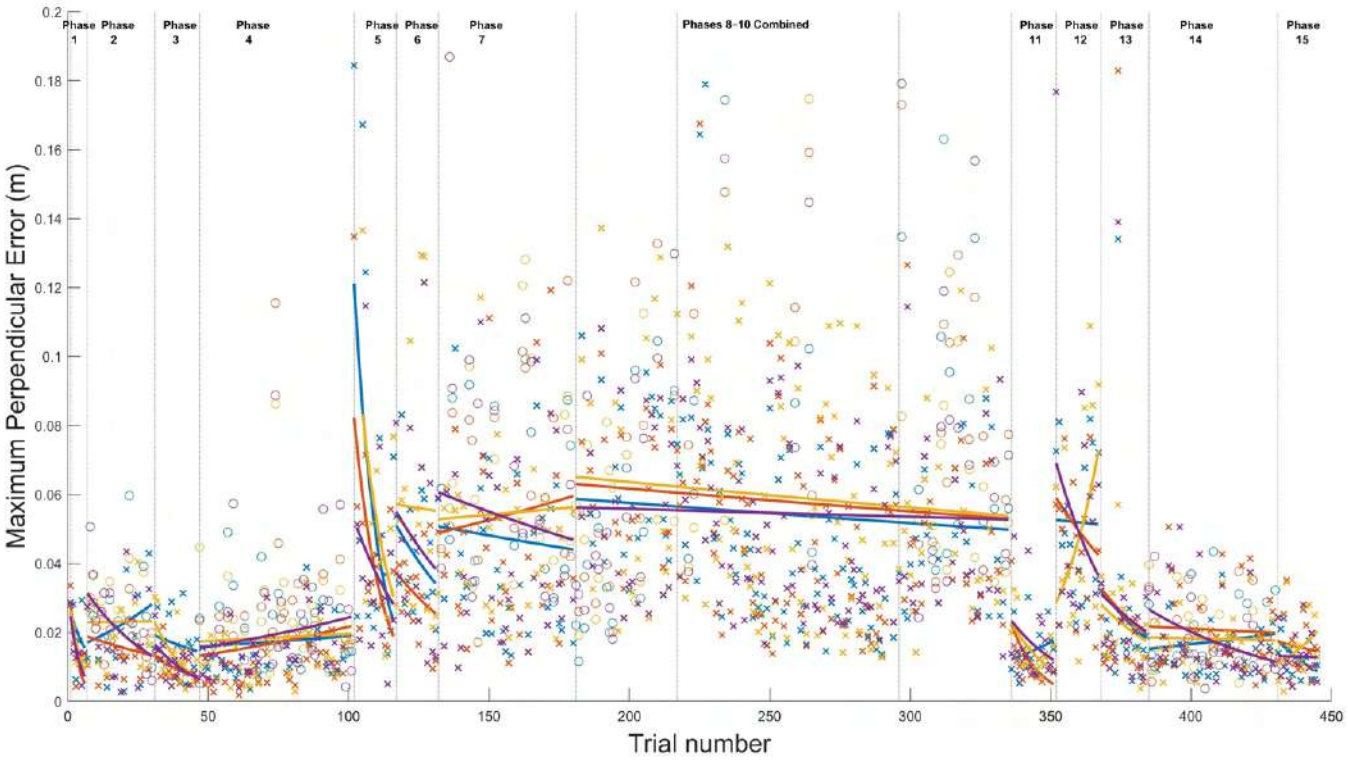

Fig. 3. Perpendicular Error (m) for all subjects (n=4) across all experiment phases. Blue represents S1, orange represents S2, yellow represents S3, and purple represents S4. Solid lines depict data fits for each subject, excluding catch trials. Catch trials are indicated by open circles, while main phase data points are marked with Xs.

suggests that the participants were getting better at navigating the virtual curl field in the isometric condition.

This experiment analyzed the movement trajectories in various phase. The individual trajectories of key phases were shown in Fig. 4, blue trajectories correspond to conditions without the velocity-dependent curl field, while red trajectories illustrate movements with the presence of the force field. These plots further support the trending argument of adaptation as after effects, as denoted by blue trajectories in Post-Training for both unconstrained and constrained appear to produce more perpendicular error when compared to the blue trajectories in Pre-Training. There appears to be little to no after effects present in the unpracticed workspace post-isometric training.

To evaluate performance changes under a virtual velocity-dependent curl field during isometric conditions, we compared the initial exposure to the field (phase 7c) with late training (phase 10), where learning was expected. A Wilcoxon signed-rank test revealed that errors during late training were significantly lower than during initial exposure ($p = 4.0721 \times 10^{-4}$). To assess the aftereffects of learning, we compared the isometric baseline (phase 6) with the catch trials of late training (phase 10c). The errors in the catch trials were significantly higher than those in the baseline ($p = 5.3518 \times 10^{-7}$), indicating substantial aftereffects.

The impact of isometric training on unconstrained reaching performance in a velocity-dependent curl field was examined by comparing initial exposure pre-training (phase 4c) with a test phase post-training (phase 14). This comparison revealed a significant reduction in perpendicular errors ($p = 2.7317 \times 10^{-5}$) following training. For aftereffects in unconstrained reaching, the baseline (phase 3) was compared with the post-training test phase (phase 14c). This showed an increase in errors ($p = 2.7317 \times 10^{-5}$) after training.

To explore the generalization of isometric training to an unpracticed workspace, we analyzed performance and aftereffects. There were no significant aftereffects(phase 1 vs 11) in the unpracticed workspace post-training ($p = 0.3313$); however, performance under the curl field(phase 2c vs 13) showed significant improvement ($p = 0.0260$). A summary of all these comparison can be seen in Fig. 5

IV. Discussion

The results of this experiment provide insights into the adaptation and generalization of motor control under the influence of a velocity-dependent curl field, particularly in the isometric condition. Statistical analyses and trajectory evaluations revealed distinct trends supporting the occurrence of learning and adaptation, though with limitations in generalizing learned behaviors to unpracticed workspaces.

A. Adaptation and Learning in the Isometric Condition

Participants demonstrated a progressive adaptation to the curl field during isometric training (phases 8–10), as evidenced by a downward trend in the maximum perpendicular error during training. This improvement suggests that participants refined their ability to navigate the virtual environment

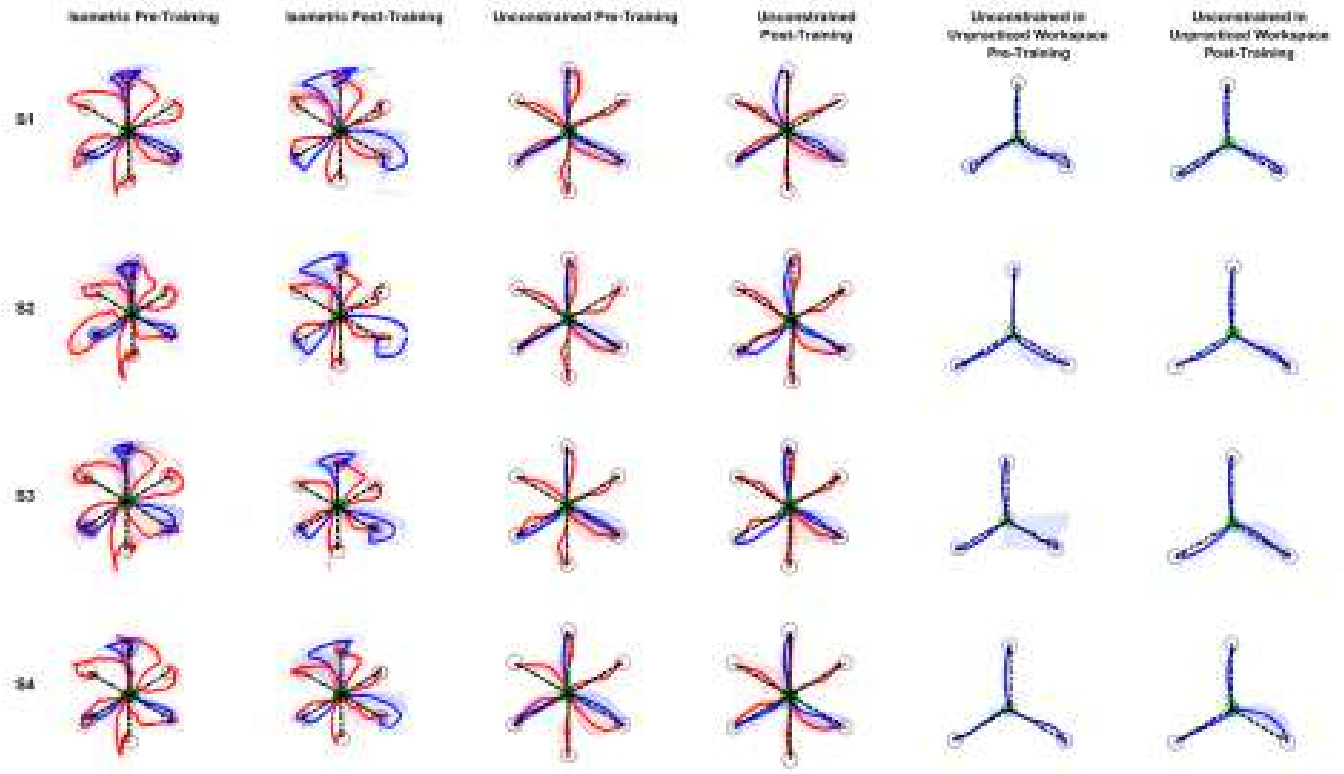

Fig. 4. Movement trajectories of key phases in the experiment. Blue trajectories represent movements without a velocity-dependent curl field, and red represents movements with the force field. Green circles indicate movement onset, darker lines represent the ensemble average trajectory and the shaded regions is the standard deviation.

despite the perturbation. While improvement in performance alone does not necessarily indicate learning or adaptation,the presence of aftereffects, indicated by higher errors during catch trials compared to the baseline, supports the belief that participants internalized the curl field dynamics and had some level of motor learning and adaptation. These findings align with previous studies showing that repeated exposure to perturbations facilitates the development of compensatory strategies and altered internal models. [21]–[24]

B. Impact on Unconstrained Reaching Performance

Isometric training positively influenced performance in unconstrained reaching tasks, as shown by the reduction in perpendicular errors under the unconstrained curl field from pre- to post-training. This implies that the abilities gained during isometric training remain present once unconstrained. Furthermore, the increased errors observed in the post-training test phase without the force field, compared to the unconstrained baseline, suggest that dynamic skills learned in isometric condition were transferred to the unconstrained arm dynamics. This observation supports the assertion by Dr. Melendez-Calderon that dynamic skills are transferable from isometric learning, although the extent of their generalizability remains unclear [10], [25].

C. Generalization to an Unpracticed Workspace

The analysis of performance and aftereffects in the unpracticed workspace provide insights into the limits of isometric training. The absence of significant changes in maximum perpendicular error when testing for aftereffects suggests that the learned dynamics in the trained workspace did not transfer to the unpracticed workspace. This result suggests that the internalized model of the curl field was either postural dependent or could be due the workspace torque being too dissimilar for proper generalization to occur as seen in literature [26].. Nevertheless, the significant improvement in performance under the curl field in the unpracticed workspace still suggests some degree of generalization. Participants were able to apply their learned strategies to perform better in the curl field, even in a novel spatial context. This increase in performance could be due to the re-weighting of visual feedback in the isometric condition, allowing participants to respond effectively to the visual cue of the curl field as opposed to the environmental forces being applied [27]. The literature also suggests that adaptation can be generalized due to the CNS creating and storing generalized control strategies from visually perceived kinematic coordinates [28]–[30]

D. Implications and Future Directions

These findings have important implications for the design of rehabilitation protocols and motor learning paradigms. The demonstrated ability of isometric training to improve performance in unconstrained tasks suggests its potential as a safe and effective training paradigm, especially for individuals with motor impairments. However, the limited generalization of aftereffects to unpracticed workspaces im-

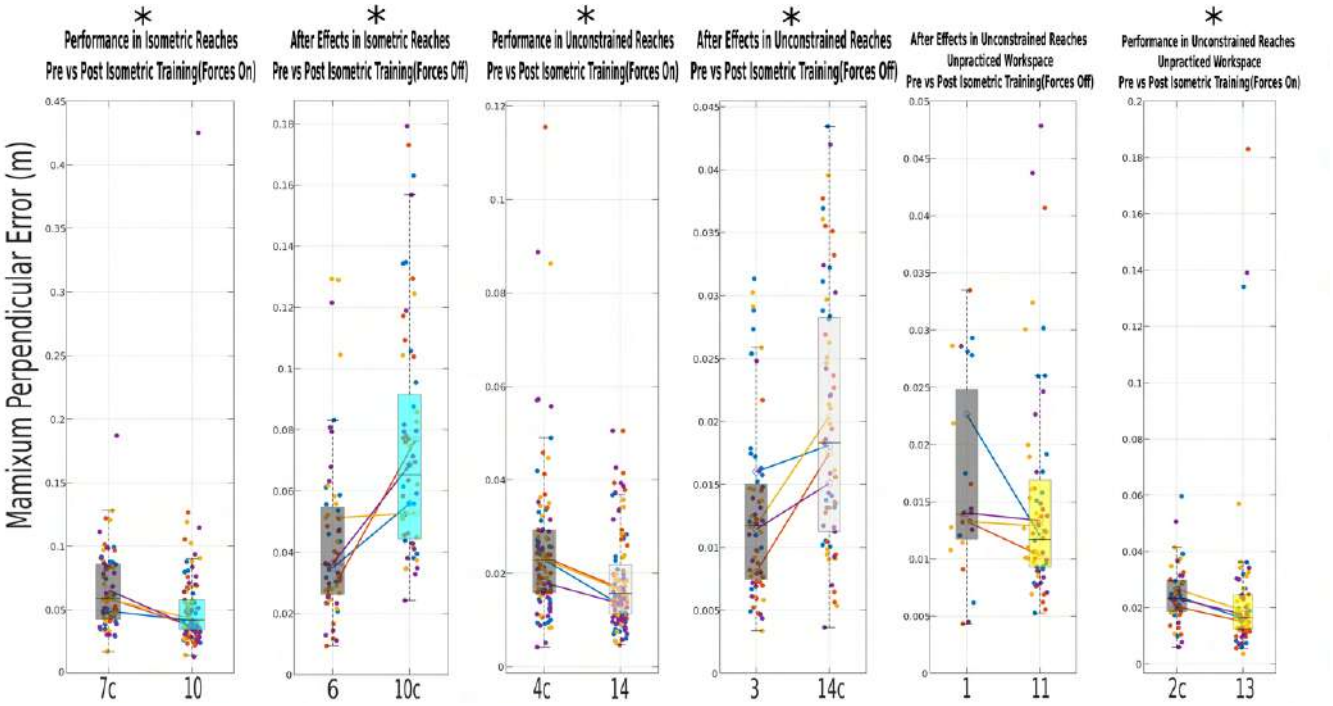

Fig. 5. Key phase comparisons are shown with gray box plots representing pre-training phases and colored box plots representing post-training phases. Box plot colors follow the same convention as the table: blue represents phases in the isometric condition, white represents unconstrained in the practiced workspace and yellow represents unconstrained phases in the unpracticed workspace. Solid lines indicate the medians for individual subjects, and asterisks above the plots denote p-values less than 0.05, indicating statistical significance.

plies the need for more robust isometric trainings that spans multiple workspaces which limits it effectiveness. Future studies should investigate the mechanisms underlying the observed workspace-specific adaptation and explore strategies to enhance generalization. There is the possibility that this training protocol did not provide sufficient time in the isometric training condition to fully learn the curl field in and a further analyses on the dynamics of the learning needs to be done to ensure steady state was reached. The rose plots suggest that learning and adaptation did not fully occur since there are still curling effects evident in late training when the expected trajectory should be close to straight. Recent study has shown that the difficulty in a task can affect the potential to encode and internalize adaptations, by increasing the speed of the targeted reaches we could potentially increase the amount of learning internalized [31]. Additionally, examining the neural systems responsible for adaptation and generalization in isometric conditions could provide valuable insights into the underlying processes and inform the development of more effective training approaches. Another future direction could be updating the arm simulation, which currently utilizes a linear torque stiffness relationship, to be more dynamic by implementing a personalized model of the user from reaching data collected using techniques like PRISM [32].

E. Study Limitations

A primary limitation of this study is the small sample size, which limits the generalizability of our findings. Future research recruiting a larger participant pool is necessary to support any observed trends on the transfer of dynamic skills and generalization. Another limitation of this study is that a bug was observed in the isometric condition in the forward direction. This bug was a misaligned ideal position for the forward direction which caused the torque feedback to apply a force toward the left of the target. This bug could have limited the amount of learning observed since it made reaching to the target much more difficult in this direction as opposed to the other two.

F. Conclusion

In summary, this study demonstrates the efficacy of isometric training in facilitating motor adaptation and improving performance in dynamic reaching tasks. While the adaptation was robust and accompanied by significant aftereffects, the limited generalization to unpracticed workspaces highlights the need for further investigation into strategies to enhance transfer. These findings still highlight the potential of isometric training as a tool for motor skill enhancement and rehabilitation and supports literature on the dynamic skills acquired from isometric conditions.

***Abstract*—State-of-the-art upper-limb myoelectric prostheses are typically controlled using classification-based models that *do not* offer simultaneous control of wrist and hand movements (degrees of freedom or DOFs). Regression-based alternatives are being studied because they *do* offer simultaneous DOF control, yielding more natural movements, but generally require longer training routines. We investigated methods to reduce the training burden for regression-based myoelectric control. Five different methods to train regression models were tested using electromyographic (EMG) data collected from the forearms of 10 able-bodied participants. First, models were either trained traditionally with data from elbows at 90° position, with data from 3 limb positions, or trained by few-shot learning (with fewer data from 3 limb positions). Then, transfer learning was employed to pre-train models using data from all other users, with the models subsequently fine-tuned using either traditional or few-shot learning with new end-user data. The resulting five models were evaluated using linear regressor-, Convolutional Neural Network-, and Transformer-based approaches. Interestingly, the transfer learning pre-trained model in conjunction with few-shot fine-tuning achieved the second-highest median R^2 of 0.76 across all participants. Our findings offer a proof of concept for regression-based myoelectric control of multiple DOFs that may more closely resemble natural limb function.**

***Index Terms*—myoelectric control, electromyography, regression, transformers, transfer learning, few-shot learning**

I. Introduction

Together, the human hand and wrist allow us to perform many activities of daily living. The hand, whose function is to manipulate, grip, and grasp, is comprised of complicated joints. The wrist is responsible for orienting the hand in space and includes three degrees of freedom (DOFs): 1) flexion/extension, 2) abduction/adduction, and 3) pronation/supination. These DOFs allow the wrist and hand to perform movements at the same time with varied velocities. Replicating these simultaneous movements with proportional control across multiple limb positions remains a challenge for the prosthetics field.

State-of-the-art myoelectric prostheses aim to restore lost function after amputation. These devices capture and use electromyographic (EMG) signals generated by the muscles of a user's residual limb. Signals are captured by electrodes embedded in its socket, and are then interpreted by its controller to initiate user-intended actions such as a hand open/close and wrist rotation [1], with variations in movement velocity offered proportionally to the user's muscle contraction strength [2].

To initialize a pattern recognition model for use, a user must first perform a series of muscle contractions, known as a training routine [1]. A prosthetic hand that is capable of opening and closing, for instance, normally needs to be trained for three distinct movement scenarios: hand open, hand close, and no movement (rest). For each such scenario, the user is prompted to contract their residual limb muscles in unique and consistent manners. Afterwards, the controller's trained model is ready to interpret new incoming EMG signals during daily device use.

Pattern recognition models for upper limb prosthesis control are typically controlled using classification-based models, which repeatedly classify short time windows of movements. Notably, these models *do not* offer simultaneous control of multiple wrist and hand movements because they can only output one class decision at a time, and as such, do not yield smooth movements.

Regression-based models, however, *do* offer simultaneous control of multiple DOFs [3], and arguably yield smoother and more natural movements. Rather than training distinct classes as with classifiers, regressors are employed to build models that map EMG data to the continuous proportional level of activation of each DOF (e.g. an output may be 50% hand open *and* 30% wrist pronation). To enable robust simultaneous and independent DOF control, regressors require training routines that involve a series of repeated dynamic movements, with users instructed to contract their muscles through a desired range of motion. Because this training typically includes combinations of DOFs, and variations within each, regressors require longer training routines than classifiers, which can be burdensome for the user.

Another challenge in myoelectric control is that unexpected changes in EMG signals can cause even well-trained models to degrade due to confounding factors [4]. Inherently,

Research supported by the Natural Sciences and Engineering Research Council of Canada (Grants RGPIN 2020-04776 and ALLRP 570710-2021).

changes in the position of the upper arm during daily device use are known to alter forearm EMG signals. These positional changes pose problems when a model is only trained with the user's arm at their side, elbow bent at $90°$, and their prosthetic hand out in front (that is, in one limb position, as is common) [5]. It has been shown that when training routines are performed in varied limb positions, confounding factors are mitigated and more reliable control results are obtained. Fortunately, machine learning models can now handle EMG data from multiple limb positions and yield performance that is robust to changes in input signals [4]. Multi-limb position training, however, increases the time and effort associated with model training [6].

The use of transfer learning approaches has been shown to reduce the duration of model training by users [7], [8]. This is particularly relevant for multi-limb position training routines and when repeated dynamic and simultaneous muscle contractions are required for training a regression-based model. With transfer learning, a model is initially pre-trained using a large amount of EMG data from other individuals to become the starting point for a new user's device control. The new user's model is then fine-tuned using a smaller amount of training data specific to their muscle activations. Although Ameri *et al.* previously investigated the use of regression with transfer learning to potentially reduce the effect of electrode shift [9], no studies have investigated whether the technique can provide accurate control in multiple limb positions and if it can reduce training burden in regression-based control.

In this work, we investigate the potential of transfer learning to reduce the training burden inherent to regression-based myoelectric control across limb positions. We evaluate this potential by comparing the performance of three regressors: a transformer, a convolutional neural network (CNN), and a linear regressor (LR). The transformer and CNN regressors were evaluated both with and without transfer learning, while the LR served as a baseline. Our evaluation focused on the impact of transfer learning on model performance and the feasibility of reducing user-specific calibration data. We explored whether transfer learning can enable accurate and proportional simultaneous control of wrist and hand devices that are robust to changes in limb position and minimize the required user training. While transformers have recently been explored for myoelectric control [10], and the robustness of regression-based models to limb position variations has been examined [11], the application of transfer learning to regression models for multi-degree-of-freedom control across limb positions remains an open question. This work aims to address this gap and determine the viability of transfer learning with advanced regression architectures, such as transformers and CNNs, for next-generation upper limb prosthesis controllers.

II. Methods

A. Participants

Ten participants without upper-body pathology or recent neurological or musculoskeletal injuries were recruited. Their median age was 23.5 years (range: 21–32), 3 participants were male, 7 were female, 8 were right-handed, 2 were left-handed, 5 had some experience with pattern recognition, and the remaining 5 had no experience. Each participant provided written informed consent. Approval of all ethical and experimental procedures and protocols was granted by the University of New Brunswick's Research Ethics Board (REB #2024-082) and performed in accordance with the Declaration of Helsinki.

B. Equipment

Six Delsys Trigno electrodes (Natick, USA) were affixed to the participants' right forearm, spaced equidistantly around the area of maximum muscle bulk, as shown in Fig. 1A. EMG signals were recorded with a sampling rate of 2000 Hz. A custom Python script captured streamed data from the electrodes and simultaneously displayed participant instructions.

C. EMG Data Collection

Participants followed onscreen instructions to ensure that they executed similarly paced continuous wrist and hand motions within their range of muscle contraction intensity capabilities.

Muscle Contractions: Participants elicited both single- and multi-DOF forearm muscle contractions for a period of 4 seconds each, by performing oscillations between extremes of the DOFs, as illustrated in Fig. 1B and described below.

Single-DOF muscle contractions included:

- Forearm muscles at rest, followed by oscillations between hand open and close
- Forearm muscles at rest, followed by oscillations between forearm pronation and supination

Multi-DOF muscle contractions included:

- Forearm muscles at rest, followed by oscillations between hand open & forearm pronation and hand close & forearm supination
- Forearm muscles at rest, followed by oscillations between hand close & forearm pronation and hand open & forearm supination

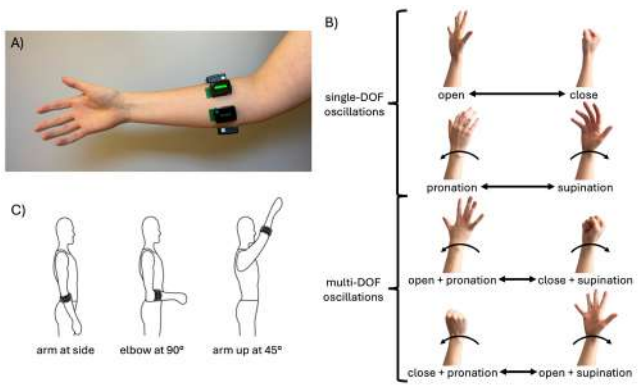

Fig. 1. A) Placement of EMG electrodes, equidistant around the forearm of each participant, over the area of maximum muscle bulk, and with hand at rest, B) single- and multi-DOF oscillating muscle contractions performed, and C) limb positions in which contractions were performed.

Limb Positions: Participants repeated the above-mentioned single- and multi-DOF oscillating muscle contractions in three limb positions, as illustrated in Fig. 1C and described below.

- With the participant's arm at their side (a total of 60 seconds of rest and 12 repetitions of each oscillation)
- With their elbow bent at $90°$ (a total of 80 seconds of rest and 16 repetitions of each oscillation)
- With their arm up $45°$ from vertical (a total of 60 seconds of rest and 12 repetitions of each oscillation)

D. Data Pre-Processing

The EMG data from the six forearm electrodes were filtered using 4^{th}-order zero-phase filters: a highpass filter with a cutoff of $20\,\text{Hz}$ and a lowpass filter with a cutoff of $450\,\text{Hz}$. Additionally, a notch filter at $60\,\text{Hz}$ was used to remove power-line interference. Data were segmented into overlapping windows with a $13.5\,\text{ms}$ increment (chosen based on the communication protocol of the Delsys electrodes). For the CNN regressor and the LR, the window length was set to $150\,\text{ms}$, which is optimal for EMG pattern recognition tasks [12]. For the transformer regressor, the window length was set to $32\,\text{ms}$. The log amplitude spectrum of each window was then computed for each window, yielding spectral feature vectors. For the CNN, each spectral vector was reshaped and presented as a 'Frequency Bin x Channel' image. Finally, for the LR, these spectral vectors served as inputs. For the transformer, 32 consecutive spectral vectors were presented as a sequence. In all cases, the spectral vectors were standardized to have zero mean and unit variance. An example spectrogram across the 6 channels is illustrated in Fig. 2.

E. Control Model Implementation

In previous prosthesis control studies, temporal classifiers such as long short-term memory (LSTM) regressors have shown promise. These classifiers can learn the dynamics of how EMG signals vary over time to yield improved predictive performance, as evidenced by real-time experimentation [13], [14]. Inspired by these results, a temporal transformer regressor was implemented in this current study to evaluate its suitability for regression-based control. For comparative purposes, a CNN regressor and an LR were also implemented.

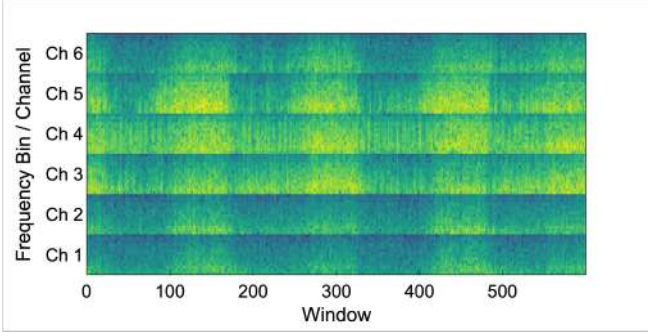

Fig. 2. An example spectrogram across the 6 channels (Ch). The y-axis shows the frequency bins in each of the 6 channels, and the x-axis shows the EMG data windows.

1) Transformer Regressor: Learnable positional encoding [15] prepared the captured EMG data for input to the transformer regressor's architecture. The architecture consisted of 4 encoder layers, each of which included a 64-dimension key space and 2 attention heads. The feedforward dimension within these layers was also 64. A dropout rate of 0.5 was applied within the encoder layers. A multilayer perceptron (MLP) with three layers followed these encoder layers, each with 128 units. Layer normalization and rectified linear unit (ReLU) activation were used throughout the MLP. A final linear layer used the MLP outputs to produce regression-based model predictions.

2) CNN Regressor: To ensure a fair comparison, the CNN regressor's architecture was kept similar to that of the transformer, with the 4 encoder layers replaced with 4 convolution blocks. Each block consisted of a 2D convolution layer, a batch normalization layer, and a ReLU activation layer. Each convolution layer had 64 filters, with a size of 3x3. The first three convolution blocks also included a 2D maximum pooling layer, with a pooling size of 2x1 and a stride of 2x1.

3) Linear Regressor (LR): LR has been established as a baseline in the literature [16]. In this work, LR was implemented on a per-DOF basis and the coefficients were obtained using ordinary least squares [16].

4) Description of Five Regression-Based Models: The EMG data were divided into 3 categories: training, validation, and testing. Specifically, five models were developed and validated, with each differing based on the data with which they were trained. Testing data were extracted from 5 seconds of rest and the final 4 occurrences of each oscillation performed in all 3 limb positions. Of the remaining EMG data, 75% were used for training of all models and 25% were used for validation of all models.

Models 1–3: The first three models were trained in a within-subject fashion, using data only from the active participant.

1) ***Standard Model (SM):*** A model trained with a total of 15 seconds of rest and 4 DOF oscillations (2 single-DOF, 2 multi-DOF) performed 12 times each, with the elbow bent at $90°$ (as per standard pattern recognition-based training routines [17]).
2) ***Full Model (FM):*** A model trained with the first 5 seconds of rest and the 4 DOF oscillations performed 4 times each in 3 limb positions (with the amount of resulting data equal to that of the SM, as less data were used per limb position).
3) ***Few-Shot Model (FSM):*** A model trained with the first 5 seconds of rest and the 4 DOF oscillations performed only once in 3 limb positions (as with the FM, but with only a single repetition of each DOF oscillation [18]).

Note that additional EMG data were collected with the elbow bent at $90°$ (as detailed in Section II-C) to facilitate training of both the SM and FM using the same amount of data.

Models 4–5: Two additional models were trained in a transfer learning fashion. Each model was pre-trained using the data from the nine other participants (15 seconds of rest and 12 seconds of each oscillation in 3 limb positions, as in the FM, per participant). The models were then adapted for the (10^{th}) participant under test by replacing their final layers and fine-tuning them using that participant's data. Subsequently, all previous layers were unfrozen and further trained using the same data. The two models with transfer learning included:

4) ***Pre-Trained Standard Model (PT-SM):*** A pre-trained model, fine-tuned for the new participant using data consistent with the SM.
5) ***Pre-Trained Few-Shot Model (PT-FSM):*** A pre-trained model, fine-tuned for the new participant using less data consistent with the FSM.

Note that LR transfer learning models were not tested, as LR is not conducive to this kind of knowledge transfer.

F. Exploration of Single-DOF vs Multi-DOF Training

To enable robust simultaneous and independent control of multiple DOFs with regression, a trained model must be equipped to handle combinations of DOFs. Researchers often assume that these combinations are implicitly learned by the models using training data only from single DOF activations [17]. In this work, we explicitly explored this assumption by comparing the transformer regressor trained with: 1) single-DOF data only, 2) multi-DOF data only, and 3) both single *and* multi-DOF data. To do so, we mimicked the FM training approach, but modified the inclusion of the DOF oscillations accordingly.

G. Performance Evaluation

Since regression can be used to control two DOFs simultaneously at varying speeds, each window was labelled with two values: one that represented the hand open/close DOF and one that represented the forearm pronation/supination DOF. Each value ranged from -1 (full hand close or full forearm pronation) to 1 (full hand open or full forearm supination), where 0 represents rest.

This data labelling scheme was based on slight modifications to a "squared proportional control" approach presented in a previous work [19]. Pilot testing of the models in an online, user-in-the-loop target acquisition test confirmed that the approach yielded a higher fidelity of control during low proportional control values (leading to an improved user experience). The labelling modifications introduced in this study included the establishment of low and high thresholds to define the shape of the target shown in Fig. 3. The low threshold was set to encourage the model to eliminate unwanted jitter during rest. It is worth noting that though many regression studies do not explicitly incorporate this threshold in labelling, they do set a threshold as a post-processing step to eliminate jitter [20]. By establishing a low threshold in labelling, our work both eliminated the need for a post-processing step and allowed each model to inherently handle hand-at-rest conditions. Furthermore, establishing a high threshold should enable users to achieve maximum speeds without overexertion during prolonged use. Although these modifications have only a minor impact on the offline results presented in this preliminary work, our experience suggests that they may be important for supporting goal-oriented online control.

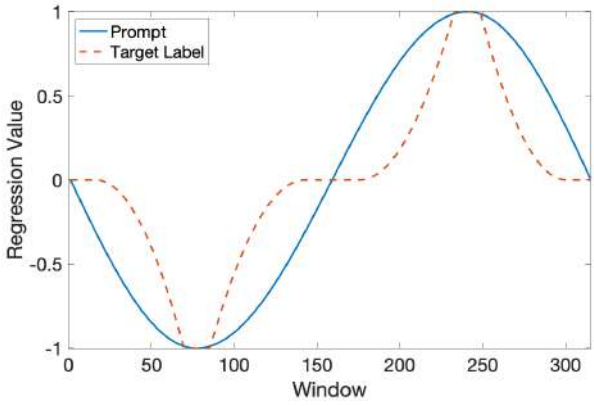

Fig. 3. Labelling scheme outcomes. The solid blue line represents the prompt displayed to the user and the dashed orange line shows the corresponding target label for the given window.

The performance of the models was evaluated by computing the coefficient of determination, R^2, values between the predictions and target labels assigned to the test data.

Finally, to identify any differences between the control models under investigation, a one-way repeated measures analysis of variance (RMANOVA) was performed on the median R^2 values across all limb positions. Data were normally distributed. When the resulting controller effects were deemed significant (that is, when the Greenhouse-Geisser-corrected p-value was less than 0.05), pairwise comparisons (t-tests) between the controllers were conducted. Pairwise comparisons were considered significant when the Šidák-corrected p-value was less than 0.05.

III. Results

Fig. 4A depicts the R^2 values by regressor (transformer, CNN, and LR) as averaged across all limb positions. When comparing within model types (SM, FM, and FSM), the statistical comparison revealed both the transformer and CNN outperformed the LR in all 3 cases. Specifically, the transformer outperformed the LR with $p<0.001$ in 3 all cases and Cohen's $d>0.401$; while the CNN outperformed the LR with $p<0.001$ in 3 all cases and $d>0.3670$.

Fig. 4B illustrates the transformer regressor's R^2 values when tested in each of the three limb positions. A high median R^2 value (close to 1) indicated that a model type was a good fit for the data. Overall, the FM predictably resulted in the highest median R^2 (0.80) across all participants. However, the PT-FSM yielded a close second-highest median R^2 of 0.76.

When comparing the 5 different model types within the transformer regressor, as depicted in Fig. 4C, the statistical

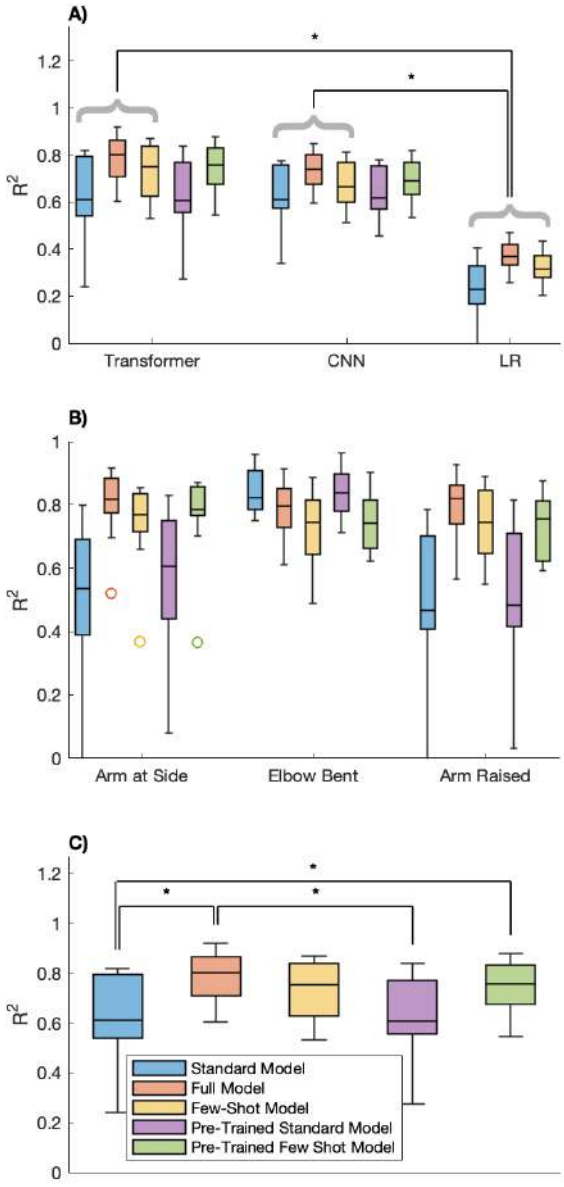

Fig. 4. Box plots illustrating R^2 values for each of the five control models investigated, with results presented A) by regressor (transformer, CNN, and LR), each across all limb positions, with statistical significances between regressors, and B) the transformer regressor in each limb position, and C) the transformer regressor across all limb positions, with statistical significances between models. * denotes p-value < 0.05. Note that in panel A), curly brackets indicate that statistical comparisons were performed on each type of model (i.e., Standard Model vs Standard Model, etc.).

comparison revealed that the R^2 values of the FM was significantly better than the SM (p=0.006, d>0.178) and the PT-SM (p=0.015, d>0.156). Furthermore, the PT-FSM performed significantly better than the SM (p=0.033, d>0.135). Notably, the FM was not significantly different from the FSM or the PT-FSM.

Fig. 5 illustrates the R^2 values of the FM when training a transformer with single- *or* multi-DOF data, or with both single *and* multi-DOF data. The highest median R^2 value (0.80) across all participants was achieved when the FM was trained with single data *and* multi-DOF datasets. Performance dropped significantly when using only the multi-DOF (p<0.001, d>0.173) or single-DOF (p<0.001, d>0.261) data. Training with only multi-DOF, however, was significantly better (p=0.047, d>0.088) than only training with the single-DOF cases.

IV. Discussion

The human arm can perform combined movements in multiple limb positions; for instance, reaching overhead to grasp an object while slowly rotating the wrist. Regression-based myoelectric control models can yield simultaneous control of multiple DOFs and independent speed control to better mimic the function and movements of an intact upper limb [3]. This control, however, comes at the expense of longer training routines that introduce user burden. Additionally, control models that predict movements across multiple limb positions can further increase training durations. For these and other reasons, classifiers remain more commonly implemented for upper limb prosthesis control, with model training conducted in a simple bent elbow position [17]. The findings from this work suggest that a shift to the use of regressors and multi-limb position training for myoelectric control is feasibly on the horizon, through the use of transfer learning and FSM approaches.

Our research capitalized on the positive attributes of transformers to implement regression-based myoelectric prosthesis control. Transformers are deep learning networks that have emerged as an architecture used for natural language processing and computer vision applications [21]. Their ability to capture long-term relationships and contextual patterns in time series signals has opened new opportunities for control that uses EMG data. This study demonstrated that regression models (as implemented using a transformer) can successfully provide accurate movement predictions across varied limb positions (when trained with data from each position).

Our results also indicated that although both transformers and CNNs significantly outperformed the LR, the transformer was slightly (though not significantly) better than the CNN. Still, the transformer exhibited larger improvements, as evidenced by the larger Cohen's d values. Our findings corroborate results in the broader literature that demonstrate the efficacy of temporal models when employed for EMG pattern recognition [22], [13].

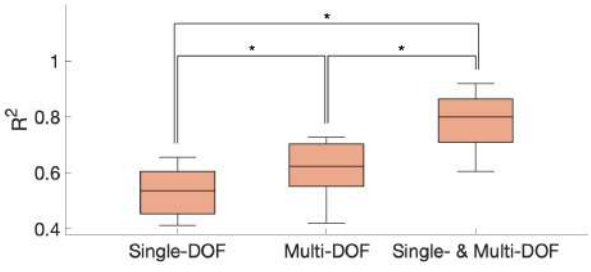

Fig. 5. Box plots illustrating R^2 values when training the transformer (FM) with single- or multi-DOF data, or both single and multi-DOF data. * denotes p-value < 0.05.

Recall that our work considered whether single- or multi-DOF training datasets (or both) provided regression-based models with the necessary data to yield accurate movement predictions. The FM was found to perform the best when trained with both single- and multi-DOF muscle contractions. This same training requirement was expected to hold true for all five models implemented through this study's transformer regressor. As such, the research findings and discussion that follow are based on this combined single- and multi-DOF training approach.

The transformer regressors outperformed the LR and the CNN while using a window that is $\approx 5\text{x}$ shorter in duration. This observation suggests that using a large window size is not a requirement when employing temporal models, likely as they are able to leverage temporal information across windows. Indeed, further pilot testing revealed that there were minimal differences in performance when increasing the window length from $32\,\text{ms}$ to $150\,\text{ms}$ for the transformer. On the other hand, this same testing revealed a significant reduction in performance for both LR and CNN regressors when decreasing the window length, further reinforcing our hypothesis that the temporal information learned across windows by the transformer alleviates the need for large window lengths.

We also compared the predictive accuracy and data fit of the five transformer models under investigation in this study. The models ranked as follows, from best to worst: 1) FM (R^2=0.80), 2) PT-FSM (R^2=0.76), 3) FSM (R^2=0.72), 4) PT-SM (R^2=0.61), and 5) SM (R^2=0.61).

As anticipated, the FM (trained with 5 seconds of rest and 4 of each oscillation performed in 3 limb positions) was top-ranked. It took a total of 3.45 minutes of training time to capture its required EMG data. Surprisingly, the PT-FSM (pre-trained by 9 participants who performed 5 seconds of rest and 4 of each oscillation in 3 limb positions, and then fine-tuned to a new 10^{th} participant) was a close second. It took only 1.05 minutes of retraining time to capture its participant-specific data—a 2.4-minute, 70% decrease in collection time versus the FM. The PT-FSM also did *not* have a significantly different median R^2 value versus the FM. Together, these findings demonstrated that transfer learning can indeed reduce the amount of training data required for regression-based models, without sacrificing model predictive accuracy.

Our work also reinforced that training a model in more than one limb position positively impacts overall device control performance. Consider that the lowest-ranked SM (trained with 15 seconds of rest before each of 4 oscillations performed 12 times, with the elbow bent at 90° as per standard pattern recognition-based training routines [17]), performed the best when tested in the same limb position in which it was trained. Conversely, it performed poorly in all other limb positions. This finding aligns with the literature surrounding the confounding factor of the limb position effect, which identifies that device control performance degrades in untrained limb positions [4]. This current work, therefore, concurs with recommendations that regression-based control solutions should be trained across multiple limb positions.

In addition, this study allowed us to consider alternative means of reducing the training burden. Interestingly, the third-ranked FSM performed favourably, even *without* implementing transfer learning. This finding supports the notion that few-shot models eliminate the need for long data collection sessions, as reported by Godoy *et al.* [18]. In their study, a few-shot approach is recommended for scenarios where data are scarce, collected in different sessions, or collected for several users. Consider that in this work, the FSM was trained with limited EMG data (trained with 5 seconds of rest and only 1 of each oscillation performed), but that the data included signals from three limb positions (that is, a richer training dataset was captured). Despite the limited training samples in each limb position, the few-shot transformer model performed well when compared to the FM. This particular finding suggests that few-shot learning is a promising means of reducing training burden, and reaffirms that more variability in training is more important than simply more data.

Finally, it is noteworthy that the targets used to train and test the models in this work were a modified version of the prompted sinusoid, as shown in Fig. 3. While this labelling scheme had minimal impact on the findings of this offline study (the re-labelling was applied equally to both the training and testing labels, providing a consistent mapping that the models could learn), our empirical observations suggest that it more accurately reflects user behaviours when responding to sinusoidal prompts. Furthermore, pilot results from our ongoing work using the models presented herein and similar models for online control, suggest that users may prefer the finer distinction between slow and fast movements afforded by such mappings. Regardless, the potential impacts of user compliance in regression training [23] and how best to map these models to control outputs is an interesting area worthy of further research.

V. Conclusions

This work uncovered promising methods to reduce lengthy and burdensome training routines inherent to regression-based myoelectric prosthesis control solutions, that are trained across multiple limb positions. These methods include the adoption of transformer regressors, transfer learning techniques, and a few-shot model approach. We recognize that our work is offline and as such, these results may not fully explain subsequent real-world control experience. Consequently, the next steps should include real-time testing of the control methods presented. We also recognize that the EMG data collected in this research results from isotonic muscle contractions, whereas isometric contractions are used to control actual myoelectric prostheses. Future work should confirm whether the control methods that we investigated yield similar results under real-use conditions. Finally, we acknowledge that only ten participants without amputation were recruited for this study. We recommend the work be repeated using more participants, as well as with those who

have limb loss to confirm results. Despite some limitations, this work is a valuable proof of concept that lays the foundation for exciting new myoelectric prosthesis control opportunities, with device movements approaching those of a healthy human wrist and hand—that is, with simultaneous control of multiple DOFs, executed at varied speeds, and performed reliably in multiple limb positions.

A First Design of the Inertially Correct Testbed Arm Platform for Testing of Wearable Devices

William White[1], Jonathan Hong[1], Scott Uhlrich[1], and Edoardo Battaglia[1]

***Abstract*— Wearable systems for rehabilitation and assistive applications presents significant challenges related to personalization to individual size and shapes of the users' limbs, which can often turn design into a slow and challenging trial and error process. Additionally, because of the limited amount of body shapes and sizes that can be tested in research settings, wearable systems risk being ill-suited when it comes to adapting to individual users, and can be perceived as difficult or uncomfortable to interact with. In this paper we propose to address this challenge through the design of simple and relatively low-cost physical simulators. In this first iteration we offer a proof of concept of this approach with the Inertially Correct Arm, a physical prototype that is designed to have the shape and inertia properties consistent with anthropometric data on the average arm for male population and is intended as a tool to aid development of a soft arm-swing exosuit. In addition to the inertia properties, we tested a few different configurations for damping obtained through deformable pads compressed between plates at fixed distances, and compared the results of free swinging from a 90 degree shoulder elevation from the ICT with results from human participants, as quantified by dynamic time warping distances. Our results show that the system follows human data more closely when a higher level of joint resistance is present.**

I. INTRODUCTION

There is an ever-increasing number of people with physical disabilities – around 16% of people in the world according to World Health Organization figures [1], with comparable numbers in the United States [2], [3] and Europe [4]. The number of people affected by pathologies that cause severe impairment, such as stroke, Parkinson's disease or other neurological disorders has been increasing steadily every year [5]–[7]. Overall, recent estimates suggest that one in three people in the world will be in the position to benefit from rehabilitation services because of an illness or injury at some point in their lives [8]. It is no surprise then that research on devices that can help facilitate this type of therapy and/or provide assistance for people with disabilities have garnered a strong interest, with applications in therapy for both lower and upper limb [9]–[15].

A particular class of robots used in assistance and rehabilitation are wearable robots, which generally take the form of exoskeletons or exosuits that are kinematically coupled to the users' limbs [9], [10], [12], [16]. This class of systems has proven to be versatile in its ability to not only provide rehabilitation for a variety of conditions, but also be used in applications augmenting the capabilities of healthy individuals [15], [17], [18]. However, their design presents unique challenges, related to the fact that actuators, links and sensing elements are coupled to the limbs of the user, leading to the necessity for the system to be able to apply any desired mechanical action in a way that can adapt to different shapes and sizes, and is safe for the user. This problem has been approached with a variety of designs, from systems that only apply forces to the lower arm, [19], to systems that connect directly to the upper limb and solve the challenge created by the tighter coupling with a more careful kinematic design [16]. However, the coupling between the user and the wearable system always has to be kept in mind, and is subject to the specific body size of the user.

This leads to challenges in the design of new systems, where modeling is generally followed by a trial and error process and careful testing. While this was done for many systems in the state of the art, it tends to be time consuming. Additionally, safety is not the only requirement for a wearable system. In [20] Sugawara et al. reported an abandonment rate of around 19% for assistive devices from a survey of 1390 users, with the rate being higher for orthoses and prostheses, and discomfort while using the device being reported as one of the leading causes for abandonment. This is consistent with a more general trend of abandonment of wearable devices that has been observed across different applications [21], [22]. It would then be helpful to be able to automate part of the testing process with evaluation on bodies of different shapes and sizes.

In this paper we proposed a first iteration of an approach to streamline this design process by building physical simulators. Specifically, we introduce the Inertially Correct Testbed arm (ICT), an upper limb physical simulator that is designed to have inertia properties consistent with the average human arm for a male user, which we named taking inspiration from the Anatomically Correct Testbed hand introduced in [23]. We will describe the design rationale and process, the physical construction of the prototype, and a test where we compare kinematic data for a passive fall movement from a 90 degree shoulder extension for both human participants and the ICT with deformable pads with different levels of contact force, to simulate passive friction/damping that is naturally present in the human body, for an intended application as a test platform for an arm swing soft exosuit [24].

II. CONCEPT

Construction of physical simulators of the human body is relatively under-explored in the state of the art, and is for the most part represented by simplified models in

[1]William White, Johnathan Hong, Scott Uhlrich, and Edoardo Battaglia are with the Department of Mechanical Engineering University of Utah, 201 Presidents' Cir, Salt Lake City, UT 84112 USA william.white@utah.edu

medical trainers and mannequins [25]–[27]. For what concerns biomechanical simulations, very powerful tools are available in software simulation, such as OpenSim [28], which enable analysis of motion as well as muscle activity and musculoskeletal models of varying complexity. However, while these simulation tools can offer important insights, they were not designed to test wearable devices and robots, and as such can be helpful in defining models that can be considered in the design, but offer limited support for simulation of the devices themselves. Some physical simulators with more advanced features do exist, but they are generally targeted for specific application, e.g. the study of kinematics and motor control in human hands [23], [29].

The motivation behind this work comes from ongoing work on development of a soft arm swing exosuit for gait rehabilitation [24], for which we felt the need for a physical platform to evaluate different ways of attaching our system to the arm and/or different types of controllers. This informs the design requirements that we set out to meet in this work, specifically: (i) we focus on simulations of passive arm movements, since muscular activity in arm swing, while present, is very limited, leading in general to very compliant behavior in the arm [30]; (ii) the arm simulator should have inertia properties close to those of a human arm; (iii) the physical simulator should have mechanical properties at the joints comparable to those of a human arm in a relaxed state; and (iv) given that the long term goal is to have different personalized physical simulators for a variety of body shapes, the system should be able to be fabricated in a relatively simple and low-cost way.

For what concerns (ii), we referred to anthropometric data collected by Plagenhoef et al. in [31] where authors collected data on weight and center of mass position for different body parts in both men and women, and reported them as a percentage of body weight and limb length. The arm simulator designed in this work is intended to represent the arm of a man weighting 153 pounds (approximately 69.4 kg). Point (iii) is more challenging, both because modeling of mechanical properties of joints is difficult, and because building adjustable mechanical damping systems to mimic them is non-trivial. In this work we evaluate the potential effectiveness of using deformable rubber pads with different levels of compressions to simulate this aspect. In the next section we report the design details for our proposed system.

III. System Design

A. Hardware

The Inertially Correct Testbed arm (ICT) was built in three distinct parts as shown in Figure 1: upper arm, lower arm, and hand. Each of these segments were constructed using silicone, to simulate human tissue, and 3D printed plastic support elements, simulating the bone. The target weight (see Table I), center of mass (COM), and moment of inertia of each segment was determined using the previously mentioned work from Plagenhoef at al. [31], and the weight was confirmed with a scale on the physical prototype (Table I).

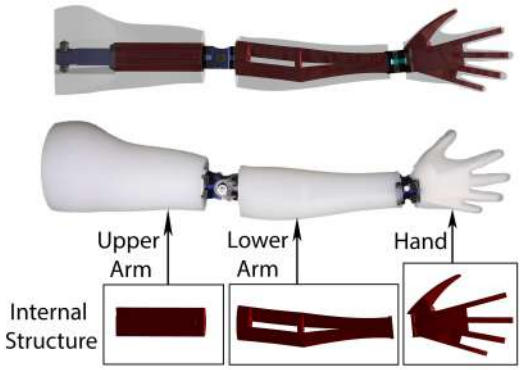

Fig. 1: Side view of the Inertialy Correct Testbed arm (ICT) and the obscured internal structural elements.

TABLE I: Estimated [31] and Actual Mass of the Inertialy Correct Arm. Weights were obtained using a digital scale with a resolution of $\pm$1g and a maximum measurement weight of 15 kg.

	Upper (g)	**Lower (g)**	**Hand (g)**	**Arm (total) (g)**
Nominal	2255	1298	451	4004
Actual	2285	1371	455	4106

In order for the ICT to better aid in the testing of ergonomic exoskeletons we molded a flexible silicone, EcoFlex 00-30 with a 1:1 ratio, into the shape of a human arm. A mold was created by segmenting a mesh rendering of a human arm in three segments as described above. The mesh was then modified to accommodate the joints for each segment (top of Figure 1). The joints were not contained within the siliconesil to prevent the silicone material properties from affecting the baseline elasticity and damping of the joints. By using silicone to construct the majority of the ICT we were able to evenly distribute the weight of each arm segment while still maintaining a coarse approximation of the compliant behavior of human arm tissue.

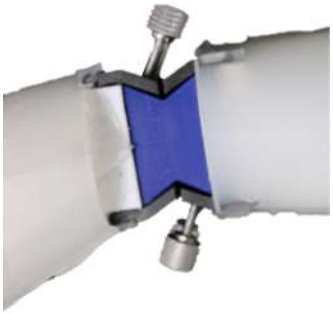

Fig. 2: Dovetail clamp and joint connections.

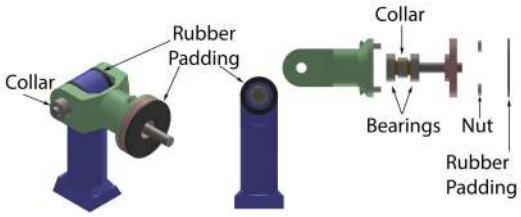
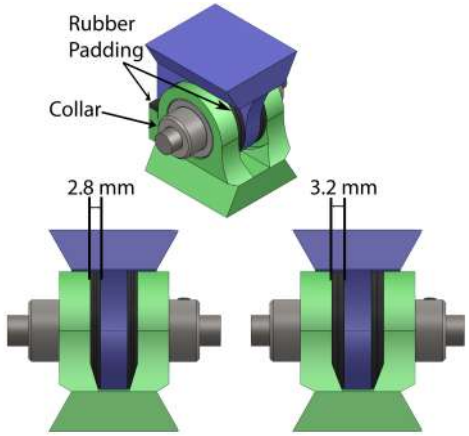


While the silicone makes the ICT durable and aids in ergonomic design, it would not be able to maintain the proper structure of each arm segment on its own. Custom designed rigid structures, intended to simulate the bones, were constructed from polylactic acid (PLA) using a 3D printer (see Fig. 1). These rigid structures serve a few

different purposes: they are used to create attachment points for the joints between each segment, they provide support for the silicone and maintain the shape of the ICT, and they have a geometry designed to place the center of mass for each limb at the location suggested by [31]. Because the mechanical properties and density of PLA are not the same as human bone, the supports were not modeled as human bones, but had a custom structure to both have better structural integrity and cause the overall system to have inertia properties comparable to those reported in [31].



The process described so far covers inertia properties of the arm, but to build a system that has equivalent mechanical properties and kinematic behavior we will also need to have appropriate stiffness, damping and friction at the joints. To facilitate iterative testing towards these desirable properties, the connection point between each arm segment utilizes a dovetail clamp (Figure 2). This solid aluminum clamp is fastened to each segment by the use of a screw and nut. Joints are held in place by the pressure exerted by the screws, but can easily slide out of the clamp when unscrewed.

In this first design for the system, we focused on a simplified model for the shoulder joint. Upper limb and arm exoskeletons typically use a ball-and-socket joint mechanism for the components that are attached to the shoulder [16]. While this is the solution that we had considered originally, we opted for a simplified two degrees of freedom (d.o.f.) design for this first iteration for the following reasons: (i) commercially available ball-and-socket joint mechanisms typically have limited range of motion; (ii) while the kinematics of the shoulder joint is often approximated as a ball-and-socket joint, this is also a simplified model that does not match the kinematic behavior of a human shoulder [32]; and (iii) for our intended application, we are mostly concerned with arm swing movement. For these reasons, we decided to implement a simplified shoulder joint with two d.o.f. to provide flexion and abduction, but not rotation. As we mentioned in the previous section and as we will show in the evaluation section, the main focus in this work was to evaluate a few different levels of damping for the arm joint, and compare passive kinematic behavior with the behavior of human arms in passive arm swing movement. Given the modular design for the connections, the joints can be swapped out and replaced easily, and the design of a more complex and anatomically correct shoulder joint is left for future work.

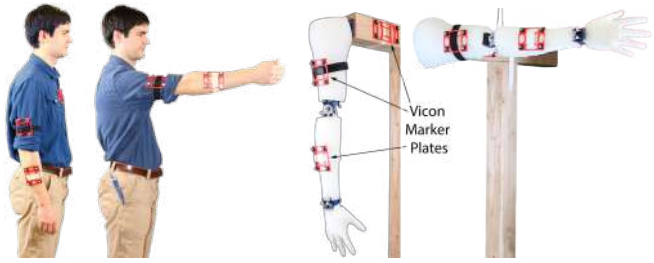
Figure 3a shows the current simplified shoulder joint, which is comprised of two parts: an inner *I* and outer *U* shaped piece. The *I* component uses two sealed 8 mm stainless steel ball bearings stacked in series to reduce friction caused by ab/adduction of the ICT. Similarly, in order to reduce friction in the flexion degree of freedom, the *U* was designed with a chamber containing two more bearings held in place by a cap fastened as shown in Figure 3a. An 8 mm 1040 carbon steel rotary shaft mounted perpendicular to the ground was inserted into the *U*'s bearings and held in place using a stainless steel screw collar. A similar shaft was used to connect the *I* and *U* components through the bearings in *I* with screw collars mounted on the outside of the *U*.

(a) 2-DOF U-joint.

(b) 1-DOF axial joint in the highest (left) and lowest (right) friction configuration.

Fig. 3: ICT shoulder joint (a) and elbow joint (b). Each joint has rubber disks separating the inner (blue) and outer (green) components. The amount of friction between components can be adjusted by changing the distance between components. Spacing between components is measured from the most compressed state, 2.8 mm apart, to the least compressed state, 3.2 mm apart.

The elbow was built as a single axis joint with a limited range of rotation (Figure 3b). Similar to the ICT's shoulder, the elbow is comprised of an inner and outer piece. A single bearing is placed in the inner piece parallel to the two bearings in the outer piece. These bearings are placed on either side of the outer piece and the assembly revolves around a shaft passed through the bearings. The shaft is held in place by a pair of screw collars on either side of the outer piece. To prevent the elbow from rotating further than desired a flat platform was placed on the back of each piece. This platform was then padded using Viton rubber to prevent jarring stops. Finally, unlike the shoulder and elbow the wrist joint was built as a solid block, made from the same PLA as the other joints. This was done to reduce the complexity of the design as we assumed that the wrist would have little affect on ICT.



Friction between joint components was added through the use of pairs of 1.6 mm thick Viton rubber washers. These washer were placed on both inside and outside joint components as well as between the shoulder's *U* component and the mounting block (see Figure 3 for a visualization of the elbow). By altering the amount of space between

each set of washers we were able to change the amount of resistance in each joint, both through increased friction and change in the properties of the pad through compression. This will cause the ICT to lose energy as it is swinging, with the goal of making it behave more similarly to a human arm. Viton rubber was chosen for its durability and high frictional coefficient which allowed for greater damping. The space was set to vary from a minimum level of resistance where the pads were barely touching (visualized for the elbow on the bottom-right drawing of Figure 3), to the highest possible pressure that we were able to achieve with the loading system (which corresponded to a 0.4 mm deformation of the pad as measured with a caliper). An additional intermediate level was considered, for a total of three levels of resistance on each joint (which we will refer to as low, medium and high resistance throughout the paper). Since we are interested in evaluating the system for arm swing movement, we considered only changes to the elbow and shoulder flexion/extension (or elevation) joints, for a total of nine possible configurations.

IV. Evaluation

A. Experimental Setup

We performed a user study with human participants to compare the kinematics of arms swinging freely with those of the different configurations of the Inertially Correct Testbed arm (ICT). For this study, we recruited eight healthy males (mean and standard deviation: age = 26.1 ± 4.4, height = 179.1 ± 8.1 cm, weight = 73.5 ± 11.5 Kg). Prior to the study, the subjects gave written informed consent to participate. The study was approved by the Institutional Review Board of the University of Utah under IRB number 00154923.

(a) (b)

Fig. 4: We evaluated the ICT in an arm swing task by comparing kinematic data from participants dropping their arm from a 90 degrees angle (a) with the same data measured on the ICT, which was raised and released using an elastic cable held by one of the experimenters.

Kinematics were measured by a 12-camera motion capture system (Vero, VICON, Oxford, UK) for both human participants and the ICT, with a sampling frequency of 100Hz. In order to track motion during the experiment, mounting plates were designed to place markers for the Vicon motion capture system. These plates were made with a platform at each corner and curved slightly to better fit on a human arm. The Vicon markers were attached to the platform with double sided tape. To help reduce the effect the plates might have on the motion of the arm, as much material as possible was removed without the structure collapsing. Elastic straps were then threaded through the platform allowing it to be attached to the participants' arm. An equivalent setup was used for the ICT, with four reflective markers on the lower-arm, upper-arm, and cross beam which served as its "chest" area (Figure 4b). For the ICT, we tested different combinations of levels of damping/friction for the shoulder and elbow by varying the amount of pressure applied between rubber pads as described in Section III, with three levels of resistance being considered for each joint (low, medium and high), for a total of nine possible configurations.

For both human participants and the ICT, each trial consisted of lifting the arm to 90° shoulder elevation, with the elbow joint being perfectly straight, and then letting the arm drop and swing freely until it came to rest. To facilitate consistency, human participants were instructed to do this by pulling their arm forward and straight in front of them as much as they could comfortably, while keeping their torso straight and still, and were asked to be fully relaxed when they let their arm drop. They were also instructed to wear relatively light clothes (such as a t-shirt or a button down shirt), to prevent potential added resistance that could come from thick clothing. For the ICT, an experimenter used a cable wrapped around the elbow joint to lift it to 90° shoulder elevation. This ensured that the elbow joint was straight before the arm was dropped, and also facilitated consistency in maintaining the correct elevation since the experimenter could feel the direction and amount of the force being applied by the weight of the ICT. A single session of ten repetitions was done for each participant and each ICT joint configuration.

B. Data Processing

Experimental data were analyzed using MATLAB (The MathWorks, Inc. Massachusetts, USA) and the R Project for Statistical Computing (version 4.4.1). Specifically, joint angles were calculated in MATLAB from marker data, and a joint angle trajectory for the shoulder elevation was calculated for each session. Joint angle data was then segmented to identify each of the ten repetitions in each session, leading to ten segments for each participant/ICT configuration. The segmentation was accomplished by selecting as start for each trial the sample where the joint angle was decreasing from a peak value, and as end the second local minimum in the oscillatory behavior. Figure 5 shows a plot of a full session (i.e., ten trials) for one of the participants and one of the ICT configurations, with segmented trials colored in red.

For each ICT configurations, and for each of the segmented trials, dynamic time warping as implemented in the R package `dtw` [33] was used to calculate the distance from each segmented trial from each participant. Dynamic time warping can be used to compare signals that have different lengths in time, by identifying an alignment between two time series that deforms them on the time axis to minimize the distance between them. The choice for the start and end

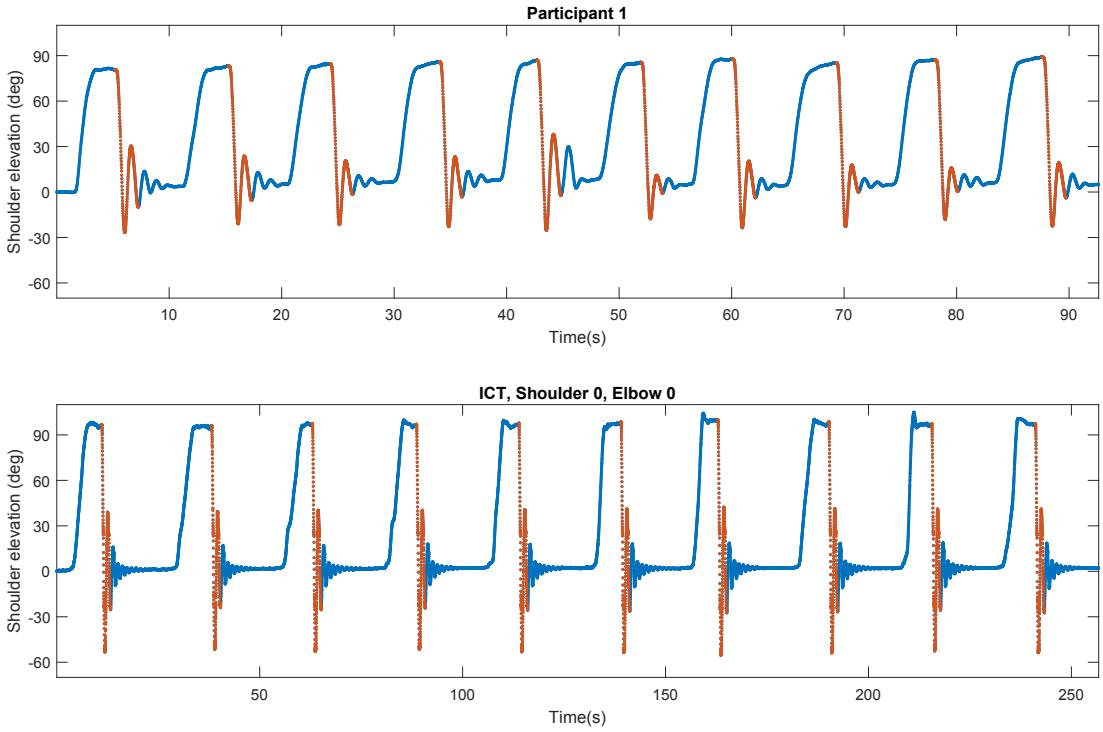


Fig. 5: Representative plots for human (top) and Inertially Correct Testbed arm (bottom). Segmented trials are shown in red.

of the segmentation was done to make such comparison meaningful: in general, systems with lower damping and friction will keep oscillating for a longer amount of time, but a difference can already be seen in the amplitude of the first few peaks, and using segments were the same oscillations are present for all systems considered will allow to match points in the time series with dynamic time warping more organically. The dynamic time warp distances for each pair of segmented trials were calculated using the ICT segment as query and human participant segment as reference, with an asymmetric step pattern to ensure one-to-one alignment, normalized with respect to the length of the ICT segment sequence according to standard practices in application of dynamic time warping [34]–[36].

C. Results

We compared dynamic time warping distances between ICT and participant trajectories for different levels of damping and friction at the joints, obtained by compressing deformable rubber pads with three different levels of pressure (low, medium and high) as described in Section III. Figure 6 shows box plots for the main effects from each joint on average data across all participants. It can be seen that lower levels of resistance are associated to higher distances between ICT and human trajectories (which is reasonable, since the ICT arm is under-damped when both joints are set at a low level of resistance). This effect seems quite pronounced for the resistance at the shoulder joint (especially for what concerns the low level of resistance), while it appears to be much smaller for the elbow joint.

We performed statistical analysis to better evaluate these effects. We first ran a two-way ANOVA for main effects and interaction from both joint resistances, but examination of a QQ plots of residuals suggested strong non-normal behavior. As a consequence of that, we ran instead the non-parametric equivalent Scheirer–Ray–Hare Test, which showed a very strong significant effect for the shoulder joint ($H(2, 63) = 28.7, p < 10^{-16}$) and non-significant effects for the elbow joint and interaction ($H(2, 63) = 1.52, p = 0.468$ and $H(4, 63) = 0.318, p = 0.989$ respectively). We followed up this result with a post-hoc Dunn test with Bonferroni correction for the p-values, which showed a significant difference between high and low ($p_{adj} = 4.78 \times 10^{-7}$) and between medium and low ($p_{adj} = 0.00106$), but not between medium and high ($p_{adj} = 0.285$).

These results suggest that the rubber pads that we used, while helpful when compared to the plain joints, are limited in their ability to get the ICT to a level of damping comparable to that of a human arm, or at least suffer from diminishing returns. A qualitative insight into this can be obtained from looking at a few of the segmented trials, extracted from three participants and the high/high and low/low ICT configurations, respectively (Figure 7). The trials from participants 6, 1 and 5 show different levels of damping (which could be ascribed to individual differences, either in their biomechanics or the state of relaxation that

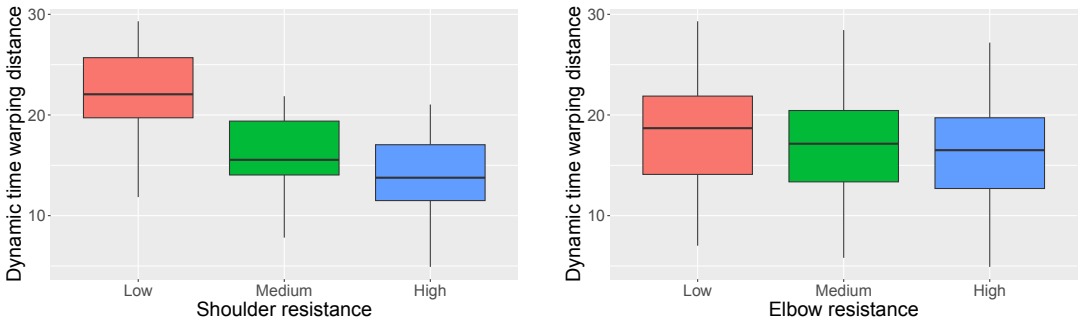

Fig. 6: Box plots showing the effect on overall dynamic time warping distance for the shoulder flexion/extension joint of different levels of resistance at the shoulder (left) and the elbow (right).

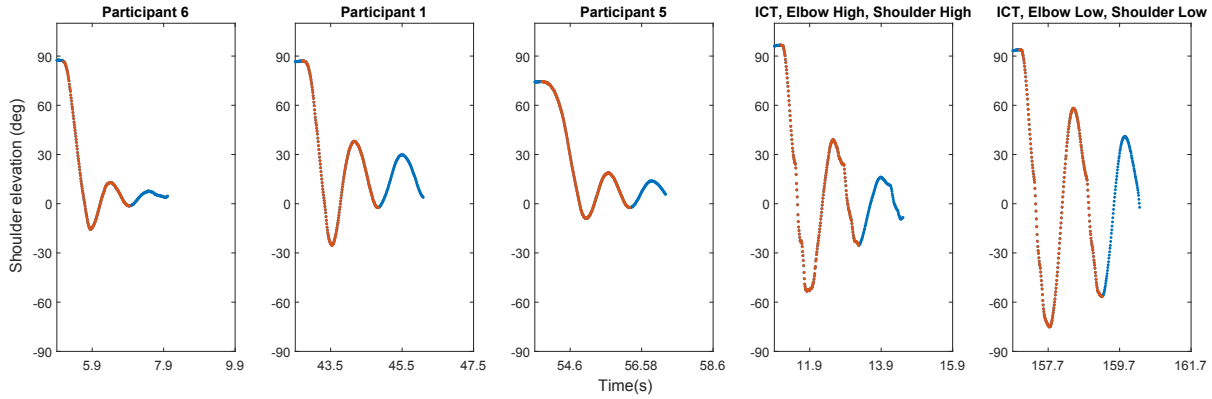

Fig. 7: Segments from individual trials from participants 1, 5 and 6, and from the high/high and low/low configurations of the ICT arm. Segmented data is shown in red.

they were able to achieve when dropping their arm). Of the two ICT trials, the high/high configuration is closer to trials from all participants, and appears relatively similar to the trial from participant 1. However, some irregularities in the trajectory for both ICT trials can be observed, which could be caused by the friction from the pad.

V. CONCLUSIONS

In this paper we have introduced a first prototype of the Inertially Correct Testbed (ICT) arm, which is intended to replicate inertia properties of a human arm for applications in test and evaluations of wearable devices for rehabilitation and assistive applications. In this first iteration of the design, we limited the scope to evaluation of kinematics in a free arm swing movement, evaluating the effect of applying deformable rubber pads with different level of pressure (obtained by changing the spacing between the pads) on differences between kinematic in a pool of human participants and the ICT. Results show that adding tightened pads at the shoulder improves the result significantly when compared to no damping, although some differences in the kinematics remain. We also showed a qualitative comparison of individual trials from two participants and two ICT configurations, which indicate that differences can be qualitatively smaller for some participants, but also highlighted some irregularities in the trajectory of the ICT which we believed to be cause by friction from the pad.

The fact that the trajectories were qualitatively similar is encouraging for what concerns our first intended application as a tool to support development of the arm swing device introduced in [24]. However, the joint resistance in the simulator might still not be sufficient to match human kinematics at a general level. Aside from the limited scope, which is for now focused on evaluation of arm swing movement, this work also has some limitation related to the fact that we are defining inertia property of the arm based on a percentage of body weight, which is in general an approximation. Still, the fact that we are able to obtain trajectories that are qualitatively similar for some participants even with the coarse solution that was tested to simulate damping is encouraging.

Future work will focus on evaluating alternative solutions to dampen the joint. We reached the limit of what can be achieved with Viton rubber, but softer material could improve performance in terms of matching human kinematics. Additionally, we are planning to start testing the arm swing exosuit introduced in [24] to refine controller design, and will complement traditional first evaluations with healthy participants with bench testing on this platform. Long term, a more anatomically correct design for the shoulder would also be desirable, and together with including actuation to simulate muscle tension could lead to applications with a broader scope.

Quantifying the Sense Agency: A Forced Choice Paradigm for Assessing Intentional Binding During Upper Limb Movements

Momchil Gavrilov[1] Katherine A. Jordan[2] Weiwei Zhou[3] Wilsaan M. Joiner[4] Daniel Blustein[5] Jonathon Schofield[6]

***Abstract*—The sense of agency is the perceptual experience of authoring our volitional actions. It is a valuable framework for assessing perceptions of control and the quality of interaction for users operating assistive devices. Intentional binding (IB) is a quantitative measure of the sense of agency where individuals perceive temporal compression between a volitional action and its sensory outcome. IB has been investigated during simple button press actions, but little work extends findings to gross whole-limb movements that are more relevant to assistive or rehabilitative robotics. This study develops and examines the feasibility of a novel, high-resolution approach for assessing IB using a forced two-choice discrimination paradigm. We designed a target acquisition task that required movement of the whole upper limb. Eight participants discriminated time durations between pairs of auditory tones coinciding with paired active and passive movements executed on a Kinarm. Participants reported which movement had a shorter time interval between tones while we varied time delays across movements and trials. We fit psychometric curves to participant responses and achieve a high-resolution estimate of IB biases while also providing a new slope dimension of analysis for IB experiences. The median bias across participants was -36.2ms (IQR: 145.1). We measured IB biases in whole limb movements with high resolution using this method and share its implications for assistive device design.**

I. Introduction

Driven by advances in mechatronics and neuroengineering, many modern assistive and rehabilitative devices (such as limb prostheses, powered orthoses, exoskeletons, and others) are seeing rapid technological transformations. However, the literature reporting on methods for evaluating the effectiveness of human-machine interactions within these technologies has lagged [1]. Contemporary evaluation metrics are needed to keep pace with this evolution which will better define functional capabilities and reveal unmet clinical and user needs. Evaluating devices relative to the sense of embodiment the user may form during robotic operation has recently become an area of growing interest across numerous fields [2], [3]. The sense of embodiment is the perceptual experience of ownership over our body and actions [4]. It offers a new dimension to assess relevant perceptual aspects of human-machine interactions with assistive technologies [5]. For example, in upper limb prostheses, high abandonment rates may be associated with a poorly formed sense of embodiment [6], [7], [8]. Thus, evaluating embodiment may offer possibilities toward improved perception of prosthesis control, forgiveness of control errors, and ultimately improved patient outcomes [6], [7], [8].

Three constituent components underpin the sense of embodiment: (1) the **sense of ownership** defining our perception that our body (or body parts) belongs to ourselves; (2) the **sense of agency** which defines the sense of authorship one has over the volitional actions they perform with their body; and (3) **body localization** which defines the perception of the environment and space immediately surrounding the body in which it can interact with the external world [5]. The sense of agency is of particular value for many rehabilitation and assistive robotic technologies. It offers an insightful avenue to assess user perceptions of controlling their body when assisted by the device. We can further break down the sense of agency into internal and external representations, where **internal agency** refers to perceptions of controlling actions and experiencing the sensory consequences in our own body, and **external agency** refers to the perceptions of controlling events and their sensory consequence in the environment that surrounds the body [4]. Most prior work has focused on evaluating external agency [9]. Although this certainly carries value in assessing

human-machine interactions, quantifying the internal sense of agency is particularly relevant to many assistive technologies aiming to seamlessly integrate with human natural sensory-motor control loops, for example, bionic prostheses or neuro-integrated exoskeleton control.

Implicit and explicit methods define two categories of metrics used to quantify the components of embodiment including the sense of agency. **Explicit methods**, such as questionnaires or survey sets, directly probe conscious perceptions of authoring the sensory outcomes of volitional actions. Such methods are typically easily implemented in most experimental paradigms and are well -validated well in numerous applications. However, they are susceptible to biases, including social desirability and impression management, that can jeopardize their reliability [10], [11], [12]. In contrast, **implicit methods** quantify indirect correlates to the sense of agency outside of human conscious control; some examples include changes in skin conductance, time perception, and histamine responses [13]. They offer the advantage of consistent results that are difficult to bias, making them reliable for retesting and tracking patient changes [13]. However, validating implicit methods as correlates to aspects of embodiment can be challenging since there is uncertainty in the causal or correlative relationships they may have [13], [14]. Nevertheless, such measures offer an important dimension of analysis to quantify the sense of agency that may form when operating assistive technologies more completely.

One prominent implicit method used to assess the sense of agency is **intentional binding**. Intentional binding describes the phenomenon where the perceived time between a volitional action and its sensory outcomes becomes compressed as the participant experiences a strong sense of agency compared to when the sense of agency is absent [11], [14], [15]. Intentional binding is most commonly measured using either a Libet clock paradigm or direct estimation of temporal intervals [12], [14]. In the Libet clock approach, participants estimate time intervals by observing the position of a rotating clock hand. Discrepancies between the actual time interval and the reported clock position quantify intentional binding effects [14]. However, there are limitations with this approach, including potential biases resulting from the requisite high attentional demands [14], [16], [17]. Direct temporal interval estimation can overcome some of the limitations of the Libet clock by having participants state their perceived time delay between experiment events without needing to monitor a clock [14]. However, direct interval estimation has a natural limitation since the small time intervals commonly used in intentional binding protocols can be difficult for participants to estimate. This limitation can introduce inconsistency in participant responses to reoccurring delay intervals and make the method more subjective, hurting its reliability.

Overcoming the challenges above, Steele et al. 2022 proposed a forced choice discrimination task to quantify intentional binding effects and remove participant inconsistency inherent in direct temporal interval estimations [9]. This paradigm involved presenting participants with a 1-degree-of-freedom cursor-to-target task, which they executed using a mouse, and then a passive replica of the same task executed by the computer. By having participants first actively control the cursor and then passively watch the same movement, this paradigm carefully controlled for the sense of agency that may form over the movement. Participants reported the movement task they perceived as taking longer while an adaptive staircase adjusted their passive movement durations to converge on a delay value where participants could no longer differentiate between active and passive movements. The converged value is a high-resolution quantification of their intentional binding bias [9]. This novel paradigm provides an effective framework to determine an implicit measure of the sense of agency while reducing subjectivity in interval estimation tasks. However, how it may scale to larger whole-limb movements relevant to rehabilitation and assistive technologies is unknown. Providing participants with proprioceptive cues associated with whole-limb motion could influence the sense of agency and would be more transferable to assistive devices aiming to restore dexterity or mobility. Whole-body limb movements can also translate to studies investigating the internal sense of agency and provide a more holistic assessment tool for researchers, clinicians, and device developers. Therefore, our current work aims to leverage the Steele et al. 2022 framework to develop and examine the feasibility of a protocol that quantifies intentional binding with high resolution across whole-limb movements.

II. Methods

Protocol Design

Our protocol incorporated the Kinarm Robot (End-Point Lab, Kingston, Canada) (Fig. 1A), a robotic apparatus with two handles that accurately tracks arm motion kinematics and can actively replicate arm movements using onboard motors. In our protocol, participants played a computer game by moving one of the robot handles to control the position of a cursor—a white dot that tracked the occluded handle/hand position.

Participants were seated at a table with the Kinarm and instructed to grasp the right handle of the robot with their right hand (Fig. 1B). The horizontal Kinarm screen, positioned 60 centimeters above the table, provided visual instructions, targets, and cursor position. The screen occluded the view of the table, Kinarm handle, and arms to participants (Fig. 1B and C). They rested their left hand on the table over two mechanical buttons that they used for reporting their perceptual decisions (described below).

We programmed the KinArm to (1) record active movements, in which the participant actively moved their arm, and (2) perform passive movements, where the handle moved the arm of the participant. Each trial consisted of a pair of movements: one active, followed by one passive replicating the previous active movement (Fig. 1D). There were no significant differences in the velocity profiles of active and passive movements. We restricted movements to the y-axis – which traced a line in the sagittal plane of the participant as they sat

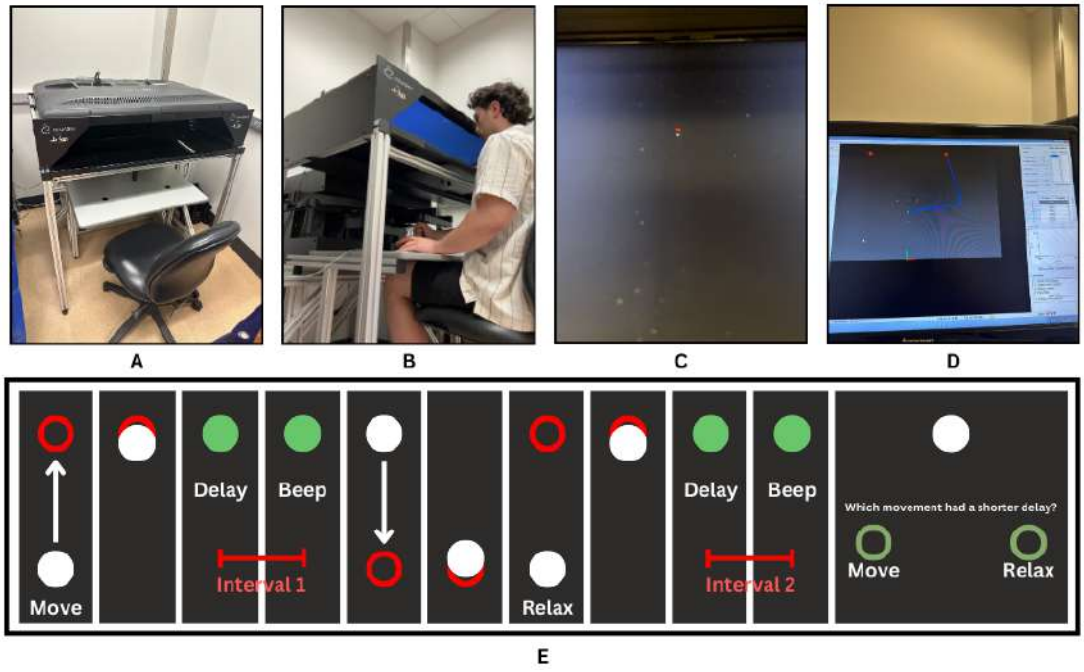

Fig. 1. Overview of experiment. A. The experimental setup with the Kinarm equipment, chair, screen, and table. B. User interacting with the Kinarm experimental setup, holding the right handle with their right hand and their left hand on the buttons while watching the screen for instructions. C. User view of the experimental screen. They move the white cursor to the red target. D. Experimenter view showing the user's execution of the task, allowing for monitoring of participant compliance. E. Sequence of one experimental trial with an active movement followed by a passive movement modulated by a delay. The participant then selects the faster trial (i.e. the smaller interval between tones).

facing the device (Fig. 1B). The participants were encouraged to move at an average velocity ranging between 13-22cm/s and received feedback from our cursor color scheme. When participants reached the target, the cursor would momentarily change to one of three colors: green, indicating that their motion was within the 13-22cm/s velocity range; red, if they were above the velocity range; yellow, if they were below the velocity range. We selected the velocity range to standardize the test between participants and limit the peak velocities they experienced from the passive movements.

We instructed participants that their goal was to achieve the highest possible accuracy on an audio acuity task, and . Participantsthey were blindnaive to the true purpose of the experiment, and we told them that the test measured their audio acuity. We did this to avoid placebo biases in their reporting . We required participants to use the buttons to select which of two-time intervals—presented as delays between auditory tones—they perceived as shorter. Participants first engaged in the active movement task, followed by the passive movement task. The active movement began with the onset of participant motion, triggering the first tone. The participant would then advance the handle to position their cursor within a circular target 12 centimeters away in the positive y-axis direction from the starting position, and after a variable time delay (described below), the second tone played. Once they completed the movement, participants returned the cursor to the starting position (Fig. 1E). The passive motion followed the same procedure except that the onset of motion started one second after the participant reached the starting position and the robot positioned the cursor within the circular target. After each active-passive pair of movements, participants reported whether the active or passive task had a shorter time interval between the tones.

We randomly perturbed the time intervals between the arrival of the cursor at the target and the second tone sounding using a set of 11 possible values. The first (active) movement always included a fixed delay of 400 ms, while the second (passive) movement had a randomly selected delay between 0 ms and 800 ms, chosen from the set of 11 values: 0 ms, 100 ms, 200 ms, 300 ms, 350 ms, 400 ms, 450 ms, 500 ms, 600 ms, 700 ms, 800 ms. Each perturbation value was presented 12 times during the experiment (132 trials total) and four times per block (44 trials per block).

Feasibility Testing

We obtained human testing ethics approval through the UC Davis Institutional Review Board (IRB ID: 1336438-7). To examine the feasibility of our protocol, we recruited eight participants. They ranged between 18-24 years of age with an average age of 20.4 years and standard deviation of 2.06 years. 5/8 were female, and 7/8 were right-handed. All subjects were healthy, taking no medication for neurological impairments, and provided informed consent prior to participation.

To examine the feasibility of our protocol and its ability to quantify intentional binding effects during whole arm movements, all 8 participants completed a full set of 132 trials with the Kinarm task, as described above. We processed the

collected data from the Kinarm using the Bkin_Toolbox_3.8 in MATLAB Software (MathWorks, Natick, USA). We used the Psignifit toolbox (Heiko Schütt, AG, NIP, University of Tübingen) to fit a psychometric curve based on how participants responded in the paired active-passive movement comparison trials. If a participant reported that active movements had shorter delays than passive movements, the 50% threshold of their psychometric curve (on the y-axis) would be shifted in the negative time direction (on the x-axis), indicating a negative time bias. The opposite is true for positive time biases. We then quantified this time bias for each participant to determine if there was an overall negative intentional binding value. This would suggest that our method has intentional binding effects that align with the literature and show that participants perceive active movement conditions and their sensory consequences (intervals between auditory tones) as shorter.

III. Results

Fig. 2 shows an example of a psychometric curve fit using the Psignifit toolbox on an example participant. The x-axis denotes each perturbation level: the passive movement delay minus active movement delay at each trial. The percentage of responses for a shorter active movement compared to total responses represents the y-axis: active responses divided by total responses. The data points shown in blue represent the percent-of-active-movement-responses at each perturbation level. The best fit psychometric curve is represented by the black trace, and the line where the curve inflects, the 50% y-axis point, intersecting the x-axis, indicates participant bias.

Fig. 3 illustrates the psychometric curves for all 8 participants with an average intentional binding curve, shown in red. The average curve was calculated by averaging the Percent-of-active-responses for all participants at each perturbation level and fitting a curve based on the averaged data. Each participant demonstrated a bias that we interpolated to a high degree of resolution from their psychometric curve. A Shapiro-Wilk normality test showed that the biases did not follow a normal distribution. The average bias of the group was -44.0 ms with a standard deviation of +77.3ms, but it would be best to report the median -36.2 ms and an interquartile range 145.1 ms since the data is not normally distributed. We used the sign test to determine that our distribution does not differ significantly from a distribution with a 0ms median ($p = 0.73$). The reason for choosing a sign test is the continuous nature of our bias values and the non-parametric nature of the test.

Unexpectedly, our psychometric curve results presented high variability in participant slopes. We quantified participant slopes by taking the x-axis value at 50% accruacy (bias) and subtracting it from their x-axis value at 75% accuracy. This strategy quantifies the amount an experimenter needs to increase the delay of the passive movement time interval to have participants consistently report that active movements had shorter time intervals. The median amount of time an experimenter would need to increase the passive movement in our group to get the above behaviour is 230ms (IQR: 109.6ms). The range of this threshold varies highly betwen participants, with one participant only needing a 99.8ms increase from their bias value as another needed a 429.9ms increase to respond consistently. Although an aggregated cohort-wide intentional binding effect was statistically not discernable across our cohort, our feasibility results clearly illustrate the potential to identify individual participant variations in intentional binding responses.

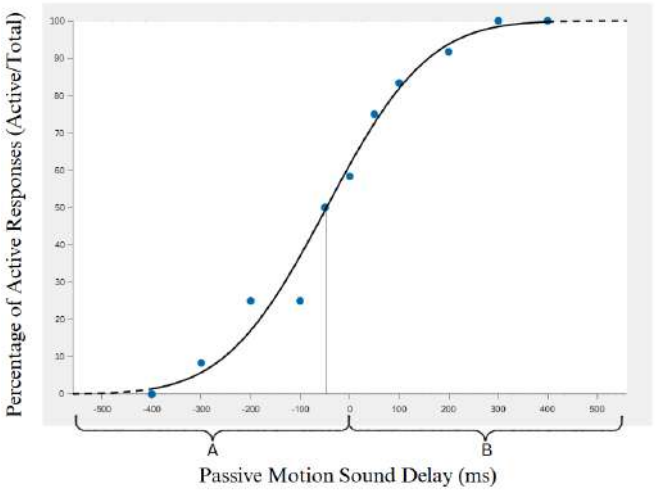

Fig. 2. An example of a participant's psychometric curve. Each data point, in blue, represents the percentage that the participant reported perceiving a shorter delay in the active movement (y-axis) at each perturbation level (x-axis). The psychometric curve was fit using the Psignifit toolbox. The line going from the curve's 50% y-axis value to the x-axis represents the participant's bias. The intersection point is the bias value: -48ms. (A) Represents the perturbation levels where the time interval between the tones of the active movement is shorter than the time interval between the tones of the passive movement. (B) Represents the opposite, where the time interval between the tones of the active movement is shorter than the time interval between the tones of the passive movement. The zero point on the x-axis represents the perturbation level where there is no difference between the active and passive time intervals.

IV. Discussion

In this work, we developed and demonstrated the feasibility of a forced two-choice discrimination movement paradigm to assess intentional binding effects during whole-limb movements with high interpolative resolution and reliability. Such an approach builds on the body of literature on implicit agency measures, which typically benefit from minimal attentional demands, consistency, impression management, and social desirability biases [9], [12], [13], [14]. Our results extend this work by offering a protocol that incorporates whole limb movements and the possibility of quantifying intentional binding biases with high resolution. This approach holds promise to be less biased and more informative for developing human-machine interfaces compared to direct interval estimation and the Libet clock.

One advantage of our method is the high-resolution interpolation of the 50% inflection point of participant psychometric curves to determine intentional binding bias. The inflection

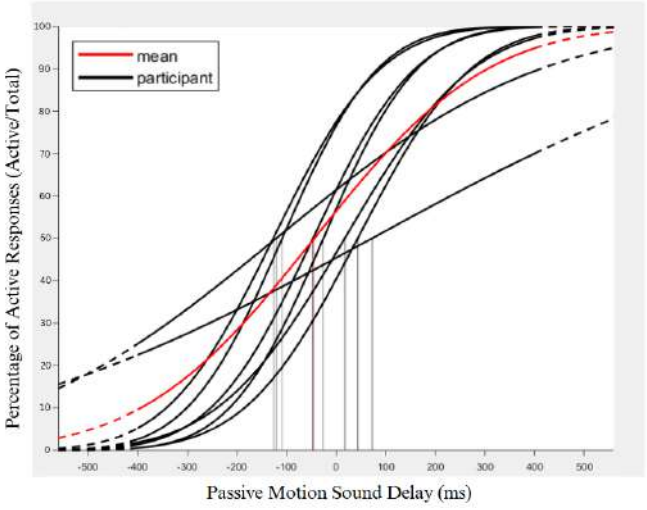

Fig. 3. Psychometric curves evaluating participant intentional binding biases based on active/passive movement voting at different delay intervals. Black curves represent individual participant voting (N = 8), red curve represents average voting of group. Biases are selected at the 50% inflection point of each curve - both individual and average. Median bias = -36.2 ms (IQR: 145.1 ms), Sign Test p-value = 0.73. The median threshold from the 50% inflection point to the 75% consistent response point is 230ms.

point indicates the time delay value at which participants cannot differentiate between the delays of the active and passive movements. In our design, a negative bias value indicates that the participant frequently reported a shorter delay following the active movement, supporting the intentional binding theory. Conversely, a positive bias value suggests that the participant frequently reported the passive movement having a shorter delay. Our results demonstrate a net-negative intentional binding bias with -44.0ms at the average, aligning with existing literature [18]. Two of our eight participants reported an average, positive, intentional binding bias, which can also be seen in well-established methods [19]. Our data did not reveal a statistically significant group bias in either the negative or positive direction which is expected since we are only reporting information on eight participants. We propose that studies with larger cohorts would provide greater power to characterize group behavior in our novel protocol. Toward this goal, this work was to develop a whole-limb intentional binding protocol, and our feasibility testing demonstrated the ability to quantify individual participant biases with high resolution.

One of the more exciting contributions of this work is the new possibility to examine the slope of individual and group-based psychometric curves to quantify intentional binding effects. These slopes quantified individual precision during the experiment. Participants who reported consistently on similar trials will have steeper slopes and smaller threshold values than participants who reported inconsistently during the experiment. We can see in Fig. 3 that two participants had shallower slopes and larger threshold values compared to the other six. We can not provide a specific explanation for why this occurred, but our protocol offers the advantage of quantifying these individual precision differences. This slope parameter provides a new dimension for assessing intentional binding and can be used to offer richer data for quantifying differences in the sense of agency.

As an example of how the slope can provide a richer analysis in agency assessments, intentional binding bias appeared to be independent of the psychometric curve slopes in our experimental cohort (Fig. 3). Although we require larger sample sizes to assess the relationships between the variables confidently, we can see that participants with steep slopes had variable biases and participants with shallow slopes also had variable biases. This result suggests that the slope metric carries additional information and may allow for further characterization of intentional binding and agency experiences.

A valuable aspect of our protocol is its natural translation into the fields of rehabilitation and robotics. For example, this work may be relevant to researchers, clinicians, and device developers interested in quantifying the sense of agency of whole limb movements using myoelectric prostheses, exoskeletons, or other assistive devices. We used a single degree of freedom whole-limb task (straight line reaching) to reduce the complexity of our experimental variables, but this does not need to be the case. Our methods can be replicated directly using the Kinarm or adapted for different tasks such as lower limb, fine, or dexterous movements. Although the Kinarm was locked to a straight line trajectory, participants were free to move their arm in complex ways to hit the target. This is in contrast to many other methods which use less complex movements such as button presses and computer-mouse clicks [9], [14]. We further suggest that our paradigm may be readily modified beyond this one degree of freedom to provide further insight into less kinematically constrained applications.

Our paradigm also offers the advantage of being adaptable to more clinically relevant applications. For example, intentional binding protocols have been developed [20] and used to assess user perceptions of prosthetic control and feedback techniques [21]. In this context, direct time interval estimates have been employed to examine binding between a virtual prosthesis first contacting a grasped object and auditory cues played shortly after this event. Our paradigm could be readily integrated by modifying the prosthesis grasping action into two control conditions: one in which the user actively controls the prosthesis and another in which they view a replay of that action. Participants would then indicate which sequence of events, from the prosthesis's first contact with the object to the auditory tone, they perceived as occurring over a shorter time interval. By varying the delay between contact and the tone, we could obtain a precise estimate of intentional binding biases, directly aligning with our active/passive paradigm described above. Beyond prosthetic limbs, this approach could be extended to various clinical and assistive-device applications by incorporating both passive and active control along with strategically timed sensory events. This would enable precise estimation of intentional binding biases, offering valuable insights into improving user perceptions.

Our study does include some limitations. Given that our goal was to develop a protocol and examine its feasibility, our sample size of N=8 limits our ability to extend our results more broadly to describe group-based results. However, given the demonstrated potential to capture individual participant differences, we argue that work with larger cohort sizes is warranted to develop data sets reflective of normative and affected populations. Such follow-up work has potential impactful implications beyond rehabilitative and assistive robotic applications to provide quantitative insights into a variety of conditions in which patients present with an atypical sense of agency and intentional binding biases, such as schizophrenia, Parkinson's disease, Tourette's disorder, and cortico-basal syndrome [22], [23].

ACKNOWLEDGMENT

The authors of this paper would like to thank the UC Davis Institutional Review Board for approving our study and letting us develop our methods. We would also like to thank the SONA recruiting system and the wonderful participants who gave their time to make this possible.

Day-to-Day User Adaptation to a Robotic Ankle-Foot Prosthesis

Sina Miri, Michael Jacobson, Matthew J. Major, Myunghee Kim*

Abstract— **Adaptation in locomotion of lower limb amputees is essential for effective interaction with assistive devices such as robotic ankle-foot prostheses (AFP), which can provide personalized assistance. Bayesian Optimization (BO) and Human-in-the-Loop (HIL) optimization frameworks have been utilized to personalize device parameters based on user feedback; however, these methods may not always fully consider the dynamic nature of human adaptation. This study investigates day-to-day adaptation to a robotic ankle-foot prosthesis by modeling socket pressure distributions across different AFP stiffness conditions using Gaussian processes. We performed a secondary analysis on data from three unilateral transtibial amputees who participated in a four-day experimental protocol involving discrete parameter sweeps and HIL optimization using BO. Gaussian process models were constructed from data collected on the discrete sweep day and the HIL optimization day. Comparative analyses using Kullback–Leibler (KL) divergence and a mean absolute error (MAE) loss metric revealed subject-specific shifts in optimal stiffness values and changes in the pressure landscape between the two days. The average KL divergence was 1.15, and the MAE loss was 0.59, suggesting adaptations in gait and limb dynamics. These findings suggest the importance of using adaptation in a short time period and personalization methods may need to not only optimize device parameters based on static performance snapshots but also accommodate the dynamic shifts that occur as users adapt over time.**

Keywords—Adaptation, Prosthesis, Human-Robot interaction, Human-in-the-loop

I. Introduction

The development of assistive devices, including powered prostheses and exoskeletons, has made significant progress toward improving mobility and reducing the physical effort required for walking in individuals with motor impairments [1], [2], [3], [4], [5], [6], [7]. These devices often rely on the integration of physiological and non-physiological signals to achieve user-specific adaptations through human-in-the-loop (HIL) optimization. This systematic approach involves iteratively tuning device parameters based on real-time user feedback [8], [9], [10]. Historically, metabolic cost has been the primary feedback metric for optimization [6]. However, recent studies have explored alternative or proxy measures, including muscle activity [11], electrocardiogram (ECG) [12], ground reaction forces, foot pressure distributions [3], [5], and user subjective preferences [1]. While these advances have improved device personalization, successful outcomes depend on the user's ability to adapt to and effectively utilize the device.

Adaptation is a critical process that enables users to effectively interact with assistive devices. It involves the modification of neural, muscular, and biomechanical patterns to optimize device utilization and improve overall performance during activities such as walking [3], [13]. This process is essential for aligning the user's motor strategies with the mechanical assistance provided by the device [4], [7].

In human locomotion, adaptation reflects the central nervous system's ability to modify walking patterns in response to environmental or mechanical perturbations, ensuring stability and efficiency [14]. Experimental setups such as split-belt treadmills demonstrate how individuals adjust gait kinematics, such as step length [15], stride time [16], and interlimb coordination [17], to accommodate new constraints [18]. These adjustments rely on both reactive and predictive mechanisms, integrating sensory feedback and feedforward control to restore symmetry over time [18], [19]. Individuals with motor impairments, including stroke survivors, also demonstrate the capacity for locomotor adaptation, though adaptation rates and extents vary with baseline asymmetries [18].

The ability to adapt gait kinematics is also influenced by sensory inputs and cognitive processes. For instance, visual feedback has been shown to enhance gait adaptation by providing real-time cues that help individuals correct deviations in their walking patterns [20]. This approach allows wearable device users to optimize their gait to the assistance, thereby reducing the metabolic cost of walking [21]. Visual feedback can also enhance the adaptation process by guiding users toward target gait patterns [4]. Additionally, the effectiveness of training and customization in exoskeleton use demonstrates the relationship between motor learning and adaptation, with gradual exposure to variable assistance profiles resulting in sustained reductions in energy expenditure [13]. Studies have shown that adaptation to assistive devices can also result in changes in gait kinematics, kinetics, and muscle activity [21], [22].

The extent and rate of adaptation are influenced by the amount and type of training provided. Research has emphasized the importance of prolonged exposure to device assistance in achieving stable adaptation [13]. Long-term adaptation, often observed over weeks or months, involves gradual recalibration of sensorimotor pathways and the nervous system's ability to integrate device assistance into walking patterns. Studies have shown that repeated exposure to robotic assistance facilitates durable changes in motor control and gait dynamics, enabling users to achieve smoother and more energy-efficient movements over time [13], [23]. In contrast, short-term adaptation occurs over hours or days and typically involves rapid adjustments to device parameters or environmental changes [24], [25], [26]. While these initial adjustments can result in notable improvements in gait symmetry and efficiency, they may lack the permanence of long-term adaptations unless reinforced by consistent practice [27]. Despite these findings, the interplay between short-term adaptation mechanisms and their contribution to long-term changes remains underexplored, particularly in the context of how device parameters modulate the adaptation process [28].

One of the conventional indicators of adaptation is the kinematic changes observed during gait [29]. Socket pressure has been well established as a measure in lower limb amputee studies. This can give insights into interfacial load transfer [30], support action of friction [31] and external moments acting on this interface [32]. Studies suggest relationships between socket pressure and muscle activation [33] as well as gait characteristics [34].

In this study, we used Gaussian processes (GP) to model the distribution of socket pressure as a function of the prosthetic stiffness parameter across multiple experimental days. GPs can be thought of as a probabilistic model for distributions over functions, generalizing the multivariate Gaussian distribution to continuous domains [35]. This approach allowed us to infer the nonlinear relationships between stiffness and pressure using limited data collected during human subject experiments [36].

In robotics research, the Kullback–Leibler (KL) divergence is employed as a quantitative measure to detect changes in kinematic behavior or overall task performance [37], [38]. A high KL divergence value between the probability distributions of expected and observed kinematic data indicates significant deviations, which may signify alterations in movement patterns, anomalies, or shifts in robot behavior [37]. Therefore, a high KL divergence during learning from demonstration may reveal that the robot's actions are not accurately replicating expert demonstrations, highlighting discrepancies in kinematic replication [39].

Another metric for the change in user gait pattern is the Mean Absolute Error (MAE) [40]. This metric quantifies the absolute average discrepancy between the models' central tendency predictions, providing a straightforward measure of divergence in their mean predictions without incorporating uncertainty. In addition to KL divergence, we calculated the MAE-based loss metric to capture the absolute differences in mean predictions between two GP models [41]. We have extended these measures to analyze alterations in human kinematics, particularly in the context of assessing adaptation using Gaussian process regression of the activity [42], [43].

We hypothesized that adaptation effects to the assistive robotic ankle-foot prosthesis could be captured through changes in the socket pressure landscape observed over two different experimental days. To describe these effects, we used explicit measures, including shifts in the optimal pressure distribution point, and quantitative metrics such as KL divergence and MAE loss metric to assess the differences in socket pressure patterns.

We conducted a four-day study with three unilateral transtibial amputees using a robotic ankle-foot prosthesis emulator. Pressure objective was obtained from the pressure sensors implemented in the socket from the last two days of experimental protocol. GP models were built to analyze the relationship between AFP stiffness landscape and socket pressure objective. Quantitative metrics were calculated based on the two GP models.

II. Methods

A. Socket pressure data collection and pressure objective calculation

We have used two pressure maps (9811E sensor, Tekscan, USA) on the anterior and lateral sides of the socket as shown in Fig.1.A. Building on this, we developed a novel pressure objective function that utilizes socket interface pressure to determine the optimal stiffness parameter by maximizing this function during Bayesian Optimization.

$$\max f(p_a, p_l) = \left(\frac{\sum_{t=1}^{T} \left(\sum_{i=1}^{n} p_a(i,t) \cdot \omega_a + p_l(i,t) \cdot \omega_l \right)}{\frac{1}{T} \left(\sum_{t=1}^{T} \max_i p_a(t) + \sum_{t=1}^{T} \max_i p_l(t) \right)} \right) \quad (1)$$

Equation (1) defines the cost function being maximized in the optimization process. Here, $p_a(i,t)$ and $p_l(i,t)$ represent the pressure values in the anterior and lateral regions at cell i and time t, respectively. The summation $\sum_{t=1}^{T}$ aggregates the pressure data over the time period T. Weights ω_a and ω_l are applied to $p_a(i,t)$ and $p_l(i,t)$, respectively, to reflect the relative importance of these pressures in the overall objective function. In the denominator, the term $\frac{1}{T}$ averages the

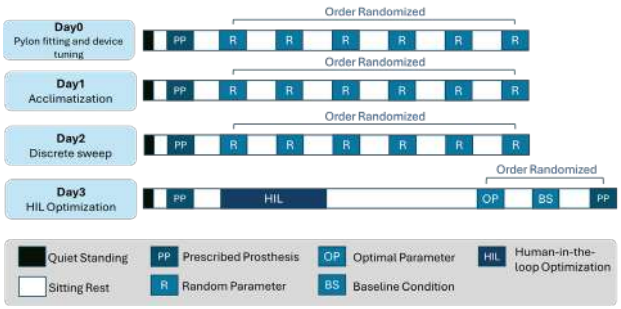

Figure 2. Experimental protocol, Day 0: Confirm fit, determine preferred speed, fit pylon, tune neutral angle, walk under multiple stiffness conditions. Days 1 (Acclimatization) & 2 (Discrete Sweep): After baseline standing and walking with the prescribed prosthesis, participants complete repeated walking trials at varying stiffness conditions with rests in between. Day 3 (HIL Optimization): After baseline measurements, participants undergo real-time iterative optimization of prosthesis parameters, followed by validation walking trials at the optimized and baseline and prescribed prosthesis conditions.

maximum pressure values over the time period T. Specifically, $\max_i p_a(t)$ and $\max_i p_l(t)$ denote the maximum pressures observed in the anterior and lateral regions at each time point t. Summing these maximum values over T provides an aggregate measure of the peak pressures in each region. The objective function expresses the cumulative and peak pressures of pressure-intolerant zones of the residual limb, enabling the selection of the optimal stiffness parameter that minimizes pressure-related discomfort.

B. Robotic ankle-foot prosthesis and controller design

We utilized a tethered robotic ankle-foot prosthesis emulator, powered by off-board system (Humotech, Pittsburgh, USA) and a real-time control system, to enable dynamic adjustments of control parameters such as stiffness and push-off energy during walking [44]. The control system was structured into low-, mid-, and high-level controllers: the low-level controller managed linear torque and position tracking, the mid-level controller generated desired ankle trajectories based on gait phases and the selected stiffness parameter, and the high-level controller employed HIL Bayesian optimization to continuously optimize stiffness in real-time. The emulator achieved a plantarflexion peak torque of 250 Nm with a control bandwidth exceeding 10 Hz [5].

C. Experimental protocol

The study included three unilateral transtibial amputees—two males and one female—aged 59, 47, and 45 years (mean ± SD: 50.33 ± 7.57 years) and weighing 98.88 kg, 56.7 kg, and 66.9 kg (74.16 ± 22.02 kg). These participants were recruited to optimize ankle-foot prosthesis parameters for enhanced mobility and comfort using a HIL optimization approach. The experimental protocol spanned four days which is shown in Fig.2. On Day 0, after informed consent and screening by a research prosthetist, participants stood upright for up to 3 minutes, followed by at least 2 minutes of seated rest, then walked with their prescribed prosthesis for up to 5 minutes to determine their preferred walking speed. A brief rest was provided before pylon fitting and device calibration. With the prosthesis emulator's neutral plantarflexion angle tuned for comfort, participants then walked for up to 5 minutes at their preferred speed for approximately six different stiffness conditions, with a minimum of 2 minutes of seated rest between conditions. Informed consent was obtained from all participants prior to the study, and the study protocol was approved by the University of Illinois at Chicago Institutional Review Board (STUDY 2019-0087).

During Days 1 and 2, participants performed discrete parameter sweeps. Each day began with standing for up to 3 minutes, followed by at least 2 minutes of rest, then walking with their prescribed prosthesis for up to 5 minutes. After a minimum 10-minute rest, participants completed about six different stiffness conditions, each lasting up to 5 minutes of walking at their preferred speed, with a minimum of 5 minutes res t between conditions.

On Day 3, the baseline routine was repeated (stand up to 3 minutes, rest at least 2 minutes, walk with prescribed prosthesis up to 5 minutes, then rest at least 10 minutes) before conducting HIL optimization using Bayesian optimization. Participants walked for up to 18 minutes while prosthesis parameters were iteratively adjusted based on participant feedback. After a minimum of 10 minutes rest, a validation session was performed: participants walked up to 5 minutes each at the optimized condition, a baseline condition, and with their prescribed prosthesis, with at least 5 minutes of rest between conditions.

D. Gaussian process modeling

The dataset used in this study was obtained from day 2 discrete sweep conditions and day 3 HIL explored parameters. A single-parameter GP was constructed based on the different robotic ankle-foot prosthesis stiffness parameters and measured pressure objective during day 2 and day 3 shown in Fig.1.C. The independent variable, stiffness, served as the input feature, while the dependent variable, standardized pressure objective, was treated as the response variable. Stiffness parameters were scaled using global Min-Max normalization to ensure values were in the range [0,1] for both days. Data preprocessing and normalization were implemented using custom Python scripts.

A Gaussian Process is a non-parametric Bayesian approach to regression that defines distribution over functions. For a given input x, the GP defines a prior over the possible values of the function $f(x)$. The GP is fully specified by its mean function $\mu(x)$ and covariance function $k(x, x')$:

$$f(x) \sim GP(\mu(x), k(x, x')) \tag{2}$$

The covariance function, also known as the kernel, encapsulates our assumptions about the function $f(x)$. We employed the Squared Exponential (SE) kernel with Automatic Relevance Determination (ARD):

$$k(x, x') = \sigma_f^2 exp(-\frac{1}{2}\sum_{d=1}^{D}\frac{(x_d - x_d')^2}{{l_d}^2}) \tag{3}$$

Where σ_f^2, l_d and D are the output variance (output scale), the lengthscale parameter and dimensionality of the input space respectively.

To model observation noise, we assume that the observed responses y are related to the latent function $f(x)$ via Gaussian noise:

$$y = f(x) + \epsilon, \epsilon \sim N(0, \sigma_n^2 I) \quad (4)$$

Where σ_n^2 represents the noise variance, and I is the identity matrix. To ensure numerical stability during optimization, the noise variance σ_n^2 is constrained to be greater than 10^{-5}.

The GP models were trained by maximizing the Exact Marginal Log-Likelihood (MLL), which serves as the objective function for hyperparameter optimization. The MLL for a GP with training data $D = \{X, y\}$ is given by:

$$log\ p(\ y \mid X\ ) = -\frac{1}{2} y^\top K^{-1} y - \frac{1}{2} log \mid K \mid - \frac{n}{2} log 2\pi \quad (5)$$

Where $K = K_f + \sigma_n^2 I$ is the covariance matrix with K_f derived from the SE kernel, and n as the number of training observations.

To optimize the hyperparameters, we employed the Adam optimizer, a stochastic gradient descent method that adapts the learning rate for each parameter. Each GP model was trained over 500 epochs. Throughout training, key hyperparameters, the lengthscale l_d, output scale σ_f^2, and noise variance σ_n^2, were recorded to monitor convergence and assess the optimization trajectory.

E. Post training model comparison analysis

To quantitatively assess the similarity or dissimilarity between the GP models for day 2 and day 3 for each subject we employed the Kullback-Leibler (KL) Divergence and MAE loss metrics. We also showed the optimal point of each GP.

The KL Divergence between two Gaussian distributions $N(\mu_1, \sigma_1^2)$ and $N(\mu_2, \sigma_2^2)$ is mathematically defined as:

$$KL(N_1 \parallel N_2) = \frac{1}{2}\left(log\left(\frac{\sigma_2^2}{\sigma_1^2}\right) + \frac{\sigma_1^2 + (\mu_1 - \mu_2)^2}{\sigma_2^2} - 1\right) \quad (6)$$

We generated 100 equally spaced test points X_{test} within the normalized stiffness range [0,1] to sample the parameter space comprehensively.

The KL Divergence was calculated at each test point to quantify the divergence between the two predictive distributions. An overall comparison metric was derived by computing the mean of the KL Divergence values across all test points, providing a singular measure of the models' similarity across the stiffness range.

In addition to KL Divergence, we used an MAE loss metric to capture the absolute differences in mean predictions between the two GP models.

For each test point in X_{test}, the mean predictions μ_1 and μ_2 from GP Model 1 and GP Model 2 were extracted.

$$MAE\ Loss = \frac{1}{D}\sum_{x \in D} |\mu_1 - \mu_2| \quad (7)$$

The MAE loss value was computed across all test points to provide an aggregate measure of the models' prediction differences. To identify the optimal stiffness value that maximizes the standardized pressure objective for each GP model, we performed an optimal point calculation based on the posterior mean predictions in both GP models. Using the same set of 100 uniformly spaced test points X_{test} within the normalized stiffness range [0,1], we evaluated the posterior distributions of both GP models with the posterior mean predictions $\mu_1(x)$ and $\mu_2(x)$. The optimal stiffness value for each model was identified by locating the test point with the highest posterior mean prediction:

$$Optimal\ Point = arg \max_{x \in X_{test}} \mu(x) \quad (8)$$

III. RESULTS

We modeled the pressure objective across different stiffness values of the robotic ankle-foot prosthesis. All hyperparameters (σ_f^2, l_d and, σ_n^2) converged within 500 epochs. Fig.3 presents the experimental results. Subject-specific analyses revealed shifts in optimal stiffness values between the discrete sweep day and the HIL day.

For Subject 1, the optimal point shifted from the low stiffness region during the discrete sweep day to the mid-stiffness region on the HIL day. Subject 2's optimal point transitioned from the high stiffness region to the low stiffness region during the HIL day, indicating a complete shift. Subject 3

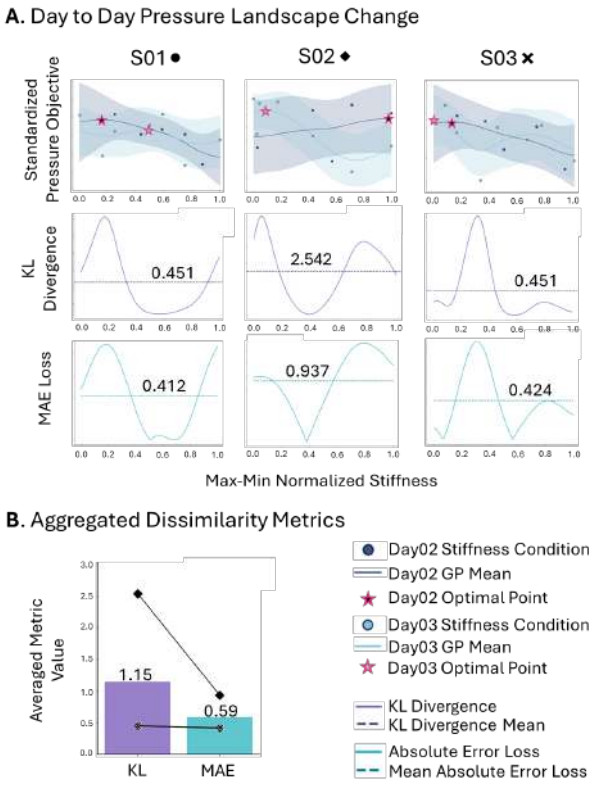

Figure 3. Experimental results. (A) Day 2 and 3 pressure landscape, KL Divergence and MAE loss of participants (shown in columns respectively). (B) Aggregated dissimilarity metrics results

exhibited a minor shift toward a lower stiffness region from the discrete sweep day to the HIL day. The averaged KL divergence values over the test points were 0.451 for Subject 1, 2.542 for Subject 2, and 0.451 for Subject 3 (mean = 1.15). A KL divergence value close to 0 indicates high similarity between the two GP models' predictions and uncertainties at that stiffness level.

The MAE loss values were 0.412 for Subject 1, 0.937 for Subject 2, and 0.424 for Subject 3 (mean = 0.59).

IV. Discussion and Conclusion

In this study, we hypothesized that users would adapt their gait patterns when using a robotic ankle-foot prosthesis (AFP) during experimental days, as evidenced by changes in socket interface pressure distributions each day. We performed secondary data analysis on three individuals with transtibial amputation. Our findings, derived from modeling the pressure landscape using Gaussian Process (GP) regressions across different AFP stiffness settings, revealed day-to-day shifts in optimal stiffness values. This adaptation effect was further supported by the observed non-zero, positive mean values of Kullback-Leibler (KL) divergence (mean = 1.15) and MAE loss metric (mean = 0.59). These results collectively indicate ongoing day-to-day changes in the underlying socket pressure landscape, suggesting that users adapted their gait patterns to accommodate the AFP over the short term.

The socket pressure objective in this study represents the distribution of forces exerted between the prosthetic socket and the residual limb in anterior and lateral directions. We used GP regression to model this pressure objective across different stiffness ranges of the AFP system. This approach allowed us to model the nonlinear relationships between AFP stiffness and socket pressure using limited data collected during human subject experiments [36]. The resulting pressure landscape provides a holistic view of the user's response to the AFP. Day-to-day changes in the pressure landscape under varying stiffness parameters indicate that users adapt their limb and gait dynamics to the device, even over short periods. This adaptation may be oriented toward optimizing loading [45] and efficiency [46]. These results align with the notion that adaptation to robotic devices involves constructing an internal model of the locomotor task [42], [43] and are consistent with findings that prolonged interaction with assistive devices leads to improved personalization of gait characteristics [5], [6].

Beyond the general adaptation effects, we also observed subject-specific patterns. Subject 2 significantly altered the optimal point, while others exhibited only minor changes. Subject 2 also showed a change in the pressure landscape, indicated by an averaged KL divergence of 2.542 and an MAE loss of 0.937. Perhaps, one of the factors of this inter-subject variability is that since subjects walked at their preferred speeds, the number of steps taken within the fixed time window varied, potentially influencing the training dosage [47], [48]. Research also suggests that adaptation to a new device does not follow a uniform trajectory [49], and training protocols must also account for individual characteristics [50]. This variability suggests the importance of personalization, ensuring that assistive devices are tailored to each user's unique adaptation patterns for optimal effectiveness.

Bayesian optimization frameworks are well suited for personalizing assistive robots due to their non-parametric, sample-efficient, and noise-tolerant characteristics [36], [51]. BO-based Human-in-the-Loop (HIL) optimization frameworks use GP models to describe the prior and posterior distributions [51] as they iteratively tune device parameters based on the objective cost. However, current BO-based methods often focus on objective functions, such as metabolic cost or gait symmetry, without fully accounting for the dynamic nature of adaptation. Instead, they tend to treat these changes as noise, overlooking the effect of human-robot co-adaptation [4], [52]. Previous research has also emphasized the need for adaptive HIL strategies that account for time-varying user-device interactions [4], [52]. Such frameworks can be extended to incorporate adaptive metrics, ensuring that device performance evolves alongside the user's changing needs and adaptation [6], [7].

A potential limitation of this study arises from the differences of data collection protocols on the discrete sweep Day and HIL-explored parameters. Future research with a similar protocol across days with a larger group of participants can be planned to provide a more comprehensive overview of short-term adaptation to assistive devices and solutions offered by personalization methods.

Acknowledgment

The authors would like to extend their thanks to the members of the Rehabilitation Robotics Lab for their invaluable support and contributions throughout the course of this project.

Biomechanical Analysis of Repetitive Lifting with Passive Exosuit Assistance: Preliminary Results

Ronak Vyas[1], Francesco Travascio[2], Vineet Vashista[1*]

***Abstract*— Repetitive lifting tasks, common in labor-intensive industries, are a significant contributor to work-related musculoskeletal disorders (WMSDs) and chronic lower back pain (LBP). The continuous physical strain associated with these tasks leads to the accumulation of fatigue, which can reduce performance and increase the risk of injury over time. This study evaluates the impact of passive back exosuit assistance on muscle activation and fatigue during repetitive lifting tasks. Surface electromyography (sEMG) and biomechanical assessments were conducted to analyze kinematics and key muscle groups under two conditions: with and without exosuit support. Preliminary findings indicate that passive exosuit assistance reduces muscle activation levels in the back and lower limbs, effectively mitigating fatigue during repetitive lifting. These results highlight its potential to enhance workplace safety and alleviate the physical demands of repetitive lifting tasks, providing valuable insights into ergonomic innovations aimed at minimizing fatigue-related risks in demanding environments.**

I. INTRODUCTION

Repetitive lifting is a common occupational activity, especially in labor-intensive sectors such as manufacturing, construction, and logistics. Workers in these settings often handle tasks that involve lifting and carrying loads for extended durations, which exposes them to significant physical strain. This prolonged exertion is a major contributor to work-related musculoskeletal disorders (WMSDs), which account for a substantial proportion of workplace injuries globally [1], [2]. Lower back pain (LBP), a prevalent manifestation of WMSDs, has been linked to over 30% of occupational injuries and is often the result of repetitive load-bearing tasks combined with poor postures and inadequate recovery time [3], [4]. These demands not only affect worker efficiency but also lead to chronic health conditions that compromise long-term well-being.

The continuous nature of lifting tasks gradually affects the body's biomechanics, particularly the musculoskeletal system [5]. Persistent engagement of muscles without sufficient recovery leads to fatigue, which diminishes the system's ability to generate necessary force during lifting. Unlike acute injuries, which are often associated with sudden trauma, the fatigue induced by repetitive lifting evolves over time. It can alter movement patterns, prompting workers to adopt compensatory strategies that increase strain on adjacent muscle groups and joints [6]. For example, studies indicate that during fatiguing tasks, individuals often transition to postures involving greater trunk flexion, placing additional mechanical demands on the lower back [7], [8]. Over prolonged periods, such compensatory mechanisms can exacerbate the risk of developing severe musculoskeletal conditions, including muscle imbalances, tendinitis, or even herniated discs [9], [10].

Ergonomic advancements have led to the development of assistive devices such as back exosuits, which are designed to reduce physical strain and support proper biomechanics during manual lifting [21]. Broadly classified into active and passive systems, these exosuits have been studied for their ability to reduce load on the lumbar spine, enhance postural control, and delay the onset of muscle fatigue [22]. Passive exosuits utilize mechanical components like springs or elastic bands to provide support without external power sources, whereas active systems incorporate powered actuators for adaptive and dynamic assistance[23]. Research in this domain has demonstrated that both types of systems have the potential to alleviate strain during repetitive lifting tasks [11], [12].

While several studies have examined the role of exosuits in improving lifting efficiency, fewer have focused on their direct relationship with muscle fatigue [33]. Preliminary findings suggest that exosuits can redistribute the mechanical load from fatigued muscle groups to other structures, thereby preserving functional performance. For instance, passive exosuits have been shown to reduce electromyographic (EMG) activity in the lower back muscles during repetitive tasks, indicating delayed fatigue onset. However, there is limited data on how these devices influence compensatory movements, postural adaptations, and overall musculoskeletal health over prolonged usage. Understanding this relationship is critical for optimizing exosuit designs to effectively prevent fatigue-related injuries.

The primary objective of this research is to investigate the effects of repetitive loading on biomechanical changes in kinematics and activation patterns of back muscles, quadriceps, and hamstring muscle groups of the lower limb. This study aims to quantify the impact of continuous lifting over time, emphasizing shifts in posture and their influence on muscle fatigue during manual material handling tasks. To address these objectives, we designed an experimental protocol involving repetitive lifting tasks under two configurations: one with passive back exoskeletal assistance and

one without. Passive exosuit assistance is hypothesized to influence kinematics by reducing the range and frequency of compensatory movements, which could otherwise amplify strain on fatigued muscle groups. Additionally, the exosuit is expected to modulate muscle activation patterns, potentially redistributing the mechanical load and delaying the onset of fatigue. A preliminary study was conducted with four participants, where surface electromyography (sEMG) data analysis and kinematic assessments were used to evaluate the influence of exosuit assistance on muscle engagement, fatigue development, and postural adjustments throughout the lifting protocol. This research provides foundational insights into the interaction between exosuit support, muscle fatigue, and biomechanical adaptations during repetitive lifting.

II. Methods

In this section we are presenting our system design, experimental protocol and data analysis procedure.

A. Exosuit Design

The Exosuit provides upper body support and includes a Taylor's Brace (TB), a detachable moment arm, a mid-thigh segment with thigh cuffs, and elastic and non-elastic straps for passive actuation, refer Fig. 1. The elastic straps link the thigh cuffs to a flat release buckle system, enabling easy stiffness adjustments without removing the suit. The elastic bands, with stiffness levels up to 850N/mm, are connected to non-elastic nylon straps via an adjustable side buckle, offering flexibility for different users [20]. The nylon strap connects to load cell (LC1), routed over a pulley in the moment arm assembly, with its other end linked to two nylon straps from shoulder-anchored buckles. Inside the TB, a padded compressive load cell (LC2) is secured with Velcro, using a stitched female strip on the TB and a glued male strip on the LC2 casing to ensure comfort and prevent pinching at the lower back. The elastic strap assists the buttocks during squatting or bending, providing torque to aid lifting, while distributing the spinal load between the trunk, shoulders, and thighs. The moment arm assembly consists of a pocketed base and a flanged-base arm, positioned 45 degrees from the back and measuring 16 cm to reduce device-to-body forces and improve comfort [13]. The arm is securely held in the pocketed base by a catcher lock and can be removed easily by disengaging the lock. The pocketed base is fixed to aluminum strips at the L5-S1 joint on the TB. The exosuit is adjustable for heights varying between 152 cm and 165 cm, which represent the average heights of Indian females and males, respectively, based on NFHS trends [34].

B. Experimental Procedure

Four healthy male participants (age 21.25±0.83 years and an average weight of 72.5±7.54 kg) with no history of spinal disorders or injuries volunteered for the study. None of the participants had a history of musculoskeletal disorders in the past six months. Before the experiment, the participants were briefed about the procedure, and signed informed consent was obtained in accordance with the institute's ethics committee (study approval no: IEC/VV/2021/013).

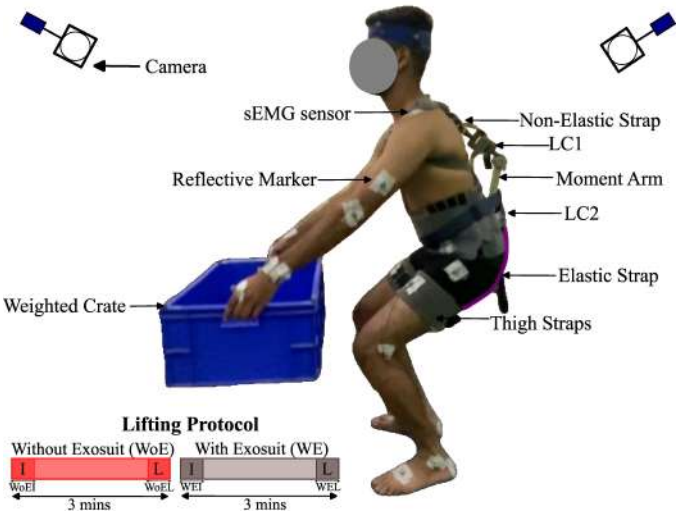

Fig. 1: The repetitive lifting experimental setup. A full-body, 37-marker model was used to track human motion with an eight-camera motion capture system, while participants lifted an 8 kg weighted crate. Eight surface EMG (sEMG) sensors were placed on specific muscles to capture muscle activity during the task. The setup includes Load Cell 1 (LC1) in the moment arm assembly and Load Cell 2 (LC2) on the inner side of the Taylor's Brace (TB), along with elastic and non-elastic straps for actuation and support. The lifting protocol comprised with exosuit and without exosuit.

The experimental setup, shown in Fig. 1, involved repetitive lifting and lowering of a weighted crate. Muscle activity was recorded using eight surface electromyography (EMG) sensors (model SX230, Biometrics, Newport, UK) placed on the multifidus, erector spinae, latissimus dorsi, and trapezius muscles of the back, as well as the rectus femoris and biceps femoris of both lower limbs. The EMG signals were sampled at 1000 Hz. Sensor placement and skin preparation adhered to SENIAM standards [17]. Additionally, 37 reflective markers full-body lumbar spine (FBLS) model was applied to analyze kinematics [18], with data collected via a motion capture system (Vicon, Oxford, UK).

C. Repetitive Lifting Protocol

In this study, the Recommended Weight Limit (RWL) was calculated using the NIOSH Lifting Equation, which takes into account factors such as horizontal, vertical, and distance multipliers, along with frequency, coupling, and asymmetry adjustments [18]. The actual load lifted was 8 kg at a rate of 10 lifts per minute over 3 minutes. Based on these parameters, the Lifting Index (LI) was determined as the ratio of the actual load to the RWL, where an LI exceeding 1 indicates a moderate to severe injury risk. The methodology and calculations adhered to the guidelines outlined in [16].

The experiment involved repetitive lifting and lowering tasks performed both without exosuit (WoE) and with exosuit (WE), refer Fig. 1. The lifting order was randomized, ensuring that either the exosuit or the non-exosuit condition could be conducted first, thus minimizing any potential bias in the

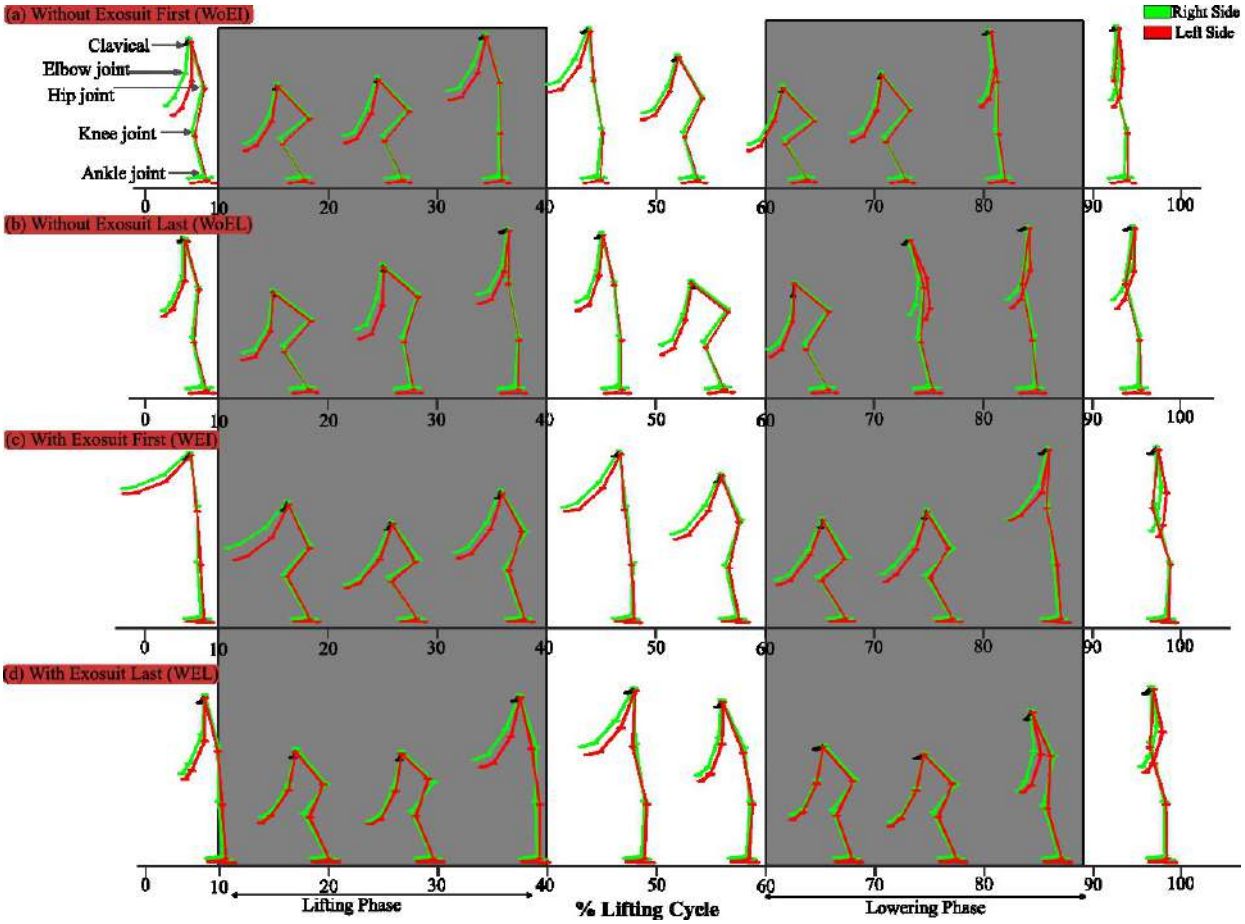

Fig. 2: The sagittal plane stick diagrams of a representative participant's repetitive lifting cycles under the without-exo first, without-exo last, with-exo first, and with-exo last conditions. The diagrams show the right side (green) and left side (red) joint movements. The highlighted regions represent the lifting and lowering of the load during each cycle.

results. To further prevent the influence of fatigue or muscle soreness, participants were given one full day of rest between sessions. This rest period helped to mitigate any confounding factors, ensuring that the results from each session were not influenced by prior performance or muscle fatigue.

D. Data Analysis

Joint angle trajectories, including peak hip and knee flexion, were analyzed during the first and last lifting cycles for both conditions: "without exosuit" (WoEI for the first cycle, WoEL for the last cycle) and "with exosuit" (WEI for the first cycle, WEL for the last cycle), refer to Fig. 1. Electromyography (EMG) signals were band-pass filtered (20–400 Hz), and root mean square (RMS) values were calculated using a 125 ms sliding window. Values were normalized (nRMS) based on the maximum voluntary isometric contraction (MVIC) method, as outlined in [13]. Muscle fatigue was analyzed using processed EMG signals, with the power spectral density (PSD) estimated using Welch's method. The median frequency (MDF) was computed for 1-second epochs, and the starting MDF values for each muscle were normalized for consistency across conditions. Linear regressions were applied to the MDF data points, allowing comparison of fatigue trends over time for each muscle under both conditions, as detailed in [14], [15].

III. Results

Repetitive lifting under two conditions, without exosuit (WoE) and with exosuit (WE), revealed notable kinematic differences during the lifting (10–40%) and lowering (60–90%) phases. As shown in Fig. 2(a-d), trunk, hip, and knee flexion varied across four conditions: Without Exosuit First (WoEI), Without Exosuit Last (WoEL), With Exosuit First (WEI), and With Exosuit Last (WEL). Further, distinct patterns of hip and knee flexion were observed in the joint angle trajectories, see Fig. 3, further support these findings.

A. Joint Kinematics

Without Exosuit (WoE): A noticeable increase in trunk flexion was observed in WoEL compared to WoEI, particularly during the lifting phase (around 20%), as shown in Figs. 2(a) and (b). The hip joint showed reduced extension and increased flexion during lifting, while knee flexion decreased during lowering (60–90% of the cycle). These adaptations, evident in the stick diagrams, Figs. 2(a) and (b), and are further supported by distinct patterns of peak hip and knee

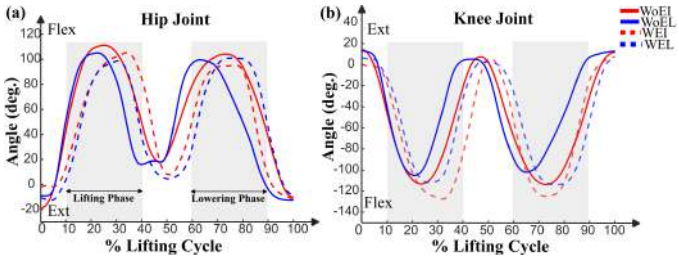

Fig. 3: (a-b) Representative participants' right leg hip and knee joint kinematics in the sagittal plane. Solid lines represent without exosuit (WoEI and WoEL), and dashed lines represent with exosuit (WEI and WEL). Highlighted regions indicate the lifting and lowering phases of the cycle.

flexion observed in joint angle trajectories Fig. 3(a) and (b), highlighting progressive kinematic adaptations across cycles.

With Exosuit (WE): During the initial lifting cycle with exosuit assistance (WEI), less trunk flexion was observed around 20% of the lifting phase compared to the last cycle (WEL), as shown in Figs. 2(c) and 2(d). This observation suggests that the exosuit in WEI assists in maintaining a more upright posture during the lift. During the lowering phase, trunk flexion was reduced by around 70% in WEL compared to WEI, indicating postural adjustments introduced by the exosuit over time. Consequently, these differences are evident with less hip flexion and controlled knee flexion observed in Fig. 3(a) and 3(b), highlighting the role of the exosuit in facilitating more efficient and controlled movement patterns during repetitive lifting.

Without Exosuit (WoEI) vs With Exosuit (WEI) - First Cycle: In the initial lifting cycle, WoEI showed greater trunk flexion (around 20%) than WEI, as seen in Figs. 2(a) and 2(c), suggesting that the exosuit helps maintain a more upright posture in WEI. The WEI condition also demonstrated more controlled hip and knee flexion during lifting (20–40%) and lowering (60–80%) phases. The joint angles during lifting in WEI showed smoother and more controlled flexion patterns in the hip and knee, as illustrated in Figs. 3(a) and 3(b), compared to the more abrupt and inconsistent flexion observed in WoEI. During the lowering phase, the WEI condition enabled smoother, more controlled hip and knee extension, as further highlighted in the joint angle trajectories, refer to Fig. 3(a) and 3(b), while the WoEI condition exhibited abrupt and uneven movements.

Without Exosuit (WoEL) vs With Exosuit (WEL) - Last Cycle: In the last lifting cycle, the WEL condition showed reduced trunk flexion and more controlled hip and knee movements during both the lifting (20–40% of the cycle) and lowering phases (60–80% of the cycle) compared to WoEL, as seen in Figs. 2(b) and 2(d). The WoEL condition exhibited greater variability in joint movements, while the WEL condition promoted smoother and more consistent motion patterns, highlighting exosuit assistance. Joint angle data in Fig. 3 further highlights these distinctions.

Kinematic analysis across participants: Peak flexion angles of the hip and knee joints demonstrated distinct patterns between conditions with and without exosuit assistance, see Figs. 4(a) and 4(b). During the lifting and lowering phases, hip flexion was higher in the conditions without exosuit assistance (WoEI and WoEL), indicating greater reliance on the hip joint to compensate for the absence of external support, see Fig. 4(a). In contrast, with exosuit assistance (WEI and WEL), hip flexion was reduced, reflecting the exosuit's ability to alleviate the demand on the hip joint. In the case of knee flexion, an opposing trend was observed. Without the exosuit (WoEI and WoEL), knee flexion was slightly lower, suggesting a compensatory strategy that relied more heavily on the hip, see Fig. 4(b). However, with exosuit assistance (WEI and WEL), knee flexion increased, reflecting a more coordinated and balanced engagement of the hip and knee joints. This increased knee flexion allowed for a greater range of motion, facilitating improved posture and motion efficiency during the lifting and lowering tasks.

B. EMG Analysis

Muscle Activation: Repetitive lifting tasks revealed distinct differences in muscle activation levels under the two conditions: without exosuit (WoE) and with exosuit (WE). Figure 5(a) highlights these variations by presenting the mean activation levels of the targeted muscle groups. Essentially, a general reduction in muscle activation was observed across all muscle groups when participants performed tasks with exosuit support. The Multifidus and Erector Spinae muscles exhibited a marked decrease in activation levels, suggesting that the exosuit effectively alleviated the workload on these muscles. On the other hand, while the Latissimus Dorsi and Trapezius muscles showed similar trends of reduced activation, the extent of reduction was more pronounced in lower limb muscles, such as the Rectus Femoris and Biceps Femoris. Consequently, the overall muscular demand during lifting tasks appeared to be redistributed and diminished with exosuit assistance.

Muscle Fatigue: The regression slopes derived from the median frequency (MDF) analysis, representing muscle fatigue under the two conditions, as shown in Fig. 5(b). Without exosuit, fatigue slopes were generally more negative, indicating a greater accumulation of fatigue over time. In contrast, with the exosuit, fatigue slopes tended to be closer to zero, reflecting a reduction in fatigue accumulation. Notably, the Multifidus and Erector Spinae muscles substantially improved fatigue resistance when using the exosuit. Similarly, the Trapezius and lower limb muscles exhibited less fatigue with exosuit support. Essentially, these findings highlight the exosuit's capacity to enhance muscle endurance during repetitive lifting tasks.

IV. Discussion and Conclusion

In this study, we aimed to investigate the biomechanical effects of repetitive lifting, focusing on kinematics, muscle activation, and fatigue. Our experimental protocol assessed these factors under two conditions: with and without passive back exosuit assistance. The findings revealed notable differences in kinematic and muscle activation patterns between the two conditions. Notably, distinct postural strategies emerged during both the lifting and lowering phases, with

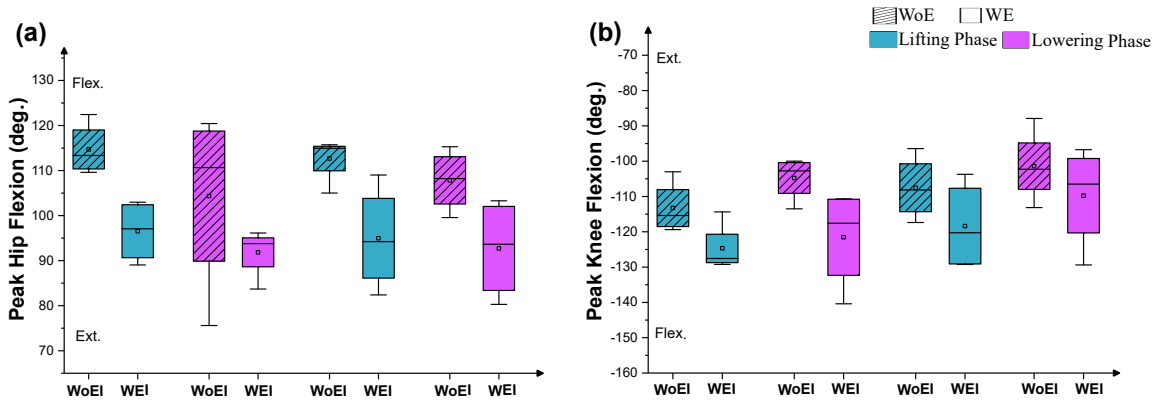

Fig. 4: (a) Peak hip flexion and (b) peak knee flexion while lifting and lowering the load for four participants under two conditions: without exosuit (WoE) and with exosuit (WE) during the first and last cycles of repetitive lifting.

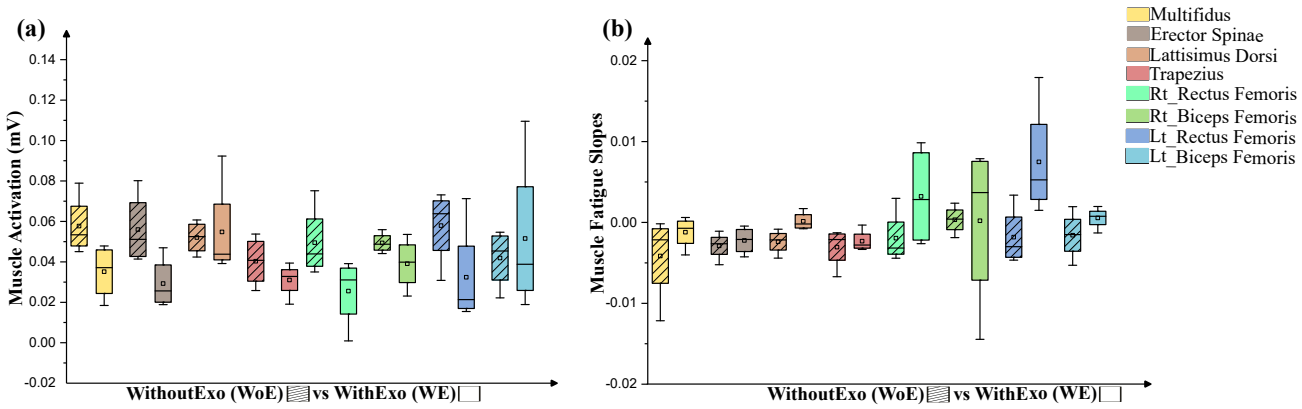

Fig. 5: (a) Muscle activation and (b) muscle fatigue results for four participants under two conditions: without exosuit (WoE) and with exosuit (WE). The targeted muscles include the Multifidus, Erector Spinae, Latissimus Dorsi, Trapezius, and lower limb muscles (Right/Left Rectus Femoris and Biceps Femoris). Activation values represent mean values, while fatigue values are represented by regression slopes from median frequency (MDF) analysis.

the exosuit playing a crucial role in reducing compensatory movements and improving movement efficiency. These results highlight the potential of passive exosuit assistance in enhancing lifting performance by reducing biomechanical strain and improving movement efficiency, with implications for improving worker safety and reducing fatigue during repetitive lifting tasks.

A key observation in this study was the reduction in muscle activation levels, particularly in the Multifidus and Erector Spinae muscles, when participants used the passive exosuit. This reduction highlights the exosuit's role in alleviating physical demands on spinal stabilizers, thereby decreasing overall muscular strain. Similar trends have been reported in previous research, where the use of passive back exosuits during lifting tasks resulted in decreased lumbar extensor muscle activation [13], [26], [27]. These findings emphasize the role of passive back exosuits in improving biomechanical efficiency and reducing the risk of musculoskeletal strain during physically demanding tasks.

The observed decrease in fatigue accumulation, as evidenced by median frequency regression slopes tending to remain closer to zero, further emphasizes the exosuit's role in enhancing muscle endurance during repetitive lifting tasks. By reducing the physical demands on stabilizing lower back muscles, the exosuit delays fatigue onset, thereby mitigating compensatory movements that can elevate strain on other muscle groups and joints [21], [31]. This aligns with the study's objective to investigate fatigue-related biomechanical adaptations, demonstrating that passive exosuits not only promote more efficient and ergonomic movement patterns but also reduce the risk of musculoskeletal injuries. These benefits contribute to safer and more sustainable lifting practices, supporting findings from prior research indicating that minimizing fatigue enhances both immediate task performance and long-term musculoskeletal health [32], [33]. Consequently, these results show that passive exosuits can improve work efficiency in tasks involving repetitive lifting.

In the current experiments, preliminary results revealed notable biomechanical adaptations introduced by exosuit assistance, largely driven by the repetitive nature of the lifting task. Without the exosuit, participants developed a stooped posture, characterized by increased trunk flexion and reduced knee involvement, as a compensatory response to the repeated demands of the task. This pattern heightened strain on lower back stabilizers, accelerating fatigue onset and exacerbating biomechanical inefficiencies [24], [25]. Over

time, these fatigue-driven compensations increased the risk of injury [28], [29]. In contrast, with exosuit assistance, participants maintained a more upright posture and better joint coordination, redistributing the repetitive workload across joints and alleviating strain on the spinal stabilizers. This delayed fatigue accumulation, supporting more efficient task execution and reducing deviations from optimal posture. These findings highlight the importance of passive exosuits in mitigating the cumulative strain caused by repetitive lifting tasks, enhancing long-term safety and performance.

While this study provides valuable insights into the potential of passive exosuits in enhancing ergonomic outcomes and reducing muscle fatigue during repetitive lifting tasks, it is important to acknowledge its limitations. The findings are based on a small sample size and lack comprehensive statistical analysis, necessitating further research to validate and expand upon these results. Direct measurements of muscle fatigue and biomechanical adaptations are essential for deeper understanding. Overall, this study underscores the utility of exosuits in occupational and rehabilitation settings, promoting worker safety, efficiency, and long-term musculoskeletal health.

Where Is My Hand? Assessing Visuo-Tactile Integration of Hand and Shoulder After Virtual Reality Training Using a Body-Machine Interface

Lucas R. L. Cardoso[1], Harriet Dempsey-Jones[1], Antonio P. L. Bo[1,2], Vanesa Bochkezanian[3], Arturo Forner-Cordero[4], Alejandro Melendez-Calderon[1,5,6]

***Abstract*— Immersive virtual reality (VR) has potential for enhancing rehabilitation in clinical populations, such as individuals with stroke, but many face usability challenges. A promising approach involves a Body-Machine Interface using shoulder movements to control a virtual hand, potentially altering body perception. Investigating bodily illusions is crucial for expanding therapeutic applications. This study examines how a single VR motor-training session, using shoulder movements to control a virtual hand, affects brain representations of the real hand and shoulder. The Crossmodal Congruency Test (CCT) was adapted to assess the visuo-tactile interaction between the shoulder and hand in neurotypical participants before and after VR training. Nine participants controlled the virtual hand with shoulder movements, while eight used their fingers, both receiving shoulder tactile feedback. No significant differences were found in hand-to-shoulder visuo-tactile integration. The results suggest that the Body-Machine Interface may not alter bodily representations of the hand and shoulder, or that tactile feedback alone could elicit changes. Although the results did not fully meet expectations, the study provided valuable insights and identified methodological limitations for future research.**

I. Introduction

In recent years, immersive virtual reality (VR) has been proposed as a tool to enhance rehabilitation practices [1]. However, despite the appeal of its immersive components and gaming elements, many individuals with conditions such as stroke or spinal cord injury face usability challenges [2], including difficulty holding controllers, pressing buttons, or using modern finger-tracking systems, which are often incompatible with non-standard hand gestures.

One promising approach to enable VR interaction for individuals with hand impairments is a Body-Machine Interface [3], which leverages alternative body parts, such as the shoulder, to control hand movements in VR [4]. However, it is still unclear how such a Body-Machine interface influences an individual's perception of their body.

If the avatar's hand, controlled by shoulder movements, is perceived as an extension of the user's actual hand (a phenomenon known as embodiment [5]), how might this control strategy affect body representation for both body parts? Could it alter interactions with the real shoulder and hand or induce neurophysiological adaptations? These questions remain largely unexplored.

Previous research showed that after prolonged training (20 sessions) with a robotic hand controlled by forearm muscle signals, participants exhibited significant body representation adaptations [6]. However, embodiment has been shown to occur almost instantaneously in illusory or immersive VR environments [5]. This study investigates how a single VR motor-training session using shoulder movements to control a virtual hand affects body representations of the real hand and shoulder.

Body representations in the brain are linked to the size of the peripersonal space (PPS)—the space around a body part where sensory stimuli are integrated. Research has shown that reaction times to tactile stimuli on the fingers are influenced by concurrent visual input within the hand's PPS. This visuo-tactile integration can assess whether objects, such as tools [7] or virtual avatars [5], [8], are incorporated into the PPS, reflecting changes in body representation.

In a prior study, we adapted this paradigm by applying tactile stimuli to the shoulder while presenting visual distractors near a virtual hand [9], aiming to measure hand-to-shoulder visuo-tactile integration. These regions are thought to be naturally connected, as suggested by brain models of bodily representation [10] and PPS interactions between body parts like the hand and foot [11]. We hypothesize that testing this paradigm before and after VR training, where shoulder elevation controls the virtual hand's pinch, will strengthen cross-body part interaction.

Although preliminary results showed no significant hand-to-shoulder interaction [9], in the present study, we modified the VR protocol by pairing virtual touches to the index finger or thumb with corresponding vibrations at distinct shoulder locations. This addition compensates for the previous reliance on proprioceptive feedback alone by introducing artificial tactile feedback.

Building on prior findings, this study examines how tactile feedback affects hand-to-shoulder PPS interactions. To obtain preliminary data before expanding to a larger cohort, we adopted a fixed-order design to minimize variability and identify trends while keeping the sample size manageable. We hypothesize that pairing tactile feedback over the trapezius with virtual index or thumb touches enhances visuo-tactile integration between the shoulder and hand.

II. Materials and Methods

A. Participants

We recruited 21 right-handed, English-speaking adults (18–65) from the university community. Inclusion required the ability to perform 30 minutes of seated upper-limb movements, while exclusion criteria included neurological conditions (e.g., stroke, spinal cord injury) or inability to provide informed consent. The protocol was approved by the University of Queensland's Ethics Committee (2022/HE002234). All participants were naive to the experimental conditions and provided informed consent.

Three participants were in the pilot phase were excluded from analysis, and one withdrew due to technical issues, leaving 17 for analysis (*Finger* group: $n = 8$, 22–35 years, 2 women; *Shoulder* group: $n = 9$,21–37 years, 1 woman). Demographics were similar between groups, with comparable age, handedness, and sleep assessments.

B. Experimental setup

Participants were seated comfortably (Figure 1A), and four vibrotactile motors (LRAs; LV101040A, Jinlong Machinery) were placed on the front and back of the right shoulder and on the tips of the right index finger and thumb, secured with hypoallergenic medical tape. The shoulder LRAs were positioned to align with the C4 dermatome. The LRAs were controlled with a custom-made *Haptic Box* integrating an Arduino Nano 33 BLE, a custom PCB, and a DRV2605 motor driver (Texas Instruments). This box also integrated input from two push buttons for participants to indicate perceived vibration locations during the CCT using their left (non-tested) hand, which rested on the desk with the two buttons under their index finger and thumb, mirroring the right hand receiving stimuli.

Shoulder elevation was tracked using OpenCV in Python with a webcam detecting two ArUco tags: one fixed on the chair and another on the participant's right scapula (Figure 1B). The system operated at 44 FPS, with tag distance increasing as the shoulder was raised. Both groups, including *Finger*, performed calibration as in [9]. Unlike our previous study, which used Inertial Measurement Units (IMUs) with a Kalman Filter for shoulder tracking [9], this study employed three IMUs (Avanti, Delsys) on the right Trapezius, upper arm, and forearm solely to record shoulder activity. Shoulder engagement during VR training was estimated from the Trapezius IMU as the highest roll angle within each trial.

Participants received instructions about the experimental protocol, prior to wearing a VR headset (Oculus Quest 2, Meta, USA) and noise-isolating headphones. The VR environment was developed in Unity 3D (2022.3.26f1) and displayed a tracked virtual hand in a fixed pinching posture (Figure 1A inset).

C. Experimental protocol

After providing consent, participants completed baseline demographic forms, the Epworth Sleepiness Scale (ESS), the Pittsburgh Sleep Quality Index (PSQI), and the Edinburgh Handedness Inventory. The EES and PSQI assessments were included to consider potential fatigue due to poor sleep. Figure 2 illustrates the experiment phases, which included a VR-based motor training task and Cross-Modal Congruency Test (CCT) phases, followed by subjective reports to assess participants' phenomenological experience. The latter consisted of (1) a six-item Ownership subscale from a standardized embodiment questionnaire [13], which assessed virtual hand ownership on a 7-point Likert scale; and (2) the NASA-TLX, which measured workload on a 0–20 scale to evaluate task load differences affecting CCT performance. CCT blocks lasted 5–6 min, VR training 10–15 min (*Shoulder* group longer due to motor learning), with total session time under 90 min.

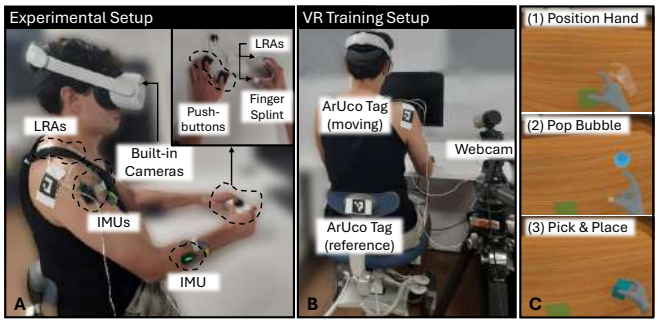

Fig. 1. **Experimental Setup.** A) Hand tracking via the headset's cameras; IMUs record shoulder activity. The Haptic Box, with four vibrotactile motors (LRAs), supports H2H and H2S implementations, and the tactile feedback during the VR training, with shoulder-mounted devices vibrating upon virtual touch. B) Shoulder elevation (only for the *Shoulder* group) is tracked using ArUco tags and a webcam. C) The VR task involves three stages: hand-shadow alignment, bubble popping, and block placement to start the next trial.

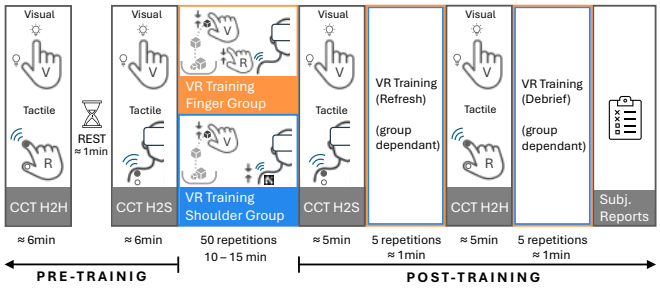

Fig. 2. **Experimental Design.** Two groups controlled a virtual pinch: *Finger* (fingers) and *Shoulder* (shoulder movements). Both received vibrotactile feedback on the shoulder during VR training. In the CCT, visual distractors appeared near the virtual hand, with tactile stimuli applied to the real hand (H2H) or shoulder (H2S). Assessments occurred *pre* and *post* training. Letters inside the hand indicate real (R) or virtual (V) body parts.

During VR training, participants interacted with objects using their virtual index finger or thumb, following a three-stage trial: (1) aligning the virtual hand with a shadow cue, (2) popping a bubble, and (3) picking and placing a block to complete the trial (Figure 1C). Training emphasized successful execution over speed. *Shoulder* and *Finger* groups experienced distinct VR training conditions. The *Finger* group controlled the virtual hand using real index-thumb movements (enabled by the Oculus Quest's vision-based hand tracker), while the *Shoulder* group used scapular elevation/relaxation (enabled by the real-time tracking of

the ArUco Tags). To maintain a similar hand shape across groups during VR training, all participants, regardless of their group, held a piece of foam with their middle, ring, and little fingers. In addition, participants in the *Shoulder* group wore a custom-fitted finger splint on the index finger and thumb to ensure a fixed curved posture between these digits. Both received vibrotactile feedback on the trapezius when touching virtual objects, but only the *Shoulder* group experienced a visuo-proprioceptive link between their shoulder and pinch motions.

CCT, described in detail in section II-D, was assessed *pre* and *post* training, using the two types, H2H (*virtual* Hand to *real* Hand) and H2S (*virtual* Hand to *real* Shoulder). The study followed a 2 (test stage: pre, post) × 2 (test type: H2H, H2S) design. To obtain preliminary data from a limited cohort while minimizing variability, we fixed the order of conditions across participants to ensure that any observed effects were not influenced by order-related differences. This approach allowed us to identify trends more clearly before introducing counterbalancing in a future full study. In the pre-stage, we ran the CCT H2H first to mitigate potential effects of the embodiment of the virtual hand, based solely on visual feedback. In the post-stage, the CCT H2S was administered immediately after the VR training to prevent potential washout effects.

The sequence was (Figure 2): pre-training CCT H2H, pre-training CCT H2S (after a short break), VR training (50 trials), post-training CCT H2S, and post-training CCT H2H (after a brief 5-trial refresh). Breaks minimized interference, and a final 5-trial VR session ensured subjective questionnaires reflected the training rather than CCT.

Each CCT block (H2H pre, H2S pre, H2S post, H2H post) had 60 trials (30 congruent, 30 incongruent) and 8 no-go trials (see section II-D). Before H2H pre and H2S pre, participants completed 10 Target-Only trials (no visual distractors) to learn vibration-button mapping and 20 Familiarization trials (with visual distractors, reaction times not analyzed), including 2 no-go trials. The CCT used the same VR environment, displaying a fixation sphere (15mm diameter) that turned green for 1–1.5s to signal trial start. After each trial, it flickered at 36Hz [15]—green for correct, red for incorrect. A stopwatch appeared if response time exceeded 1500ms [15]. Visual distractors (blue spheres, 15mm diameter) flickered at 36Hz for 200ms [15] near the index finger or thumb. All participants, regardless of the group, wore a custom-fitted finger splint on their right index finger and thumb, and held a piece of foam with their middle, ring, and little fingers, to maintain hand shape.

D. Crossmodal Congruency Test

To access the visuo-tactile integration between the shoulder and hand, we used an adaptation of a psychophysiological assessment, Crossmodal Congruency Test (CCT) [12].

In the classical CCT, participants rapidly discriminate between two tactile stimuli at distinct body locations (e.g., index finger and thumb) while ignoring visual distractors near one location. The test includes congruent trials, where tactile and visual stimuli coincide, and incongruent trials, where they differ [12]. Reaction times are typically slower in incongruent trials, a difference termed the Crossmodal Congruency Effect (CCE) [8], [12], [14], [15]. This effect is amplified when tactile and visual stimuli are spatially close, a phenomenon known as *Spatial Modulation*, which is used to study tool incorporation [16].

In our adaptation, *CCT H2S* (*virtual* Hand to *real* Shoulder), tactile stimuli were applied to the shoulder, while visual distractors appeared near the virtual hand. We also tested the classical (but virtual) *CCT H2H* (*virtual* Hand to *real* Hand), where tactile stimuli were applied to the real hand.

CCE and Spatial Modulation were calculated as:

$$CCE = \frac{\sum_{n=1}^{N} RT_{incong}}{N} - \frac{\sum_{n=1}^{M} RT_{cong}}{M} \quad (1)$$

and

$$Spatial\ Modulation = CCE_{H2H} - CCE_{H2S} \quad (2)$$

where RT_{incong} and RT_{cong} are reaction times (RTs, in seconds) for incongruent and congruent trials, occurring N and M times, respectively. RTs were measured as the duration between the vibration stimulus (shoulder or fingers) and the button press (contralateral index or thumb).

H2S results indicate (virtual) hand to (real) shoulder visuo-tactile integration, while H2H reflects integration between the virtual and real hand. Comparing CCEs between H2S and H2H provides insights into Spatial Modulation, as H2H involves co-localized stimuli, whereas H2S spatially separates them.

The protocol includes *no-go* trials, where the finger and thumb visual distractors appear simultaneously, prompting participants to withhold responses to maintain attention and prevent eye closure. Visual feedback after each trial categorizes responses as correct, incorrect (green or red sphere between index and thumb), or too slow (a stopwatch in the same size and location as the sphere).

E. Data analysis

Analyses were conducted using MATLAB® 2022a and GraphPad Prism. Trials with reaction times between 200–1500ms were included [14], [15].

Given the study's exploratory nature, we used the Least Significant Difference (LSD) method [17] to identify trends for future research. Normality was assessed via Shapiro-Wilk tests, with non-parametric tests (Mann-Whitney and Wilcoxon signed-rank) used when assumptions were unmet.

To validate CCT data, a repeated measures ANOVA examined adaptation effects across the last five correct trials, followed by Tukey's post-hoc tests. Spatial Modulation variance was assessed using Pitman-Morgan's and Levene's tests.

Demographic variables (age, handedness, sleepiness, VR practice, shoulder engagement) were compared using independent t-tests. Subjective reports were analyzed with the Mann-Whitney test.

Statistical significance is denoted as $*$ ($p \leq 0.05$) and $**$ ($p \leq 0.01$).

III. Results

The results indicated successful adaptation to VR training for both groups, but no significant group differences in CCE, Spatial Modulation, or subjective ownership reports.

A. Validity of the CCT Data

In target-only trials, all participants exceeded 80% accuracy, confirming task comprehension.

Reaction time analysis of the last five correct trials per CCT block, including pre-stage Target Only and Familiarization blocks (Figure 3), showed a significant block effect in incongruent trials ($F(3.68, 58.92) = 11.45, p < 0.0001$), but not in congruent trials ($F(2.95, 47.21) = 2.154, p = 0.1069$).

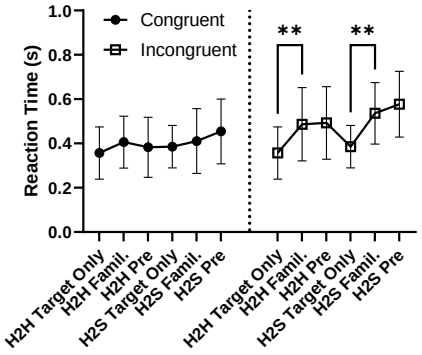

Fig. 3. **Adaptation During CCT.** Mean reaction times for the last five correct trials, segmented by congruency type.

Tukey's test showed visual distractors significantly increased reaction times in incongruent trials for H2H ($t(16) = -4.25, p = 0.0067$) and H2S ($t(16) = -4.97, p = 0.0016$), but no other consecutive block comparisons were significant, indicating stabilization post-familiarization.

False alarm rates in no-go trials (7%) align with previous studies [14], supporting data validity.

B. VR Training

The graph in Figure 4 shows *time per trial* fitted to an exponential function and *shoulder movement amplitude*, measured as the highest roll angle from the IMU on the Trapezius muscle. These metrics indicate participants' adaptation during VR training.

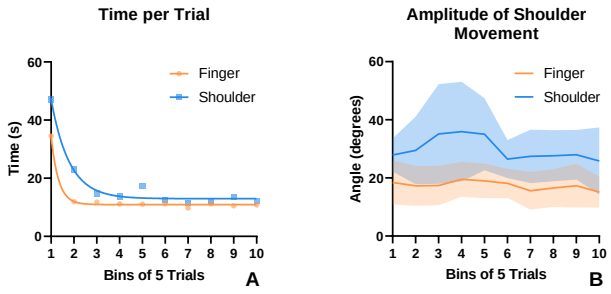

Fig. 4. **Adaptation During VR Training.** A) Average trial time for *Finger* and *Shoulder* groups, binned in sets of 5 trials. Solid lines show exponential least squares fits. B) Mean shoulder engagement, measured as the highest roll angle from the accelerometer.

The *Finger* group started with 12 seconds lower trial time and had a faster decay constant ($\tau = 0.80$) than the *Shoulder* group ($\tau = 0.32$). No significant difference was found in the last five bins' average trial times ($t(15) = -1.99, p = 0.064$), indicating both groups effectively learned to control virtual pinching.

The *Shoulder* group had significantly higher shoulder engagement than the *Finger* group ($t(12) = -3.39, p = 0.005$), consistent with their control modality.

C. Reaction Times and Crossmodal Congruency Effect

Trials with too-fast, too-slow, or incorrect responses were excluded (20, 0.5%, and 184, 4.5%, respectively). Exclusions were similar across groups, with 10 too-fast and 10 too-slow in each, and incorrect responses resulted in 79 exclusions for the Finger group and 105 for the Shoulder group.

Wilcoxon signed-rank tests on average reaction times showed significant differences ($p < 0.05$) in all CCT stages, trial types, and participant groups (Figure 5A). For between-group CCE analyses, no significant effects were found: stage ($F(2.16, 32.45) = 1.78, p = 0.181, \eta_p^2 = 0.11, 1 - \beta = 0.15$); group ($F(1, 15) = 2.07, p = 0.171, \eta_p^2 = 0.16, 1 - \beta = 0.42$); or interaction ($F(3, 45) = 0.76, p = 0.521, \eta_p^2 = 0.05, 1 - \beta = 0.07$).

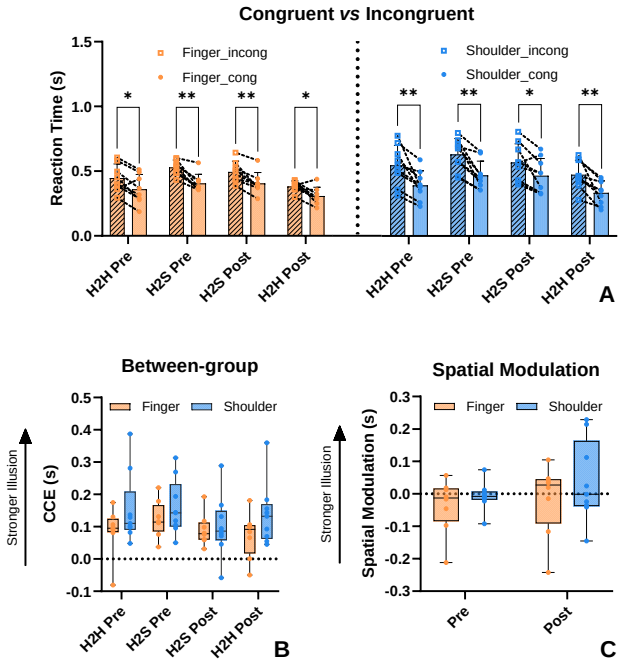

Fig. 5. **Summary of Reaction Times, CCE and Spatial Modulation Across Stages and Groups.** A) The reaction times for congruent and incongruent trials, with error bars representing the standard deviation. B) The between-group comparison for the CCE. Greater values mean stronger illusion (or visuo-tactile integration). C) The bottom-right panel shows Spatial Modulation results. Greater values mean stronger illusion.

D. Spatial Modulation

Results for Spatial Modulation are shown in Figure 5C. Wilcoxon signed-rank and Mann-Whitney tests (pre vs. post within- and between-group) were not significant: stage ($F(1, 15) = 0.86, p = 0.369, \eta_p^2 = 0.05, 1 - \beta = 0.07$);

group ($F(1,15) = 1.78$, $p = 0.202$, $\eta_p^2 = 0.09$, $1-\beta = 0.11$); interaction ($F(1,15) = 0.11$, $p = 0.744$, $\eta_p^2 = 0.01$, $1-\beta = 0.05$).

Homogeneity tests found no variance difference in the *Finger* group ($t(6) = 0.70, p = 0.511$), but a significant difference in the *Shoulder* group ($t(7) = 4.15, p = 0.0043$), with an 8.4-fold variance increase post-training.

E. Subjective Reports

For both subjective assessments (Ownership and NASA-TLX), no significant group differences were found across all questions and dimensions (Figure 6).

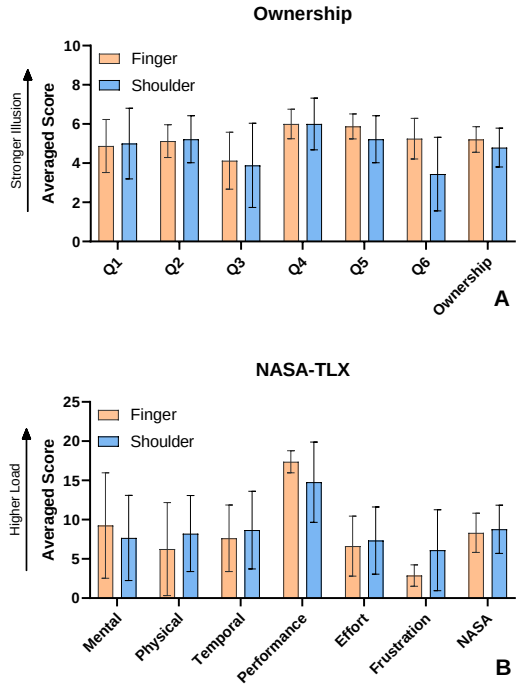

Fig. 6. **Results from the Subjective Reports.** A) Results from the Ownership questionnaire, where higher values indicate a stronger illusion of ownership in VR. B) The NASA Task Load Index scores for the Finger and Shoulder groups, with higher values indicating greater physical or cognitive load experienced during the VR training.

IV. Discussion

Interacting with VR via a Body-Machine Interface, using body parts like the shoulder to control hand movements in virtual environments, provides a valuable solution for clinical applications, such as for individuals with stroke or spinal cord injury. By inducing VR illusions to alter body perception, the technology's therapeutic potential extends beyond assistive use.

This study explores how a single VR motor-training session, using shoulder movements to control a virtual hand, affects body representations of the real hand and shoulder in neurotypical participants. Building on previous work [9], we address the lack of tactile feedback during VR training. The aim was to examine hand-to-shoulder visuo-tactile integration in two groups: one using shoulder movements to control the virtual hand's pinch and the other using finger movements. Finger tracking, used in both VR training for the *Finger* group and all CCT blocks, improves upon our prior setup, where participants held a controller to detect hand movements.

We adapted the Crossmodal Congruency Test (CCT) to assess visuo-tactile interaction and the relationship between the PPS of the shoulder and hand. The main variables were the Crossmodal Congruency Effect (CCE), reflecting the difference in reaction times between congruent and incongruent trials, and the Spatial Modulation of the CCE, quantified as the difference between the CCE for the virtual and real hand (CCT H2H) and the virtual hand and real shoulder (CCT H2S). CCT blocks (H2H and H2S) were performed pre- and post-VR training to assess the intervention's impact.

A. Incongruent vs Congruent Trials

We expected longer reaction times in incongruent trials, resulting in a positive CCE. For the *Shoulder* group, we hypothesized an increased CCE H2S post-training, indicating enhanced hand-to-shoulder visuo-tactile integration, with no changes in CCE H2H. To control for practice effects, we analyzed CCT adaptations (Section III-A). Our results showed significantly higher reaction times for incongruent trials. However, as shown in Figure 5B, some participants had negative CCEs, consistent with previous studies [8], [15]. Further analysis is needed to investigate potential causes, including outliers (e.g., attentional deviations) affecting the global mean.

B. Changes in CCE and Spatial Modulation

For the *Finger* group, we expected no change in CCE H2S (pre vs. post) as passive shoulder feedback alone (actile feedback, but no active movement engagement) was insufficient for integration, but anticipated an increase in CCE H2H due to active finger engagement. In the *Shoulder* group, we hypothesized an increase in CCE H2S due to both shoulder feedback and active movement, and a higher post CCE H2S compared to the *Finger* group. We expected CCE H2H in the *Shoulder* group to remain stable (or decrease) due to lack of active finger engagement, while the *Finger* group was expected to show a larger post CCE H2H. Finally, we predicted increased Spatial Modulation post-training in the *Shoulder* group, but no change in the *Finger* group.

Contrary to expectations, no statistical differences were found within or between groups. While the small sample size limits conclusions, these findings suggest two possibilities: (1) a lack of hand-to-shoulder visuo-tactile integration in both groups, or (2) equivalent integration in both groups, indicating shoulder tactile feedback alone could induce changes without active movement. This may be due to visual feedback dominating the embodiment effect, as prior research suggests visual dominance in body ownership and perceptual integration [19]. The virtual hand's visual representation may have strongly influenced ownership, overshadowing tactile feedback and motor control effects.

Data showed a visual trend toward reduced CCE post-training, particularly in the *Shoulder* group, suggesting both methods reduced hand-to-shoulder integration. An alterna-

tive explanation is increased participant awareness of VR elements, reducing the illusion effect over time. This aligns with findings that CCE is lower for naturalistic hands than non-naturalistic ones [5].

Regarding Spatial Modulation, trends were consistent with expectations. The significant pre-post change in variance in the *Shoulder* group suggests a differential intervention effect. Further investigations are needed to explore this.

While results didn't fully align with expectations, this study has provided valuable insights, helping us identify methodological limitations and areas for improvement in future iterations.

C. Subjective Reports

The lack of between-group differences in the Ownership questionnaire suggests that both groups experienced a similarly high sense of ownership over the virtual hand, regardless of the effector used, aligning with the CCE and Spatial Modulation results. Similarly, the NASA-TLX scores indicated comparable motor and cognitive load, as well as performance perception, suggesting that the *Shoulder* group found the new motor skill intuitive and easy to acquire.

D. Limitations and Future Work

This experiment has several limitations. First, it is underpowered due to small group sizes. While studies with groups of $N \leq 10$ have been conducted [8], our power analysis indicates that at least 30 participants are needed for 80% power. Increasing the sample size would reduce variability and improve power. However, adjustments to the experimental design could also help. Of the 15 studies reviewed using CCE as the primary outcome, only one compared two groups [18], highlighting inter-subject variability as a limitation. Future studies could adopt a within-subject design to mitigate this. Additionally, more robust methods, such as gaze tracking available in other VR headsets, could replace the no-go trials to control attentional deviation.

In our setup, participants discriminated between tactile stimuli on the front or back of their shoulder, with the right hand positioned with the index finger distal and the thumb proximal. However, the left hand mirrored the right, introducing a confounding factor that disrupted tactile stimuli and enhanced visual distractors, potentially affecting response accuracy. Using foot pedals, as in classical CCT implementations [12], would address this issue.

Similarly, although the tactile stimuli and finger positioning during the CCT were both normal to the coronal plane, this alignment was not maintained during training, as participants could grip in any direction. This variability may have influenced the assimilation of virtual touches to the respective shoulder locations. Future implementations should ensure that grip positioning consistently aligns with tactile placement during training.

Additionally, our CCT protocol may be susceptible to a washout effect, limiting the capture of lasting VR practice effects. In studies measuring tool incorporation, interleaving CCT trials with tool-use trials enhances retention [16]. Since our protocol separated VR practice from post-training CCT, the effects may have diminished. Future research should incorporate "active CCT" to strengthen retention.

Finally, our design did not control for visual feedback, which could have influenced results. This may have limited our ability to isolate the effects of hand-to-shoulder integration in VR. Future studies should include a control group with an abstract hand avatar to better isolate these effects.

Evaluating Convolution Neural Network Architecture for Neural Drive Decoding from High-Density Surface Electromyography

Jirui Fu[1,2], Helen J. Huang[1,2,3], and Yue Wen[1,2]

***Abstract*—Prior studies demonstrated encouraging results in the application of convolution neural network models (CNN), one-dimensional (1D CNN), or three-dimensional (3D CNN) convolutional layers to decode the neural drive to muscles from high-density surface electromyography (HD-sEMG) signals. However, the impact of the dimensionality (1D or 3D) of the convolutional layers on the performance of the deep CNN models using the same dataset has yet to be investigated. This study assesses the performance of 3D CNNs and 1D CNNs in extracting the neural drive as a cumulative spike train (CST) under various window sizes and step sizes that are critical parameters in decoding neural drives. Experimental HD-sEMG dataset sourced from the gastrocnemius medialis muscle of three participants, alongside the corresponding neural drive decoded using the convolution kernel compensation (CKC) algorithm, was employed to train and validate the 1D and 3D CNN models. We compared the F1 score and correlation coefficient between the CST from CKC and those from both 1D and 3D CNN models, revealing that 1D CNN performs more effectively with larger sliding window sizes (80 or 120 samples) with a peak F1 score of 0.84 and a correlation of 0.94. In contrast, 3D CNN achieves peak F1 score (0.83) and correlation (0.92) with smaller sliding window sizes (20 or 40 samples), indicating reduced latency in using 3D CNN to decode neural drives. Both models experience a performance decline as the step size increases. Furthermore, this research evaluates the computational cost of 1D and 3D CNN models, finding that the 3D CNN model requires significantly more computational resources (938G FLOPs) than the 1D CNN model (60G FLOPs). The results elucidate significant distinctions between CNN architectures and identify optimal parameters and model selection for precise and real-time neural drive decoding.**

I. Introduction

Surface electromyogram (sEMG) signals represent the electrical activity of motor units (MUs) and are recorded non-invasively by placing electrodes on the skin. Based on the number of reference electrodes, sEMG signals can be categorized as bipolar sEMG in which each channel has a specific reference electrode, or high-density sEMG (HD-sEMG), in which all channels on the HD-sEMG grid share a single reference electrode [1]. Compared to bipolar sEMG, HD-sEMG provides both temporal and spatial information, enabling the decomposition of signals into MU spike trains for estimating neural drive to muscles. Neural drive estimation is used in wearable robotics for tasks like predicting wrist kinematics for prosthesis control [2], estimating finger extension forces for exoskeletons [3], employing an attention-based hybrid CNN-RNN for hand gesture estimation [4], and using a physics-informed CNN for muscle force estimation from EMG signals [5], highlighting the need for precise methods to extract neural drive from HD-sEMG signals.

The conventional methods to decode neural drive always employed the blind source separation (BSS) algorithm, such as gradient CKC algorithm [6], [7], FastICA-based frameworks [8], or a CKC-FastICA algorithm [9]. While these approaches have advanced MU spike train decomposition, they often lack the capability for real-time estimation due to the variability and complexity of HD-sEMG signals, limiting their use in wearable robotic systems. To overcome these limitations, CNNs have been explored for their ability to automatically extract spatial and temporal features from HD-sEMG signals. For instance, 1D CNNs have demonstrated success in estimating neural drive across varying contraction intensities and joint angles [10], [11]. Building on this success, 3D CNN models leverage the spatial features of HD-sEMG electrodes to simultaneously capture spatial and temporal features, improving accuracy and robustness [12].

Despite these advancements, gaps remain in the current research. No studies have directly benchmarked the performance of 1D CNN models and 3D CNN models in neural drive estimation from HD-sEMG signals using the same dataset and protocol which hinders the systematic evaluation of their strengths and weaknesses. Additionally, the characteristics of HD-sEMG signals that influence the accuracy and computational cost of 3D CNNs in neural drive estimation, such as window size and step size, still need further exploration.

To address these challenges, this paper provides a comparison of 1D CNN and 3D CNN architectures for neural drive decoding from HD-sEMG signals using the same dataset. The study evaluates the effect of window size and step size on the performance of 1D and 3D CNN models in decoding neural drives and investigates their computational costs for potential real-time applications. The findings aim to guide the design of robust CNN architectures for real-time neural drive estimation thereby advancing their application in wearable robotics and rehabilitation.

In the following sections, the protocol used to collect the HD-sEMG signals, the framework of the 1D and 3D CNN

architectures to decode neural drive from HD-sEMG signals, and the pipeline to prepare HD-sEMG signals for the training of 1D and 3D CNN are described (Section II) The protocol to train and validate the CNN model is illustrated (Section III), and the preliminary result are presented (Section IV). Finally, the insight from experimental results, as well as the challenges and future extensions are discussed (Section V and VI).

II. Methods

A. Collection of HD-sEMG Dataset

1) Participants: This study used a subset of experimental data from a previously published study [13]. Three participants (mean $\pm$ SD; age 34 ± 8 years, height 178 ± 6 cm, body mass 76 ± 7 kg) with no recent lower leg injuries participated in this study. The data collection was approved by the University of Queensland ethics committee (Approval No. 2013001448) and adhered to the Declaration of Helsinki. Informed consent was obtained.

2) Experimental Procedures: Participants laid prone on a custom-made dynamometer, knees fully extended and ankles at $10°$ plantar flexion (Fig. 1(a)), to measure ankle joint torque. After a warm-up, they performed three maximum voluntary contractions (MVC) for $3-5$ s with 120 s rest. Submaximal contractions followed at 10 %, 30 %, and 50 % MVC each for 5 s (ramp-up), $15-20$ s (plateau), and 5 s (ramp-down), with $60-120$ s rest to minimize fatigue, using MVC torque for feedback (Fig. 1(c)).

3) Collection of HD-sEMG Signals: HD-sEMG signals were recorded from the gastrocnemius medialis (GM) muscle using a 64-electrode grid (13×5, 8 mm distance; SpesMedica, Italy; Fig. 1(d)), aligned with muscle fascicles via ultrasound. Skin was prepped with shaving and cleaning. The grid was secured with adhesive and elastic bands. Signals were recorded in mono-polar mode, band-pass filtered ($10-900$ Hz), and digitized at 2048 Hz using OT Bioelettronica's system (Fig. 1(b)).

4) Motor Unit Decomposition: We used the CKC algorithm to decompose the HD-sEMG signals into MU spike trains [7]. The CKC algorithm was implemented in the DEMUSE tool software (v4.9; University of Maribor, Slovenia) developed on MATLAB (The Matkworks Inc, Natick, Massachusetts, USA). Before the decomposition, the HD-sEMG signals were filtered by a band-pass filter (Butterworth 2nd order, 20-500 Hz) to remove the artifacts. After the decomposition of the HD-sEMG signals, all of the identified MU spike trains were visually inspected and manually edited when a false positive (FP: labeled artifact) or a false negative (FN: non-labeled discharge) was observed by an experienced operator. Only then MUs with a pulse-to-noise ratio (PNR) $>$ 30 db and at least 150 spikes per contraction segment were selected to ensure high sensitivity (> 90 %) and low false-positive rates (< 2 %) for further analysis. The processed HD-sEMG signals and the decomposed MU spike trains were used to train and validate the deep CNN models [13].

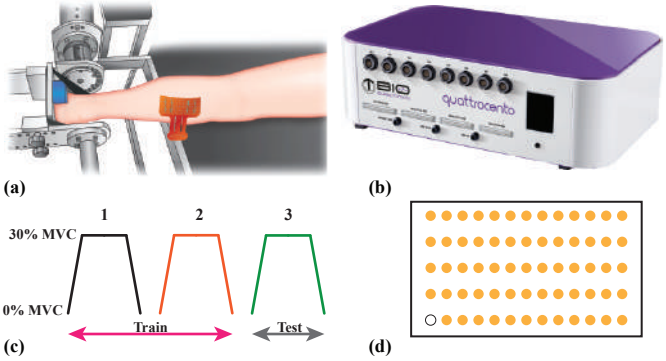

Fig. 1: (a) The participant performed a sub-maximal plantar flexion in a custom ankle dynamometer, and a grid of 64 high-density electrodes was placed over the GM muscle [13]; (b) The OT-Bioelettronica HD-sEMG acquisition system; (c) To this end, torque feedback was displayed, and three contractions were performed for each intensity level; (d) The arrangement of electrodes for the 13×5 HD-sEMG electrode grid used to collect HD-sEMG signals.

B. Structure of the Deep Convolutional Neural Network for Neural Drive Decoding

1) 1D CNN Architecture for Decoding Neural Drive: This study investigated two types of CNN models for decoding neural drive to muscles from HD-sEMG signals (Fig. 2). The architecture of the 1D CNN model was adopted from the work in [13], and the model consisted of two serially connected convolutional blocks followed by multi-head outputs that included four heads, each with two dense layers (Fig. 3(a)). Each convolutional block contained two one-dimensional convolutional layers, each followed by a rectified linear unit (ReLU) activation function to introduce non-linearity (Fig. 3(a)). After the activation function of the second convolutional layer, max pooling was applied with a kernel size of 2 and a stride size of 2. This operation reduced the spatial dimensions of the feature maps while retaining the most prominent features, enhancing computational efficiency and robustness to spatial variations. To prevent overfitting, a dropout layer was added at the end of each convolutional block, randomly deactivating 50 % of the neurons in the output feature map. The input channel of the first convolutional layer processed the 64-channel HD-sEMG signals with 64 input channels and 128 output channels. The size of the input and output channels of the rest convolutional layers is 128, and the kernel size of each convolutional layer is 3.

After the convolutional blocks, a flatten layer was used to convert the feature maps into a vector, preparing them for input to the dense layers. The number of parallel dense layers matched the number of spikes the CNN could detect from the input HD-sEMG signals. Based on findings from [10], four parallel dense layers were chosen for their optimal performance.

Each dense layer head consisted of two fully connected layers. The first fully connected layer took the flattened feature

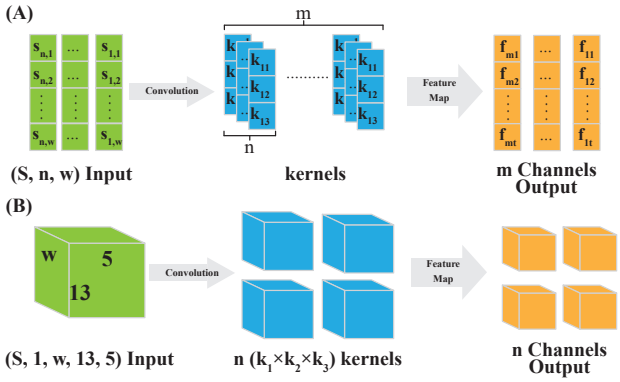

Fig. 2: (a) The mechanism of 1D CNN architecture in which the number of input channels equals the number of HD-sEMG channels and the length of each channel equals the size of the sliding window. (b) The mechanism of the 3D CNN architecture.

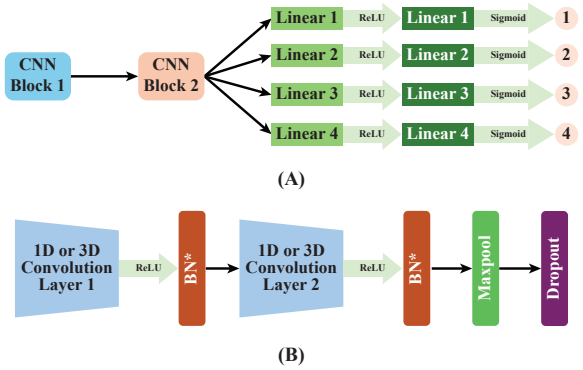

Fig. 3: (a) The architecture of the 3D CNN model. The number of input channels equals the number of HD-sEMG channels and the shape of each channel equals the size of the sliding window. (b) The network structure in each CNN block. Note that only the 3D CNN model includes the batch normalization layers (BN*).

map as input, with its shape determined by the input HD-sEMG signals. This layer had 128 neurons, defining both its output size and input size for the second fully connected layer. A ReLU activation function was applied between the layers to introduce non-linearity. Finally, a Sigmoid activation function was used after the second layer to constrain outputs to the range $[0, 1]$. We rounded the neural network output greater than 0.5 to 1 and interpreted it as a spike [13].

2) 3D CNN Architecture for Decoding Neural Drive: The second CNN architecture was a three-dimensional extension of the 1D CNN architecture (Fig. 2(b) and Fig. 3(b)). Different from the 1D CNN architecture, the 3D CNN architecture implemented 3D convolutional layers with 32 kernels in each layer and each kernel with a size of 3. Additionally, other modifications were made to improve the performance of 3D CNN. First of all, a batch normalization layer was added to the output of each 3D convolutional layer after the activation function. The purpose of batch normalization was to stabilize and accelerate training, reduce internal covariate shifts, and improve generalizability which has been widely used on 2D- and 3D CNNs [14]. Additionally, padding of two elements was applied to the input of each convolutional layer. This ensured that the spatial dimensions of the input feature maps were preserved after convolution, retaining edge information and enabling consistent output sizes across layers. Furthermore, the input channels of the first layer differed from the 1D CNN architecture; for the 3D CNN model, the reshaped HD-sEMG signals resulted in a single input channel, while subsequent layers had equal input and output channels set to 32. Aside from these modifications, another minor modification was the max-pooling algorithm which was replaced by the 3D max-pooling algorithm to adapt to the 3D CNN blocks.

C. Data Preparation

To prepare the dataset for 1D and 3D CNN models, we normalized HD-sEMG signals to a range -1 to 1 to preserve spatiotemporal information and generated the cumulative spike train (CST) by summing MU spike trains. We then segmented the HD-sEMG signals and CST with a sliding window method from [13]. The window size and step size were denoted as WS and SS respectively (Fig. 4), defining the width of the sliding window and the overlap between consecutive windows. Moreover, the CST (specifically the number of identified spikes) was used to label the corresponding HD-sEMG signals, and they were used to train the deep CNN models.

Therefore, a batch of HD-sEMG windows after segmentation by sliding window method was directly used to train the 1D CNN model, in which each window consists of a $64 \times w$ matrix, where 64 corresponds to the number of HD-sEMG channels and w to the width of sliding window.

In contrast, the 3D CNN model required a three-dimensional tensor input. Given the 13×5 electrode configuration of the HD-sEMG grid, with one corner electrode absent which reflects the spatial arrangement of the HD-sEMG grid.

The segmented HD-sEMG signal was reshaped to a $w \times 13 \times 5$ tensor for the 3D CNN model. Firstly, the segmented HD-sEMG signal ($64 \times w$) was zero-padded at index 0 to become a $65 \times w$ array. Then, the padded $65 \times w$ array was reshaped to a $13 \times 5 \times w$ tensor to preserve the spatial information coded in the electrode location. Finally, the $13 \times 5 \times w$ tensor was permuted to a $w \times 13 \times 5$ so the depth of the input equals the width of the sliding window because we found this setting achieved the best performance.

III. Experiment

A. Training and Validation Protocol

A three-fold cross-validation methodology was employed to train and validate the 1D CNN and 3D CNN models, aiming to ensure their robustness. Unlike traditional random splits, we treated each contraction as an independent fold. The model was trained on two contractions and validated on the third to evaluate performance. This process was repeated three times,

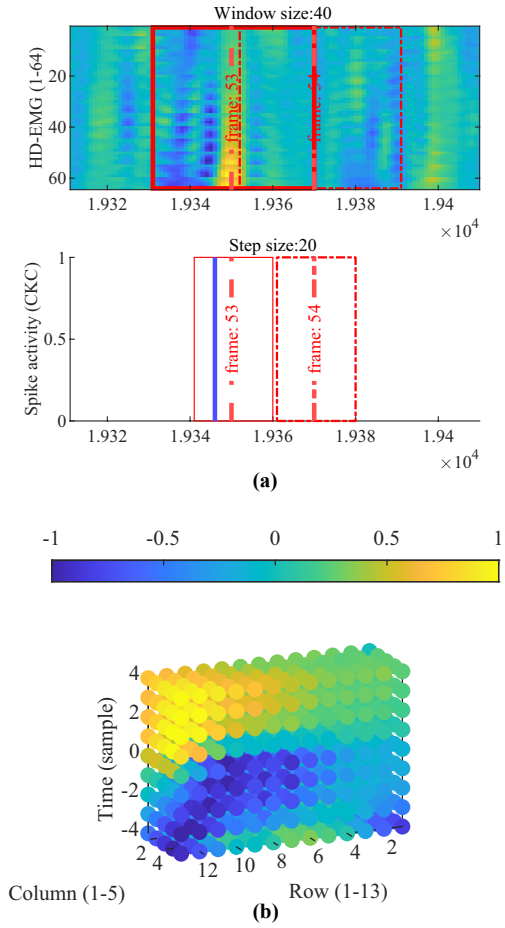

Fig. 4: (a) The sliding window approach to segment the HD-sEMG signals and the CST, as this figure shows, a sliding window with a window size of w (red box) samples the HD-sEMG signals along the temporal axis. The distance between consecutive windows is the step size (top); Segmentation of the CST using the same step size (bottom); The y-axis of this figure represents the channel of HD-sEMG signal while the x-axis represents the number of samples. (b) A segment of reshaped HD-sEMG signals for the 3D CNN model.

with each contraction used as the validation set once. The overall performance was calculated as the average across the three validation runs.

The training and validation were performed on the workstation equipped with an NVIDIA RTX 4090 graphics card. During training, a batch size of 64 was used to optimize the computational process. The training process was configured to stop after 200 epochs. Training timestamp and F1 score for each epoch were recorded for post-analysis. The model achieving the highest F1 score during training was saved. For validation, this best-performing model was loaded and evaluated on the validation data segment to predict the CST. The detected CST and the time required for each inference were recorded for further analysis.

B. Evaluation Criteria

This study focuses on evaluating the impact of CNN architectures on decoding the neural drive from HD-sEMG signals, with a specific emphasis on the ability of CNN to identify the CST. For this purpose, the F1 score was adopted as the primary performance metric which provides a comprehensive measure of the network's ability to accurately decode the neural drive in the form of CST.

Additionally, the neural drive decoded by the CNN model was compared with the neural drive decoded by the CKC algorithm. This comparison calculated the Pearson correlation coefficient (PCC) between the smoothed CSTs from the CNN model and the CKC algorithm.

Finally, we also investigated the inference time of the 3D and 1D CNN models which is the average processing time of the CNN models to decode neural drive from a window of HD-sEMG signal.

IV. Results

A. Evaluation of 3D CNN and 1D CNN Models for Decoding Neural Drive

Table I presents an in-depth analysis of the F1 scores achieved by both the 1D CNN and the 3D CNN. This analysis elucidates how varying the window and step sizes can impact the accuracy of neural drive decoding. For the 1D CNN model, the optimal F1 score of 0.84 was attained with a configuration comprising a window size of 120 combined with a step size of 20. A robust performance range, approximately from 0.79 to 0.82, was consistently observed when utilizing step sizes of 5 and 10 across the majority of window sizes tested. Conversely, employing larger step sizes such as 40 significantly compromised performance, particularly in scenarios involving smaller windows (e.g., yielding a mere 0.33 with a window size of 20). On the other hand, the 3D CNN model reached its peak F1 score of 0.83 with a step size of 10 and a window size of either 40 or 20. Consistent performance was delivered with smaller step sizes, notably 5 and 10, across various window sizes. In contrast, larger step sizes like 40 induced substantial declines in performance, especially with smaller window sizes (e.g., achieving only 0.39 with a window size of 20).

B. Evaluation of CST Estimation by CNN Models versus CKC Algorithm

An in-depth analysis of the correlation results, as summarized in Tables II, reveals that both 3D CNN and 1D CNN models achieved maximum correlation values of 0.92

TABLE I: F1 Score for 3D CNN and 1D CNN Models under various window sizes (WS) and step sizes (SS)

F1 score WS / SS	20	40	80	120
5	0.82 (0.79)	0.81 (0.79)	0.79 (0.79)	0.74 (0.77)
10	0.83 (0.80)	0.83 (0.82)	0.80 (0.82)	0.80 (0.83)
20	0.76 (0.71)	0.80 (0.82)	0.78 (0.82)	0.74 (0.84)
40	0.39 (0.33)	0.65 (0.58)	0.57 (0.66)	0.54 (0.66)

with the CKC algorithm when evaluated using smaller step sizes of 5 and 10 samples. However, the models demonstrated distinct performance trends based on window sizes. Specifically, 1D CNN exhibited superior correlation performance at larger window sizes, demonstrating its capability to capture temporal dependencies over extended durations. In contrast, 3D CNN showed greater effectiveness at smaller window sizes (20 and 40 samples), probably benefiting from its ability to exploit both spatial and temporal features. For a direct visual comparison of the CST decoded by the CNN models and the CKC method, we selected a combination of window size and step size that the 3D and 1D CNN trained with HD-sEMG dataset segmented by this window-step size that have marginal differences in the correlations of CST as shown in Table II. According to Table II, we selected a window size of 40 and a step size of 10. These CST results were smoothed using a Hanning window of 400 ms to facilitate comparison. The corresponding visualization of CST is shown in Figures 5(a) and (b), respectively.

C. Evaluation of Computational Load and real-time efficacy of 1D CNN and 3D CNN Models

Additionally, this work examined the computational cost and real-time efficacy of the 1D CNN and 3D CNN models for neural drive decoding. The computational cost was assessed by computing the FLOPs (Floating-point operations) of both 1D CNN and 3D CNN using the optimal window size and step size as determined by the F1 score in Table I. The 3D CNN model, when trained and validated with HD-sEMG data segmented using the optimal window sizes of 20 or 40 samples, exhibited an average of 938G FLOPs. In contrast, these metrics for the 1D CNN model, trained and validated with HD-sEMG data segmented using an optimal window size of 120 samples, manifested as 60G FLOPs.

Furthermore, real-time efficacy was assessed via inference time, defined as the duration required for the neural network model to decode the neural drive with a sample of HD-sEMG signal ($1\times64\times w$ for 1D CNN, $1\times1\times w\times13\times5$ for 3D CNN). Similar to the FLOPS, inference time calculations for both the 3D CNN and 1D CNN, trained and validated with the HD-sEMG dataset segmented by the optimal window size as per Table I, were conducted. Consequently, the average inference time for the 3D CNN trained on HD-sEMG signals segmented by 20 or 40 samples is 4.3 ms, whereas for the 1D CNN trained on signals segmented by 120 samples, it is 1.28 ms.

TABLE II: The Correlation Coefficient of CST Estimated by 3D CNN or 1D CNN and the CKC under various window sizes (WS) and step sizes (SS)

PCC: WS / SS	20	40	80	120
5	0.98 (0.96)	0.97 (0.97)	0.97 (0.98)	0.97 (0.97)
10	0.97 (0.96)	0.97 (0.97)	0.96 (0.96)	0.98 (0.96)
20	0.96 (0.94)	0.97 (0.97)	0.95 (0.96)	0.95 (0.96)
40	0.88 (0.91)	0.94 (0.95)	0.94 (0.92)	0.93 (0.93)

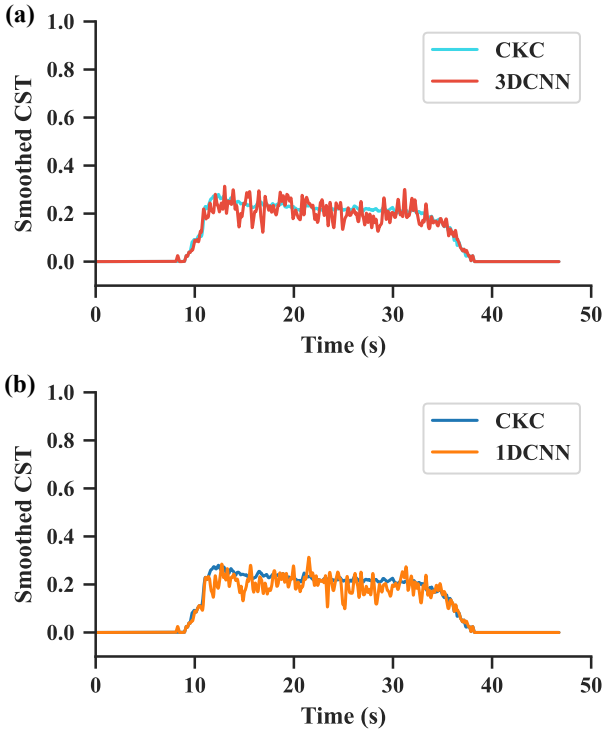

Fig. 5: The smoothed CSTs estimated by the 3D CNN (a) and 1D CNN (b) vs the CSTs identified by the CKC algorithm. Note: the window size and step size combination was selected from Table II which reaches the best correlation coefficient.

V. Discussion

This study investigates the impact of the dimensionality (1D or 3D) of the convolutional layers on the performance of decoding neural drive from HD-sEMG signals using the same dataset by comparing their decoding accuracy (F1 score), computational cost (FLOPs), and real-time efficacy (inference time).

The results of this study reveal that both the 1D CNN and 3D CNN models can effectively decode the neural drive from HD-sEMG signals, with performance contingent upon step size and window size parameters. The 1D CNN model achieved a marginally superior peak F1 score (0.84) compared to the 3D CNN model (0.83), with the optimal configuration determined as a window size of 120 and a step size of 20. This finding indicates the particular efficacy of the 1D CNN model when extensive sliding window size is accessible. Nevertheless, its performance exhibits a decline with increased step sizes, particularly for smaller windows, underscoring the necessity of balancing input granularity to maintain accuracy. In contrast, the 3D CNN model demonstrated resilience at smaller step sizes (5 and 10), reaching its peak performance (0.83) with a step size of 10 and a window size of 20 or 40 (Table I). This advantage highlights the ability of the 3D CNN model to decode neural drive when a brief window size is necessary (less latency). Nonetheless, the 3D CNN

model exhibits greater sensitivity to larger step sizes, with more abrupt performance declines compared to the 1D CNN model, thus restricting its applicability in contexts where larger sliding window size is required.

The CST correlation analysis further emphasize the strengths and limitations of both models. While both achieve high correlations with CST from CKC at smaller step sizes (5 and 10), the 1D CNN model sustains higher correlations at larger step sizes, indicating greater robustness. The 3D CNN model excels in exploiting spatiotemporal features at small window sizes, achieving peak correlations comparable to those of the 1D CNN model.

Visual comparisons of smoothed CSTs underscore the fidelity of both models in extracting the neural drive in the form of CST, generating CSTs analogous to those decoded by the CKC algorithm, which is the benchmark for CST decoding. By employing optimal window and step size configurations (WS120-SS20 for the 1D CNN model and WS40-SS20 for the 3D CNN model [window size-step size]), both models proficiently capture CST. These findings emphasize the criticality of application-specific trade-offs between accuracy, efficiency, and parameter sensitivity when choosing between 1D and 3D CNN models for neural drive decoding.

However, a significant limitation of the 3D CNN is its exceedingly high computational cost (938G FLOPs) compared to the 1D CNN (60G FLOPs). The substantial computational cost of 3D CNN could hinder its implementation on devices with limited computational resources, such as embedded computers on exoskeletons or prosthetics. Moreover, high computational cost hinders its real-time efficacy. According to the results, the 3D CNN exhibits worse inference time while using a much smaller window size (20 or 40 samples) than the 1D CNN models (120 samples), contrary to our hypothesis that the 3D CNN would have better real-time efficacy than the 1D CNN due to its superior F1 score under smaller window size. Therefore, with respect to the current structure of 3D CNN and 1D CNN models, the 1D CNN should be more suitable for real-time neural drive decoding even if it performs suboptimally compared to 3D CNN under small window size conditions. And further studies should focus more on the development of lightweight 3D CNN models that consume less computational power than current architecture.

VI. Conclusion

This study examined the influence of convolutional layer architecture (either 1D or 3D) on neural drive decoding performance by assessing the two different CNN models—namely, the 1D CNN and the 3D CNN—using an identical dataset. The investigation focused on distinguishing the 1D and 3D CNN models in terms of accuracy, computational cost, and real-time efficacy. The findings indicated that the 1D CNN model exhibits greater potential for real-time applications due to its reduced computational cost and shorter inference time. Conversely, additional research is necessary to decrease the computational cost of the 3D CNN model, thereby enhancing its performance in real-time applications.

Normalizing Task-Oriented Human-Robot Interaction for Large-Scale Virtual Environments

Burak Balta*, Khandaker Nusaiba Hafiz*, and Jonathan Realmuto

***Abstract*—Physical simulation platforms, including haptic manipulanda and robotic rehabilitation systems, enable controlled human-robot interaction, but variability in users' physical attributes impacts consistency across individuals. Here, we present a method to standardize user effort in a physical tracking task, a common paradigm in rehabilitation and motor learning, where participants interact with a manipulator simulating a virtual environment. In addition to optimizing the initial configuration and scaling of the task trajectory, we analyze the effect of different scaling factors on the robot's virtual stiffness matrix, the impedance parameter that largely determines the effort required during the task. Simulations of nine virtual participants with varying heights and masses show that allometric scaling of robot's virtual stiffness by a factor of $(\mathrm{m}/\mathrm{h})^{2/3}$ best minimizes effort disparities. These findings advance the development of adaptive physical simulation platforms for rehabilitation, training, human motor control experiments, and human-robot collaboration.**

***Index Terms*—Physical Human-Robot Interaction, Haptics, Human Motor Control.**

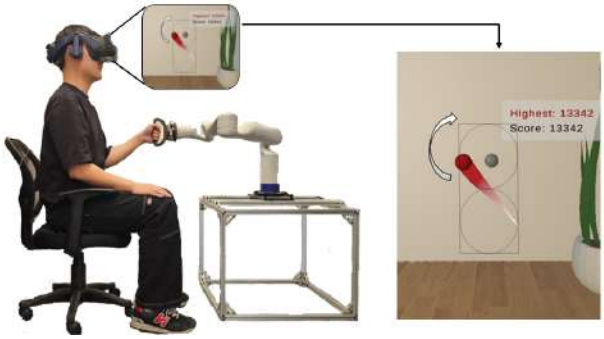

Fig. 1: Large-scale physical simulator integrating a virtual reality (VR) headset with a 7-DOF manipulator. During a task, the human participant interacts with the manipulator's end-effector. Task-space impedance control enables programming the end-effector's behavior for various simulated environments, including the virtual-spring environment explored in this work. This setup supports immersive and controlled experimentation with dynamic force rendering.

I. Introduction

Physical simulation platforms, including kinesthetic haptic manipulanda, provide an adjustable virtual environment that is mechanically rendered at the human-robot interaction point [1]. These systems have become essential tools for motor control research [2], [3], and neurorehabilitation where they enable patient-centered interventions, post-surgery recovery, and address limitations of traditional therapy, including high resource demands and geographic constraints [4], [5]. These devices have evolved from simple assistive tools to adaptive systems capable of modulating impedance and force feedback based on user interaction [6], [7]. Advances in virtual reality and robotic-assisted neuromotor therapy further expand rehabilitation possibilities, facilitating engaging and interactive treatments that improve motor function, cognition, and user motivation [8]. However, disparities in user effort and task difficulty due to individual physical differences remain a challenge in standardizing human-robot interaction.

Human-robot interaction plays a crucial role in these physical simulation systems and enables intuitive and adaptive interaction between humans and robotic devices. Impedance control is the dominant method for regulating the robot's response to user interaction [9]. Prior research has demonstrated benefits of variable impedance control in enhancing compliance, adaptability, and safety. A learning-based time-varying impedance controller has been shown to autonomously adjust robot stiffness based on human input [10]. Biomechanics-driven methods to adapt robot impedance for improved interaction comfort have also been explored [11]. Another approach leverages learning-based variable impedance frameworks, enabling robotic arms to adapt stiffness and damping from human demonstrations, improving trajectory accuracy and compliance across diverse tasks [12]. While these advancements allow robots to dynamically adjust to user input, they do not account for differences in body size and strength, leading to inconsistencies in task difficulty and effort.

Adaptive techniques are widely used in virtual reality to personalize user experience, dynamically adjusting task difficulty and parameters based on individual progress and physical characteristics. This is particularly crucial in rehabilitation, where patient needs vary widely. Adaptive virtual reality has been shown to enhance motor skill development, balance training for post-stroke patients, and real-time feedback for para-athletes by tailoring exercises to individual capabilities [13], [14], [15]. Integrating biosignal feedback further improves engagement by allowing virtual reality systems to adjust exercises based on brain and muscle activity [16]. Systematic reviews indicate that adaptive virtual reality enhances user engagement and therapeutic effectiveness compared to static systems, but standardization remains a challenge [17], [18]. Such adaptive strategies have yet to be fully leveraged in physical simulation platforms, where variability in user attributes can similarly impact task difficulty and effort. Addressing this gap requires normalization techniques that ensure consistent interaction dynamics across diverse users.

Normalization in physical performance assessments ensures

fair comparisons by accounting for body size differences. Allometric scaling is widely used to adjust strength and movement data, making them independent of body mass [19]. Standardized methods recommend normalizing muscle torque by body mass, muscle force and power by body mass$^{2/3}$, and body-weight-supported exercises by body mass$^{-1/3}$ [20]. Studies comparing different normalization techniques suggest that body weight is the most effective parameter for adjusting muscle strength, particularly in sports such as baseball pitching [21]. While some research supports height-based normalization [22], other findings indicate that weight provides more accurate adjustments [23].

While previous research has explored adaptive impedance control and task customization in human-robot interaction, existing methods primarily focus on optimizing performance, compliance, or user comfort rather than ensuring standardized task difficulty across individuals of varying body sizes. Current approaches do not explicitly normalize human effort in physical interaction tasks, leading to variability in perceived difficulty based on participant anthropometrics. In contrast, this work introduces a novel allometric scaling strategy, scaling the robot's virtual stiffness by $(m/h)^{2/3}$, to ensure that participants experience a consistent level of effort regardless of their mass and height. Additionally, we scale the task trajectory based on participants' height to ensure that extreme task points remain within each participant's reachable workspace. We further propose adjustments to the participant distance from the robot, and initial human and robot poses, tailoring them to individual physical attributes. Together, these three normalizations, robot impedance, task trajectory, and initial interaction configuration, ensure fairness and consistency, allowing all participants to face comparable challenges regardless of their physical differences. To the best of our knowledge, this is the first study that systematically applies biomechanical scaling principles to adjust robot impedance for standardizing task effort in human-robot interaction, bridging a critical gap in the design of adaptive physical simulation platforms for rehabilitation, motor learning, and collaborative robotics.

II. Dynamic Model of the Human-Robot Interaction

We model the human-robot interaction as a coupled dynamical system with virtual stiffness and damping between the human hand and the robot's end-effector [24]. The model integrates the dynamic properties of both the human and the robot, including inertia, Coriolis effects, and gravitational forces, into a unified representation. Virtual stiffness and damping terms enforce the kinematic constraint between the hand and end-effector. This approach eliminates the need for differential-algebraic equations that arise in analytical coupling models, thereby reducing computational complexity while preserving fidelity. In this framework, the robot is controlled by a task-space impedance controller with a fixed equilibrium, emulating spring-like behavior to provide a compliant response to external forces. Meanwhile, the human is modeled as a task-space proportional-derivative controller, designed to follow the desired trajectory.

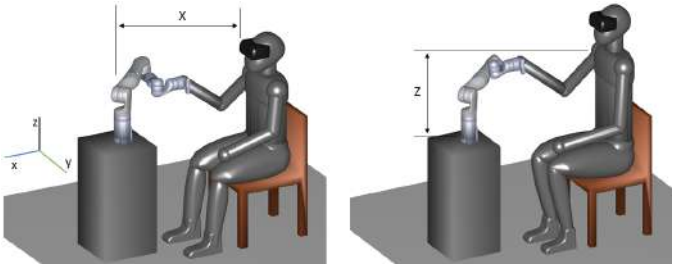

Fig. 2: Two individuals with different heights in our simulation, highlighting the variation in shoulder positions determined by height and optimization.

The human arm is modeled with three revolute joints at the shoulder (allowing for flexion-extension, abduction-adduction, and internal-external rotation) and one revolute joint at the elbow (for flexion-extension). This configuration was implemented as a two-link four-joint rigid body system, where the links corresponds to the upper arm and forearm segments, and the joints replicate the shoulder and elbow motions. The model includes a fixed base to represent the participant's body, providing a realistic dynamic representation of human upper limb movement. The length and mass of the arm segments were calculated using standard anthropometric ratios based on the participant's height and weight, with segment lengths as proportions of height and masses as proportions of body weight [25].

The coupled human-robot dynamics are expressed as:

$$\begin{bmatrix} M_h(q_h) & 0 \\ 0 & M_r(q_r) \end{bmatrix} \begin{bmatrix} \ddot{q}_h \\ \ddot{q}_r \end{bmatrix} + \begin{bmatrix} C_h(q_h, \dot{q}_h) & 0 \\ 0 & C_r(q_r, \dot{q}_r) \end{bmatrix} \begin{bmatrix} \dot{q}_h \\ \dot{q}_r \end{bmatrix} + \begin{bmatrix} g_h(q_h) \\ g_r(q_r) \end{bmatrix} = \begin{bmatrix} \tau_h \\ \tau_r \end{bmatrix} + \begin{bmatrix} J_h(q_h)^\top \mathcal{F}_{r,h} \\ J_r(q_r)^\top \mathcal{F}_{h,r} \end{bmatrix}, \quad (1)$$

where M_h, M_r are the inertia matrices for the human and robot; C_h, C_r the Coriolis matrices for the human and the robot; τ_h, τ_r the joint torques for the human and robot; g_h, g_r the gravitational torques for the human and robot; J_h, J_r the Jacobian matrices for the human and robot; $\mathcal{F}_{r,h}$, $\mathcal{F}_{h,r}$ the interaction wrenches applied to the human and robot. The interaction wrenches are formulated as:

$$\mathcal{F}_{h,r} = K_c(\mathcal{S}_{r,h} - \mathcal{S}_{r,h,0}) - K_d\left(J_r(q_r)\dot{q}_r - J_h(q_h)\dot{q}_h\right) \quad (2)$$

$$\mathcal{F}_{r,h} = K_c(\mathcal{S}_{h,r} - \mathcal{S}_{h,r,0}) - K_d\left(J_h(q_h)\dot{q}_h - J_r(q_r)\dot{q}_r\right) \quad (3)$$

where K_c is the coupling stiffness matrix, K_d the coupling damping matrix, $\mathcal{S}_{h,r}$ the screw vector representing the difference between the human and robot end-effectors relative to the human, $\mathcal{S}_{r,h}$ the screw vector representing the difference between the robot and human end-effectors relative to the robot, and $\mathcal{S}_{h,r,0}$, $\mathcal{S}_{r,h,0}$ the screw vectors representing the initial differences (e.g., at the start of the simulation). The screws are formulated as follows (see, e.g., [26]):

$$[\mathcal{S}_{i,j}] = \log(T_i^{-1} T_j) \quad (4)$$

where T_i, T_j are the homogeneous transformation matrices for i^{th} and j^{th} end-effectors, log is the matrix logarithm, and $[\mathcal{S}_{i,j}]$

is the matrix representation of the screw between the i^{th} and j^{th} end-effectors. A matrix representation of the screw is given by:

$$[\mathcal{S}] = \begin{bmatrix} [\omega] & v \\ 0 & 0 \end{bmatrix} \tag{5}$$

with $[\omega]$ the skew-symmetric matrix representation of the unit angular velocity and v unit linear velocity. The skew-symmetric matrix is:

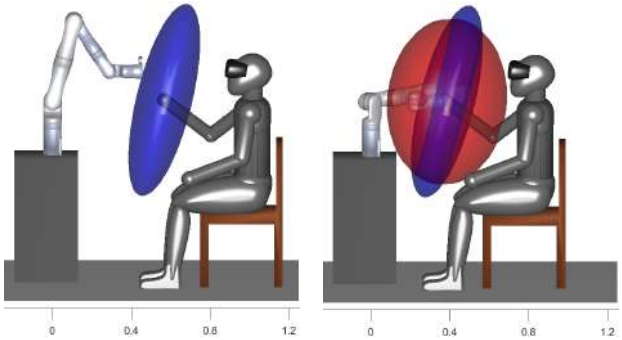
$$[\omega] = \begin{bmatrix} 0 & -\omega_z & \omega_y \\ \omega_z & 0 & -\omega_x \\ -\omega_y & \omega_x & 0 \end{bmatrix}. \tag{6}$$

Then the screw vector is:

$$\mathcal{S} = \begin{bmatrix} \omega_x & \omega_y & \omega_z & v_x & v_y & v_z \end{bmatrix}^T. \tag{7}$$

The human tracking controller is formulated as:

$$\tau_h = J_h(q_h)^\top (K_{p,h}\mathcal{S}_{h,d} - K_{d,h}J_h(q_h)\dot{q}_h) + g_h(q_h) \tag{8}$$



with $K_{p,h}$ the human's proportional gain matrix, $\mathcal{S}_{h,d}$ the screw representing the error from the desired transformation T_d, K_d the derivative gain matrix, and g_h the gravitational torque. The robot impedance controller is formulated in a similar way:

$$\tau_r = J_r(q_r)^\top (K_{p,r}\mathcal{S}_{r,d_0} - K_{d,r}J_r(q_r)\dot{q}_r) - b\dot{q}_r + g_r(q_r) \tag{9}$$

where $K_{p,r}$ the robot's stiffness impedance parameter, $\mathcal{S}_{r,d_0}$ the screw representing the deviation from the center of the desired trajectory, $K_{d,r}$ the robot's damping impedance parameters, b joint damping coefficient which models friction in the motors (and enhances the stability of the simulation), and g_r the gravitational torque which provides gravity compensation. The impedance controller is designed to emulate spring-like behavior, providing a compliant response to external forces with the equilibrium fixed at the center of the trajectory. In this way, the task can be interpreted as trajectory tracking in a spring-like environment with the springs zero-force point at the center of the trajectory. The human arm joint states were directly available in the simulation, the Jacobian was computed analytically from the kinematic chain, and the gain matrices in were determined for the mean participant and iteratively tuning for stability.

III. Normalizing the Configuration

Our method configures the initial pose of both the human and robot, and the task trajectory, with all parameters tailored to the participant's height and mass for normalized interaction. The human shoulder position is defined in Cartesian coordinates x, y, z, where $y = 0$ ensured lateral alignment with the robot, z represented the shoulder height relative to the robot's base, and x was determined through optimization. Figure 2 highlights participants with two different heights, demonstrating that their shoulder positions vary in the x and z coordinates. This difference is critical for identifying the interaction point, as the shoulder position influences the participant's reachable workspace and determines the optimal location for interaction. Tailoring the interaction to these variations ensures comfortable and efficient task execution for participants of different body dimensions.

(a) human arm pose (b) robot pose

Fig. 3: Initial pose for human arm, chosen as the maximum manipulability of the hand, and of robot end-effector, chosen as the minimum ratio of the longest to the shortest axis of the translational manipulability ellipsoid.

Our first aim is to maximize the human's manipulability at the initial arm pose, and therefore we use Yoshikawa's manipulability index [27], $\mu_h = \sqrt{\det(J_{v,h}J_{v,h}^T)}$, where $J_{v,h}$ is the 3×4 matrix corresponding to the translation part of the human's Jacobian matrix. This approach ensures that the arm starts and operates in a posture that provides the greatest flexibility and agility for task execution [28].

The optimization for arm joint angles were performed using MATLAB's `fmincon` function to solve constrained nonlinear optimization problems. While our methodology shares similarities with ergonomic human-robot collaboration research, particularly in optimizing human arm manipulability, our objective differs. Prior work primarily aims to enhance comfort and efficiency in collaborative manipulation tasks [29], whereas we focus on standardizing task effort based on participant anthropometrics. The optimization of human arm manipulability serves a critical role in our study by ensuring that all participants begin the task in a biomechanically neutral, high-dexterity posture. This removes postural biases, allowing a direct evaluation of how impedance scaling affects effort across individuals with different body sizes. The objective function was set as the negative of the manipulability metric, effectively maximizing manipulability. The optimizer adjusted four revolute joints: three at the shoulder (flexion-extension, abduction-adduction, and internal-external rotation) and one at the elbow (flexion-extension). The resulting joint angles (q) for all the participants' starting arm pose are as follows (in rad):

- Abduction/adduction of the shoulder: $q_1 = -0.0137$;
- Flexion/extension of the shoulder: $q_2 = 0.6613$;
- Rotation of the humerus: $q_3 = 0$;
- Flexion/extension of the elbow: $q_4 = -1.3670$.

Next, we aim to maximize the robot's freedom of motion at the point of contact by minimizing the ratio of the longest axis ($\sqrt{\lambda_1}$) to the shortest ($\sqrt{\lambda_3}$) axis of the robot's translational manipulability ellipsoid ($\mu_r = \sqrt{\lambda_1/\lambda_3}$). This approach encourages an isotropic ellipsoid, improving the

robot's dexterity and adaptability during dynamic interactions. Additionally, the optimization determines the optimal position of the human participant along the x-axis, x_c. The constraints ensured precise alignment of the robot's end-effector with the human's end-effector to enable effective interaction, while also maintaining realistic robot configurations by adhering to joint limits. The optimization problem for the parameter vector $\mathbf{x}$ was formulated as:

$$\min_{\mathbf{x}} \ \mu_r \tag{10}$$
$$\text{subject to:} \quad \underline{\mathbf{x}} \leq \mathbf{x} \leq \bar{\mathbf{x}}$$

with the parameter vector $\mathbf{x} = [q_1, \ \cdots \ q_7, \ x_c]$, which includes the 7 robot joint angles and the human-robot interaction point x_c, along the x-axis. The initial pose of the robot for human-robot collaboration is found using a global optimization process, combining MATLAB's `patternsearch` and `fmincon` within a loop. To select the starting points for the optimization, we used a multi-start approach. This ensured that the optimization began from multiple diverse initial configurations, increasing the likelihood of finding a globally optimal solution. The outputs of the two optimizers for human and robot poses determined the interaction point, e.g., the center of the trajectory, which is defined by the coordinates x_c, z_c, ($y_c = 0$) as shown in Fig. 3. Only x_c is a parameter in the optimization, since z_c is determined based on the participant's height.

We also scale the desired human trajectory based on the person's height:

$$p_d(t) = \begin{bmatrix} x_c \\ A_y \sin(2t) \\ z_c + A_z \sin(t) \end{bmatrix}, \tag{11}$$

where, p_d is the task space desired position of the hand, A_y and A_z are the amplitudes of sinusoidal motion along the y and z axes and are expressed as percentages of the individual's height. Here, we choose $A_y = 0.06 \cdot h$ and $A_z = 0.12 \cdot h$, where h is the participant's height. This scaling ensures that the task trajectory is customized to the participant's reach limits, maintaining consistent effort across participants with varying physical attributes. The values were arrived at through an iterative process, ensuring that the task trajectory was challenging yet achievable for participants. Note that in this work, we do not consider a desired orientation of the human hand, only the translational position p_d.

The final component used to ensure a consistent and standardized experience for participants of varying physical attributes during human-robot interactions is scaling of the robot's stiffness matrix $K_{p,r}$. Human biomechanics, such as limb length, body mass, and muscle strength, vary significantly with height and weight, and these factors can influence the perceived stiffness and overall interaction dynamics. By normalizing the stiffness matrix using these scaling factors, we aim to account for individual differences in physical characteristics, thereby improving the fairness, reproducibility, and biomechanical relevance of the experimental conditions across

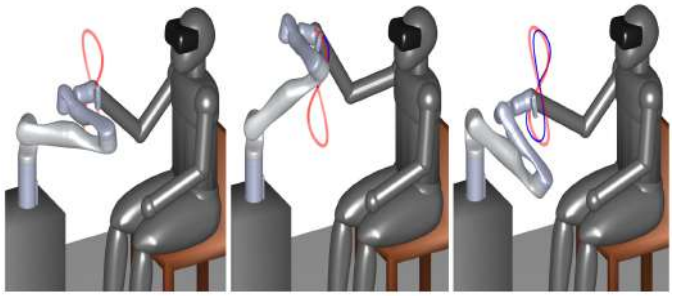


Fig. 4: A sequence of the human-robot interaction task at three different time instances. The task involves tracking a moving target in a figure-eight pattern. The robot acts as a spring-like environment, providing compliant resistance to the human participant.

participants. Since the proper scaling is unknown, we systematically explore common biomechanical relationships that could influence human-robot interaction dynamics. We compare the following scalings: mass (m), mass power $2/3$ ($m^{2/3}$), height (h), inverse height ($1/h$), mass divided by height (m/h) and mass divided by height power $2/3$ ($(m/h)^{2/3}$). We apply the scaling as follows: $K_{p,r}(P) = \alpha(P) K^0_{p,r}$, where $\alpha(P)$ is the scaling factor for participant P, and $K^0_{p,r}$ is the nominal stiffness matrix, which is found for the averaged sized participant first. The scaling factor $\alpha(P)$ is determined by the participant's height and mass as described above. The results of this analysis will provide insights into the impact of these scaling strategies on the human-robot interaction dynamics, helping to optimize the experimental setup for participants with diverse physical attributes.

In contrast, the human controller gains are kept constant to maintain consistency in modeling human motor control. Unlike the robot's stiffness matrix, which directly interacts with and needs to adapt to the participant's physical characteristics for standardization, the human gains reflect the inherent neuromuscular properties and motor control strategies. These properties are relatively stable across individuals. Keeping these gains constant ensures the experimental focus remains on how variations in the robot's stiffness matrix influence the interaction, without introducing additional variability from altering human control parameters.

IV. Results

To account for variations in participant height and mass, we considered three different heights: 1.54 m, 1.74 m (average

TABLE I: Simulation parameters.

Parameter	**Value/Description**
$K_{h,p}$	$10^6 \cdot \text{diag}([0,0,0,1,1,1])$
$K_{h,d}$	$500 \cdot I_6$
$K_{r,p}(h = 1.73, m = 73)$	$1.5{\cdot}10^5{\cdot}\text{diag}([0.01, 0.01, 0.01, 1, 1, 1])$
$K_{r,d}$	$1000 \cdot \text{diag}([0.01, 0.01, 0.01, 1, 1, 1])$
K_c	$2.8 \cdot 10^6 \cdot I_6$
K_d	$10^5 \cdot I_6$
T	2π
dt	0.01

height), and 1.94 m, representing a range of possible participant statures. For each height, a nominal corresponding body mass was determined using a body-mass index (BMI) of 24.1, a standard value representing average body composition. This calculation resulted in masses of 57.2 kg for 1.54 m, 73.0 kg for 1.74 m, and 90.8 kg for 1.94 m. To capture a diverse range of participants, we considered nine profiles by permuting the three different masses among the three heights.

For all nine virtual participants, we simulated the human-robot interaction task using our optimization method in conjunction with each of the six scaling factors for the robot's stiffness $K_{p,r}$, a nominal simulation, where the placement and configuration of the robot was chosen as the optimal configuration for an average-sized participant, and a case where the robot's stiffness matrix was not scaled. All simulations were integrated using an implicit solver with variable order method (`ode15s` in MATLAB) with a time step of 0.01 s. The simulation parameters are shown in Table I and a sequence of one of the simulations at three different time instances is shown in Fig. 4.

For each simulation we calculated the human effort as the total norm of the human joint torque over the entire simulation and then normalized by mass times height (mh) of the individual. The rational for normalization is to produce a dimensionless magnitude that can be compared across participants. Since torque has units of $N \cdot m$, a reasonable normalization factor would be mgh and g can be dropped since it is common to all participants. Our main outcome measure, the effort ratio, was defined as the human effort for each participant normalized by the human effort required for the average-sized participant minus 1, thus positive values indicate higher effort than the average-sized participant while negative values indicate lower effort.

The results of this analysis are shown in Fig. 5. The scaling strategies demonstrate noticeable changes in the effort distribution, highlighting how adjustments affect task difficulty for participants with diverse body compositions. Our optimization method with the scaling factor of $(m/h)^{2/3}$ shows the most consistent effort ratio across participants, indicating an effective strategy for standardizing the task effort across individuals with varying physical attributes.

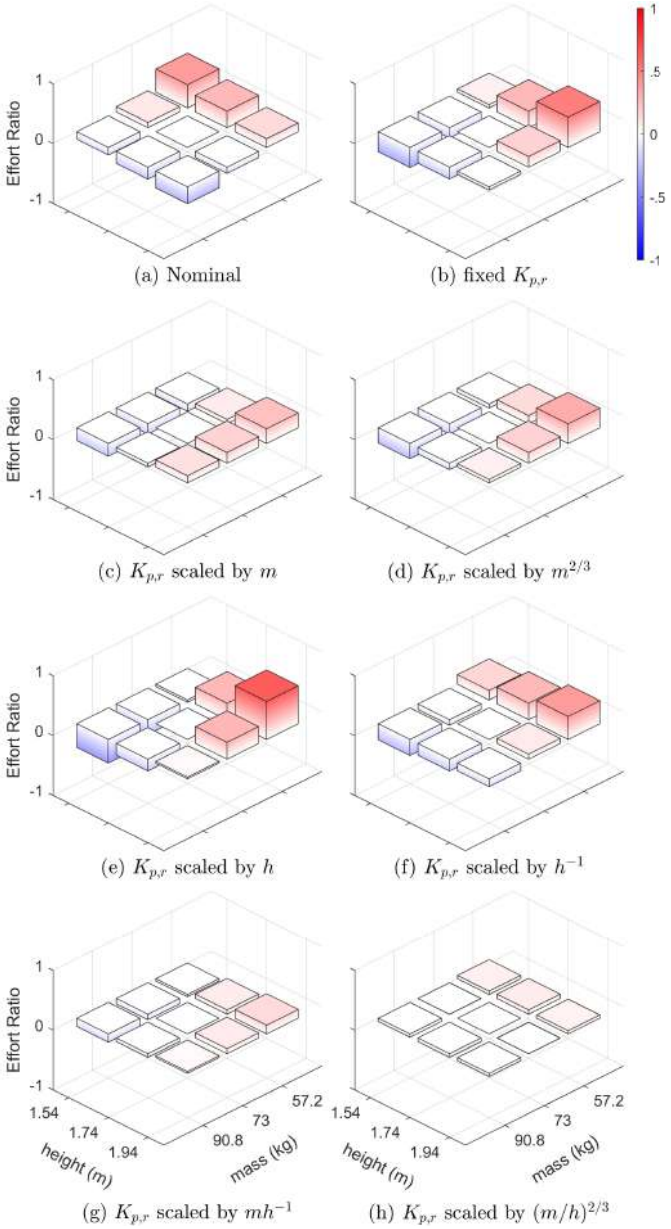

Fig. 5: Human effort ratio for different scaling of $K_{p,r}$ for all virtual participants.

V. Discussion

Our goal was to ensure equitable task difficulty and physical effort across participants with varying attributes. Differences in participant height and weight significantly influence their reachability and exertion capabilities, leading to disparities in task performance and overall experience. To address this, our approach involves standardizing key interaction parameters: the initial poses of both human and robot and the task trajectory. For humans, having the same initial pose across subjects ensures consistent task difficulty, while optimizing the robot's initial pose improves its efficiency. The interaction must balance human accessibility and robot reachability, ensuring seamless interaction. This alignment sets the foundation for smooth task execution and effective human-robot interaction.

Additionally, we observed that tailoring the robot's stiffness matrix $K_{p,r}$ based on the participant's physical attributes (height and mass) further normalizes the effort across individuals, promoting fairness in the interaction. There is a noticeable variation in effort across participants in the nominal configuration (Fig. 5a), with taller and heavier individuals experiencing lower effort. Our optimization method with a fixed $K_{p,r}$ (Fig. 5b) reduces this disparity but causes lower-mass and taller subjects to exert more effort than others, leading to an imbalance in effort distribution. Scaling $K_{p,r}$ by mass (Fig. 5c) produces moderate normalization across participants with different masses but same height. This adjustment reduces the robot's resistance for subjects with lesser mass, who would otherwise experience excessive effort. The robot's

gain should also be scaled inversely with height, as taller participants follow larger trajectories; if not, it would apply greater resistance to them. As observed, mass-inverse-height scaling (Fig. 5g) effectively balances the effort ratio across all participants. Initially, we used a power of 1 for both mass and height, but Jaric et al. [20] showed that muscle strength scales with $m^{2/3}$. While their work only considers mass, height also plays a role in our task by influencing reachability and interaction dynamics. Directly measuring individual muscle strength would be impractical for large-scale studies and may not generalize well across populations. Instead, we apply the same allometric scaling principle to both mass and height, resulting in $(m/h)^{2/3}$, which achieves the most consistent effort ratio across individuals (Fig. 5h). While non-physical factors such as experience and reflexes may influence task performance, our approach ensures that the baseline physical effort remains standardized, independent of these variations. These findings highlight the importance of customizing stiffness parameters in human-robot interaction.

VI. Conclusion

We developed a method to standardize human-robot interactions during physical tracking in a virtual environment, optimizing key interaction parameters to ensure equitable task difficulty and effort across participants with varying physical attributes. Our findings highlight the need for individualized task configurations experiments to enhance fairness and user experience. By tailoring the robot's stiffness matrix and optimizing interaction parameters, we can reduce physical disparities, enabling participants with varying body compositions to perform tasks with comparable difficulty and effort. Future research should explore the physiological and cognitive effects of these adjustments, as well as their impact on long-term engagement and task performance. Factors such as neuromuscular control strategies, muscle strength, experience, skills, and reflexes may also influence task difficulty and should be considered. Our approach offers a framework for designing inclusive systems that adapt to diverse participant needs, paving the way for broader adoption of physical simulators in rehabilitation, training, and entertainment.

***Abstract*— Motion assist robots have been studied to assist human motion for elderly, disabled, injured persons. The motion assist robots can be classified into two types: wearable robots which are directly attached to the user's body and external robots which assist the user's motion from the outside of the user. It is important for those robots to estimate motion intention of users in real-time to assist their daily motion effectively. This paper presents a method to estimate human lower-limb motion intention and its motion phase in real-time for the motion assist robots. By detecting motion phase in addition to the intended motion in real-time, the robots can figure out when and how human motion are assisted even in the middle of the motion. In the proposed method, integrated information about human physical and biological data and the surrounding environment are used to estimate the motion intention and its phase. Damping neuron has been applied in the artificial neural networks for the intended motion estimation and also for the motion phase estimation. Furthermore, changing velocity from the output of the artificial neural network is considered to figure out the intended motion in early stage. Experimental results show that lower-limb motion and its phase are effectively estimated with the proposed method. Furthermore, it is shown that the motion phase is correctly estimated even if the user gives up the intended motion during the motion.**

Keywords—real-time estimation, human motion intention, motion phase estimation, motion assist robots

I. INTRODUCTION

Motion assist robots have been studied to assist human motion for elderly, disabled, and injured persons [1]-[5]. The motion assist robots can be classified into two types: wearable robots which are directly attached to the user's body [1]-[3] and non-wearable external robots which assist the user's motion from the outside of the user [4][5]. It is important for the motion assist robots to automatically assist the user to perform movements according to the user's intention appropriately and safely. In addition, it is important to estimate the series of whole target motion for the robots which assist the user's motion as necessary from the outside of the user like a human assistant. Therefore, recognizing the user's motion intention at an early stage and planning appropriate assistance to achieve the user's intended motion is necessary for appropriate and effective assistance by the motion assist robots. By estimating the user's intended motion and its phase in the early stage of the motion, the assist robot can provide appropriate assist for the user as necessary. In that case, the robot will be able to support the users properly to complete the intended motion even if they give up the intended motion in the middle of the motion.

Although many studies have been performed to estimate human motion [6]-[8], those methods may not be applied for the user's intended motion estimation for the motion assist robots since the intended motion and the actually generated motion are different sometimes especially in the case of elderly or disabled persons. Furthermore, the intended motion must be estimated in real time without time delay to assist the motion with the robots. The intended motion estimation is basically derived from information that reflects user's intention, such as skin surface electromyography (sEMG) and Electroencephalography (EEG) [9]-[13]. By using sEMG, body acceleration information can be taken into account in advance so that the intended motion can be estimated in real time at an early stage of the motion [10][11]. Furthermore, several studies on real-time estimation have employed artificial neural network to conduct real-time estimation, examining the relationship between the time required for estimation and its accuracy [10][12]. Accurate estimation at the start of a motion allows the robot to proper support the user's intended motion like a human assistant. In the case of motion phase estimation, however, few estimation methods that represent the motion phase as a percentage from 0 to 100% have been studied [14]. Therefore, further study is required realize more accurate early estimation of the intended motion and its motion phase simultaneously.

This paper proposes a method for real-time estimation of intended motion and its motion phase for nine types of daily human lower-limb movements. The proposed method estimates the intended motion and its phase using artificial neural networks (ANNs) that can learn high-dimensional nonlinear relationships based on integrated data from human body motion captured via motion capture systems, electromyogram (EMG) signals, and environmental information. The proposed method is a modified method of our previous study [14]. Intended motion and its phase estimations have been performed in our previous studies, applying damping neurons to the ANN for motion phase estimation to appropriately accelerate or decelerate the output. In the modified method, the motion intention estimation

This work was supported by JST [Moonshot R&D] [Grant Number JPMJMS2034].

model takes into account the change from the output of the ANN to estimate the intended motion earlier at the early stage. By introducing the change of the outputs of the ANNs, the first and second candidate motions alternate more quickly, enabling estimation earlier in the early stage. In the phase estimation, although one ANN was used for all estimations in our previous method, the specific ANN is used for each motion in the modified method to learn specific motion phase of each motion accurately. Therefore, a separate ANN is used for each motion to specifically train and estimate the phases.

In the case of motion assist robots, especially the external robots, it is sometimes important to start assisting the user's motion even during the movement if the user requires help of the robots. In order to allow the robot to assist the user even though the user gives up the intended motion in the middle of the movement, the effectiveness of the proposed method under those situations is evaluated for the first time. This evaluation is extremely important in assessing the feasibility of introducing a robot, since it assumes a scenario where robotic assistance is required. Experiments have been carried out to evaluate the effectiveness of the proposed method.

II. PROPOSED METHOD

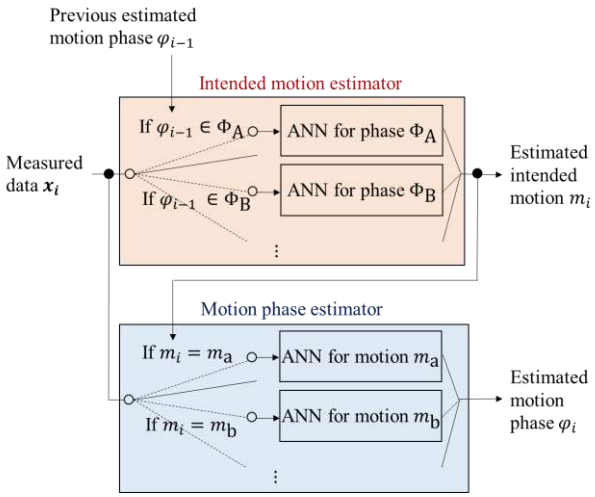

Fig 1 Estimation system for intended motion estimation and phase estimation

In this paper, the input information for estimating the intended motion and phase includes various parameters. These are the 2D position, velocity, and acceleration in the sagittal plane of knee, ankle, heel, and toe of the user's supporting and swinging leg, and both shoulders. If both legs are stationary, the leg that moved most recently is considered the swing leg. Additionally, the input data include lower limb joint angles, the Zero Moment Point (ZMP), and the relative position between the swing leg's toe and the nearest obstacle. The time series information of the swing leg position and 8 sEMG signals (the rectus femoris, biceps femoris, gastrocnemius, and tibialis anterior of both the swing and supporting legs) are also used as important input information. Here, the coordinates are defined as x-direction in the sagittal plane horizontal direction and y-direction in the vertical upward direction, with user's waist as the origin.

The output from intended motion estimator for the intended motion estimation is the estimated daily lower-limb activity (stand up, sit down, squatting, descending, ascending, push, step, standing still, and sitting still), and the output from the motion phase estimator is the numerical value from the start to the end of the activity, expressed between 0 and 1.

This paper proposes a method for real-time estimation of human lower-limb intended motion and their phases. The proposed method consists of two estimators: the intended motion estimator and the motion phase estimator (Fig. 1). Each estimator consists of ANNs. The input for both estimators is the measured data x_i at time step i, the output of the intended motion estimator is the estimated intended motion m_i, and the output of the motion phase estimator is the estimated motion phase φ_i. The ANN for each estimator is switched among multiple ANNs depending on estimation results of intended motion or phase. The ANNs of intended motion estimator is provided for each phase range and switched based on the motion phase (φ_{i-1}) estimated by the motion phase estimator. The ANNs of motion phase estimator is provided for each motion and switched based on the intended motion (m_i) estimated by the intended motion estimator.

As in previous work [14], damping neurons are applied to ANNs for motion intention estimation and phase estimation in order to effectively learn the dynamic characteristics [15]. Damping neurons can effectively learn the dynamic characteristics of the input data.

A. Intended Motion Estimation

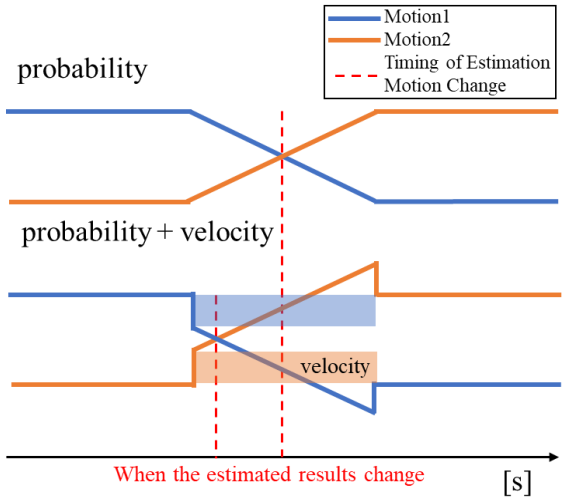

Fig 2 Timing of intended motion estimation considering change of output

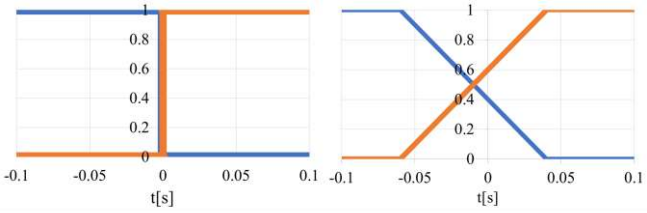
For the intended motion estimation, two kinds of ANNs, *i.e.*, a standard ANN and an early estimation ANN, are prepared. For early estimation, we propose a method to ascertain the intended motion in the early phase by considering the change of the ANN output.

In intended motion estimation, during the early phase of a motion transition, the movement often resembles the previous motion. As a result, it is more likely to be misclassified as the previous motion, leading to lower

estimation accuracy compared to the middle phase of the motion. In this study, by adding the time variation of the estimation result, the second and first candidates of the estimated motion are alternated earlier, and the estimation is performed earlier (Fig. 2). The equation that takes into account the time variation of the output from the ANN is written below.



$$z = y + c_v\dot{y} \tag{1}$$

where y is the output of the ANN, $\dot{y}$ is the time variation of y, c_v is a constant, and z is an estimate considering the change.

For the neurons in the output layer of the ANN for motion intention estimation, damping neurons are used in order to effectively learn the dynamic characteristics included in sEMG and other input data. The output equation of the damping neuron is shown below.

$$y = f_x(w_x x) + w_v f_v(\dot{f}_x(w_x x)) \tag{2}$$

where x is the input signal to the neuron and f is the activation function. This damping neurons is used in the output layer of the intended motion estimation model .

(a) Regular labeling (b) Labeling in this method

Fig. 3 Intended motion labeling method

Figure 3 shows the labeling method. Usually, the labels are switched between 0 and 1 as shown in Fig. 3 (a). However, in Fig. 3 (b), the labeling is designed so that the rate of probability increase or decrease gradually before the operation is switched.

B. Maintaining the Integrity of the Specifications

In the motion phase estimation, the progression of a motion from start to end is represented by values ranging from 0 to 1. This real-time estimation of movement phases enables external robots to assist with the remaining phases of movement, even if a user, such as an elderly person, stops moving partway through the target movement.

To effectively learn the dynamic characteristics contained in sEMG, etc., damping neurons are also applied to the neurons in hidden layer 3 and the output layer of the phase estimation model. Additionally, a separate motion phase estimation model for each motion is developed and the results of intended motion estimation is utilized to select the appropriate phase estimation model for a given motion.

III. EXPERIMENTS

To evaluate the effectiveness of the proposed method for estimating intended motion and its phase, the lower limb movements shown in Fig. 4 and the continuous movements ("descending to step," "stand up to step," and "step to ascending") were performed 10 times each. The sEMG data and position data were measured during the movements. The sEMG data at the rectus femoris, biceps femoris, tibialis anterior, and gastrocnemius muscles on both sides were measured with 2000Hz using Noraxon's Ultium system. The data were processed using RMS with a sampling size of 200. Positional data of joint positions of the lower-limbs, shoulders, obstacles, and chairs were measured with 2000Hz using Natural Point's Opti Track system.

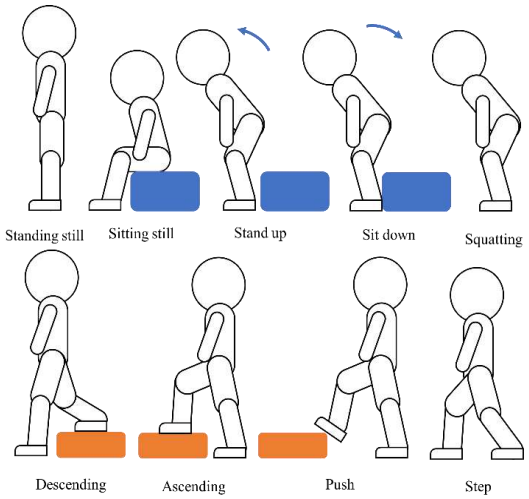


Fig 4 Motion of collected data

The subjects were three young adults, and the experiment collected movement data as "young individuals" and as "pseudo-elderly" subjects wearing aging simulation suits (Sanwa Seisakusho, Model Number 4562363578061), respectively. The aging simulation suit restricts the range of motion by applying resistance to each joint and simulates the difficulty of lifting the legs by adding weights. The "young adult" movements were performed at three different speeds, "slow," "normal," and "fast," while the "pseudo-elderly" movements were performed at two different speeds, "slow" and "normal. In this study, data from all subjects and all speeds were trained together. The experiments were performed based on a protocol approved by the Ethics Committee of the Faculty of Engineering, Kyushu University. Movements were defined as the period during which the foot or waist was in motion. For stair descent, stair ascent, and step, the movement was defined as the time from the start of foot movement to the change between the swing leg and the supporting leg. Table 1 shows the number of neurons in the hidden and output layers of each ANN used in this study. K-fold (K = 5) cross-validation was conducted. Phase estimation was also performed for ANNs without damping neurons to investigate the effect of damping neurons.

The error functions for the motion intention estimation and the motion phase estimation model were the squared errors as shown below:

$$E = \frac{1}{2}K_x e^2 + \frac{1}{2}K_v \dot{e}^2 \tag{3}$$

where K_x is the coefficient of error, K_v is the coefficient of velocity error, e is the estimated phase error, and the optimization algorithm is Adam.

IV. DISCUSSION

Table 3 demonstrates that the proposed estimation system (Fig. 1) effectively leverages the advantages of both standard ANN and early estimation ANN for its predictions. In the early phase of operation (0-10%), the early estimation ANN has 3.5% higher estimation accuracy than the standard ANN. In the proposed estimation system, by using the early estimation ANN for phases less than 20% and the standard ANN for phases above 20%, the accuracy up to phase 10% was 2.5% higher than that using the standard ANN, and from 90 to 100% was 6.6% higher than that using the early estimation ANN. By using phase estimates, it is possible to improve accuracy at the phase 0-10% without significantly reducing accuracy at the phase 90-100%, thereby achieving an overall improvement in accuracy.

Table 5 Phase errors

	Without damping		With damping	
	average	minimum	average	minimum
Stand up	0.02600	0.00439	0.01985	0.00103
Sit down	0.00626	0.00133	0.00889	0.00058
Squatting	0.02235	0.00556	0.01920	0.00125
Descending	0.04401	0.00674	0.04393	0.00247
Ascending	0.04225	0.00823	0.04023	0.00409
Push	0.02234	0.00421	0.01884	0.00174
Step	0.04720	0.00492	0.04626	0.00452

Table 4 shows that the accuracy of the phase 0-10% is 87.3% or better, and the accuracy of the phase 10-80% is 92.9% or better. While the accuracy of ascending, push, and step estimation is mostly below 93% during the phase 0-20%, the accuracy for stand up, sit down, squatting and descending, is 96% or higher, except for the phase 0-10% of squatting. This may be due to the similarity of the initial operation of descending, push, and step.

The experimental results shown in Table 5, Fig. 5 and Fig. 6 show that damping neurons effectively works for the accurate phase estimation. Table 5 shows that the use of damping neurons reduced the errors for all items except sit down, and for stand up, the errors equation (3) were reduced by 23.7%. In addition, the estimation results shown in Figs. 5 and 6 show that the one with the minimum error follows the correct phase from the initial stage of motion to the end of motion. It was also confirmed that, on average, the estimated phase was accurately tracked in the motion of push, squatting,

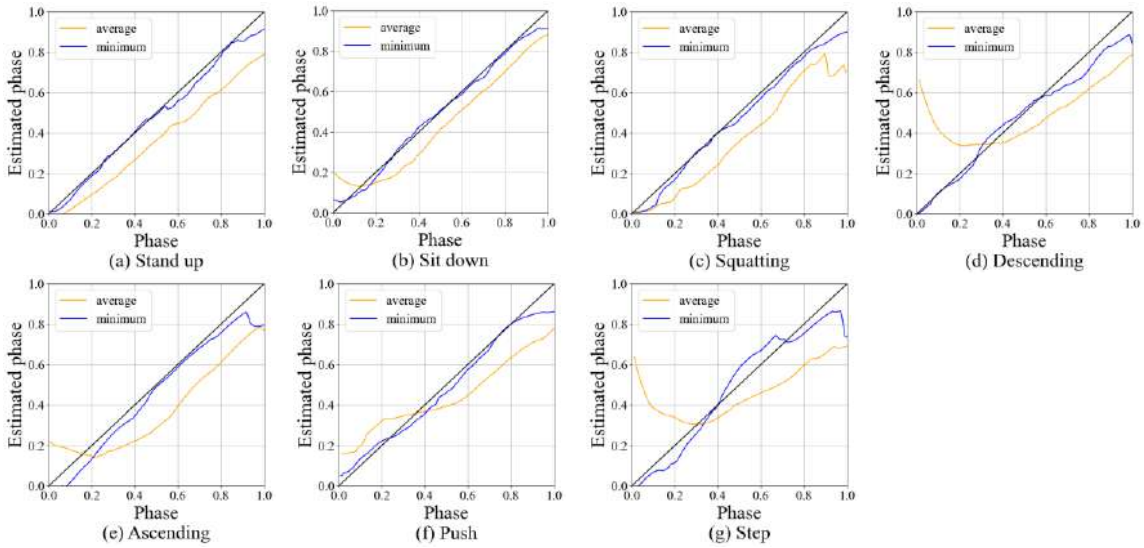

Fig. 5 Motion phase estimation results with damping neuron

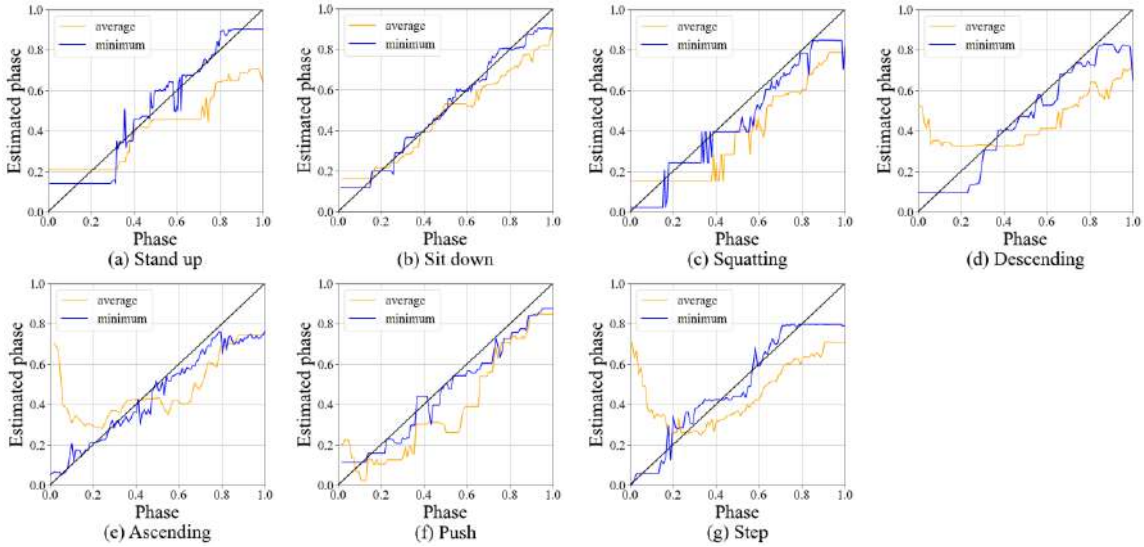

Fig. 6 Motion phase estimation results without damping neuron

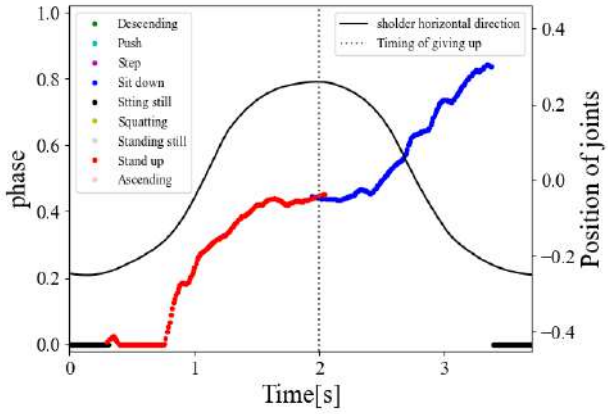

Fig.7 Motion estimation and phase estimation results when the intended motion is changed

sit down, and stand up. The damping neurons effectively accelerate the output moderately and suppress excessive changes, thereby improve the estimation accuracy. However, for descending, step, and ascending, the error was more than twice as large as for the other movements, as shown in Table 5, and a large phase was estimated, especially in the early phase of the movement.

Figure 7 demonstrates that motion estimation is possible even when the intended motion is changed in the middle of the movement. Around the timing when the intended motion was changed, the estimated motions alternate between sit down and standing up. It was observed that before and after this point, the respective motion was estimated accurately. Additionally, the phase estimation shows less gradient around the timing when the intended motion was changed, indicating that the motion was performed more slowly and its motion phase was properly estimated during this period.

V. CONCLUSION

In this paper, we proposed a method for real-time estimation of the intended motion and its motion phase for nine types of daily human lower limb movements, such as sit down, stand up, and so on. The proposed method consists of two estimators: the intended motion estimator and the motion phase estimator. Each estimator, based on the conditions, is accompanied by multiple switched ANNs. For intended motion estimation, both a standard ANN and an early estimation ANN are provided. The early estimation ANN performs its function by taking changes into account. For phase estimation, ANNs were prepared for each movement and damping neurons were applied to all of them. Experimental results show that the proposed method is effective in simultaneously estimating the intended motion of the lower limb and its phase. Furthermore, it is confirmed that the proposed method can be applicable even if the intended motion is changed in the middle of the motion. For future studies, it is suggested to incorporate actual elderly individuals or persons with disabilities into the experiments, rather than relying on simulated elderly scenarios, in order to enhance the applicability and reliability of the findings.

Examining Postural Responses to Perturbations in 3D: A Pilot Study

Rhet O. Hailey *Student Member, IEEE* and Chad G. Rose *Member, IEEE*

***Abstract*— Affecting muscle spasticity, strength, and coordination, stroke results in alterations to muscle control and ability to compensate from unexpected perturbations. Post-stroke, upper extremity movements are heavily modified from perturbations, which increase the difficulty of activities of daily living (ADLs). Postural responses from upper extremity perturbations in healthy and stroke populations have been examined in movements constrained to 2D planar motion, and may provide insight as an assessment tool to help inform therapists to better structure rehabilitation training regimens towards individualized health care for improved long-term outcomes. However, implications on constraining motion in the horizontal plane are not clear and may reduce the generalizability of the findings to the movement through unconstrained 3D space necessary for ADLs. In this paper, we explore the effects of joint perturbations on the elbow and shoulder in unconstrained, gravity-compensated position holding tasks. We present a metric-diverse, dynamic task framework building upon previous 2D experiments designed to better assess rehabilitative efforts in movement trajectories with applied gravity compensation in three dimensional space aimed towards the generalizability of 3D motion. Results suggest that motion of multi-DoF joints display varied movement qualities in 3D space with robotic gravity compensation when compared to constrained planar movements.**

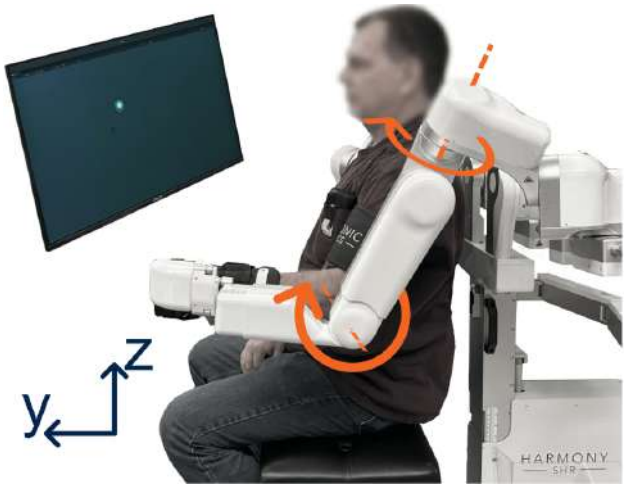

Fig. 1. The Harmony exoskeleton, a bimanual upper body exoskeleton with joint level impedance control, applies a model-based gravity compensation torque to participants to replace planar constraints on movement and enable analysis of unconstrained, 3D postural responses to joint torque perturbations in shoulder and elbow rotation. Task visual feedback of target position of the end-effector is shown on screen.

I. INTRODUCTION

Over the last 30 years, stroke incidents have increased by 70%, which can create long term motor and proprioceptive impairments leading to physical, mental, and cognitive decline [1]. In recent years, robot-assisted therapy methods have been shown as a promising avenue in combination with traditional rehabilitation therapies [2], [3]. Exoskeletons enable high resolution data acquisition for increased assessment metrics to improve robotics, control, and rehabilitative research. Robotic exoskeletons geared towards stroke rehabilitation use multiple control strategies to provide assistance to the wearer. Most common control strategies aim to assist the user to uncover neural pathways for the re-learning of a new subset of movement patterns such as gravity compensation, assist-as-needed or other control methods [4]–[7]. Upper extremity exoskeletons, such as the Harmony Exoskeleton (Fig. 1) can be used for task-based interventions with high levels of repetition to mimic the repeatability of locomotion tasks similar to lower extremity gait mechanics.

Given that many lower-extremity movements are centered around walking locomotion under different loading conditions, any unknown disturbances in locomotion can lead to trips or fall episodes that can lead to increased complications especially in an impaired population. During gait rehabilitation, a common therapy method is to emulate trip episodes in a safe environment to train kinematic compensation tactics and response [8], [9]. Through a mechanical perturbance in gait biomechanics, bipedal movements are analyzed to assess rehabilitative improvements post-stroke via a double treadmill with muscle usage, kinetic and kinematic responses, and movement quality.

With most upper-extremity trajectories being acyclic and moving in free space without the loading body weight and maintaining being upright, task compensation and improvement creates added difficulties to observe rehabilitative improvements. Without the cyclical loading of bipedal locomotion, upper-extremity recovery and rehabilitation has not fully utilized perturbance response for movement recovery and improvement. From stroke, damage to the cortical regions of the brain results in erratic motions with inappropriate muscle coordination patterns [1], [10]. In addition to kinematic measures of movement quality on reaching or pointing movements (e.g., [11], [12]) where the robot is transparent, motor function assessment modalities have been proposed where the robot applies torque perturbations to elicit response movements [13]–[15] with other works examining the role of perturbations at measuring proprioceptive function [16]. Bourke et al. demonstrated the use of joint perturbations

*This work was supported by NSF Grant 2230971 and the Samuel Ginn College of Engineering at Auburn University. All authors are in the Wearable and Bio-Robotics Lab, Department of Mechanical Engineering, Auburn University, Auburn, AL 36849. rhet.hailey@auburn.edu

to assess stroke in planar tasks in an acute stroke population [17]. This study was restricted to a planar task space and a subacute stroke population with a focus on the correlation between assessment modalities. Planar restraints may impact the interpretation of movement results and the generalizability to ADLs. Testing postural joint perturbations in three dimensions may expose new insight into into human movement and compensation.

In this paper, we examine the impact of removing the planar constraint on this motor function assessment. Specifically, we examined the motion in the directions perpendicular to the plane of perturbation, and present the results for a healthy cohort and a single participant with chronic stroke. Section II introduces the experimental methods and metrics. The results presented in Section III are discussed in Section IV, along with the limitations of the study and direction for future work before concluding in Section V.

II. Methods

A reaching perturbance assessment framework has been designed to assess kinematic compensation modalities correcting for unknown task disturbances in patients with chronic-stroke in unconstrained free space. This assessment framework is possible through the use of the Harmony Exoskeleton and its three-dimensional gravity compensation abilities to remove the wearer's arm-load weight [4]. Outlined in Fig. 2, this framework provides useful insight to the differences between constrained, planar tasks and movement in free-space [17].

A. Experimental Setup

The perturbation experimental assessment was performed using the Harmony exoskeleton, a bi-manual upper-extremity exoskeleton. Seen in Fig. 1, the Harmony exoskeleton promotes proper scapulohumeral rhythm focused on stroke rehabilitation through series elastic actuators [18], [19]. The 14-degree of freedom (DoF) exoskeleton allows for free movement through three dimensional space that may be obfuscated by arm weight via the added robotic gravity compensation.

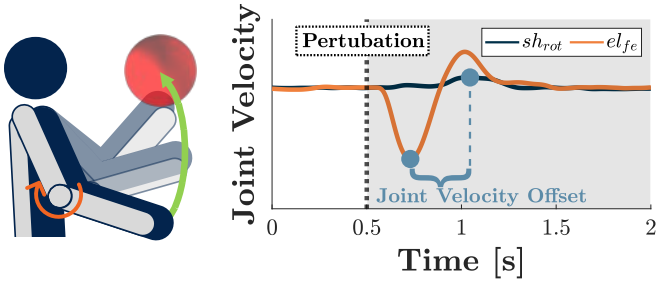

Fig. 2. Exemplary graphic of movement task wearing the Harmony Exoskeleton in unconstrained, gravity supported 3D space for an elbow perturbation. Participants were instructed to maintain end-effector position in the target location (sphere) and were perturbed by a joint torque at random intervals. The plot on the right shows the joint velocity of shoulder internal/external rotation (blue) and elbow flexion/extension (orange). The black line indicates perturbation onset while the two highlighted points show the peak joint velocity, with the time difference between the two resulting in the joint velocity offset time.

In this assessment, user arm weights were calculated and fine tuned during each session. All participants were within 5-95% of normal human sizes to fit inside the Harmony exoskeleton. Participants were tasked with maintaining hand position at a target goal held in front of them with a radius of 1 cm. Visual feedback of hand end-effector point position was shown in computer simulation using Unity-3D where users were given a green light within the target bounds via an isometric viewpoint of the target goal. During this assessment, joint perturbations were applied at the shoulder for internal-external rotation at ± 2 Nm and ± 1 Nm at the elbow for flexion-extension and is shown in a diagram in Fig. 2. As per the joints laid in out Kim 2017, these constant torques were applied in the Harmony Exoskeleton at J4 for shoulder internal-external rotation and J6 for elbow flexion-extension [19]. Perturbation order was decided randomly per each trial for a total of 9 blocks of 8 perturbations, which allowed for 2 identical perturbations per each block set. Prior to each joint torque, a delay of 1.75-2.25 seconds occurred before a constant torque was applied for 3 seconds followed by a 5 seconds wait period before the next perturbation. Prior to assessment, participants were given the opportunity to interact with the visual feedback simulation and an individual perturbation block.

B. Data Acquisition & Statistical Analysis

All data was recorded directly on board the Harmony Exoskeleton at 200 Hz for joint angles, joint torques, and end-effector position. During post-processing, all differentiated data was filtered via a 4^{th} order Butterworth low pass filter with a 6 Hz cutoff frequency [20]. All movements were segmented at perturbation onset for the entire 3 seconds. Metric data was tested for normality via the Shapiro-Wilk test. Following, a Wilcoxon signed rank one-sided test between healthy and impaired populations was used to evaluate the assessment metrics used in this 3D perturbation task [21]. Resultant assessment metrics were considered significant with a $p-\text{value} < \alpha = 0.05$.

C. Performance Metrics

Following the guidelines set out by Bourke et. al, the following task assessment metrics were quantified: Posture speed ($|\text{cm/s}|$), acceleration time (s), return time (s), endpoint error (cm), maximum displacement error (cm), and joint velocity offset (s) [17]. Posture speed was quantified as the 95^{th} percentile of the median hand speed for the first 0.5s before perturbation onset, which indicated difficulty to maintain target position. Acceleration time is quantified as the peak velocity in hand speed post-perturbation onset. Return time was the time taken to return back to the target volume if the hand position ever left the target range. Endpoint error was the mean error after returning to the target volume. Joint velocity offset was the difference between peak elbow and shoulder rotation joint velocities where a positive value indicates the elbow joint moving first. Fig. 2 shows an example trajectory highlighting the joint velocity offset time.

D. Participant Demographics

Ten healthy participants and one impaired participant were recruited as volunteers to participate in this preliminary assessment study. All demographic information was self reported and is shown below in Table I. Target impaired population met the following criteria: (1) post-stroke $>$ 6 months with chronic symptoms of impairment (2) age between 18 and 65, (3) body dimensions within the 5-95% range of mean sizes [21]. The impaired participant (S1) suffered from an ischemic stroke in the occipital lobe in the right hemisphere resulting in left side sensorimotor impairments. S1 is 25 months post onset and requires assistance in ADLs with a modified Rankin Score (mRS) of 3 and a Fugl-Meyer Upper Extremity (FM-UE) score of 36. Ten participants are right hand dominant and one left hand dominant. The impaired participant used their affected, left hand for the study. This protocol was approved by the Auburn University IRB protocol #22-559 MR 2301.

TABLE I
PARTICIPANT DEMOGRAPHICS

	Age (yr)	Weight (lb.)	(M/F)	FM-UE	mRS
Healthy	27.5 ± 9.1	170.5 ± 43.3	(9/2)	-	-
Stroke	54	250	(M)	36	3

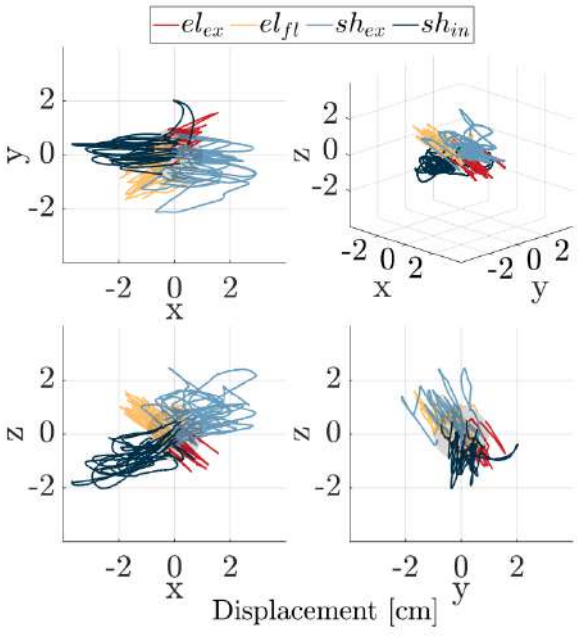

Fig. 3. Shown above is healthy example of individual reaching motions from perturbation onset until target return in centimeters. The top left has a top-down view of the transverse plane (X-Y) with an isometric view on the top right. The bottom graphs show planar representation of the Z-deviation of these reaching trajectories of the frontal plane (X-Z) and the sagittal plane (Y-Z) respectively. Hand trajectories are color coded by perturbed joint. Trajectories that did not escape the target volume were excluded.

III. RESULTS

A set of performance were outlined previously to assess upper-extremity movements in unconstrained 3D space. Fig. 3 shows the individual hand trajectories for an entire trial of a healthy participant. Multiple planar views are given to give better viewpoint to understand the underlying tasks dynamics. It is evident from the plots that the perturbations at the elbow encouraged near-parallel movements as the trajectories are in line at every viewpoint. In contrast, shoulder perturbed movements generated more non-parallel trajectories when returning to the target volume. Given the unconstrained nature of the upper extremities, shoulder flexion and extension and the high DoF in the shoulder joint, it is a natural response that the shoulder shows increased trajectory curvature in a reaction to a 1DoF perturbation.

In response to mechanical perturbations, the means and standard deviations of the healthy participants population and S1 are shown in Table II. When comparing the mean results of S1 to healthy participants, all values were shown to be statistically significant with all p-values $< \alpha = 0.05$. Most significantly, the acceleration time was much higher in the S1 with a mean difference of 0.4s. The return time of hand to the target also was increased in S1 by 0.4s. Joint velocity offset was the most significantly different showing that the elbow joint angle peak velocity occurred after the shoulder rotation peak velocity. Following the expected results for this assessment task, S1 performed worse and took more time all with much higher deviation throughout the task.

Compared to a healthy participant, S1 showed less variance in repeated movements. Fig. 4 shows the difference in individuals trajectories and the variance plots between trials for a shoulder internal perturbation. It is important to note in Fig. 4 that S1 showed slower hand speeds and joint velocities than the healthy example, H1, which remained consistent across all healthy participants. After perturbation onset, the H1 showed intent to reduce z-error without overshooting the target while S1 consistently overshot the z-error after each perturbation, taking longer to return to the target volume. Interestingly, it can be seen that the joint velocity of shoulder flexion and extension was activated as compensation without direct influence on the joint space.

IV. DISCUSSION

These results provide healthy movement quality baseline, which can be used when establishing the motor function of impaired populations, and lead towards development of individualized assessment profiles.

A. Unconstrained 3D Movements

Compared with planar movements, 3D trajectories move in an unconstrained manner, with much more potential for deviation and lack of precise repeatability. Free space allows for less generalizability in movement assessment, even more obscured with the added spasticity of post-stroke patients.

Given the expected outcome, S1 performed statistically significantly different in all assessment metrics except for endpoint error, which was statistically insignificant. Since endpoint error was the mean error after returning to the target volume, it is expected that there be little to no

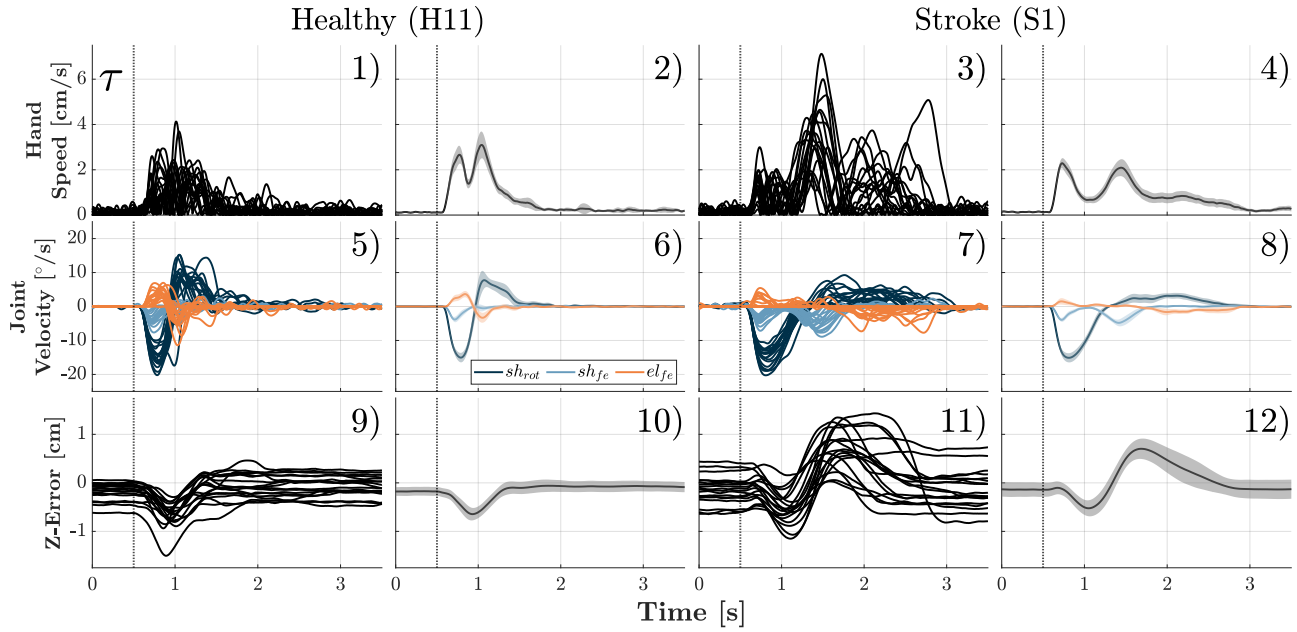

Fig. 4. Healthy movements from a single, age-matched participant, H11, (left columns) and S1 (right columns) for hand speed (1-4), joint velocity (5-8), and height deviation (9-12) from perturbation onset (gray vertical line) for the entire 3 seconds of applied perturbation torque. This data is shown from a shoulder internal rotation perturbation. For each set of columns, the left most column represents individual movements while the right most column showcases movement mean and variance.

difference as the data implies. As well, the mean return time is skewed since all individual reaches that did not leave the target volume were excluded from this metric. Due to the faster, more erratic movements, S1 showed far less controlled movement capabilities in the affected arm. S1 had much higher deviations in performance from the increased spasticity from chronic stroke. S1 showed increase in posture speed, which indicates difficulty of maintaining hand position inside the target volume. However, S1 was always able to return back to the target. Instructed to hold the hand out in front of them, all healthy participants held their hands at breast height, but S1 did not have the range of motion to achieve this same target position, and thus gravitated back towards the same position from increased stiffness and lack of volitional control.

From Fig. 5, S1's assessment metrics may be seen overlaid healthy participants for all perturbations types. For the healthy participants, all movements that did not leave the target volume were not assessed and withheld from the metric data to reject falsely positive data points, which slightly skews the data for the return time and endpoint error. Even in unconstrained space with added gravity compensation, volitional movements must still overcome some added inertia that the robotic exoskeleton provides in order to maintain the impedance controlled gravitational assistance.

Planar motions of elbow compared to the spatially curved trajectories of shoulder movements suggests that the added DoF at the shoulder reduce repeatability of exact movements and make assessment of shoulder movement far more difficult in 3D space. Focusing on flexion, extension, and

Z-Deviation $[cm]$	0.06 ± 0.33	0.13 ± 0.41	$2.2e-04$

internal and external rotation, shoulder biomechanics in one plane do not react in the same plane in both healthy and impaired participants to postural perturbations. Shown in Fig. 3, shoulder flexion and extension perturbations result in spatially curved trajectories in unconstrained space.

B. Limitations

The presented study had a few limitations in the experiment design which may reduce the generalizability of the findings. One limitation in perturbation-based assessments is the difficulty in separating volitional control responses from those potentially generated through increasing joint impedance through co-contraction. In our experiment, joint torques were relatively low (1 and 2 Nm) and applied smoothly via impedance control from the Harmony Exoskeleton.

Another concern is that the joint axes, and therefore the joint torques applied by the exoskeleton may not exactly

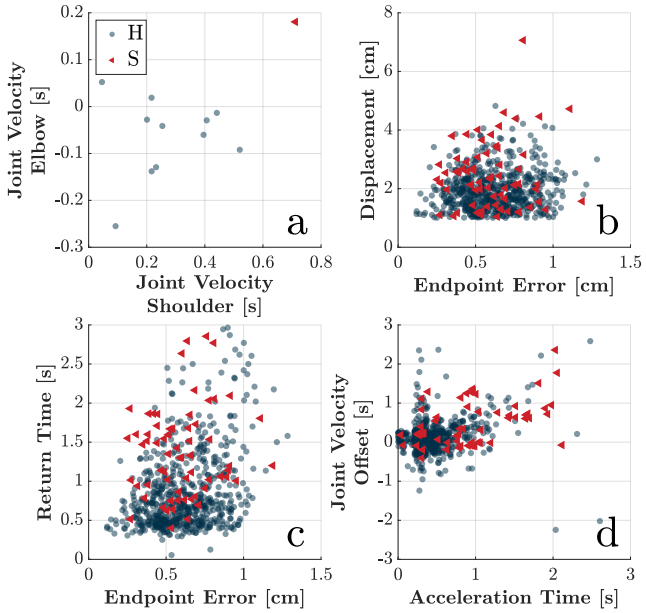

Fig. 5. Participant task performance of healthy participants compared to S1. In these plots, healthy data is shown with blue points while S1 data is shown shown as red triangles. a.) mean joint velocity offset is shown compared between the perturbed joints. Positive values in time indicate that the elbow peak velocity occurred later than the shoulder peak joint velocity. b.) maximum displacement vs. endpoint error c.) return time vs. endpoint error d.) joint velocity offset vs. deceleration time.

mirror the joint axes of the wearer. However, prior work with the Harmony Exoskeleton has shown high quality mapping between robot and human joints when donned correctly [22]–[24] suggesting that misalignments can be minimized, and the consideration of Cartesian space or otherwise normalized metrics (e.g., hand speed) are robust to misalignments.

Next, the target position was ambiguously suggested to be a comfortable position with the elbow, shoulder flexion, shoulder abduction and shoulder flexion. As such, this user-selected comfortable position may have resulted in slightly different orientations between participants, resulting in changes to passive joint properties or other biomechanical features. However, it is reasonable to assume that the volitional control examined in this study was not significantly impacted. As mentioned earlier, this may have resulted in a type 1 error with S1 have significantly better endpoint error given that the S1 had a reduced range of motion and control of the affected hand. This may have resulted in a decrease of positional error with a lack of overall movement and compensation abilities.

Next, the healthy cohort was not age-matched to the single chronic stroke participant, potentially reducing the validity of the direct comparison of trajectories. Further, the use of a single impaired participant reduces the potential generalizability of the findings. However, even in this preliminary pilot study, the results motivate further examination and comparison of the traditionally explored 2D planar arm movements with unconstrained, 3D movements.

While the model-based gravity compensation approach implemented in this study [4], [19] is feedforward, which can introduce errors in the amount of gravity compensation as a function of position, the relatively small workspace used in this study should prevent potential inaccuracies in the model from significantly impacting the results.

Most healthy participants raised concern about the visual feedback simulation in regards to the depth perception of the hand position and the target size and how this effects the assessment task. Participants also had visual feedback of the robot and hand in addition to the computer simulation for depth. Future work could address this limitation by adding a second view of the task in the transverse plane, or by using an immersive display (i.e., VR headset) to more effectively render depth.

C. Future Work

Future studies look to increase participant population. As one impaired participant is not indicative of an entire population, results suggest further investigation into three dimensional postural perturbations. Alongside current metric assessments, a unit force will be applied at the end-effector to investigate postural responses to complex upper-extremity disturbances. This will reduce complications that may arise from joint misalignment with the activation of multiple joints at once to study multi-DoF curvature.

An additional consideration in this study was the use of gravity compensation to replace the planar constraint of prior works. However, it may be the case that gravity compensation may reveal improved motor function obscured by the strength required to perform unassisted movements [4], [25]. Future studies should seek to understand the potential interactions between gravity compensation, sensorimotor impairment, and the metrics presented here.

Ultimately, this framework could identify movement quality shifts from the assessment to be used in real time in accordance with robotic rehabilitation. Given user postural responses to perturbations, an online agent could help clinicians in the assessment and suggest rehabilitative exercises in 3D space.

V. Conclusion

Robotic devices such as exoskeletons have unique interaction and measurement capabilities towards understanding, rehabilitating, and assessing sensorimotor function. Prior studies of the sensorimotor responses to mechanical perturbations have focused on planar upper extremity motion. However, in this work we showed that motions of multi-DoF joints such as the shoulder display different movement qualities than single DoF joints when the planar movement constraint is replaced with gravity compensation (of robot and human arm). These 3D perturbation metrics provide insight into movement quality in pre-defined tasks and could provide objective feedback in real time in a standardized task design for potential human in the loop solutions. These pilot results from one impaired participant suggest that future study is needed to explore the implications and correlation

of our findings on motor function and assessments, as well as sensory assessments both with and without gravity compensation in 3D space.

Reimagining Assistive Walkers: An Exploration of Challenges and Preferences in Older Adults

Victory A. Aruona[1], Sergio D. Sierra M.[1], Nigel Harris[1], Marcela Munera[1], Carlos A. Cifuentes[1]

***Abstract*— The well-being of older adults relies significantly on maintaining balance and mobility. As physical ability declines, older adults often accept the need for assistive devices. However, existing walkers frequently fail to consider user preferences, leading to perceptions of imposition and reduced acceptance. This research explores the challenges faced by older adults, caregivers, and healthcare professionals when using walkers, assesses their perceptions, and identifies their needs and preferences. A holistic approach was employed, using tailored perception questionnaires for older adults (24 participants), caregivers (30 participants), and healthcare professionals (27 participants), all of whom completed the survey. Over 50% of caregivers and healthcare professionals displayed good knowledge, positive attitudes, and effective practices regarding walkers. However, over 30% of participants perceived current designs as fall risks, citing the need for significant upper body strength, potentially affecting safety and movement. More than 50% highlighted the importance of incorporating fall detection, ergonomic designs, noise reduction, and walker ramps to better meet user needs and preferences.**

I. Introduction

Mobility is fundamental for performing essential tasks and actively participating in societal life, allowing older adults to live more independently [1]. In 2017, the global population over 60 years old was 962 million, and it is forecast to double again by 2050, reaching 2.1 billion [2]. With the rising life expectancy among older adults, more of them are facing mobility issues that may require assistance with daily tasks [3], [4].

Loss of physical mobility makes full participation in desired activities more complicated and could prevent social involvement [5]. The impact of limited mobility on mental health, the risk of falls, disability, hospitalization, and mortality rates cannot be understated, as indicated by studies [6]–[8]. Therefore, mobility plays a pivotal role in fostering independence, social engagement, and overall well-being as individuals age [9], [10].

Assistive technologies can enhance autonomy, safety, and quality of life of the ageing population [11]. Among these technologies, assistive walkers stand out for their potential to improve ambulation and promote physical activity [12]. For instance, walkers are used indoors by 22% and outdoors by 44% of older adults in the UK [13]. This category of devices includes canes, standard walkers, and wheeled walkers.

*This work was supported by the UKRI Medical Research Council [grant number MR/Y010620/1], EPSRC, and FARSCOPE CDT.

[1]All authors are with the Bristol Robotics Laboratory , University of the West of England, Bristol, UK. victory2.aruona@live.uwe.ac.uk, {sergio.sierramarin, nigel2.harris, marcela.munera, carlos.cifuentes}uwe.ac.uk

While mobility devices have been shown to boost independence, foster social participation, and improve the quality of life in older adults [14], the use of assistive walkers presents its own set of challenges. Despite some studies suggesting that walking aids may prevent falls in older individuals [15], the association remains poorly understood [16]. This is because walking aids can alter gait patterns by preventing normal arm swing, changing posture, decreasing gait speed, and increasing standing time [17]. Difficulty in navigating stairs, destabilizing biomechanical effects, upper limb pain, and an increased risk of falling are among the potential drawbacks [18], [19].

Moreover, assistive walkers frequently fail to satisfy the needs of older adults, and this misalignment between their needs and the adoption of these technologies stymies their capacity to achieve independence [20]. For instance, canes and wheeled walkers may fall short in providing adequate support during essential sit-to-stand transfers that are crucial for daily activities [21]. Several studies have examined older adults' experiences and satisfaction with mobility aids. The study in [22] found high user satisfaction with rollators and manual wheelchairs. However, differences were noted in how users assessed the usefulness and characteristics of each device. The systematic review in [23] analysed 45 studies to assess the usability of rollators, focusing on aspects such as ease of use, comfort, and safety. Using a deductive approach, they found that while these factors were frequently discussed, areas like repairs, servicing, and durability received less attention. The study highlights the lack of dedicated research on rollators' usability and calls for future user-centred, participatory studies to improve satisfaction and evaluation in assistive mobility device design.

Thus, understanding the challenges faced by older adults using assistive walkers, analysing their perspectives, and examining the insights of healthcare professionals and caregivers are essential steps towards the development of more effective, user-centric solutions. This study explores the challenges encountered by older adults using assistive walkers to enhance gait activities. We aim to analyse older adults' perspectives on the features they desire in an ideal assistive walker, aligning future advancements with their unique requirements and preferences. Additionally, we explore the perspectives of healthcare professionals and caregivers, who possess valuable first-hand experience with the mobility difficulties faced by older adults. This approach aims to bridge the gap between existing assistive walker technologies and the evolving needs of the ageing population.

TABLE I
CHARACTERISTICS OF THE OLDER ADULTS

Participants	n = 24, 6 Male, 18 Female
Age Mean (SD)	88.67 (6.64) years
Weight Mean (SD)	75.98 (6.90) kg
Health conditions	
Vision Problems	79.0 %
Hearing problems	58.0 %
Mobility difficulty	92.0 %
Health conditions affecting mobility	
Arthritis	42.0 %
Osteoporosis	5.0 %
Parkinson disease	8.0 %
Paralysis	8.0 %
Knee and hip condition	42.0 %
Stroke	8.0 %

II. MATERIALS AND METHODS

This section outlines the perception questionnaires for older adults, healthcare professionals, and caregivers.

A. Demographics

Information about the older adults' demographics was recorded (See Table I). The information from healthcare professionals and caregivers, including job titles and experience, was included in the questionnaire.

B. Knowledge, Attitude, and Practice (KAP)

According to [24], the KAP standardized questionnaire measures a population's knowledge, attitudes, and practices, identifying the initial misconceptions, beliefs, and behaviours in relation to a specific health-related topic. This questionnaire also provides information on needs, issues, and barriers related to technology. The questionnaire aimed to gather information from health professionals and caregivers regarding their knowledge base, overall perception, and everyday activities using assistive walkers. Questions were phrased as statements and graded on a 5-point Likert scale ranging from -2 (strongly disagree) to 2 (strongly agree).

C. Closed-Ended Questions

The functionality and limitations of conventional assistive walkers (CAWs) were assessed using a series of statements that were developed following a literature review. A 5-point Likert scale was used. Questions aimed at assessing the walker's effectiveness, safety, comfort, stability, and support for daily activities, mobility, and transitions both indoors and outdoors. Questions also included perceptions of fall risk, navigation support, user-friendliness, complexity, movement limitations, and physical effort required.

D. Open-Ended Questions

The open-ended questions evaluated the features of CAWs that older adults consider necessary. These questions also collected suggestions, perceived drawbacks and benefits, ideas for improvement, and overall perceptions from caregivers and healthcare professionals. Questions assessed preferences, concerns, and ideal walker features. Moreover, questions inquired about perceptions of familiar walkers, emphasizing limitations faced and proposed enhancements.

E. Research setting and protocol

The study was conducted in two private residential care homes in south-west England, selected for their high number of older adults using assistive walkers and participants' cognitive abilities. Caregivers and physiotherapists with relevant experience were recruited from these homes, while additional caregivers and healthcare professionals were recruited from other facilities and institutions. All participants provided informed consent after reviewing the consent statement. They then submitted demographic information and completed the survey. Ethical approval was granted by the University of West of England's Ethics Committee.

F. Participant Recruitment

The study included older adults selected using non-random convenience sampling. Medical information regarding memory function was reviewed with the physiotherapist prior to interviews. Inclusion criteria were: (1) aged 75 or older, (2) living in residential or home care settings, (3) requiring mobility assistance and having visited a hospital for related issues, (4) relying on a walker for daily transportation, or (5) prescribed a walker. Exclusion criteria included: (1) inability to walk and (2) cognitive impairment.

The study also included physiotherapists, occupational therapists, and general practitioners with experience working with older adults, as well as caregivers providing support to individuals using assistive walkers. Inclusion criteria were: (1) providing care to older adults, (2) working in care homes, and (3) at least six months of experience in elderly care. Exclusion criteria included: (1) no experience attending to older adults.

G. Data Analysis

The study employed a mixed methods approach to explore participants' perceptions towards the use of CAWs among older adults. The primary focus was qualitative, aiming to capture the depth and richness of participants' experiences and preferences through open-ended questions. To complement the qualitative insights, a Likert scale was utilized to quantify the levels of agreement with specific statements related to assistive walkers. Responses were summarized by examining the percentage of agreement, neutrality, and disagreement, providing a comprehensive view of participants attitude and preference.

III. RESULTS

Data were collected from a total of 81 participants (24 older adults, 30 caregivers and 27 clinicians). The outcomes from the KAP survey, the closed-ended and the open-ended questions, are discussed as follows.

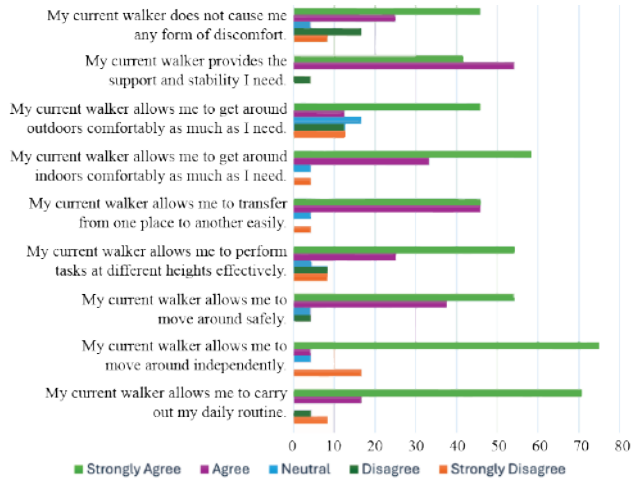

Fig. 1. Older adult's opinions on the functionalities of the assistive walkers

A. Older Adults

A total of 24 older adults took part in the study. Table I details their characteristics; most participants had a visual or hearing impairment, with arthritis and/or hip or knee problems affecting their mobility. Figure 1 presents older adults' opinions on the assistive walker's functionalities. Most older adults perceive their current walkers as effective tools for maintaining daily routines and ensuring independent mobility, with 88% and 96% respectively agreeing with these statements. However, opinions on specific aspects of walker use are more varied. While 79% feel safe using their walkers, concerns persist regarding stability and comfort, with 21% questioning safety and 25% experiencing discomfort. Walkers are generally considered effective for indoor use, as 91% of users report comfort within their homes. Outdoor usability is less favourable, with only 59% finding their walkers suitable for external environments. Additionally, while 79% agree that their walkers help in performing tasks at different heights, and 92% find them useful for easy transfers, there are still notable percentages of users who disagree.

B. Healthcare professionals and Caregivers

A total of 30 caregivers and 27 healthcare professionals took part in the study. Regarding work experience in elderly care, approximately 60% of caregivers had more than 2 years' experience and 78% of healthcare professionals had more than 2 years' experience. Regarding the number of older adults being cared for, 64% of caregivers cared for more than 10 older adults while 59% of clinicians attended to more than 10 older adults.

Figure 2, Figure 3 and Figure 4 present the level of agreement of healthcare professionals to the KAP questions. As expected, Figure 2 shows that health professionals have a high level of knowledge, with 50% and above agreement with the statements in this category, but with some uncertainty around safety precautions and prescribing. Figure 3 shows health professionals' attitudes, which are overwhelmingly positive, with 75% and above agreement with most statements in this category, reflecting a positive attitude to the

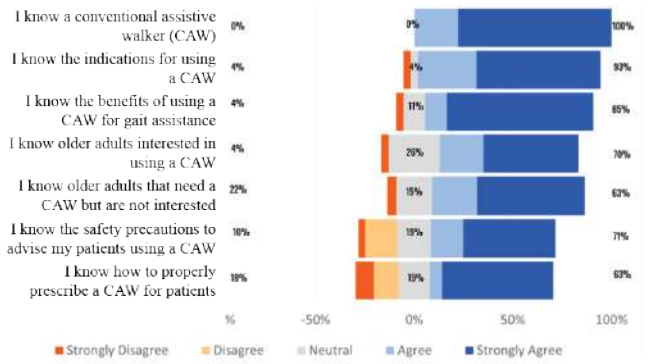

Fig. 2. Knowledge of healthcare professionals regarding the use of an assistive walker. Percentages show total disagreement, neutral and agreement.

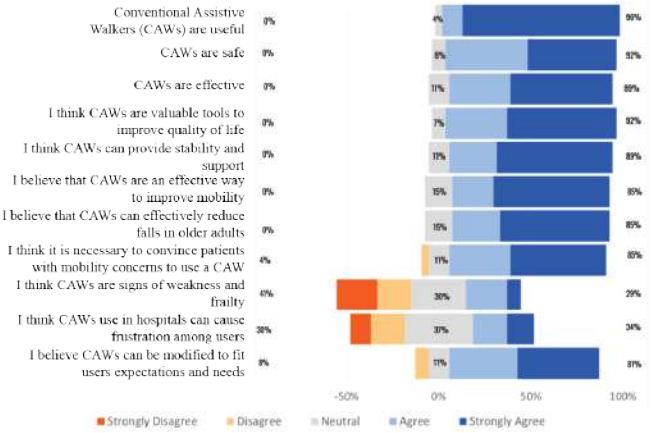

Fig. 3. Attitude of healthcare professionals regarding the use of an assistive walker. Percentages show total disagreement, neutral and agreement.

use of assistive walkers. However, there is 50% neutral agreement with statements "I think assistive walkers serve as a sign of weakness and frailty" and "I think CAWs used in hospital settings can cause frustration among users". Figure 4 explores practice, there is 50% and above agreement with statements in this category showing good practice by these respondents on the usage of assistive walkers. However, there is 50% neutral agreement with statements "I have a procedure for evaluating patients requiring a CAW", "I perform regular follow up on mobility improvements with patients who use a CAW", and "I have observed older adults are reluctant to use a CAW due to fear".

Figure 5 shows there is 50% and above agreement to the statements in knowledge, highlighting a strong foundational knowledge of caregivers regarding using an assistive walker. Figure 6 shows there is 100% agreement with most statements in attitude, reflecting a positive attitude to the use of assistive walkers. However, there was a 25% mixed perception with the statement "I think assistive walkers serve as a sign of weakness and frailty". Figure 7 shows 75% agreement with statements in this practice showing good practice by these respondents on the usage of assistive walkers. However, 50% of respondents were neutral on whether older adults avoid CAWs due to usage factors or design.

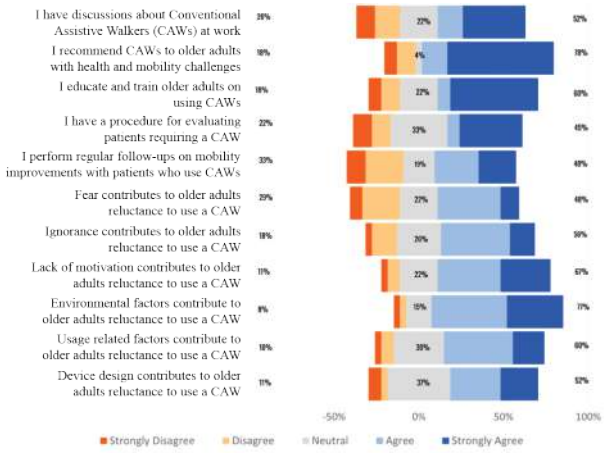

Fig. 4. Practice of healthcare professionals regarding the use of an assistive walker. Percentages show total disagreement, neutral and agreement.

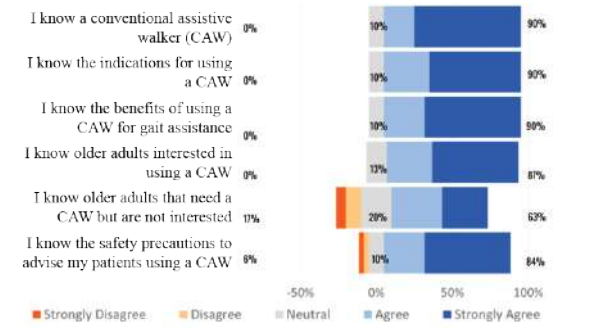

Fig. 5. Knowledge of caregivers regarding the use of an assistive walker. Percentages show total disagreement, neutral and agreement.

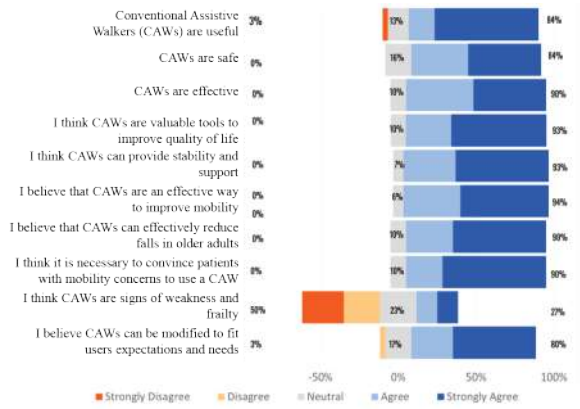

Fig. 6. Attitude of caregivers regarding the use of an assistive walker. Percentages show total disagreement, neutral and agreement.

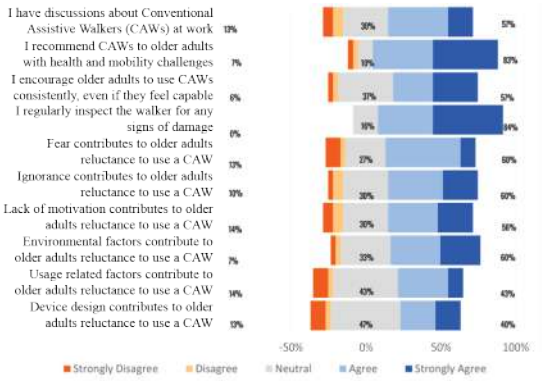

Fig. 7. Practice of caregivers regarding the use of an assistive walker. Percentages show total disagreement, neutral and agreement.

C. Limitations of assistive walkers

The analysis of perceptions revealed diverse concerns and satisfaction levels. While 55% of older adults feel safe using walkers, 37% of both older adults and caregivers, along with 33% of healthcare professionals, perceive walkers as fall risks due to stability issues. A major gap identified is the lack of navigation systems, highlighted by 96% of older adults, suggesting a need for technological enhancements. Usability is generally rated positively, with 80% of older adults, 60% of caregivers, and 59% of healthcare professionals finding walkers easy to use, though some complexity remains for 21% of older adults. Movement restrictions are less of a concern for older adults, but some caregivers and healthcare professionals disagree, indicating design adaptability needs. The physical effort required to use walkers is noted by 42% of older adults and 40% of caregivers, pointing to the need for ergonomic improvements to enhance safety and ease of use.

D. Perception of Older adults, Caregivers and Healthcare professionals towards the use of an assistive walker

The result shows consistent preference of assistive walkers across all groups. Common challenges included fear of falling, difficulty navigating tight spaces, and usage challenges relating to size, noise, and brakes. To mitigate this, more than 50% of each group recommended the need for innovative features such as navigation systems, ergonomic designs, and threshold ramps. Above 50% of caregivers and healthcare professionals also noted the need for additional safety and convenience features including alarm buttons, user-friendly brakes, and fall detection systems. Additionally, over 50% of healthcare professionals advised the inclusion of noise reduction features and enhanced device designs[1].

IV. Discussion

Most caregivers and healthcare professionals demonstrated a strong understanding, positive outlook, and proficient usage of these walkers, emphasizing their significance for older adults. The respondent groups expressed concerns about the frequent falling incidents related to the walker usage, with older adults sharing their experiences of falling while transferring and navigating with the walker. Older adults and caregivers blamed walker deficiencies, such as wheel issues and poor brakes. However, healthcare professionals attributed falls to poor balance and cognitive impairments, this was particularly problematic in cognitively impaired patients, as also stated in previous studies by [25], [26]. This implies

[1]See complementary material with perception answers: here

there would be benefit in incorporating cognitive assistance features into these walkers to facilitate smoother transfers.

Healthcare professionals reported walkers to be heavy, requiring so much strength and effort, further exacerbating the issues and increasing the risk of falling which supports a study by [27]. Both older adults and caregivers reported that the walkers were not enough to support their weight, causing discomfort, pain, and psychological distress. This statement is consistent with [28] indicating that individuals with a much higher weight find it difficult to move around comfortably. In addition, caregivers reported that the noise from the walkers, particularly from the wheels and brakes, could cause discomfort, stress, and agitation, leading to reluctance to use the walkers.

All respondents' groups expressed concerns about walkers' limited manoeuvrability in certain situations, like stairs, narrow doorways, and thresholds. The walker's size, including width, length, and height, significantly affects its ability to move effectively in confined spaces [29]. Older adults reported getting stuck while taking turns or negotiating tight corners, while caregivers confirmed experiencing this with the older adults they care for. This situation can be particularly challenging in places like bathrooms or crowded areas, where precise navigation is crucial for the user's safety and convenience [30], [31].

The results from this research have outlined additional features:

A. Smart Design

Integrating an alarm function allows users to access emergency assistance quickly, especially during outdoor falls where pendant alarms may fail. While studies [32], [33] highlight the importance of such features, their feasibility depends on factors such as cost, power consumption, and user familiarity with GPS-enabled devices. Simplified interfaces and low-maintenance designs could enhance adoption among older adults.

Assisting users in navigating unfamiliar environments, detecting obstacles, and guiding posture, this feature could improve walker interaction. However, implementation must balance functionality with ease of use, ensuring it does not increase device complexity or require high technological literacy.

Measuring grip force could support fall risk assessments and intervention. Older adults showed strong interest in this feature (85% approval). However, maintenance and battery requirements must be considered to ensure long-term usability. Studies [34] indicate stability benefits, but further evaluation is needed to confirm cost-effectiveness.

B. Ergonomic Design

An ergonomically designed walker should accommodate various user heights and body types, promoting optimal posture while reducing physical effort. Features like adjustable size, wheels, and brakes [35] could enhance stability on uneven terrain. However, adjustable mechanisms must be intuitive to prevent usability barriers.

C. Mechanical Design

Integrating noise reduction features, such as noise-absorbing materials in wheels and brakes, could dampen vibrations and improve user experience. Additionally, an attachable threshold ramp could aid smoother transitions over door thresholds [36]. While these features enhance accessibility, factors such as added weight, durability, and maintenance requirements must be considered to avoid potential trade-offs that could deter usage.

D. Limitations

Older adults and some caregivers preferred in-person surveys, while clinicians and other caregivers preferred virtual formats. This approach, while ensuring broader participation, is not believed to have biased the findings. Older adults were recruited exclusively from two private care homes, while caregivers and healthcare professionals came from these homes and other institutions. Variations in knowledge, attitudes, and practices (KAP) may exist; however, they likely reflect normal professional differences. The use of non-random convenience sampling, based on availability and willingness to participate, and the exclusive focus on care home residents may have introduced bias. Future studies should aim for a broader sample, including older adults living independently and participants from more diverse cultural and socioeconomic backgrounds to enhance generalizability.

The study's applicability is also constrained by its sample size of 81 participants, though this remains one of the largest studies of its kind. Additionally, the questionnaire did not explicitly differentiate between various types of assistive devices (e.g., canes, standard walkers, wheeled walkers), which may have led to overly broad conclusions. Future research should refine the survey design to distinguish between device types and provide more targeted recommendations. Furthermore, our survey design did not incorporate reverse semantic questions, which are often used to assess response reliability. While we mitigated this by structuring the survey clearly and ensuring logical consistency in responses, we acknowledge that incorporating additional validation techniques could strengthen data robustness, particularly for older adult respondents.

Finally, some inconsistencies in user perceptions, such as differing views on navigation systems, highlight the diverse needs of assistive walker users. Our study aimed to capture a broad spectrum of experiences; however, these discrepancies suggest that additional segmentation or subgroup analysis may be beneficial in future research. Additionally, since our findings rely primarily on self-reported data, they may be influenced by subjective biases. Incorporating observational or experimental methods in future studies could provide a more comprehensive understanding of the real-world effectiveness and limitations of assistive walker designs.

V. Conclusions

This study establishes a foundation for designing improved assistive walkers tailored to the specific needs of older adults. The positive attitudes and knowledge among healthcare

professionals and caregivers highlight the potential of these devices to enhance the quality of life for the elderly. By integrating advanced features such as GPS-enabled alarms, internal navigation systems, and grip force sensors, walkers can become safer, more user-friendly, and better address existing limitations.

This research emphasizes the importance of adaptability in walker design to meet the diverse needs of older adults. A user-centred approach, including real-world testing, is critical to creating devices that genuinely improve mobility and independence. Future research should explore integrating advanced technologies, ergonomic designs, and noise reduction features while increasing sample sizes by including independently living older adults.

Amplifying Human Strength Through a Virtual Sprung Inertia

Anthony Petrakian, Zachary Bucknor-Smartt, Crystal Q. Scott, and Gray C. Thomas

***Abstract*—While better known for their ability to work autonomously in structured tasks, robots have the potential to aid human workers in unstructured tasks via force control. More specifically, cobots and exoskeletons that physically interact with human operators can amplify human strength by feeding back measurements of their interaction forces, agnostic to the task the operator is performing. However, due to limited control bandwidth and coupled human–robot dynamics, naive force-feedback can easily result in instability similar to pilot-induced oscillation in planes. Controllers that amplify strength while also guaranteeing some stability properties have become the standard approach in the space, often at the cost of the user's perception of a transparent system. This paper 1) extends a previously theorized virtual-mass-based exoskeleton controller to a strength-amplifying robot arm, 2) theoretically and experimentally demonstrate the improved stability properties that result from the inclusion of the virtual mass term, 3) identifies the robot's end-effector compliance and self-deflection transfer functions, and 4) determines the extent to which the robot can reliably measure the stiffnesses of a spring-box apparatus in order to better understand its ability to identify human mechanical impedance.**

I. INTRODUCTION

In demanding physical tasks, such as in rehabilitative healthcare, robots have the potential to assist or replace humans, with recent focus shifting toward assistive collaboration between humans and robots [1]. Unlike the inherently unsafe nature of older position-based control schemes [2], modern robot force sensing allows for safer physical contact in human-robot interaction. The main challenge is then to control the robot to work with humans in a desirable manner.

The paradigm of collaborative robots or "cobots" builds toward this challenge from an autonomous robotics baseline. Cobots are robots designed to share a workspace with humans, and are usually able to apply control schemes such as impedance control to ensure only safe levels of force are applied in the event of an unexpected collision or intentional handoff [3], [4]. However, since they are autonomous, they must reliably understand their role in the interaction or risk unwanted and unexpected behavior that interferes with the human. While studies have tried to design architectures that can sense/anticipate unexpected human behavior and plan accordingly, it remains a difficult task [5]. Even more difficult is helping the human operator to understand what the robot thinks is going on; a lack of transparency can understandably make the cobot a suspicious coworker.

For less structured and more physical tasks like those associated with rehabilitative environments and patient care, simple dynamic robot behaviors offer to be simpler for the operator to understand and rely less on complex robot decision making. Some assistive exoskeletons, for example, are attached to and directly positioned by the human as they provide assistive torque according to gravitational load of a known weight [6], acceleration of a known inertia [7], or a virtual potential energy function [8]. This removes the understanding component of the task from the robot's responsibilities, and allows for greater flexibility for the human, provided that they can anticipate the exoskeleton's behavior in new tasks. This assumes that the patient has some capability to perform self-movement, with the general goal to reduce the load/effort the patient needs to apply. However, these approaches are not suited for interacting with the general environments posed in rehabilitative healthcare settings, since they cannot distinguish between identical poses with different amounts of environmental interaction forces. This problem motivates the inclusion of force sensors to allow amplification of human strength in a truly task-agnostic way [9].

Feedback control of the human–robot interaction force can allow a human operator to perceive amplified strength in manipulation tasks, at least at frequencies within the

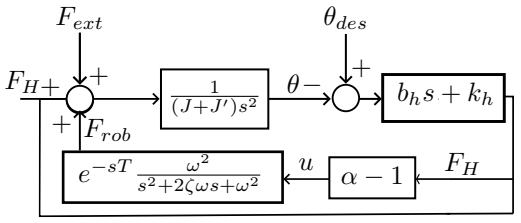

Fig. 2. Control Block Diagram: Naive Force-Feedback Controller

bandwidth of the control [9]. However, practical implementations have tended to be low and sluggish in order to avoid instabilities in the control algorithm [10]. These instabilities (uncontrolled oscillations, etc.) are in large part due to a coupling between the exoskeleton and the human's mechanical impedance behavior [11], [12], [13], which are not unlike those found in pilot-induced oscillation [14]. Unfortunately, the human element is hard to model; they are not linear and their stiffness can change due to muscle co-contraction, fatigue, and pose [15]. Adapting to this changing behavior has required extra sensors for muscle activation and subject-specific training [16]. This means any stiffness measurements made can potentially be unreliable since they are dependent on the conditions under which the measurements occurred. Thus, even if a stiffness model is taken into account in designing the controller, amplification robots based on only force sensors are sensitive to uncontrollable stiffness changes [13], pushing designers toward low-bandwidth, conservative control tunings [17].

In this paper, we implement a controller that both amplifies human strength and adds a virtual inertia to reduce sensitivity to operator stiffness. While virtual inertia has been used before in controllers, using it for the purposes of force feedback/strength amplification is novel to this paper. More specifically, we 1) extend a previously theorized virtual-mass based energy-shaping controller approach [18] to a MIMO strength-amplifying robot arm application, 2) theoretically and experimentally demonstrate the improved stability properties that result from the inclusion of the virtual mass term, 3) identify the robot's end-effector compliance and self-deflection transfer functions, 4) validate a testing apparatus that can mimic human stiffness in multiple directions, thus allowing for experimental determination of a multi-degree-of-freedom stiffness model, and 5) experimentally validate the controller design and the robot's ability to infer the dynamics of the human surrogate. The controller is validated through comparison with a naive force-feedback approach to demonstrate the superior performance under stability constraints.

II. METHODS

A. CONTROLLER DESIGN

This paper considers two controller structures for comparison. The first, the *Naïve Controller* (Fig. 2), uses unfiltered force feedback to amplify user strength and serves as a control group in our experiment. The second, the *Virtual-Mass Controller* (Fig. 4), applies our proposed innovation and serves as an experimental group in our experiment. Both controllers interact with the same fundamental robot physics.

1) Plant Model: We consider a 1-DOF linearized translational idealization of our system in which the mass of the robot, J, and any supported object, J', are acted upon by an external force, F_{ext}, a sensed human interaction force, F_H, and a robot force F_{rob}. This model is similar to the tuning model used in [17]. Applying Newton's laws, the dynamics can be written as

$$(J + J')\ddot{\theta} = F_{rob} + F_{ext} + F_H, \tag{1}$$

where θ represents the position of the robot's end-effector, and all the forces are reflected to act in the end-effector frame.

Since the robot torque is an imperfect input that is subject to bandwidth limits, we also consider an actuator limiting transfer function,

$$\eta(s) = e^{-sT}\frac{\omega^2}{s^2 + 2\zeta\omega s + \omega^2}, \tag{2}$$

where e^{-sT} represents a time delay, and the other term is a second-order low-pass filter with critical frequency ω (bandwidth of the actuating system) and damping ratio ζ. This bandwidth limit is representative of the lowest frequency issue of the many potential bandwidth limiting effects we have not modeled, for example: electrical dynamics in the electric motor, or mechanical dynamics in the cable-drives of the robot. Including the actuator limitations, the robot force is

$$F_{rob} = \eta(s)u, \tag{3}$$

where u is the desired robot force, the input used by the feedback controller.

Thus, we consider this *open-loop* system, Σ_{open} to have three inputs (F_{ext}, F_H, and u) and one output (θ). Connecting a model for human behavior, we obtain a *human-included* system, Σ_{human}. For this purpose, we use a simple human impedance model,

$$F_H = (k_h + b_h s)(\theta_{des} - \theta), \tag{4}$$

where k_h and b_h is a human perturbation-response stiffness and damping respectively, and θ_{des} is a human desired position. The parameters k_h and b_h are not necessarily known at any given time, and are assumed to be arbitrary/allowed to take on any reasonable (positive) value. We neglect to use an inertial term, as it is only relevant at higher frequencies and is typically a very small value relative to the stiffness and damping. This system Σ_{human} is also three-input, one-output, with inputs F_{ext}, θ_{des}, and u, with output F_H.

2) Naïve Controller: The naïve force-feedback strength amplification controller is simple,

$$u = (\alpha - 1)F_H, \tag{5}$$

where $\alpha > 1$ is the intended amplification rate (Fig. 2). This amplification rate reflects the closed-loop dynamics resulting from the approximation $\eta(s) \approx 1$,

$$(J + J')\ddot{\theta} = F_H + (\alpha - 1)F_H + F_{ext} = \alpha F_H + F_{ext}, \tag{6}$$

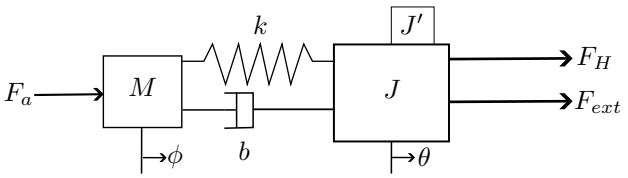

Fig. 3. FBD showing the dynamical system that would be achieved by the Virtual-Mass Controller under ideal actuation assumptions ($\eta(s) \approx 1$). The system features a virtual mass M coupled to the physical masses $J + J'$ by a virtual spring and damper. An amplification force $F_a = (\alpha - 1)F_H$ is applied to the virtual mass rather than to the physical mass in order to avoid amplification at high frequencies.

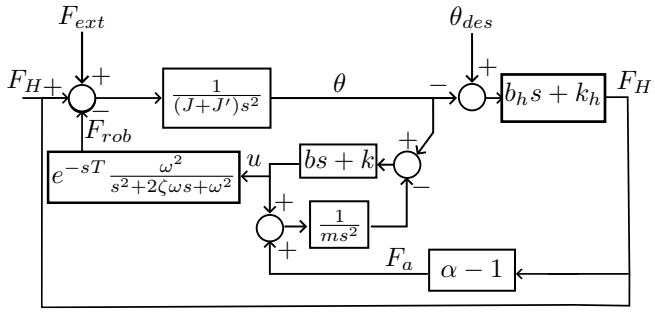

Fig. 4. Control Block Diagram: Virtual-Mass Based Controller

which shows F_H amplified by a factor of α. Naturally, such ideal behavior is not achievable with a more realistic $\eta(s)$ consideration, since it implies a meaningful change to the system dynamics at all frequencies.

3) Virtual-Mass Controller: It was previously theorized that an energy-shaping controller for exoskeletons could achieve an energetically passive mechanical interface for the human-side of an amplification behavior by simulating some specialized virtual dynamics that are coupled to the physical robot [18]. These virtual dynamics included a second copy of the robot's inertia, coupled to the physical robot by virtual springs, where the virtual inertia felt an amplified version of the human interaction force. However, the concept was only evaluated in a planar simulation of a lower-body exoskeleton with ground-contact sensing.

This paper explores a similar virtual-mass based controller for this robot arm model (Fig. 3). The dynamics of the virtual mass are denoted

$$M\ddot{\phi} = F_a + k(\theta - \phi) + b(\dot{\theta} - \dot{\phi}), \tag{7}$$

where M is the virtual mass, ϕ is the position of the virtual mass, k is the virtual spring rate, b is a virtual damper, and F_a is the ideal amplification force $F_a = (\alpha - 1)F_H$. This virtual system then imparts a force F_{rob} on the physical system using the control input u (*i.e.,* it is filtered by the actuator limitation transfer function),

$$u = k(\phi - \theta) + b(\dot{\phi} - \dot{\theta}), \tag{8}$$

resulting in a two input, one output closed loop system known as $\Sigma_{virt\ con}$ (Fig. 4), with inputs F_{ext} and θ_{des} and output F_H.

4) Steady-State Analysis: Steady-state analysis shows that this new system preserves the desired amplification behavior at low frequencies. Let $\dot{\phi} = \dot{\theta} = \ddot{\theta} = \ddot{\phi} = 0$, and (1), (2), (3), (7), and (8) reduce to

$$\begin{cases} 0 = F_{ext} + F_H + k(\phi - \theta) \\ F_a = k(\phi - \theta) \end{cases}, \tag{9}$$

where $F_a = (\alpha - 1)F_H$. The resulting steady state force balance is

$$0 = F_{ext} + \alpha F_H, \tag{10}$$

as expected. The human force required to balance the arbitrary external load is therefore reduced by a factor α, and environment-side perceptions of human strength magnified by α.

5) Stability Analysis: Whether it's rehabilitation or industrial work, an unstable control system can cause unintended harm or injury to the user. Due to the human-robot interaction in strength amplification, it is important to ensure stability of the system when a human operator is present in the control loop. The goal of this section is to show that the virtual mass controller improves the potentially attainable ratio without compromising stability.

To determine the stability of the system, we consider the two input one output system,

$$\theta(s) = G_H(s)F_H(s) + G_{ext}(s)F_{ext}(s). \tag{11}$$

Assuming θ_{des} is zero, the transfer function between the human input and theta is,

$$\theta = -H(s)F_H, \text{ where } H(s) = \frac{1}{b_h s + k_h}. \tag{12}$$

Substituting (12) into (11), we attain a closed-loop SISO system experienced by the environment,

$$\theta = (1 + H^{-1}(s)G_H(s))^{-1}G_{ext}F_{ext}. \tag{13}$$

This indicates that looking at the phase margin of the open-loop transfer function $H^{-1}(s)G_H(s)$ is enough to determine stability for the closed-loop system. In this case, the phase margin is

$$PM = \angle G_H(j\omega_c) - \angle H(j\omega_c) + 180^\circ, \tag{14}$$

where ω_c is the crossover frequency such that $\|H^{-1}(j\omega_c)G_H(j\omega_c)\| = 1$.

We use Simulink (Mathworks, Natick, MA) to model the naïve and virtual mass controller approaches, with the time-delay approximated by a first-order Padé approximation and the robot actuation bandwidth represented by a second-order low-pass filter (Fig. 5). The system parameters of the simulation are found in table I. The model does not include the human feedback in order to assess the open-loop properties. For consistency, the time-delay and bandwidth for the virtual mass simulation are the same as for the naïve approach. Picking $m = (\alpha - 1)J$ ensures the virtual mass and real mass have the same acceleration in response to human inputs, since the force due to the human that the virtual mass feels is amplified by $(\alpha - 1)$.

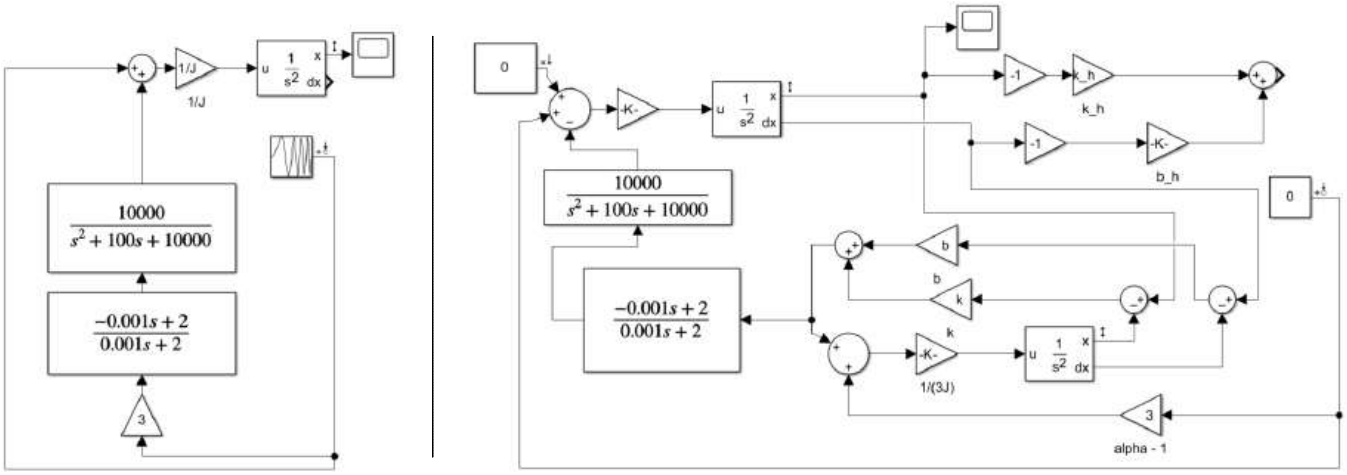

Fig. 5. Simulink model of naïve controller (left), Simulink model of virtual-mass controller (right). The model on the right shows the human model in the upper right to demonstrate how it would be included in a simulation, although it is shown to be not closed in order to assess the open-loop bode plots. The inputs are set to zero, as their value does not matter for forming the bode plots.

TABLE I
SIMULATION PARAMETERS

Parameter	Value
Strength Amplification Ratio, α	4
Time Delay, t_d	1 ms (0.001 s)
Low Pass Filter Frequency, ω_c	100 rad/s ($\approx$ 16 Hz)
Robot Inertia (including unmodeled inertia), J	15 kg
Virtual Mass, $m = (\alpha - 1)J$	45 kg
Virtual Stiffness, k	4500 N/m
Virtual Damping, b	450 N·s/m

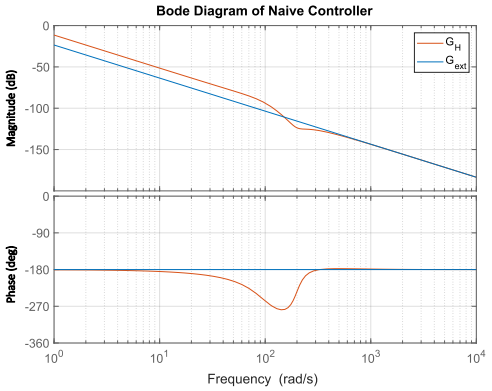

Fig. 6. Bode Plot of Naive Controller

The Bode plot of the naïve controller system (Fig. 6) shows both the $G_{ext}(s)$ and $G_H(s)$ transfer functions. The phase of the human-side integral admittance, $G_H(s)$, for the naïve controller is either at or below $-180°$ for the entire frequency range, with a significant phase drop to $\approx -275°$ around the actuation limit/bandwidth ($\approx$ 16 Hz). The reason for the phase drop is that at frequencies past the actuation bandwidth, the system must tend towards its natural dynamics $\frac{1}{(J+J')s^2}$. This means the transfer function representing G_H ($\frac{X}{F_H}$) must end up following the natural dynamics, and thus

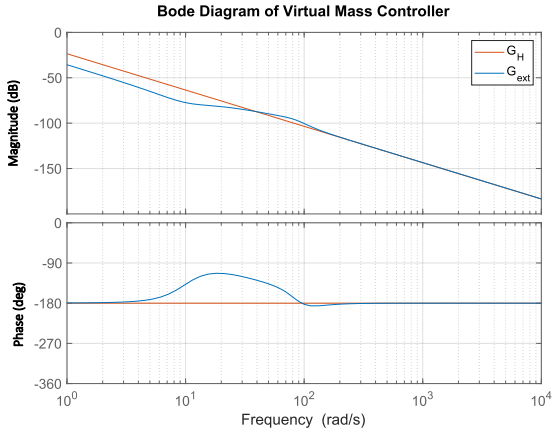

Fig. 7. Bode Plot of Virtual Mass Controller

requires a rapid drop in magnitude and phase in order to meet this requirement, as shown in the Bode plot.

Evaluating the PM from (14) for this model shows that the closed-loop SISO system risks instability if the human does not have damping, and is unstable for crossover frequencies near 16 Hz even *with* significant human damping. Past experiments have shown that it can be feasible for the system to be stable if the amplification ratio is small and the human stiffness is also very small (i.e. the operator is holding on loosely), however for practical purposes it is not usable.

In contrast, the Bode plot for the virtual mass controller (Fig. 7), shows a $G_H(s)$ transfer function with a constant phase of $-180°$, or a close approximation thereof. Rather than dropping below $-180°$ phase like in the naïve controller, the phase for the human transfer function remains at a constant $-180°$, which indicates passivity. Calculating the PM from (14) with this shows that the PM will always be positive, even with the slightest human damping. This means that the controller will remain stable under any positive k_h and b_h values in the human impedance model. However, this

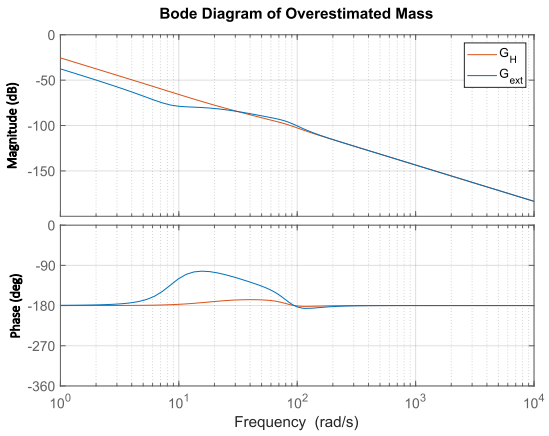

Fig. 8. Bode Plot of Overestimated Mass

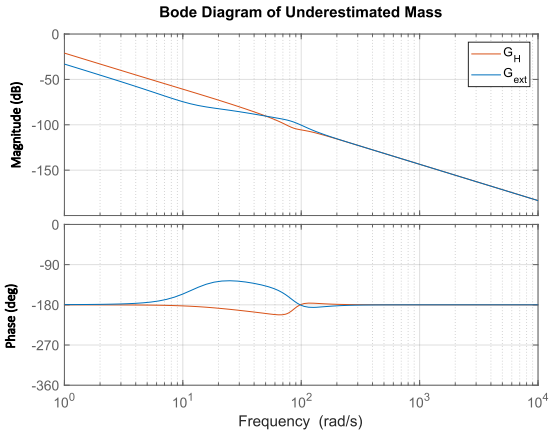

Fig. 9. Bode Plot of Underestimated Mass

comes with the assumption that J can be predicted perfectly and m chosen appropriately. The problem setup assumed an unknown inertia J', so it is instructive to see what happens if the inertia $J + J'$ is either underestimated or overestimated in the calculation of m.

Overestimation of m (Fig. 8) maintains the positive phase margin of the system and guarantees stability of the closed-loop SISO system due to the increase in phase of the human transfer function. However, underestimation (Fig. 9) causes a noticeable phase drop below $-180°$ in the $G_H(s)$ transfer function, although the phase drop is not as severe as that of the naive controller. Thus, over-estimating the inertia parameter m appears to be the conservative choice. Another consideration is the slight dip below $-180°$ that the G_{ext} transfer function exhibits in the bode plots. While this is not a passive transfer function, that doesn't necessarily mean that it will exhibit unstable behavior. Since the non-passivity is due to a combination of time delay and a low-pass filter (acting as an actuation bandwidth filter), it can be shown that the passivity requirements can be relaxed for these types of systems [19].

It is instructive to think of the physics behind what is happening. In the naive control approach, the human-side force relative to the environmental force and the robot inertia is amplified. As shown in (Fig. 6), this causes a phase drop below $-180°$ since the artificially attenuated robot inertia must act like its natural dynamics after a certain frequency.

Fig. 10. A side view of the spring box apparatus

In the virtual mass approach, by carefully choosing the acceleration (Fig. 7), the inertia of the robot relative to the human-side remains unchanged while still amplifying the human-side force relative to the environmental force. This is why the plots in (Fig. 6) and (Fig. 7) appear switched. This maintains the stability of the closed-loop system force-feedback system. For the overestimated and underestimated robot inertia cases, they have the effect of artificially adding and decreasing the robot inertia respectively. This is why there is a small potential for instability in the underestimated case. However, the phase drop is much smaller than the naive controller and is thus less likely to be unstable. With these results, the next step is to apply these two controllers in an experiment to validate the stability analysis.

B. HARDWARE DESIGN

During this study, we deploy strength amplification controllers on the 6 degree of freedom Haption Virtuose 6D TAO™ High Force robotic manipulator (Fig. 1). Due to its low gear ratios and backdriveability, the manipulator can provide force control at its end-effector. We modify the Haption arm end-effector by integrating a 6-axis force-torque sensor between two 3D-printed plates. The plates interface with the Haption arm end-effector handle and the remaining components of the end-effector joint. This modification enables the force-torque sensor to differentiate between applied loads at the handle where the human grasps, and the end of the end-effector joint. Care was taken to ensure no force leakage could occur between the interface of the force torque sensor and the end-effector components by creating gaps between the force torque sensor and the opposing human and environment sides of the apparatus. This analysis ensured that

under maximum deflection, the two end-effector plates never collided, resulting in corrupted system identification data.

Since a major facet of strength amplification involves the coupling between the human and the robot, testing a controller can be difficult and is subject to the availability of human testing. However, this coupling is one of the major factors responsible for the instability from force-feedback, so it is necessary to have in order to test controllers in a realistic setting. One potential solution to this is to design an apparatus that can simulate human stiffness in a multiple-degree-of-freedom fashion. Not only does this allow for testing without relying on human test subjects, but it provides an avenue for testing how different stiffness values affect the controller.

We use an adjustable, spring-loaded end effector mount to simulate human arm stiffness in response to force input. Our "spring box" apparatus (Fig. 10) includes a 3D-printed PLA mount interfaces with the force torque sensor and handle on the human side. The exterior of the mount is equipped with six eye bolts secured by heat-set inserts, with each eye bolt supporting two extension springs. The springs are secured to corresponding eye bolts a long cube-shaped frame constructed from aluminum extrusion. This makes it easy to change out the springs and allows for easier testing.

In total, twelve springs in tension hold the mount in a centered equilibrium within the frame. The springs are configured such that four are oriented along each Cartesian axis. Both the spring box and the Haption arm are affixed to the same ground surface, ensuring a rigid base. The spring box was evaluated using sets of springs with rates of $k_1 = 175.13\frac{N}{m}$, $k_2 = 437.817\frac{N}{m}$, $k_3 = 893.146\frac{N}{m}$, $k_4 = 1821.31\frac{N}{m}$, and $k_5 = 4220.55\frac{N}{m}$ which provide total spring stiffness values of $4k_n$ in each Cartesian direction.

C. SYSTEM IDENTIFICATION

We empirically identified a multi-degree-of-freedom model of the human–robot coupling dynamics using system identification. Since robot position measurements cannot be trusted in calculating the estimated stiffness of the spring box due to self-deflection of the robot, we estimated a model of this self-deflection using a chirp test with a locked end-effector. The end-effector was affixed to the table using a special purpose variant handle, and a chirp of desired end-effector frame force was applied in each Cartesian direction.

The derived compliance matrix, C_γ, is then

$$C_\gamma(\omega) = R(\omega)F_l(\omega)^{-1}, \tag{15}$$

where R is the robot's recorded position, and F_l is the measured force via the 6-axis force-torque sensor, all as a function of frequency. After performing the locked test in all three directions, a matrix C'_γ of bode plots (Fig. 11) characterizes the compliance, and matrix inversion yields a low-frequency stiffness.

With this robot compliance model, similar chirp tests using the spring box were performed to quantify the robot's ability to measure the mechanical impedance of the environment or human. The spring box compliance matrix, C_S, can be calculated in a similar manner to C_γ, now with a subtractive term $(R - C_\gamma F_s)$ to extract the true end-effector position as the spring box emulates human contact,

$$C_S(\omega) = (R(\omega) - C_\gamma(\omega)F_s(\omega))F_s(\omega)^{-1}, \tag{16}$$

where R is the robot's recorded position, and F_s is the measured force via the 6-axis force-torque sensor in the spring box test. Inverting the matrix of compliance bode plots C'_S to achieve K'_S then yields the spring box stiffness matrix, where the low-frequency response of the system represents the spring box stiffnesses mentioned previously (Fig. 6, 7).

Performing system identification on the spring box with $k_1 = 175.13\frac{N}{m}$, $k_2 = 437.817\frac{N}{m}$, and $k_3 = 893.146\frac{N}{m}$ produces the following predicted stiffness matrices:

$$K_{1\,(N/m)} = \begin{bmatrix} 171.55 & 43.275 & 15.240 \\ 8.87 & 214.37 & 43.4172 \\ 36.11 & 87.028 & 217.57 \end{bmatrix} \tag{17}$$

$$K_{2\,(N/m)} = \begin{bmatrix} 257.392 & 64.877 & 63.574 \\ 125.749 & 526.829 & 137.478 \\ 282.815 & 71.431 & 538.710 \end{bmatrix} \tag{18}$$

$$K_{3\,(N/m)} = \begin{bmatrix} 2030.453 & 716.413 & 1659.375 \\ 235.748 & 1398.485 & 481.472 \\ 914.981 & 3536.165 & 3350.282 \end{bmatrix} \tag{19}$$

By comparing each predicted stiffness matrix with the theoretical expected stiffness matrix given by $K_i = diag(k_i, k_i, k_i)$, a Frobenius-norm error vector can be used to provide a quantitative accuracy of the prediction for each of the three tested spring stiffnesses.

$$\text{Error_Vector} = \begin{bmatrix} K_1 \text{ Error} \\ K_2 \text{ Error} \\ K_3 \text{ Error} \end{bmatrix} = \begin{bmatrix} 42.09\% \\ 55.75\% \\ 319.85\% \end{bmatrix}. \tag{20}$$

We believe the large error is most likely due to bandwidth limits in the force and position sensing, as the motion of the end-effector in the apparatus during testing is too small to have any noticeable coupling effects from the springs.

III. CONTROLLER VALIDATION EXPERIMENT

Using the spring box apparatus shown in (Fig. 10) to mimic the human stiffness shown in the control block diagrams (Fig. 2, 4), an experiment was carried out to compare the naive force-feedback controller compared to the virtual-mass based controller. The main goal of the experiment was to test stability. The amplification ratio α was chosen to be 1.5, a fairly small amount (at least for small forces). This value was picked to demonstrate that even at small amplification ratios, the naive force-feedback controller can go unstable very fast. For the virtual-mass controller, the parameter values are: $m = 5$, $k = 500$, $b = 100$.

The experiment was performed by applying the controller while the robot arm was attached to the spring box apparatus. The experimental setup is shown in (Fig. 1). After a short time, the robot arm was perturbed by a small force, and the corresponding displacement in the perturbed direction was measured. This allowed for experimentally determining stability.

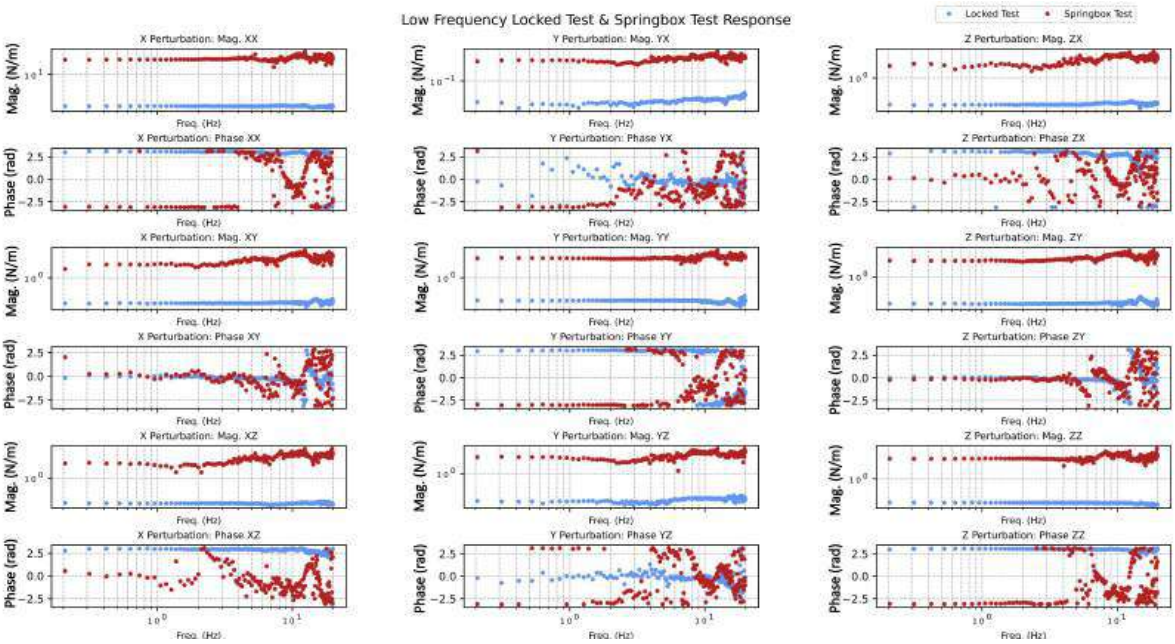

Fig. 11. Stiffness matrix of bode plots overlaying the results of the locked test as compared to the spring box test.

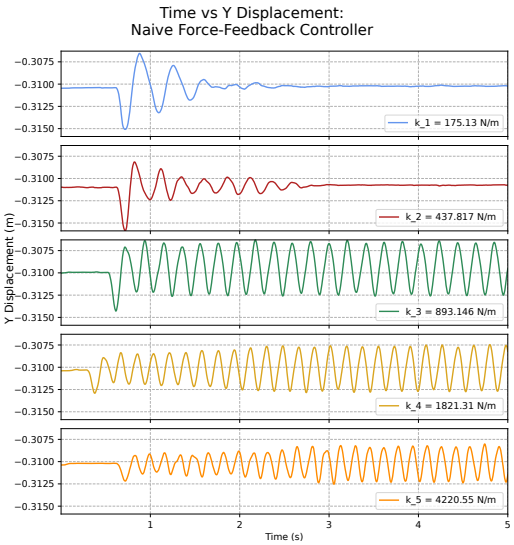

Fig. 12. Time series data of naïve force feedback control results for spring box spring constants of: k = (175.13, 437.817, 893.146, 1821.31, 4220.55) $\frac{N}{m}$ in order of top to bottom.

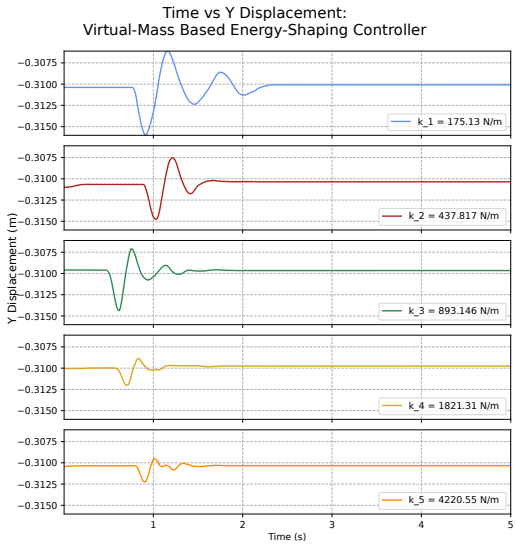

Fig. 13. Time series data of virtual-mass based force feedback control results for spring box spring constants of: k = (175.13, 437.817, 893.146, 1821.31, 4220.55) $\frac{N}{m}$ in order of top to bottom.

IV. RESULTS

The naïve controller was destabilized by increasing spring stiffness (Fig. 12), whereas the virtual-mass controller was not (Fig. 13). The naïve controller appears stable at $\alpha = 1.5$ for the first two stiffnesses ($< 500N/m$), but sustains persistent or slowly-growing oscillations for the higher stiffness configurations of the apparatus. This demonstrates that the stability of the naïve controller is dependent on the stiffness of the human surrogate. In contrast, the virtual-mass controller shows clearly decaying perturbation responses for all five tested configurations of the apparatus (Fig. 13). As the spring box stiffness increased, the robot arm returned to its original position faster, which is expected of the mass-like theoretical behavior of this port (see $G_H(s)$ in Fig. 7). In comparison to the naive force-feedback tests, the virtual-mass controller showed much less oscillatory behavior for the two plots which were stable for both controllers, which is consistent with our predictions of improved phase margin.

V. DISCUSSION

Theoretically and in a simple experiment, the use of a virtual mass to reduce the environment-side admittance

reduces sensitivity to human stiffness in comparison to increasing the human-side admittance with the naïve control. Increasing the controller's estimate of the inertia furthermore allows conservative decreases in both admittances, while decreasing the controller's mass estimate smoothly transitions back toward human-side admittance increase. Notably, this result is achieved in the absence of virtual damping, a reliance on friction in the robot (none modeled in simulation), or minimum damping requirements sought from the human. While it is easy to override the dynamics of the human with a damping-based admittance controlled robot—one that only moves as fast as the human is willing to push—the approach presented here builds on an energy-conservative backdrivable robot and, with an appropriate mass estimate, does not alter the human-side dynamics of the robot relative to that behavior.

The experimental validation was, however, superficial in relation to the simulation. Only five springs were tested physically, whereas a simulated bode plot implies a stability result with all possible springs through the phase margin criterion. Future testing could reach further toward this goal if a second robot arm were available to perform frequency-domain system identification on the first arm's closed-loop behavior. In relation to the hardware, the compensation for parasitic robot compliance and torque actuation bandwidth relied on a simplifying linearization, which would need to be extended to appropriately compensate these effects throughout the workspace of the robot, and this would be a pre-condition to realistic testing with a human performing a manipulation task.

The accuracy of measurement toward the spring apparatus deteriorated for the higher stiffness configurations. This is a natural result of the increased sensitivity to the robot's imperfect compliance model when measuring stiffnesses higher than the robot's own stiffness.

Both experiment and theory stopped short of an analysis of the amplified human in feedback with a set of realistic environments. However, practical experiments suggest that interacting with the table, other humans, or small objects on the table is unlikely to destabilize either of the two tested controllers if the human grasping the handle does not. In other words, if the controller is stable under the human feedback loop, then it seems to be stable under the environmental feedback loop as well. Empirical validation of such properties might make use of yet a third robot arm for environment-side perturbation.

***Abstract*—This study investigates participant engagement with various types of virtual reality (VR)-integrated passive ankle robotic rehabilitation offered by the BALANSens platform, using surface electromyography (sEMG) signals to quantitatively assess involvement. The low adherence rates in robotic rehabilitation, often due to the monotonous nature of exercises, highlight the importance of enhancing patient motivation. VR is shown to improve patient engagement by providing immersive and interactive therapy environments, ultimately increasing training time, reducing dropout rates, and enhancing motivation. The role of VR in robotic rehabilitation is further explored through a comparison of motivation-related outcomes across different rehabilitation modalities, such as robot-assisted gait training and upper limb rehabilitation, where VR demonstrates increased patient engagement. Additionally, the study evaluates the cognitive demands of VR during active ankle therapy. By combining subjective self-reports with psychophysiological measurements, including sEMG, the study seeks to offer a comprehensive analysis of how VR-integrated rehabilitation influences patient motivation and adherence. The results are expected to contribute valuable insights into the design of more engaging and effective robotic rehabilitation systems, highlighting the need for dynamic and stimulating therapy environments to sustain long-term patient commitment.**

***Index Terms*—Effective rehabilitation, robotic rehabilitation, surface electromyography signals, virtual reality environment**

I. Introduction

The effectiveness of robotic rehabilitation for musculoskeletal disease is frequently compromised by poor patient adherence to therapy protocols. Studies indicate that adherence rates in clinical settings can be as low as 50% [1]. A key factor contributing to these low adherence rates is a lack of motivation, often driven by the repetitive and monotonous nature of rehabilitation exercises.

Virtual reality (VR) environments play a crucial role in robotic rehabilitation by providing immersive, interactive settings that enhance patient engagement and motivation during therapy. The effect of a semi-immersive VR environment on robot-assisted gait training (RAGT) is evaluated by comparing motivation-related outcomes between a VR group and a control group. The VR group demonstrates increased training time, a lower dropout rate, and higher acceptability, indicating enhanced motivation [2]. Moreover, the use of a semi-immersive VR environment in post-stroke rehabilitation is analyzed by comparing the intrinsic motivation inventory (IMI) scores between a control group and an intervention group. Patients in the VR group showed slightly higher motivation scores and positive reactions to VR therapy, as observed through video recordings [3]. A self-designed and validated questionnaire measures patient engagement in a non-immersive VR environment during upper limb rehabilitation. The results indicated high engagement levels, with patients demonstrating strong flow, presence, and low distraction during VR-based therapy [4].

Beyond its integration with robotic rehabilitation, the features and design elements of VR directly impact an individual's adherence to therapy. A self-designed questionnaire is utilized to evaluate the user experience of patients undergoing ankle rehabilitation with the Rutgers ankle rehabilitation robot in various VR environments [5], [6]. The questionnaire assesses the quality of the VR environment, patient fatigue, and overall enjoyment of incorporating VR into therapy, with patients consistently expressing strong agreement regarding

their enjoyment of VR-based rehabilitation. Along the same line, the experiences of children with cerebral palsy using the PedPot Home, a home-based ankle rehabilitation robot, were assessed through a questionnaire aligned with the Home Exercise Program (HEP) Adherence Theory and the PYTHEIA scale. The results indicated that while the integrated game initially increased motivation, it decreased over time due to its repetitive nature, highlighting the need for alternative forms of challenge to maintain engagement [7].

Subjective self-reports, such as post-experiment questionnaires, are commonly used to assess user experience due to their broad relevance and ease of statistical analysis [8]. However, these methods are prone to biases, such as social masking or the inability of participants to effectively articulate their emotions. To address these limitations, psychophysiological measurements, which capture the body's electrophysiological activity (e.g., electrocardiogram (ECG), electromyography (EMG), and electrodermal activity (EDA)), have been increasingly utilized as complementary techniques [9]. While facial EMG is commonly used to analyze emotional states, the relationship between muscle activity in other body regions and emotional or motivational states remains underexplored.

The literature demonstrates that sEMG signals can serve as an effective biofeedback method within VR interfaces, not only enhancing patient motivation and compliance but also improving awareness of the rehabilitation process. Additionally, this approach enables therapists to quantitatively assess the patient's progress [10], [11]. Previous studies report that fun and game-based rehabilitation tasks yield more effective results compared to traditional physiotherapy exercises [12], [13]. Motor skills acquired through game-based training in a virtual reality (VR) environment are utilized more effectively in daily activities. To maximize therapeutic effectiveness, a high number of repetitions, continuous supervision, clear rewards, and long-term application are required. Hence, maintaining motivation is considered essential for enhancing patient engagement and treatment effectiveness. These movements should be performed in an interactive environment that supports cognitive, motor, and emotional components [10].

Studies integrating EMG-based assessments with surveys on motivation are limited. In this context, the effects of EMG-controlled video games on muscle activation and motivation in individuals with upper limb amputation are particularly examined [10]. It is reported that maximum voluntary contraction values increase before training (6,8%) and in the follow-up session (7,1%). Assessment with the IMI records high scores in interest, perceived competence, choice, and usefulness subscales, while low scores are observed in pressure and tension. Survey responses indicate that video game use during training maintains patient engagement, enhancing motivation, exercise intensity, and adherence throughout rehabilitation.

When a stroke patient moves their limbs, the automatic and active tracking of each movement phase indicates that the patient can place their limbs. This means that patients with good sensory input can fire the correct motor units to move. In this study, muscle activation changes during passive movement while playing games are measured using sEMG signals of healthy individuals. This aims to determine the development of the ability to actively and automatically engage in movement during passive motion when the game is visually challenging [14].

Active joint movement increases the potential for motor control development, supports motor learning processes, and enhances neuroplasticity by encouraging greater participation in rehabilitation [15]. The relationship between motor learning and neuroplasticity is directly related to how challenging, meaningful, and specific the exercises are. A high number of repetitions performed during a targeted muscle movement (e.g., gait training) can lead to lasting changes in the brain [16]. In this context, rehabilitation involving active movements integrated with technologies like VR increases neuroplasticity by encouraging patients to focus more on their movements and participate more in the treatment [16], [17].

Evaluating muscle activation with EMG during both passive and active movements allows for the objective assessment of the effectiveness of VR-based rehabilitation programs and motor learning [17]. The aim of this study is to assess and compare muscle activation and motivation levels during passive and active ankle dorsiflexion and plantarflexion movements, both with and without VR, as well as during monotonous and engaging VR games. Additionally, the effects of two different VR scenarios with slow and fast speeds on motivation are included in the study results. In this context, the effects of VR under different scenarios and speeds are thoroughly examined.

II. Methodology

The evaluation encompasses both passive and active ankle therapy on the BALANSens platform, with a focus on task-specific VR design and sEMG signal detection.

A. BALANSens Robotic Platform

The BALANSens robotic platform features a 3-degree-of-freedom (3-DOF) parallel manipulator utilizing a revolute-prismatic-spherical (RPS) configuration, tailored for lower limb and balance rehabilitation and assistance with multiple feedback modalities within the I-BAR framework [18], [19]. Its design connects the upper and lower platforms via prismatic joints, which are motorized, and passive revolute and spherical joints [20], [21]. The complete BALANSens system, as depicted Fig. 1 has been specifically engineered to support rehabilitation objectives effectively. The range of motion (RoM) of the 3-RPS robot can be adjusted to the upper limit of each participant, ensuring safe interaction during the evaluation.

B. Design of Virtual Reality Environment

According to Ryan and Deci [22], motivation can be either intrinsic, where an activity is pursued for its inherent enjoyment, or extrinsic, where the activity is performed to achieve an external outcome. Unlike intrinsic motivation, extrinsic motivation is often perceived as less fulfilling, as individuals may

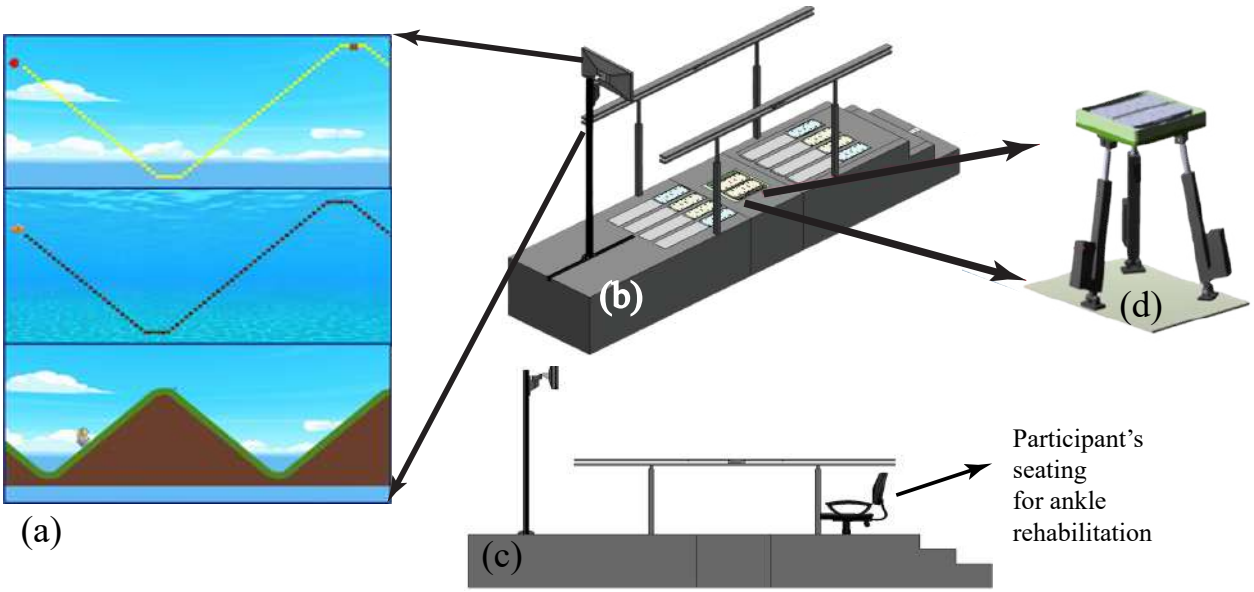

Fig. 1. BALANSens Platform with VR feedback (a) Designed games for passive ankle rehabilitation (b) Isometric view of BALANSens platform (c) Rear view of BALANSens platform, prepared for ankle rehabilitation (d) 3RPS parallel manipulator

engage in such activities with reluctance or disinterest, driven only by obligation. In the context of VR-based rehabilitation, patients' motivation is typically extrinsic—they participate in the game not for its enjoyment but as part of their therapy. The challenge, then, is to encourage patients to engage in the activity without feeling coerced. This can be achieved by making the activity sufficiently interesting [22].

The focus shifts to how VR environments can be designed to captivate patients' interest. Mader et al. [23] proposed a model outlining key criteria for creating therapeutic games. According to their framework, two essential features are challenge and variability. *Challenge* is defined as the uncertainty a player feels about their ability to achieve their goals, while *variability* encompasses curiosity—either cognitive, which reflects how much new information a player can acquire, or sensory, which pertains to the diversity in the game's presentation. To sustain motivation, the model emphasizes that challenge levels must be carefully calibrated to avoid frustration or boredom, and the environment must incorporate sufficient variability to maintain long-term engagement.

In VR environments designed for rehabilitation and motor recovery, maintaining an appropriate challenge level is crucial, as initial failure may lead players to attribute their performance to poor motor abilities, reducing engagement and participation [24]. Moreover, providing patients with feedback on their progress plays a key role in sustaining their motivation. What's more, a *flow state*, defined as a condition where an individual is fully immersed, focused, and satisfied with an activity, is considered crucial for enhancing patient performance in rehabilitation. In such a state, the VR environment should include clear goals, minimal distractions, appropriate difficulty, feedback, and a reward system to foster focus and satisfaction. From the therapist's perspective, the expectations closely align with the benefits of VR for the patients. Therapists value gaming features such as ease of setup, clear patient instructions, and easily interpretable feedback [25].

In accordance with the design criteria outlined in the literature, the VR environments in this study are purposefully crafted to meet these standards using the Unity game development platform. During ankle rehabilitation, participants perform dorsiflexion (DF) and plantarflexion (PF) to control a VR proxy, such as a bird, which collects objects like coins placed along a specific trajectory. This trajectory is designed to align with the RoM limits of the ankle.

C. Real-time sEMG Recording and Conditioning

sEMG signals are collected in real-time with Biosignal Plux© EMG sensors. The electrodes are placed on the tibialis anterior muscle and gastrocnemius muscles responsible for DF and PF of the ankle, respectively. sEMG signals are relayed to MATLAB through the lab streaming layer communication protocol, operating at a sampling rate of 2000 Hz. The acquired signal undergoes processing with a fourth-order Butterworth filter, employing cutoff frequencies of 20 Hz and 500 Hz to isolate the desired frequency range. The absolute value of the signal is computed to capture its full energy. Additionally, a moving average window is applied to further refine the signal. After normalization, the signal's energy is assessed using both the Hamming window method and a traditional energy evaluation approach. The energy method provides a representation of the signal's energy in the time domain but does not account for the irregular distribution of amplitude in sEMG signals, which often exhibit random structures. Energy deviation is employed to gain a deeper understanding of the signal's characteristics. This deviation is exposed by dividing the signal into smaller segments, with each segment

representing the variation in energy distribution over time. In this study, the Hamming-windowed sEMG energy feature vector is extracted to analyze muscular energy over time. The signal is divided into three segments, each multiplied by a window function, smoothing the signal by suppressing the edges and enhancing the center. The energy of each windowed segment serves as a feature, with the number of windows determining the feature vector size. Overlapping regions, set to three-tenths of the window length, are included to capture finer signal details [26]. Finally, both energy features are employed to construct sEMG feature vectors, which are utilized to gauge the participant's engagement in the rehabilitation process.

D. Experimental Procedure

The assessment of participants' engagement and cognitive contribution to therapy facilitated by VR environments is conducted in two main sessions. In the first session, engagement during passive ankle therapy is analyzed based on sEMG analyses, focusing on the immersive and interactive qualities of the VR environment, with additional insights derived from questionnaire responses. The second session emphasizes active participation in ankle therapy, integrating sEMG-based evaluations with questionnaire results to provide a comprehensive analysis.

In this experiment, seven healthy volunteers (three women, aged 20, 26, and 42 and four men, aged 22, 26, 29, and 30) participated, with informed consent obtained prior to the experiment following approval from the Institutional Review Board (IRB) of Istanbul Medipol University. During the experimental procedures, participants are positioned in a prolonged seated posture with knee support. A physiotherapist determines the normative RoM for ankle DF and PF using a baseline goniometer. Accordingly, the RoM of the 3-RPS manipulator for DF and PF is set individually for each participant to prevent neuromuscular issues, such as tendon strain or muscle fatigue. The hypothesis of the experiment was withheld from the participants. During the experiment, the participant sits on a chair with their foot strapped to the moving platform of the 3-DOF manipulator. The robot's rotational motion is used to train the participant's DF and PF RoMs.

In the first session, the participant's foot is strapped to the manipulator and follows the VR proxy passively with position control. This session consists of three subsessions, each lasting 3 minutes, with a 1-minute break in between. The order of the sessions is randomized for each volunteer. The subsessions include passive ankle rehabilitation without VR, monotonous VR-based passive ankle rehabilitation, and passive ankle rehabilitation with a relatively entertaining VR experience. In the second session, the manipulator's impedance control is activated, requiring the subject to interact and move the VR proxy. This session consists of two subsessions, each lasting 2 minutes, with a 1-minute break in between. The difficulty level of the tasks varies between the two subsessions, with the challenge being increased by a faster trajectory flow in the second subsession. An illustration of the experiment is available at the following link: https://youtu.be/AdOYldMuLgg. After each subsession, the volunteers are given a questionnaire to score the games.

III. Results

The sEMG-based evaluation of participants' engagement with the VR environment is illustrated in Fig. 2. During the experiment, sEMG signals are recorded from the Tibialis Anterior and Gastrocnemius muscles, which are responsible for DF and PF functions, respectively. A Student's t-test is performed to assess statistical significance between groups. As shown in Fig. 2(a) and (b), the results from the entertaining VR feedback condition demonstrate a statistically significant difference compared to both the monotonous VR condition and the non-VR condition. Additionally, the comparison between the non-VR and monotonous VR conditions is found to be marginally significant, with a p-value ranging between 0.05 and 0.1. These findings suggest that participants exhibit greater engagement with VR-based rehabilitation, even when no physical interaction is required, as the visual component alone appears to be sufficient to enhance their involvement. Immediately following each experiment, participants are presented with the IMI questionnaire [27] to evaluate the VR environment across dimensions of intrinsic motivation, including interest/enjoyment, perceived competence, effort, perceived choice, tension/pressure, and value/usefulness. Notably, the interest/enjoyment scores show a significant increase, rising from an average of 2 (out of 7) in the non-VR condition to an average of 5.87 (out of 7) in the enjoyable VR condition. This score is directly correlated with the EMG-based findings, supporting the conclusion that the participant's engagement with the game can be demonstrated through sEMG feature.

In the literature, it is well-established that EMG amplitude increases with greater effort. However, the extent to which engagement in the game contributes to EMG energy remains unclear. Building on the findings of the first session, the correlation we established between questionnaire results and sEMG feature is also investigated in the context of the active ankle rehabilitation experiment. In this session, the VR environment remains constant, but the difficulty level is adjusted by increasing the speed of the game (i.e., the trajectory to be followed in the VR environment). sEMG normalization is performed based on each participant's maximum contraction level during the session. Results from both muscle groups reveal a significant increase in sEMG energy across all participants, with a t-test confirming the statistical significance of differences between the subsessions. Following the experiment, participants are presented with the same questionnaire. The interest/enjoyment scores increased from an average of 6.2 (out of 7) in the easy task to 6.7 (out of 7) in the challenging task condition. Similarly, the effort scores rose from 4.2 (out of 7) in the easy task to 4.8 (out of 7) in the challenging task. These findings indicate that the sEMG features correlate with both effort exertion and participant engagement.

IV. Discussion

In this study, the implementation of VR environment with both passive and active rehabilitation provides a critical

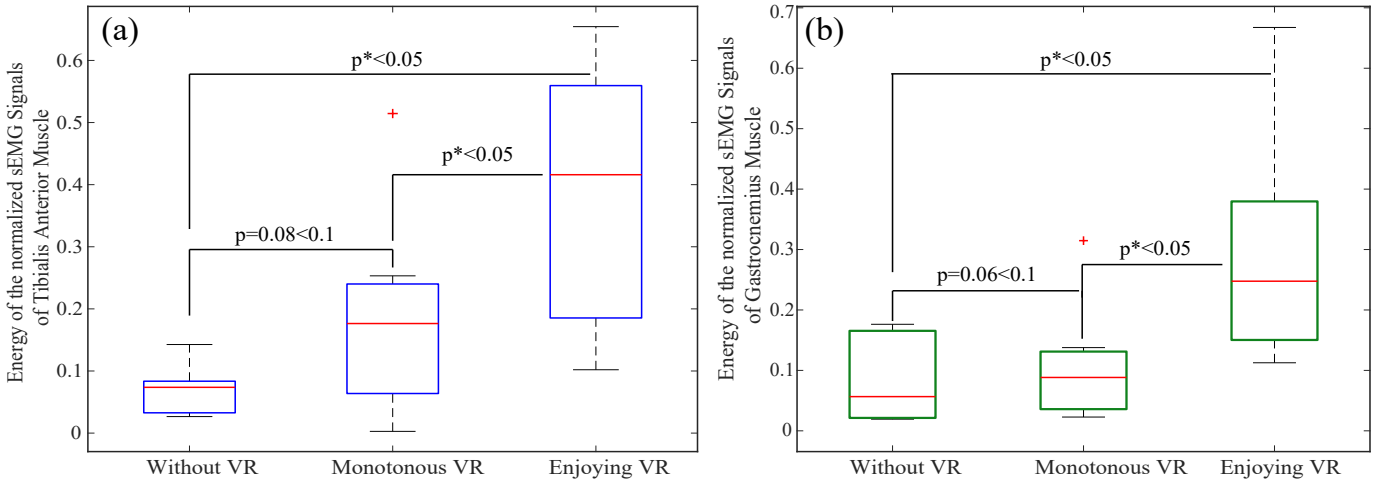

Fig. 2. Experimental evaluation of the participants during passive ankle rehabilitation with BALANSens (a) sEMG features from Tibialis Anterior muscle (b) sEMG features from Gastrocnemius muscle

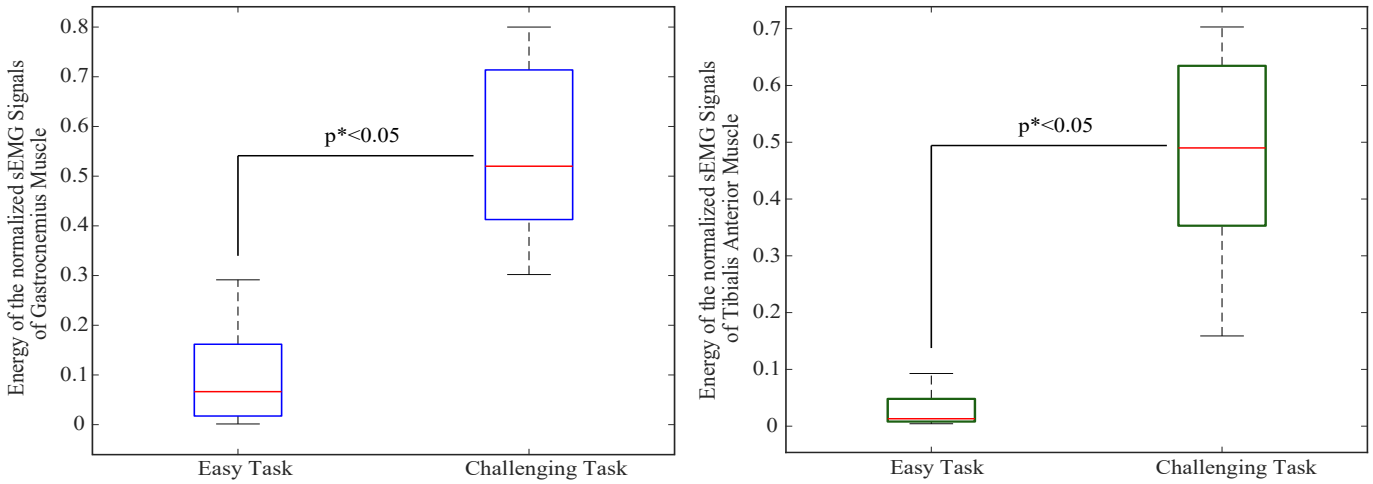

Fig. 3. Experimental evaluation of the participants during active ankle rehabilitation with BALANSens (a) sEMG features from Tibialis Anterior muscle (b) sEMG features from Gastrocnemius muscle

foundation for evaluating the effects of different intervention methods. While passive rehabilitation in monotonous VR environments may lead to low engagement, incorporating active movements can enhance participants' interest [16]. In our study, higher energy features of sEMG signals are recorded during passive movements with VR compared to movements without VR. Enjoying and challenging VR environments can foster active participation, yielding significant effects on motor control, muscle strength, and the neuromuscular system. Similarly, energetic EMG signals are observed during active ankle therapy with VR, enabling the assessment of participants' engagement in the rehabilitation process.

One of the primary advantages of VR technology in neurological rehabilitation is its ability to provide goal-oriented and highly repetitive training opportunities. VR creates enriched learning environments that support problem-solving, complex task execution, and the acquisition of new skills in individuals with stroke. Offering an alternative to the monotonous structure of traditional therapies, VR-based interventions are perceived by patients as more engaging and enjoyable. These attributes encourage a higher frequency of repetitions and improve adherence to treatment programs.

VR technology is effective in improving motor skills, balance, gait disorders, and cognitive functions (such as attention, memory, executive functions, and dual-task performance) in individuals with stroke. While VR enhances motivation and participation, monotonous environments can diminish motivation and reduce task duration. In contrast, engaging VR applications improve attention and performance, support neuroplasticity and motor control, and optimize learning by tailoring task difficulty to individual capacity. Excessive difficulty, however, can hinder effectiveness. Although traditional methods are effective, they often fall short in boosting motivation. VR addresses this gap by promoting interaction with the environment and supporting gains in range of motion (ROM) and muscle strength. In this study, it is observed that

games enriched with enjoyable elements and cognitive tasks led to higher muscle activation—and thus greater participation—compared to monotonous games. Such an observation is quantitatively evaluated by means of sEMG characterization.

The combined use of motivation surveys and sEMG features offers a valuable approach to evaluating rehabilitation processes both behaviorally and physiologically. The literature demonstrates that motivation positively influences muscle activity and task performance. Examining the relationship between these metrics can provide a more comprehensive understanding of VR's effectiveness in rehabilitation. Future research explores the impact of VR scenarios on motivation and sEMG outcomes to develop more personalized rehabilitation programs.

V. Conclusion

As the study is limited to healthy individuals, the generalizability of the findings to pathological populations remains uncertain. The sEMG and motivation responses of healthy individuals may not fully reflect the processes of neuroplasticity in patient groups, where these processes operate differently. Furthermore, only short-term effects have been evaluated, and it is unclear whether these findings will translate into functional improvements over the long term. Therefore, additional studies focusing on patient populations and long-term effects are needed.

A key strength of this study is determining individuals' level of engagement during passive movement using both the motivation questionnaire and sEMG data. The combined use of these two outcome measures provides a significant contribution to the literature by emphasizing the importance of individual adaptation and physiological responses in rehabilitation processes. The study may serve as a pioneering example of how VR applications can be an effective tool in personalized passive and active treatment plans.

Our research will expand to include a larger cohort of healthy individuals and stroke patients, with preliminary findings undergoing validation through data and survey evaluations collected from an expanded sample. These refined results will be presented to offer deeper insights into the effectiveness of the EMG-driven evaluation in assessing VR-mediated engagement during the rehabilitation process.

Curating User-Defined Interface Maps For Robot Teleoperation

Demiana R. Barsoum[1,2], Michelle H. Zhang[1], Larisa Y.C. Loke[1,2], and Brenna D. Argall[1,2]

***Abstract*— The interfaces used to operate assistive robots typically employ fixed, predefined maps to associate interface-level commands to robot control commands. User-defined control maps instead consider an individual's preferences and capabilities, moving away from a one-size-fits-all mapping paradigm. This work presents novel methods for (1) eliciting user-defined control maps, (2) identifying and addressing issues in control signal data that arise from such a user-centered design, and (3) methodologies to filter erroneous signals and construct synthetic data in an effort to address these issues. We experimentally evaluate our proposed methods by conducting a user study that elicits user-defined, interface-level commands for controlling a powered wheelchair and a robotic arm through four control interfaces. Our results highlight the differing suitability of user-defined, data-driven control maps for the various interface-platform pairings, and provide an analysis of the errors generated during dataset definition and the impact of our postprocessing methods.**

I. Introduction

Assistive robots—such as robotic arms and powered wheelchairs—play a crucial role in improving quality of life for many individuals living with motor impairments. By enhancing manipulation and mobility capabilities, these technologies advance user ability to complete daily functions with independence.

When an individual is fitted for an assistive device, an accompanying control interface—such as a joystick, head array, or sip/puff—is chosen and customized to best meet their needs and abilities. However, the limitations of such interfaces can render assistive devices difficult or unintuitive for users to control. A leading cause for the abandonment of assistive devices is lack of adaptability and configurability [1], which forces users to conform to interfaces and control schemes that do not adequately adapt to meet their individual needs. Research on device customization typically focuses on the interface hardware, including novel sensor setups and more diverse input options [2]. By contrast, less attention is given to the customization of control mappings used by interfaces that are the standards for assistive device control in clinical and real-world settings.

When a user actuates an interface, there is *noise* and *bias* associated with their issued control signals that is shaped by their physiology, psychology, and preferences. For example, handedness may result in biases in joystick actuation. Due to these noise and bias patterns, the ability of an individual to use an interface depends heavily on the alignment between their behavioral patterns and those expected by the control mapping. This dependence can restrict the accessibility of an interface for users whose behaviors do not align well with predefined expectations.

[1]Northwestern University, Evanston, IL., USA
[2]Shirley Ryan AbilityLab, Chicago, IL., USA

Interface control maps moreover can be unintuitive to operate, and require extensive practice before users are able to control devices effectively [3]. We posit that to investigate the noise and preference patterns in user control signal data is useful not only for identifying these patterns, but also for uncovering improved methods able to accommodate individual differences within the control interface design. Such an analysis ultimately might enable the creation of interfaces that are more accessible to a wider range of users.

In this paper, we propose and evaluate methods for constructing task-agnostic, user-defined control maps for robot teleoperation that adapt interface operation to the unique capabilities and preferences of a given user. This work makes the following contributions:

(1) We present a protocol for constructing datasets of task-agnostic interface use, for the purpose of generating customized interface maps for teleoperation.

(2) We design methods to identify, quantify, and filter artifacts that arise in datasets generated from user-defined, data-driven control interface design.

(3) We introduce an approach for generating synthetic data from users' verbal statements to capture their intended control mappings.

(4) We evaluate our proposed methods by conducting a participant study that elicits user-defined, interface-level commands for controlling a powered wheelchair and a robotic arm through four control interfaces (Fig. 1).

The rest of the paper is organized as follows. Section II outlines related literature. Section III details the proposed data processing methods. Section IV presents the user data collection pipeline, including experimental setup and protocol. Results and discussion are presented in Section V, including limitations and avenues for future work in Section VI, with conclusions presented in Section VII.

II. Background

In this section, we present a summary of related literature on teleoperation control and customization.

A. Control Interfaces and User Customization

Assistive devices and robots can be teleoperated using a variety of accessible interfaces such as joysticks, sip/puffs, eye gaze trackers, head arrays, brain-computer interfaces, body-movement interfaces, tongue-controlled interfaces, and lip-controlled interfaces, as well as customized setups and multi-interface systems.

Customization of these interfaces is a widely researched topic [4]–[6]. Joystick handles, for example, can be re-

designed to allow control using wrist movements [7], accommodating users with limited or no hand motion. Interfaces such as the sip/puff and MouthPadˆ (Augmentalˆ, California, USA) are designed for individuals with upper body paralysis. While their actuation mechanisms are accessible, the learning curve for using accessible interfaces to operate assistive devices and robots can be high [5], particularly as many issue lower-dimensional signals than the device being controlled and, as a result, use modal control paradigms (mode switching) [8].

B. Control Mappings for Teleoperation

Teleoperation is an attractive means of controlling assistive devices because it allows users to remain maximally in control, preserving user agency. However, the mismatch between a user's physical capabilities and the input requirements of standardized control mechanisms can hinder effective device operation, leading to frustration, fatigue [4], and device abandonment [1]. Work in the design of control maps that explicitly aim to address such a mismatch is overviewed here.

In detail, the mapping from interface actuation signal ϕ (e.g., joystick deflection) to machine control command u (e.g., joint or end-effector velocity) is typically static and defined *a priori* by experts (system engineers or assistive technology technicians). There is work that investigates instead learning user-preferred mappings for intuitive robot control [9], where the learned mapping is task-dependent. Customizing standard control maps to accommodate users' characterized physiological variability is also explored [10], using an approach that relies on a predefined baseline map. Other work aims to explicitly model discrepancies between intended ϕ_i and measured ϕ_m interface commands [11], where discrepancies might arise due to physiological factors such as fatigue or motor impairment, or an incomplete understanding of the robot system. All of these works evaluate a single combination of interface and platform.

In this paper, we propose a methodology for the design of *user-defined* control maps that are *task-agnostic* and leverage knowledge of intended interface commands—by capturing user biases and preferences— to postprocess noisy and scarce data. We also evaluate this methodology on multiple interfaces, operating two robot platforms.

III. Technical Methods

In this section, we provide an overview of our proposed methods for constructing datasets for the purpose of learning user-defined interface maps.

We first present a methodology to elicit users' preferred interface commands for task-agnostic robot actions (Sec. III-A). However, a dataset gathered from examples of human-issued interface commands and associated robot motion labels can be prone to data sparsity and inconsistencies between the human's intended versus issued interface commands (Sec. III-B). We therefore propose a suite of data processing tools that aim to address these potential pitfalls (Sec. III-C and Sec. III-D). In particular, our methods leverage verbal descriptions from the user of their intended interface commands, which we convert to automated scripts

Fig. 1: Experimental Hardware. Robot platforms (*top, left to right*): Sunrise Quickie powered wheelchair and Kinova JACO robotic arm. Control Interfaces *(bottom, left to right)*: 3-axis Joystick, Sip/Puff, 3-switch Head Array, and x-IMU3 sensors.

that generate both *filtered data* that refines the raw signals and *synthetic data* based on the user's vocalized intent.

A. User-Defined Control Interface Maps

We consider a user-defined interface-level command to represent the user's intended actuation of an interface to produce an observed robot motion. These commands can be continuous, discrete, or both, depending on the control interface. Continuous signals can be interpreted proportionally, while discrete signals, such as button presses, only provide an indicator of activation without magnitude. An "intuitive" control map has previously been defined [9] to have the following properties:

- Proportional: The system's response scales with the command's input intensity.
- Reversible: Opposing interface actuations (e.g., left-right deflection) correspond to inverse commands.
- Consistent: Users can remember the correspondence between interface actuations and system controls, and reliably issue them.

In this work, we prompt users to issue their preferred interface-level command ϕ in response to observed robot motion a. We furthermore propose a data collection protocol that *annotates* this data with vocalizations of their intended interface-level commands—capturing complete, unfiltered interface interactions, including noise and incorrectly issued (unintended) commands that may diminish the quality of the data. The purpose of these intent annotations is to provide a means for repairing such artifacts.

While such an approach leaves the control design in the hands of the user, it can also result in violations of the aforementioned properties of an intuitive control map, as well as artifacts in the data that pose considerable challenges for model training. These challenges ultimately inform our data postprocessing and synthetic data generation methods (Secs. III-C, III-D).

B. Implications of User Design

The usage characteristics of a given interface, combined with the user's understanding of its control method, leave

TABLE I: Discrepancies observed in user-defined datasets and proposed methods to handle these issues.

Artifact	Sources	Data Processing Techniques
Incorrect Command	(1) Unfamiliar with interface (2) Struggle to actuate interface (3) Forget how to issue a command or how to actuate the interface	(a) Replace with synthetic data (b) Replace with correct data from user (c) Remove from dataset
One-to-Many Command	(1) Issue similar (or identical) signals for different robot actions	(a) Replace with synthetic data
Data Sparsity	(1) Insufficient training data for command (2) Similar signals for different robot actions	(a) Add synthetic data (b) Add copies of raw user data
Noisy Signal	(1) User actuation behavior (2) Environmental interference	(a) Replace with synthetic data (b) Replace with correct data from user

a distinct imprint on the signal intended for robot control. This imprint can be beneficial if it helps produce a control mapping tailored to the user's unique behavior, or it can be problematic if the user develops inefficient or inconsistent control patterns. Additionally, the inherent variability in allowing users to design their own control maps may result in unusual or unpredictable control signals.

In this work, we identify four *categories of user-induced dataset artifacts*, along with their potential sources, summarized in Table I. We highlight potential strategies for mitigating issues that arise from these artifacts in the *Data Processing Techniques* column.

Furthermore, we identify and define five notable *types of actuation error* that can result from these artifacts and contribute to the aforementioned dataset challenges. To do so, we first define an interface channel to be an independent input signal of a control interface. Each channel is activated through an actuation mechanism: for example, joystick deflection, head array button press, or sip/puff respiration. Channels can be discrete or continuous in value. The types of actuation error then are defined as follows:

(1) Incorrect Activation: At least one intended channel is activated but in the wrong direction, or at least one unintended channel is activated with a magnitude greater than or equal to that of the intended channel(s).

(2) Additional Channel Activation: The intended channel(s) is activated, but there are also nonzero signals in one or more extraneous channels with magnitudes lower than those of the intended activations.

(3) Missing Channel Activation: The intended channel is not activated for a substantial portion of the command duration.

(4) Transient Zero: At least one intended channel momentarily reports zero activation when it is expected to have a consistent nonzero value.

(5) Leading/Trailing Zero: An intended channel exhibits periods of zero activation, as a result of the user pausing before and/or after issuing a command.

In our implementation, the groundtruth intended channels are derived (Sec. III-C) from a user's vocalized annotations.

C. Methodology for Filtering

Here, we present our methodology for identifying and filtering out the aforementioned dataset artifacts based on the error type. We propose a ***filtering methodology*** that *removes* instances of:

(1) Incorrect activation.

(2) No channel activation, which includes missing channel activations, transient zeros, and leading/trailing zeros.

In order to determine signal correctness, we leverage user annotations of intended interface signals. Specifically, our data collection protocol (Sec. III-A) annotates examples of interface→robot control mappings with vocalizations of the intended interface command. Our application of this filtering methodology is coarse and applies only to:

(1) Signal *absence* or *incorrect sign* on intended channels.

(2) Signal *presence* on unintended channels.

Notably, such an application may not catch all errors—incorrect patterns of interface activations, for example, will be missed. However, the likelihood that it filters correct signals will also be minimized.

D. Methodology for Synthetic Data Generation

Next, we present our methodology for generating synthetic data to rectify dataset artifacts. We propose a ***synthetic data generation methodology*** that *replaces* instances of:

(1) Signal *absence* or *incorrect sign* on intended channels.

Notably, this replacement approach retains unintended channel activations, as well as commands whose magnitudes differ from those of the intended signals, in order to preserve real-world variability and noise to enrich the dataset.

For a user annotation to be eligible for synthetic data generation, it must meet the following criteria:

(1) Non-varying in magnitude.

(2) No intended transient zeros (patterns).

As with our filtering methodology, such an application will not generate data for all annotations: only straightforward and unambiguous intended inputs will qualify. We leave the interpretation of more complex annotations and input patterns to future work.

To generate synthetic data, we define replacement rules for the three most common interfaces used to operate powered wheelchairs: joystick, head array, and sip/puff. We build these synthetic representations by hand, according to the following prescription:

(1) **Joystick Mapping**: The joystick interface utilizes a three-axis control scheme, denoted as $[x, y, z]$. Based on the deflection direction, the joystick mapping translates to the corresponding channel activations as follows:

- **Forward**: [0.0, 1.0, 0.0]
- **Backward**: [0.0, -1.0, 0.0]
- **Left**: [1.0, 0.0, 0.0]

- **Right**: [-1.0, 0.0, 0.0]
- **Twist Left (Counterclockwise)**: [0.0, 0.0, 1.0]
- **Twist Right (Clockwise)**: [0.0, 0.0, -1.0]

(2) **Head Array Mapping**: The head array interface consists of multiple pads that once pressed map to specific channel activations:

- **Back Pad**: [1, 0, 0, 0]
- **Right Pad**: [0, 1, 0, 0]
- **Left Pad**: [0, 0, 1, 0]
- **Chin Switch**: [0, 0, 0, 1]

(3) **Sip/Puff Mapping**: The sip/puff interface maps to continuous values based on respiration pressure. The range for a user is based on their intent vocalizations:

- **Sipping**: Ranges from 0.0 to 1.0
- **Puffing**: Ranges from -1.0 to 0.0

These rules are applied to data that meet the replacement criteria defined above.

IV. Experimental Procedure

In this section, we overview the details of our evaluation study in which participants observe the movements of a robotic wheelchair and a robotic arm, and are asked to vocalize, practice, and issue their intended interface-level commands corresponding to the movements.

A. Participants

A total of ten participants without motor impairment (6 female, 4 male) and with ages ranging from 23 to 52 years (mean 30.1$\pm$8.18) were recruited for this study. Participants gave their informed, signed consent to participate in the experiment, which was approved by Northwestern University's Institutional Review Board (STU00217536). None of the participants had prior experience with powered wheelchair driving. One participant (F, 25) had experience operating robotic arms, but not the robotic arm used in this study.

Each volunteer participated in two study sessions, during which a single robot platform was operated. The order of platform presentations was random and approximately balanced across participants (6 of 10 interacted with the robotic wheelchair in the first session).

B. Hardware

Two robotic platforms and a total of four control interfaces are utilized in the study (Fig. 1).

Robot Platforms. The first robot platform is a robotic wheelchair, built atop a Sunrise (Arizona, USA) Quickie Q500M base. Platform control is achieved through the LUCI ROS 2 SDK [12]. The wheelchair is a differential drive robot, which operates in 2-D, allowing for translational (forward/backward) and rotational (spinning) movement.

The second robot platform is a Jaco Gen2 robotic arm from Kinova Robotics (Quebec, Canada). Platform control is achieved through the Kinova SDK [13]. The Jaco is a 7-DoF non-anthropomorphic robotic arm with a 3-finger gripper—offering 6-D control (3-D translation and 3-D rotation) in task space.

Participants have no control over the motion of the robots during the study. All movements (Sec. IV-C) are prerecorded and controlled by the experimenters.

Control Interfaces. Three of the four interfaces—joystick, sip/puff, and switch-based head array—are commercial standards for powered wheelchair operation, selected to encompass a broad range of dimensionality, continuity, and actuation mechanisms. The fourth interface is not a commercial standard, but offers a richer input space to better match the higher-dimensional output space of a robotic arm. It uses a set of n inertial measurement unit sensors (IMUs) to track the upper body motions of participants, where n is determined based on the movements chosen by the participant (e.g., two-arm versus one-arm motions).

- Joystick. A 3-axis joystick (CH Products, California, USA) with 3 axes of deflection and 12 buttons.
- Sip/Puff. A 1-D USB Sip/Puff Breeze Switch (Origin Instruments, Texas, USA) that is operated via respiration and outputs a continuous-valued pressure signal.
- Head Array. A 3-switch FUSION Proportional and Digital head array with a chin switch (Adaptive Switch Laboratories, Inc., Texas, USA) that detects head taps to the back, left, and right pads and chin presses to the chin switch. This interface is used with the ASL ATOM Wireless Mouse Emulator which converts pad and button activations into discrete mouse inputs for data recording on a computer.
- IMU Sensors. The IMU-based motion tracking interface consists of x-IMU3 sensors (x-io Technologies Limited, Bristol, UK) attached to the participant via x-IMU3 elasticated straps. Each IMU outputs a 4-D (quaternion) velocity signal, corresponding to the motion of the participant body part to which it is affixed.

Participants are free to issue commands over any number and combination of channels on the given interface in use.

C. Study Protocol

Setup for Wheelchair. During the powered wheelchair session, each participant is seated in the wheelchair and asked to physically actuate the joystick, head array, and sip/puff interfaces. The head array is positioned for optimal activation. Participants observe 8 prerecorded, task-agnostic robot motions: *forward, backward, clockwise-spot-turn, counterclockwise-spot-turn, forward-clockwise, forward-counterclockwise, backward-clockwise,* and *backward-counterclockwise.*

Setup for Robotic Arm. During the robotic arm session, each participant is seated a safe distance from the arm and asked to physically actuate the joystick, sip/puff, and IMU interfaces. Participants are presented with 12 prerecorded, task-agnostic robot motions: *forward, backward, left, right, up, down, roll-clockwise, roll-counterclockwise, pitch-up, pitch-down, yaw-left*, and *yaw-right*.

Study Procedure. The study consists of two phases that are repeated for each interface:

(1) *Familiarization*. Participants are instructed on all avail-

able channel activations of the given interface.[1]

(2) *Map Data Collection*. Participants observe the prerecorded robot motions, presented as reversible pairs (e.g., forward/backward) in a randomized order that is balanced across participants. (The presentation order within the pairs themselves is also randomized and balanced.) For each observed motion:

- Participants first verbalize the interface-level command they would like to associate with the observed motion and are encouraged to practice issuing this command through the interface.
- Participants issue the interface-level command they have verbalized. To help anchor their command, the prerecorded robot motion is repeated as they issue their intended command through the interface.

Control signal data from the interface is recorded during both steps, including practice. For the sip/puff interface, visual feedback in the form of a pressure signal plot is provided.

D. Datasets

We generate *six* datasets based on our data processing methodologies presented in Section III:

- *Raw*: User's issued interface actuation signals.
- *Filtered*: Refines the raw signals according to the methodology described in Section III-C.
- *Synthetic*: Contains data generated based on the user's intended interface commands according to the methodology described in Section III-D.
- *Synth-raw*: Union of raw and synthetic datasets.
- *Synth-filtered*: Union of filtered and synthetic datasets.
- *Balanced*: Upsamples the raw signals to ensure all classes have the same number of samples as the most populated class in that raw dataset.

The *Synth-raw* formulation expands the size of the dataset while preserving the richness of the raw user interface-level commands. By retaining the inherent noise of the raw signals, the machine learning model is encouraged to tolerate variability and identify underlying patterns within the data. By contrast, the *Synth-filtered* formulation removes this noise.

We also compare the performance of our synthetic data generation method against state-of-the-art techniques:

- *SoTA-cont:* Random noise augmentation [14] by adding Gaussian noise to the raw signals ($\mu = 0, \sigma^2 = 0.05$).
- *SoTA-disc:* A Conditional Generative Adversarial Network (CGAN) [15].

While random noise augmentation is broadly deployed throughout the field, it is not suitable for discrete inputs. We therefore train a CGAN on the set of $\{(\phi_m^t,\ a^t)\}$ pairs for the head array interface. By conditioning both the generator and discriminator on a^t, the CGAN is able to produce meaningful synthetic data that mirrors the original dataset and is contextually relevant to the robot's actions.

We thus generate seven datasets (six based on our methodologies and one SoTA) for each interface-robot combination, with one notable exception: the IMU Sensors. None of the data generated using the IMU Sensors interface met the eligibility criteria for our Filtering or Synthetic Data Generation methodologies (Sec. III-C and III-D). Thus, only *raw* datasets are generated for this interface.

E. Machine Learning Algorithms

We select a subset of open-source machine learning algorithms to assess the viability of our proposed dataset generation methods using the open-source package PyCaret [16], which uses Scikit-learn [17] for the implementation and automated hyperparameter tuning of multiple algorithms.

Given the structure of our data, $(\phi_m^t,\ a^t)$, which includes robot motion labels, we focus on a supervised learning approach. We frame our problem as a classification task, requiring each model to predict a probability distribution over robot action labels given an interface signal input, and outputting the highest probability action. We explore a total of 16 machine learning algorithms, ranging from simple and lazy such as K-Nearest Neighbors (KNN) to more complex architectures such as Neural Networks (NN)—plus a chance classifier baseline that predicts a random label. Our selection spans a diverse range of capabilities, including models suited for high-dimensional data (e.g., Gaussian Naive Bayes [18]) and those effective for handling complex, high-variance data (e.g., ensemble methods [19]).

We implement a Feed-Forward Neural Network using TensorFlow and Keras [20], while our CGAN is implemented in PyTorch [21]. The hyperparameters for these two models, which are not included in PyCaret, are detailed in Table II.

To build and validate our models, we perform an 80/20 split into training and testing sets for each dataset. We conduct 10-fold cross-validation on the training set and take the best-performing of these to be our model, which is then evaluated on the holdout test set data. The results in Section V report on this test set performance.

TABLE II: Neural Network and CGAN model parameters and training hyperparameters.

Machine Learning Model	**Hyperparameters**	
Neural Network (NN)	activation function	relu & softmax
	loss function	CCE
	learning rate	0.001
	epoch	200
	optimizer	'Adam'
Conditional Generative Adversarial Network (CGAN) (Generator only)	activation function	relu & softmax
	loss function	BCE
	learning rate	0.001
	epoch	5000
	optimizer	'Adam'

F. Analysis Methods

To evaluate the performance of our models across the different datasets, we use both entropy and accuracy. *Entropy*, H, quantifies the level of uncertainty in a prediction. Lower entropy values indicate reduced uncertainty in the model. The

[1]For robotic arm sessions, prior to interface familiarization, participants additionally are presented with the prerecorded robot arm motions (which are more complex and unfamiliar).

following equation [22], modified to include normalization, is used to calculate H:

$$H_{\text{norm}}(X) = -\frac{1}{\log_2(n)} \sum_{i=1}^{n} p(x_i) \log_2 p(x_i)$$

where n is the number of class labels for each robot platform.

For each prediction, we compute H on the probability estimates for the most likely class label, classifying the prediction into one of four categories: (a) correct and certain, (b) wrong and certain, (c) correct and uncertain, and (d) wrong and uncertain. We define a second performance metric, *certain-accuracy*, which accounts for both model certainty and accuracy, using the formula:

$$\textit{Certain-Accuracy} = \frac{|a|}{|a| + |b|}$$

We define a baseline threshold for whether a model is predicting with certainty to be the entropy of a random classifier, which varies by participant-platform-interface-dataset type combination. All models' entropy values are compared to this threshold.

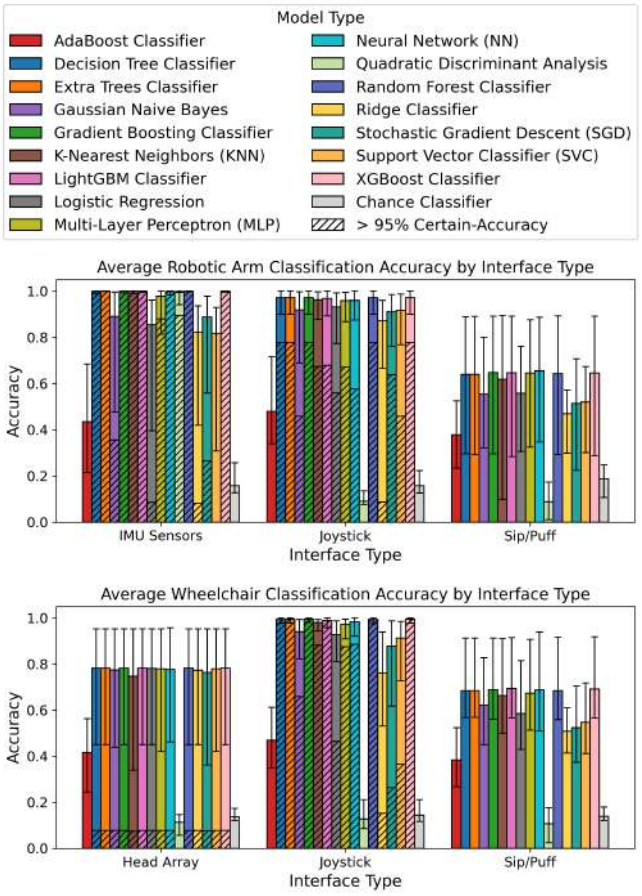

Fig. 2: Average model accuracy across all participants (S01-S10) for the robotic arm (top) and robotic wheelchair (bottom) platforms, clustered by interface type. For each bar (interface-platform-model combination), the proportion of participants whose model demonstrated a certain-accuracy greater than 95% is indicated with hatch lines.

V. Results and Discussion

We first evaluate the performance of a suite of machine learning models trained and tested on the raw datasets. For models that fall below a performance threshold of 60% prediction accuracy, we analyze the impact of our postprocessing methodologies. We also quantify the types of actuation errors (Sec. III-C) observed in the raw datasets.

A. Performance of Models

For each classification algorithm, Figure 2 shows the average accuracy aggregated across all 10 participants grouped by interface type for each robotic platform. These results indicate that multiple algorithms are able to successfully learn control map models for the joystick and IMU sensors interfaces, while all algorithms struggle to learn models for the sip/puff and head array interfaces. This struggle is evident in both the overall accuracy and the certain-accuracy demonstrated by the resulting models.

Notably, the sip/puff and head array interfaces offer less complex—lower-dimensional and/or discrete—input signals, which introduces challenges such as data sparsity and one-to-many command mappings (if participants develop difficult-to-disambiguate patterns to compensate for limited input options). By contrast, the IMU sensors interface offers the richest input signals and achieves the highest performance of all interface-platform combinations, with multiple algorithms demonstrating perfect accuracy.

Table III summarizes the algorithms that are high-performing on the raw datasets.[2] Here, the determination of *high performance* is a prediction accuracy that exceeds the 95% threshold, when averaged across all participants.

Of these 10 algorithms, 9 are high-performing on half of the interface-platform combinations. Among these, 6 are ensemble methods—Decision Tree, Extra Trees, Gradient Boosting, LightGBM, Random Forest, and XGBoost—which combine predictions from multiple weak models with high variance to produce a single prediction with low variance. Such an approach appears to be well-suited to the high variability, low sample volume, and sparsity present in our datasets. The remaining algorithms that are high-performing but are *not* ensemble methods are the Neural Network, Multi-Layer Preceptron (MLP), and K-Nearest Neighbor algorithms, all of which are able to model highly nonlinear decision boundaries.

B. Analysis of Methodologies

We analyze the impact of our postprocessing methodologies on *prediction accuracy* and *prediction certainty* for participants whose (*raw*) models are low-performing, meaning they achieve less than 60% prediction accuracy. For raw datasets that are already high-performing, postprocessing methodologies are of limited utility. We assess prediction certainty through a measure of entropy, where lower entropy correlates with lower uncertainty. Two platform-interface combinations meet this low performance criteria: **robotic arm & sip/puff** (participants S04, S08, and S09) and **wheelchair & head array** (participants S05 and S10).

[2]Four algorithms are never high-performing on any dataset, so they are omitted from this table: AdaBoost, Gaussian Naive Bayes, Ridge Classification, and Stochastic Gradient Descent (SGD).

TABLE III: High Performance Algorithms on the Raw Datasets.

Platform	Interface	Decision Tree	Extra Trees	Gradient Boosting	KNN	LightGBM	MLP	NN	Quadratic Discriminant Analysis	Random Forest	XGBoost
Robotic Arm	IMU Sensors	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
Robotic Arm	Joystick	✓	✓	✓	✓	✓	✓	✓		✓	✓
Robotic Arm	Sip/puff										
Wheelchair	Head Array										
Wheelchair	Joystick	✓	✓	✓	✓	✓	✓	✓		✓	✓
Wheelchair	Sip/puff										

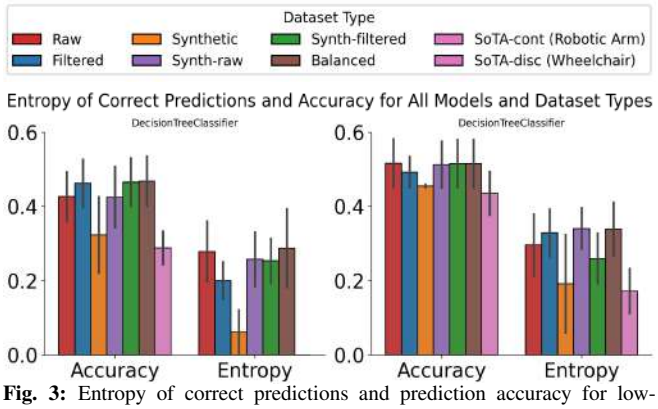

Fig. 3: Entropy of correct predictions and prediction accuracy for low-performance (lower than 60% accuracy) models trained and tested on the raw datasets: robotic arm & sip/puff (*left*, participants S04, S08, and S09) and wheelchair & head array (*right*, participants S05 and S10).

Only these five participant-platform-interface combinations are evaluated in the following postprocessing methodology analysis.

Figure 3 presents the entropy of correct predictions and prediction accuracy for each low-performance platform-interface combination, averaged over the five participants. For presentation clarity, only one representative algorithm is shown (Decision Tree Classifier); results for all algorithms are summarized next.

For the robotic arm & sip/puff combination shown in Figure 3, only one methodology noticeably reduces entropy without a sacrifice in prediction accuracy (in fact, accuracy slightly improves): our *Filtered* methodology. Across all tested machine learning algorithms, 62.5% (10 of 16) exhibit this trend of decreasing entropy while preserving or slightly increasing accuracy with the *Filtered* methodology, in comparison to the raw dataset. Additionally, 10 (of 16) exhibit this trend with the *Synth-filtered* methodology, and 1 (of 16) with *Synth-raw*.

Any other methodologies that reduce entropy do so at the cost of prediction accuracy, while other methodologies that preserve prediction accuracy do so without reducing entropy. Notably, the SoTA (*SoTA-cont*) and the standard data postprocessing technique of upsampling (*Balanced*) exhibit this trend for only *one* algorithm; in all other cases, our postprocessing methodologies outperform both the SoTA and standard postprocessing technique.

For the wheelchair & head array combination shown in Figure 3, it is also the case that only one methodology noticeably reduces entropy without a sacrifice in prediction accuracy: our *Synth-filtered* methodology. This trend again holds across 62.5% (10 of 16) of the tested machine learning algorithms. Additionally, 2 (of 16) exhibit this trend with the *Synthetic* methodology, and 1 (of 16) with each of *Filtered* and *Synth-raw*.

Notably, for this platform-interface combination, *neither* the SoTA (*SoTA-disc*) nor the standard data postprocessing technique of upsampling (*Balanced*) ever exhibit this trend for *any* algorithm. Our collective postprocessing methodologies thus outperform both the SoTA and standard postprocessing technique.

C. Quantifying Errors

For interfaces that meet our criteria for filtering (joystick, sip/puff, head array), we quantify actuation errors as defined in Section III-B. Errors are tallied for each participant, and the aggregated counts are reported in Figure 4. An illustration of selected individual participant error counts and types is also provided for the robotic arm & joystick combination—showcasing the variability in errors across participants. Note that a single actuation can contribute to multiple error categories (e.g., both "wrong command" and "missing activation").

The most frequent errors across all interfaces are **incorrect activation** and **leading/trailing zeros**. As expected, given the challenges of using the sip/puff device, **incorrect activation** errors are more prevalent for this interface. For head array, a notable number of **missing channel** errors are observed, likely due to suboptimal device positioning that can hinder a user's ability to issue simultaneous commands.

VI. Limitations and Future Work

A major limitation of this work is that our method was evaluated solely using data from people without motor impairment. In practice, motor impaired users may experience interface actuation difficulties unique to their conditions that were unobserved in the data we collected, and could affect the performance of our methodologies.

Future work will extend this work to end-users, evaluating how user-defined interface maps can be customized to their specific interfaces, needs, and preferences. We will also evaluate the utility of these user-defined control maps when used for robotic teleoperation. For the sip/puff interface, where a clear method for filtering data is currently lacking due to user variations in definitions for Φ, future efforts will explore better methods to filter noise both online (real-time) and offline (post-hoc), as well as investigate practical strategies for synthesizing data. While user-driven design is important, due to artifacts that can arise, a more collaborative design process will also be explored where researchers provide feedback on the feasibility of preferred commands.

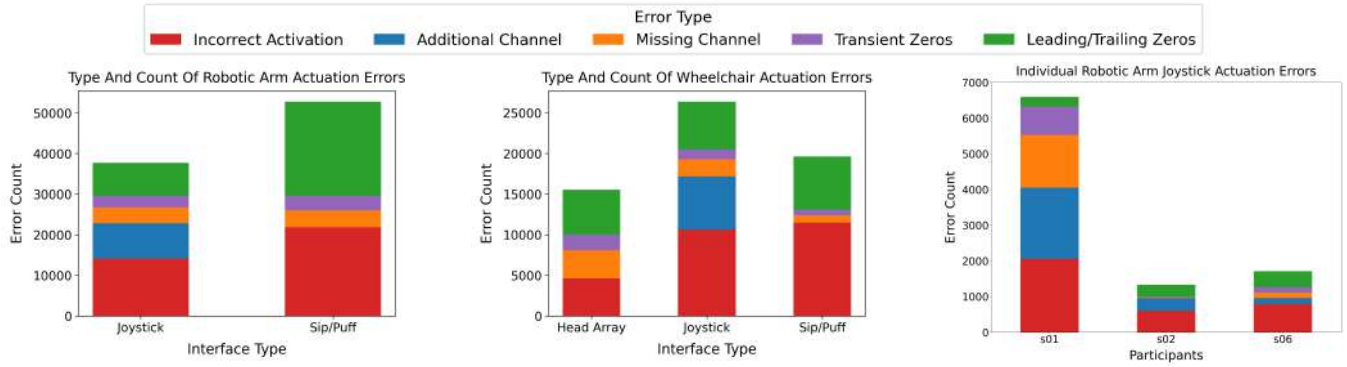

Fig. 4: Aggregated counts and types of actuation errors in the raw dataset for each platform-interface combination meeting the filtering criteria (Sec. III-C), tallied across all participants (left and center) and showcasing the variability between individual participants (right).

VII. Conclusions

In this work, we presented methods for curating user-defined interface control maps, addressing challenges in user-centered design, and filtering actuation errors to enhance dataset quality. Our experimental work evaluated, in a participant study, user-defined interface maps for two robotic platforms and four control interfaces. The performance of a suite of machine learning models on this data showed that multiple algorithms were able to successfully learn maps derived from raw joystick and IMU sensor signals. For platform-interface combinations that struggled to learn mappings between interface-level commands and robot actions, training on datasets curated via our postprocessing methodologies was demonstrated to decrease uncertainty. These results underscore the differing suitability of user-defined, data-driven control maps for various interface-platform combinations. By enhancing adaptability and personalization in assistive device control, this work contributes to more user-customized robotic teleoperation systems.

Design of a Pneumatic Splint for Forearm Fracture Immobilization

Tristan McCarty[1], Jared Dube[1], Omar O'Mari[1], Christopher Rico[1], Adam Farha[1], Mark McHugh[1], Robert McKee[1], Konstantinos Karydis[2], Elena Kokkoni[1*]

***Abstract*— This paper introduces a pneumatic splint design for managing distal radius and ulna fractures which are injuries commonly occurring in adults. The proposed design capitalizes on the advantages of pneumatically-actuated splints while mitigating airflow complications associated with conventional designs. The designed splint comprises two primary components: 1) a pressure cuff that wraps around the forearm and inflates to apply pressure on the injury site, and 2) a forearm support platform that combines all the different components together to contribute to forearm immobilization. Modeling and simulation results that informed the design selection process are presented, offering insights on component selection and system integration. Results demonstrate the preliminary feasibility of the proposed design and provide pointers toward the fabrication of a prototype in future work.**

I. Introduction

Upper extremity injuries are a significant public health concern, with forearm fractures being among the most frequently observed in hospital trauma units worldwide [1], [2]. Prompt stabilization is crucial for healing (e.g., reducing the time it takes for the injury to heal completely, avoiding further injury, etc.), but factors like heavy patient loads and long waiting times can hinder timely intervention [3], [4]. This can lead to a delayed union, characterized by slower-than-normal bone healing, or non-union, characterized by a complete failure of the bone to heal [5]–[7]. Consequently, patients may experience persistent pain, swelling, and functional limitations, impacting their quality of life and incurring significant healthcare costs [3], [4]. Addressing the impact of delayed stabilization on fracture healing is essential for optimizing patient care and improving outcomes.

Splints provide initial stabilization to the injured area while the patient is transported to the hospital for advanced treatment. Gypsum-based plaster of Paris splints have been the cornerstone of fracture management for centuries, with historical references dating back to the 18th century [8], [9]. While other materials (e.g., fiberglass) have emerged as an alternative, gypsum remains the most economical and versatile material for immobilization due to its adaptability and cost-effectiveness [8], [9]. Such splints offer quick and easy application. However, their rigid nature, poor ventilation, and potential for improper fit can increase the risk of complications, such as compartment syndrome. This serious condition occurs when pressure within a muscle compartment builds to dangerous levels, restricting blood flow and potentially leading to tissue damage [9]–[11]. Lastly, while effective for many fractures, traditional splints may not be ideal for acute fractures requiring complete immobilization [12].

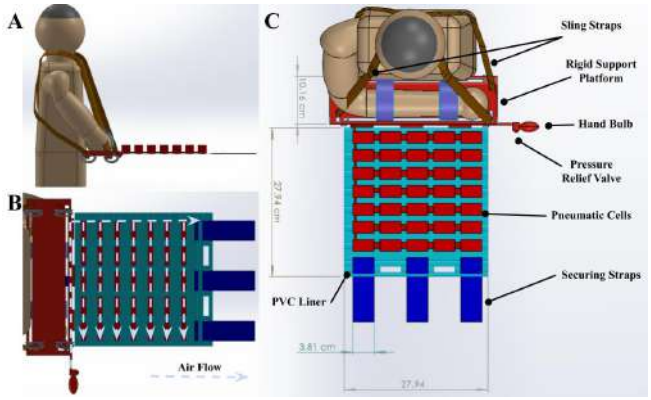

Fig. 1: Schematic views illustrating the cross sling design, rigid support platform for the arm, actuator placement, as well as the direction of airflow within the pressure cuff; the distribution of the inflatable components is visible too. (A) Side view of the double D-rings and sling being worn. (B) The bottom view with the pressure cuff is shown unrolled to clearly present the cutouts within the PVC cuff liner. (C) Top view showing how the pneumatic flow occurs between the hand pump and pneumatic cells.

The limitations of traditional splinting methods have driven the development of unconventional alternatives, such as pneumatic splints. These splints, often constructed from vinyl, Polyvinyl Chloride (PVC), or polyurethane, offer a unique approach to fracture immobilization [13], [14]. Once wrapped around the injured body segment and secured with straps, air is pumped into the splint until it becomes firm, providing compressive support to the fracture site. This pressure contributes to reduced pain, stiffness, inflammation, and swelling [15]. Pneumatic splints are highly adaptable, accommodating a wide range of adult body segment sizes through adjustable inflation. While pneumatic splints offer an innovative approach to fracture immobilization, they also present certain limitations. Excessive continuous pressure from full inflation can potentially compromise blood flow to the injured extremity [16]. Additionally, the development and application of pneumatic splints have primarily focused on fractures of the lower extremities [17], [18]. As such, the potential of pneumatic splints for treating forearm fractures remains largely unexplored.

This paper proposes a new design of a pneumatic splint for fracture management. The trauma of interest for this splint design is a distal fracture or a fracture isolated to either the radius or ulna, which are common sites of fractures in adults [19], [20]. Our design leverages the benefits of

(B) The straps are inserted into the rail slot closest to the body and under the rigid support platform. (C) The straps are inserted into the opposite slot and pulled away from the body to create a tight fit around the arm.

pneumatic splints while addressing limitations such as airflow complications associated with traditional and existing models. A mechanical valve is designed to maintain adequate forearm pressure, thereby aiming to reduce the incidence of delayed union and non-union. Manually-operated pumps are also included to maintain adequate pressure and mitigate potential blood flow restrictions. The various components of our design are evaluated through simulations, encompassing pressure, immobilization, and lifetime assessments. The following sections provide information on the design and simulation results for each component.

II. Approach

The proposed pneumatic splint design comprises two main components: (1) Pressure Cuff, and (2) Support Platform. These components contain various sub-components intended to work in synergy to provide effective fracture immobilization (Fig. 1). The pressure cuff wraps around the forearm and is secured with safety straps (Fig. 2). An interconnected manually-operated hand pump is used to inflate a system of pneumatic cells within the cuff, exerting pressure on the forearm. A spring-loaded pressure relief valve regulates the air pressure within the cells, releasing excess air as needed. The rigid support platform keeps the injured forearm fixed, minimizing movement and reducing the risk of further damage. Lastly, the sling supports the weight of the forearm and stabilizes the shoulder and elbow joints during application.

Our approach to the proposed design is twofold, focusing on component and material selection, as well as interfacing of the different components, to ensure a non-intrusive, adjustable, and user-friendly solution for fracture immobilization. Soft pneumatic actuators are selected for pressure application on the skin over rigid alternatives to enhance patient comfort and device adaptability. This approach aligns with recent trends in wearable device design, where pneumatic actuators are increasingly favored due to their low mass, high power-to-weight ratio, inherent safety, affordability, and ease of fabrication [21]–[25]. Additionally, a hand-operated pump offers several advantages over electrical control boards or inflation by a user directly blowing into a tube. It allows the professional or user to precisely regulate pressure, providing a sense of control and agency during injury management [26]. By utilizing atmospheric air for inflation (rather than human breath), moisture and bacterial buildup are minimized, reducing infection risk and extending the device's lifespan. Complex electrical components are eliminated, simplifying the design, lowering overall costs, and thus improving accessibility.

Building upon this foundation, the choice of PVC as the primary material for the splint further enhances the device's aim. PVC's antimicrobial properties (e.g., resistance to bacterial and fungal growth) facilitate disinfection through various methods, including alcohol rinse, and soap and water [27]. This variation in sanitation methods allows for appropriate cleaning of the device in both clinical and at-home settings. PVC also offers a favorable combination of mechanical properties: high tensile strength for durability, compressibility for adaptability to different limb shapes, elasticity for comfortable fit, and thermoplasticity [27]. Additionally, PVC's radiolucency allows for medical imaging (i.e. x-ray) without the need for removal, facilitating diagnostic procedures [28]. The proposed compact device design, enabled by PVC's properties, further enhances its portability and storage. The cost of parts, including the hand pump, would round up to be around 10$ per splint, making it economically feasible and as such accessible for all medical emergency units. The proposed device design can be scaled to accommodate both adult and pediatric needs.

The subsequent sections provide detailed information on the design of each component of the pneumatic splint, incorporating results from modeling and simulation to achieve optimal design parameters, such as material properties, reaction forces, and expected lifespan. The analyses were performed in AutoCAD (AutoDesk, San Francisco, CA) and COMSOL (COMSOL Multiphysics, Burlington, MA).

III. Design

A. Pressure Cuff

The cuff provides the primary stabilizing pressure to the affected area of the forearm. It consists of pneumatic cells, interconnected tubing, a pressure relief valve, and straps (Fig. 1). The cells are arranged in seven parallel rows each containing five cells connected in series with each other. Each cell measures about 4.6 cm by 3.3 cm and is designed based on a 12-gauge PVC sheet and separated from adjacent cells by 0.6 cm spacing. The multi-cell design, with spaced-out cells, facilitates ventilation around the forearm, mitigating heat accumulation at the injury site. The cuff design has a rectangular shape measuring 30.5 cm in length, to comfortably wrap around the forearm, and 26.7 cm in width, to accommodate the forearm segment's length. When deflated, the design allows for compact storage, folding to a size of about 35.6 cm x 10.2 cm x 2.5 cm. Its dimensions are based on the 50th percentile forearm measurements of 20-year-old individuals (32.3 cm for females; 34.7 cm for males [29]), ensuring a proper fit for many adults. However, it may not be suitable for individuals under 18 (females) or

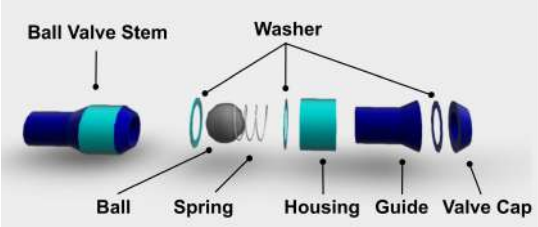

Fig. 3: CAD visualization of the pressure relief valve to regulate internal pressure without involving any electronic components.

15 (males), as their smaller forearm dimensions could cause the pneumatic cells to overlap when the cuff is wrapped around the forearm.

The pneumatic cells inflate in response to positive pressure input from the manual pump integrated into the splint. Air flows from the pump through tubing and into the cuff's network of cells (Fig. 1). Within each row, air progresses sequentially from one cell to the next, inflating all five cells. This design might lead to varying pressure distribution throughout the cuff, with cells farther from the primary air source experiencing lower pressure, or taking longer to inflate. To optimize pressure distribution, inflation time, and user effort, each cell incorporates a small cavity. This cavity allows for efficient inflation, reducing the required pumping effort by minimizing the volume of air needed to achieve the desired pressure without compromising the device's overall volume. To be effective, there should be no more than 20 mmHg air pressure build-up within the cells [30]. A spring-loaded pressure relief valve working synergistically with the manual pump is designed to regulate pneumatic pressure, releasing excess air if the aforementioned critical value is exceeded (Fig. 3). Simulations guided the design of the individual cells to ensure they could generate the necessary forces for this application.

B. Forearm Support Platform

The forearm support platform acts as a means to balance between providing uniform pressure around the forearm while also having a rigid surface to support the weight of the forearm. The rectangular support platform is designed to be out of a 12-gauge PVC sheet measuring 35.6 cm x 27.9 cm. It houses the pump, tubing, double D-rings with screws, and two straps. Sling straps going around the body and over the neck hold the weight of the forearm while stabilizing the elbow and shoulder joints. The double D-rings and screws secure the straps to the support platform, allowing the user to wrap the cuff around the forearm and fasten it securely. The straps are designed to be made out of 6-gauge PVC. Padding is also added to the support platform for comfort. Sling straps have a cross design, which was selected following a series of simulations. The model was created so that the sling straps were 2.54 cm wide and 76.2 cm long.

IV. Simulation Analysis and Results

This section presents the results of modeling and simulation, which informed the design selections presented before.

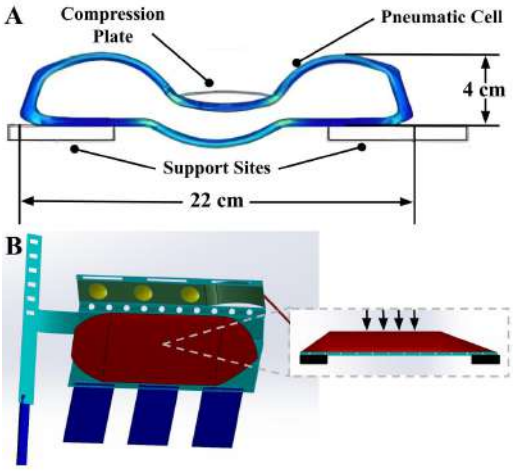

Fig. 4: (A) Compression testing of a single 22 cm pneumatic cell when placed directly on the injury and secured using two straps at the wrist and elbow areas. (B) CAD visualization of an earlier pressure cuff design version. The inset displays a cross-sectional view of the single pneumatic cell. Arrows represent the forces applied by the compression plate during simulation testing.

The inset displays a cross-sectional view of a single pneumatic cell. Arrows represent the forces applied by the compression plate during simulation testing.

A. Forearm Immobilization Afforded by Different Pneumatic Actuation System and Support Platform Selections

Simulations evaluated the appropriateness of different setups to lead to immobilization of the affected area of the forearm. A first set of simulations considered the use of a single (larger) pneumatic cell placed on top of the affected area and secured in place using two straps around the arm. Figure 4 visualizes this condition for the case of a 22-cm-long actuator. The two ends remained fixed, and a load (shown as a 'compression plate') was used in COMSOL as a means to emulate the reaction force exerted from the forearm to the inflated cell. Results show that the cell would deform too much and would be thus unable to apply the

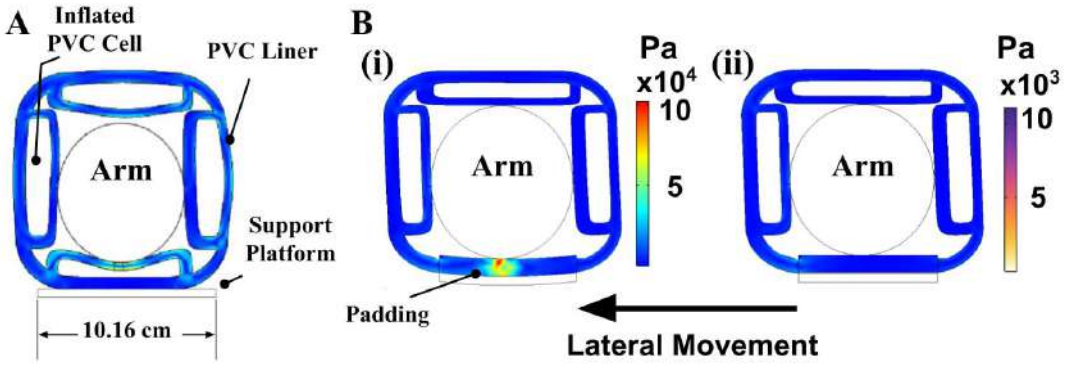

Fig. 6: Cross-sectional views of different iterations of multi-cell splints wrapped around the forearm. (A) 4-cell design where an inflatable cell is placed on top of rigid support platform at the bottom of the forearm. (B) 3-cell design, where the bottom cell is replaced with soft padding. Within this iteration, we considered (i) curved and (ii) flat platforms, and assessed which one can provide better immobilization with respect to lateral movements of the forearm.

proper pressure onto the forearm.

We also assessed the effect of cell wall thickness on pressure applied to the cell when fully inflated and in contact with a compressive plate (modeling the contact with the forearm). Two test cases are shown in Fig. 5. The first case (Fig. 5A) corresponds to one extreme case of a thin (approximately 0.75 mm) wall cell acting upon a flat surface. It can be seen that the pressure is applied relatively uniformly over the cell's wall, with high values at the center point of contact with the plate. In the second case (Fig. 5B), a thicker cell (12-gauge) with a thin indentation at its bottom (approximately 0.5 mm) was considered. The analysis in the second case reveals a smaller maximum pressure overall. The maximum values are also observed at the cell's indentation, and not at the point of contact with the arm (top part of cell). The use of a curved compressive plate (which is closer to the actual type of contact with the forearm) further demonstrates that such a design might be preferred over thin-wall cells.

Given that a single cell placed on top of the forearm does not yield satisfactory performance, we then considered multiple inflatable cells connected with each other via PVC liner and wrapped around the forearm. The performance of several different iterations was analyzed. First, we considered a 4-cell design that employs long, thick-wall cells placed along the top, bottom, and side parts of the forearm (Fig. 6A). The bottom cell is supported by a rigid support platform since earlier results (Fig. 4) showed that support over the two ends alone does not yield satisfactory performance. Results show that while this design approach is in principle feasible, it was still unable to apply sufficient pressure to the affected area since the bottom support cell yielded as pressure increased, eventually failing to immobilize the forearm (note the gap between the top cell and arm).

The follow-on iteration then featured removing the bottom inflatable cell and replacing it with soft non-actuated backing (for comfort) directly situated upon the rigid plate. An early design iteration visualizing this design is shown in Fig. 7. Figure 6B depicts a cross-section view. Within this iteration, we considered two subcases, one with a flat rigid support and

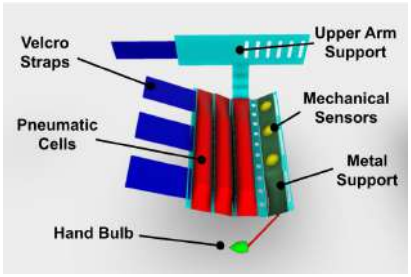

Fig. 7: Early iteration of the design for the pneumatic splint, visualizing an initial 3-cell design.

one with a curved design, in an effort to test immobilization with respect to lateral movement (i.e. motion along the horizontal plane in terms of the forearm's frontal plane shown in Fig. 6B). One main distinction between the two is in terms of manufacturing; a flat sheet is more directly obtainable and requires minimal machining, whereas a curved sheet would need additional processing (heating and possibly pressing) to be molded in the right shape, thus increasing costs. However, simulated force testing revealed that a curved rigid support platform can lead to higher pressure exerted onto the splint by the forearm's lateral movement which in turns results to higher resistance to arm motion and hence successful forearm immobilization as compared to when a flat rigid support platform was selected.

In our final design, we elected to make two revisions to the above down-selected characteristics (namely: curved rigid support platform with soft padding at the bottom of the arm and thick-wall pneumatic cells warped around the forearm and connected with each other and the platform via PVC liner). The first one involves splitting each long cell to multiple shorter ones (here we elected seven cells to facilitate manufacturing of a physical prototype). Using more distributed cells instead of a single one can yield faster pressurization and a more uniform application of pressure as the splint inflates. In addition, if desired, advanced pneumatic control systems can be deployed for actuating different cells at different rates, e.g., by using microfluidics [31]. The

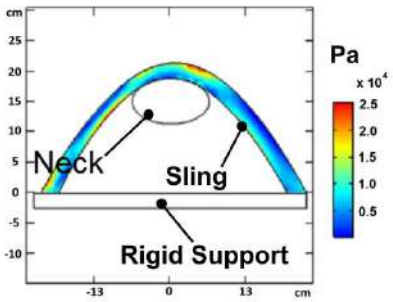

Fig. 8: Simulation on material stress distribution over a single-loop sling as depicted. Force is applied to the two ends via the rigid support, and the neck is simulated as a rigid plate. High stress points around the neck area in the sling imply that a higher pressure will be applied to the user's neck.

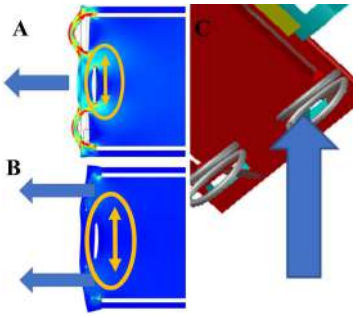

Fig. 9: Material stress in response to regular use load applied via the sling. Stress when the double-d rings are mounted on (A) the outer side of the cut-out slot and (B) the inner side. (C) Detailed view on the placement of the double-d rings used to connect the rigid support with the sling onto the rigid support platform.

second revision involves increasing the number of cells wrapped around the arm while keeping the platform as is. We elected to use five cells (from three shown before) to increase surface contact with the arm and lead to improved arm stabilization and comfort. Each of the five actuators 'lines' is operated in parallel, with the seven components within each line to be actuated in series (cf. Fig. 1).

B. Pressure Distribution on the Body via the Sling

We also sought to understand how the combined weight of the arm and the device should be distributed to the rest of the patient's body, and specifically at the back of the neck. Simulations showed that a direct application of a sling around the neck and connected to the two ends of the support platform would lead to large stress values (Fig. 8). As such, we elected to use a secondary sling that also wraps around the back, to reduce the load on the neck.

C. Structural Integrity

The last set of simulation experiments considered studying points of failure (in terms of structural weaknesses) of the splint. We specifically considered cracks in the rigid support of the splint. The rationale is that even if (some of) the individual cells fail, the use of multiple ones as proposed adds redundancy and can hence expand usage although some cells may have failed. However, cracks in the rigid support platform can propagate fast since the applied pressure at the platform is, in general, larger, and were thus modeled.

Recall that the proposed rigid support has cut-out slots for the sling and the sling straps to attach to (Fig. 9). When the splint is in use, these are the points of large forces being applied to the rigid support. The side slots are used to mount the double D-rings. We tested the difference in the stress applied to the rigid plate when placing the rings on the outer (Fig. 9A) over the inner (Fig. 9B) side of the slots. It can be directly verified that there is significantly higher material stress when forces are applied to the rings places on the outer side, which led to the decision to place the rings on the inner side, as detailed in Fig. 9C).

We also investigated how small cracks occurring around the slots would propagate to the rest of the platform under loading (via the sling when the device is in use, as before) over different usage cycles. Results are depicted in Fig. 10. The crack growth rate with and without rails shows that the rails significantly increase the rate of crack growth propagation (note the orders of magnitude difference). Hence, small cracks can still lead to material failure if the rails are present.

V. Discussion

This paper presents the design and validation of a pneumatic splint for forearm fracture immobilization. While not intended for long-term rehabilitation, this splint offers a promising solution for stabilizing injuries during transport to a medical facility. Our design approach offers key advantages in ease of use, affordability, and low production cost, significantly undercutting the price of the most expensive modern-day materials being used for splints [32]. The model was rigorously tested via simulation to evaluate its core components. Results demonstrate the feasibility of this design and its potential to effectively immobilize fractures in a simulated environment.

Previous work with pneumatic splints have highlighted their effectiveness at providing stability to injury sites by conforming to the arm of the user, as opposed to forcing the injury to conform to the splint [13]. Additionally, positive feedback has been received from clinicians regarding the effectiveness and ease of use for multiple fracture types, but long-term patient comfort has been an issue [13], [33], [34]. As these splints conform to the injury site uniformly with high pressure, problems with maceration and blood flow restriction to the injury site have arisen while steps have not been taken to ensure sufficient ventilation and proper pressure regulation [35]. Our work aimed to address these issues by integrating a grid-like network of interconnected pneumatic cells in a pressure cuff with a built-in user-friendly pump to inflate and a novel mechanical pressure relief valve to deflate. To the best of our knowledge, this is the first pneumatic splint designed for forearm fracture immobilization. Future steps involve the construction of the physical prototype, and assessing its maximum lifetime, applied pressure, and user comfort.

Robotic Individualized Driving Evaluation (RIDE): Design and Preliminary Evaluation

Tim D. Yang[1,2], *Student Member, IEEE*, Laura Rice[1], Seth Hutchinson[3,4], *Fellow, IEEE*, and Yih-Kuen Jan[1]

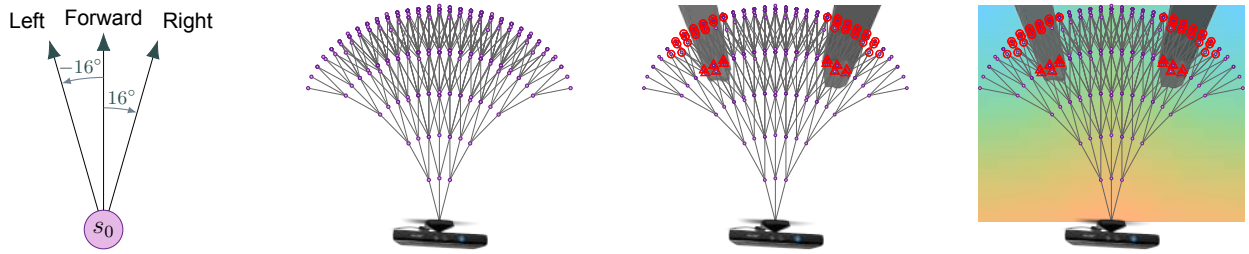
***Abstract*— Power wheelchair driving entails safety risks, including tips and collisions. Thus, driving assessments are important to safeguard both drivers and their surroundings. However, current driving assessments are deterministic, whereas driving itself is stochastic due to individual and environmental uncertainty. Moreover, disabilities magnify this uncertainty. In this study, a robotic wheelchair was used for a novel function: stochastic assessment of PWC driving. The Robotic Individualized Driving Evaluation (RIDE) is a stochastic assessment that contrasts with deterministic assessments by accounting for individual differences via assessment profiles. The robotic wheelchair acquired the information needed for the stochastic model, and a probabilistic risk score was formulated. The purpose of this preliminary study was to test the effect of assessment profiles within and between driving tasks. Within tasks, there were significant differences in RIDE risk between the profiles. Between tasks, there were significant differences in the new stochastic RIDE metrics but not in the conventional deterministic metrics. Results demonstrated potential for this novel use of robotic wheelchairs to support personalized assessment and training in power mobility rehabilitation.**

I. INTRODUCTION

Power wheelchairs (PWCs) increase autonomy in people with severe mobility impairments [1] insofar as the user can drive effectively. However, functional steering is "extremely difficult" for many PWC users [2]. Day-to-day usage entails safety risks, including tips and collisions [3]. Thus, PWC assessments are used to ensure the safety of both the users and their surroundings. Clinicians perform a comprehensive evaluation of the client's personal and environmental factors. This iterative process of in-clinic evaluations and at-home trials [4] includes clinical ratings and measurements.

Clinical ratings target various levels of the International Classification of Functioning, Disability, and Health [5] (e.g., function [6], activity [7], participation [8]–[10], and environment [11], [12]). Clinical measurements target either wheelchair trajectory (e.g., driving duration, driving error, driving variability, driving speed, and driving acceleration) or human performance (e.g., information processing capacity, reaction time, fatigue, target accuracy, joystick activations, and joystick directional variability) or both [13]–[17].

However, driving contains complexities that are difficult to formalize with ratings and measurements. Driving is a dynamic, stochastic, and nonlinear process [18] involving real-time adaptation mediated by personal and environmental factors. Individual differences in motor skill, cognitive skill, visual acuity, etc., inject uncertainty into the driving process, and disabilities magnify that uncertainty which in turn influences the optimal driving strategy. For example, whereas an unimpaired driver might choose the most efficient trajectory in a given scenario, an impaired driver (i.e., with higher uncertainty in driving control) might instead choose a less efficient trajectory in favor of more safety. By measurements, the impaired driver chose a worse plan (e.g., longer driving time). In practice, they demonstrated good decision-making by accounting for their impairment. These contextual driving decisions are difficult to formalize with ratings and measurements. While a rating may account for some context, it lacks in objectivity and granularity. While a measurement may be objective and granular, it lacks in context.



Stochastic analysis can complement measurement statistics by objectively accounting for contextual differences. A stochastic model can balance task objectives against personal and environmental factors [19]. In this study, a robotic wheelchair was used for a novel function: stochastic assessment of PWC driving. The Robotic Individualized Driving Evaluation (RIDE) was developed on the basis of a Markov model and was configurable via assessment profiles, represented internally as Markov transition models. The robotic wheelchair acquired the information needed for the model, and a probabilistic risk score was formulated. In practice, a clinician would use their expertise to determine a suitable RIDE profile befitting their client's individual differences. The resulting RIDE score would then represent a personalized measure of driving risk. In this preliminary study, the purpose was to test the effect of RIDE profiles within and between driving tasks. It was hypothesized that:

1) within tasks, there will be significant differences in stochastic metrics between assessment profiles; and
2) between tasks, there will be significant differences in stochastic metrics but not deterministic metrics.

Fig. 1. Markov decision process components. (a) The action space consists of left-, for-, and rightward actions. (b) The state space is formed by propagating actions into a 3-branch, 6-depth directed acyclic graph. (c) The state graph is overlaid on a point cloud with two obstacles. (d) The point cloud is further overlaid on a Markov reward function that penalizes obstacles based on proximity and directness of path.

II. SYSTEM DESIGN

The RIDE algorithm was based on a first-order Markov decision process (MDP) [20], consisting of a set of states (i.e., wheelchair positions), set of actions (i.e., wheelchair headings), probability distribution of movement transitions (i.e., movement uncertainty), and reward function (i.e., environmental cues) (Table I). These components were used to model PWC driving as a sequence of MDP decisions, accounting for differences in driving skill and environmental context. Driving risk was determined by contrasting the driver's observed actions with the MDP's computed actions.

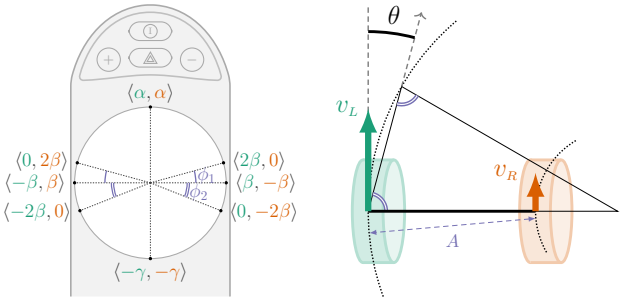
A C300 power wheelchair (Permobil, Inc., Lebanon, TN) was robotized, although computational navigation functionality was not used; the participants retained full driving control, as the purpose of the study was to assess their own driving. The robotic wheelchair facilitated the capture and extraction of information needed for the MDP—i.e., the driver's actions and the environment's context.

To capture the driver's actions, an Arduino Mega 2560 R3 (Smart Projects SRL, Strambino, Italy) was interfaced with the joystick's microcontroller board to intercept `FORE_AFT` and `LEFT_RIGHT` voltages. The model's action space $A(s)$ (Fig. 1a) consisted of three discrete actions: left ($-16°$), forward ($0°$), and right ($16°$). These actions were propagated into the state space S (Fig. 1b): a directed acyclic graph with three branches and six levels. To determine the driver's action $a \in A(s)$ in a given state s, the PWC heading was computed. The turning of a PWC is actuated via differential steering, in which new headings are based on relative wheel torques. For example, the PWC actuates a right turn by increasing the left wheel's velocity relative to the right wheel's velocity. In this study, joystick excursions were used to ascertain the wheel velocities, which in turn were used to compute the PWC headings:

$$\begin{array}{ccccccc} \text{Joystick} & & \text{Wheel} & & \text{PWC} & & \text{MDP} \\ \text{excursion} & \mapsto & \text{velocities} & \mapsto & \text{heading} & \mapsto & \text{action} \\ (r,\theta) & & \langle \mathbf{v}_L, \mathbf{v}_R \rangle & & \theta & & a \in A(s) \end{array}$$

Joystick excursions fell within eight regions, each with its own excursion-velocity mapping. The regions were bounded by the polar angles 0, ϕ_1, $\frac{\pi}{2}$, $\pi - \phi_1$, π, $\pi + \phi_2$, $\frac{3\pi}{2}$, and $-\phi_2$ (Fig. 2a). The boundary angles and output velocities were parameterized by five constants, which were derived from empirical testing on the standard speed setting of the indoor driving profile. The linear velocities were computed from angular velocities based on the PWC's wheel radius. Using the resultant wheel velocity tuple, the PWC heading θ was computed via rigid body dynamics (Fig. 2b),

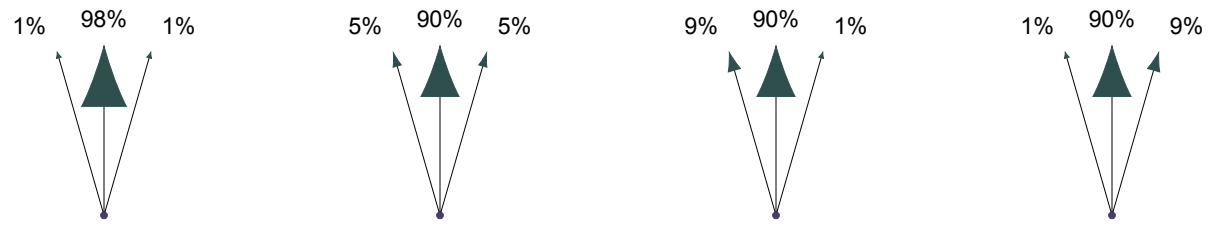
$$\theta = \frac{v_L - v_R}{2Af_s} \tag{1}$$



where v_L and v_R were the wheel velocities, A was the axle length, and f_s was the sampling frequency.

To capture the environment's context, the headrest was retrofitted with a Kinect (Microsoft Corporation, Redmond, WA), containing a depth sensor with 11-bit depth, $57°$ horizontal field of view, $43°$ vertical field of view, and $4\,\mathrm{m}$ radial distance. Each depth image was transformed into a point cloud of obstacles onto which the state graph was overlaid (Fig. 1c). The reward function $R(s)$ (Fig. 1d) was then used to determine the reward value at each graph node. Obstacle nodes and their descendent nodes were penalized inversely by the distance from the driver,

$$R(s) = \lambda\sqrt{(x_{\max} - |x_s|)^2 + (y_{\max} - |y_s|)^2}, \quad \lambda < 0 \tag{2}$$



where x_s and y_s were the coordinates of state s, and λ was a negative penalty coefficient. Thus, $R(s)$ was scaled both for proximity and directness of path to the driver.

The joystick data and depth images were acquired simultaneously using MATLAB (The MathWorks, Inc., Natick, MA) at sampling frequencies of 2 Hz and 10 Hz, respectively.

Fig. 3. The four assessment profiles for the stochastic model. The profiles were represented internally as Markov transition models. (a) The unimpaired profile contained 2% overall variability. (b)–(d) The bilateral and unilateral assessment profiles each contained 10% overall variability.

III. EXPERIMENT DESIGN

A. Protocol

The experiment was conducted in a university building hallway. Two driving tasks were defined per [7]:

1) turn left 90° while moving forward and
2) turn right 90° while moving forward.

To prevent interference from passersby, the hallway was cordoned off for the duration of the protocol. Three healthy participants completed the experiment. The impairment level of the participants was not relevant, as the purpose of the study in this preliminary stage was to test the effect of assessment profiles versus tasks. Each participant was a right-handed joystick user and was given time to acclimate to the wheelchair and joystick before performing the experimental task. Each task was repeated twice with brief resting periods in between. The joystick data and depth images were extracted from the robotic wheelchair for offline analysis.

B. Data Analysis

For each driving trial, two deterministic and four stochastic metrics were analyzed. The deterministic metrics included driving duration and joystick variability per [15]. The stochastic metrics included four RIDE risk scores (i.e., one per profile) computed from the Markov model.

Markov decisions were optimized into a policy of actions maximizing the driver's expected utility according to the Bellman equation,

$$U(s) = R(s) + \gamma \max_{a \in A} \sum_{s' \in S} P(s'|s,a)U(s'), \quad 0 < \gamma < 1 \quad (3)$$

where $U(s)$ was the utility value for state s, $R(s)$ was the reward for state s, γ was a discount factor, and $P(s'|s,a)$ was the transition model for transitioning to state s' given the current state s and action a.

For PWC driving, a transition model with higher or lower variability suggests a driver with stronger or milder impairments, respectively. This transition model $P(s'|s,a)$ can be viewed as an *assessment profile*. In practice, a healthcare provider could use their clinical expertise to determine a suitable profile befitting their client's individual differences. In this study, four basic profiles were used (Fig. 3) as a preliminary test of the system:

1) unimpaired (1% left and 1% right variability),
2) bilateral (5% left an 5% right variability),
3) unilateral-left (9% left and 1% right variability), and
4) unilateral-right (1% left and 9% right variability).

For each profile, an optimal policy was computed numerically via backward induction [21].

For each optimal policy, a RIDE risk score was formulated under the rationale that suboptimal decisions are not inherently risky and do not necessarily preclude functional driving. Mathematically, a deviation simply means that the driver can no longer achieve the highest possible utility. Functionally, the impact could range from trivial to substantial. The severity of a deviation can be quantified in terms of the expected utility difference. Thus, at the root node of each graph, the observed actions and computed actions were compared by their respective expected utilities. RIDE risk Γ was defined as the inverse hyperbolic sine (IHS) [22] of the relative error,

$$\Gamma(t) = \sinh^{-1}\left(\frac{\hat{U}(t) - U(t)}{U(t)}\right) \quad (4)$$

where $\hat{U}(t)$ and $U(t)$ were the observed and computed utilities, respectively, at time t. Thus, when the observed action matched the computed action at a given time t, the RIDE risk evaluated to zero; otherwise, riskier mismatches evaluated to higher values. The IHS transformation was chosen to dampen the effect of runaway scores (e.g., 2,000% risk is not pragmatically different from 200% risk).

Data analysis was performed in GNU Octave.

C. Statistical Analysis

RIDE risk was normalized to the interval $[0, 1]$. Based on the Shapiro-Wilk test and quantile-quantile visualization, it was determined that the data were not normally distributed. Thus, nonparametric comparisons were used. All tests were conducted using $\alpha = .05$.

1) Within Tasks: RIDE risk was compared between the four assessment profiles using the Kruskal-Wallis one-way analysis of variance. Given a significant difference across profiles, the Conover-Iman test with Holm-Bonferroni correction was used for post hoc pairwise comparisons.

2) Between Tasks: RIDE risk, driving durations, and joystick variabilities were compared using the Wilcoxon signed-rank test.

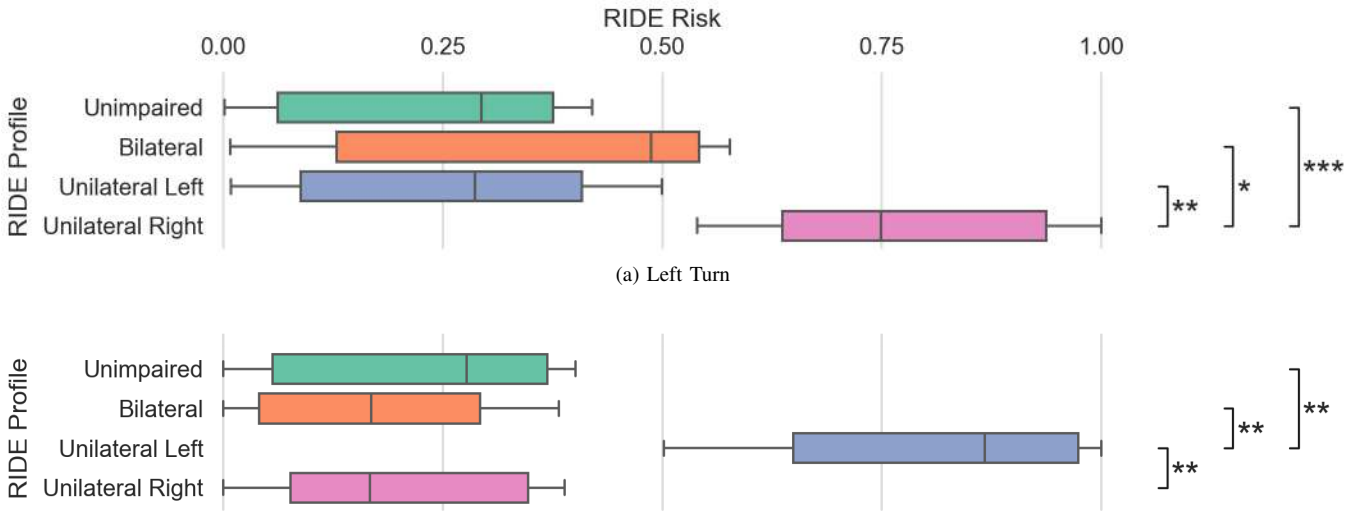

Fig. 4. Intra-task comparisons of driving risk across assessment profiles. (a) For the left turn task, risk from the unilateral-right profile was significantly higher than that of the unimpaired, bilateral, and unilateral-left profiles. Other differences were not significant. (b) For the right turn task, risk from the unilateral-left profile was significantly higher than that of the unimpaired, bilateral, and unilateral-right profiles. Other differences were not significant. Abbreviations: * ($p < .05$), ** ($p < .01$), *** ($p < .001$), RIDE (Robotic Individualized Driving Evaluation)

Statistical analysis was performed in Python using the `pandas`, `scipy`, and `scikit-posthocs` libraries.

IV. RESULTS

A. Intra-Task

1) Left Turn: There was a significant difference in RIDE risk across the four assessment profiles ($p = .003$). Post hoc comparisons (Fig. 4a) indicated that the RIDE risk from the unilateral-right assessment profile (median[IQR], $0.75[0.64 - 0.94]$) was significantly higher than that of the unimpaired profile ($0.29[0.06 - 0.38]$, $p < .001$), bilateral profile ($0.49[0.13 - 0.54]$, $p = .021$), and unilateral-left profile ($0.29[0.09 - 0.41]$, $p = .002$). Other differences were not significant.

2) Right Turn: There was a significant difference in RIDE risk across the four assessment profiles ($p = .008$). Post hoc comparisons (Fig. 4b) indicated that the RIDE risk from the unilateral-left assessment profile ($0.87[0.65 - 0.97]$) was significantly higher than that of the unimpaired profile ($0.28[0.06 - 0.37]$, $p = .003$), bilateral profile ($0.17[0.04 - 0.29]$, $p = .001$), and unilateral-right profile ($0.17[0.08 - 0.35]$, $p = .003$). Other differences were not significant.

B. Inter-Task

1) Stochastic: For the unilateral-left assessment profile, there was a significant difference in RIDE risk between the left turn task ($0.29[0.09 - 0.41]$) and right turn task ($0.87[0.65 - 0.97]$, $p = .031$). For the unilateral-right assessment profile, there was a significant difference in RIDE risk between the left turn task ($0.75[0.64 - 0.94]$) and right turn task ($0.17[0.08 - 0.35]$, $p = .031$). For the unimpaired and bilateral assessment profiles, there were no significant differences in RIDE risk between tasks (Table II).

2) Deterministic: There were no significant differences in either driving duration or joystick variability between tasks (Table II).

V. DISCUSSION

In this paper, the design and preliminary results of RIDE are presented. RIDE uses a robotic wheelchair to assess PWC driving stochastically. In integrating context from the driver and environment, this stochastic approach complements deterministic assessments by providing a more standardized method for personalization. Individual differences are configurable via the model's assessment profiles.

Clinical profiles are routinely used for diagnosis, prognosis, and treatment throughout the healthcare industry, from internal medicine [23] to sports medicine [24] to rehabilitation medicine [25]. Clinical decisions are made with a breadth of information, including client demographics, biomedical measurements, clinical ratings, etc. Healthcare providers develop clinical recommendations through the lens of the client's profile. In this study, the profile-based design mirrors this approach. RIDE computes risk through the lens of a given assessment profile. It was hypothesized that PWC driving actions would yield significantly different RIDE risk scores as viewed through different assessment profiles.

Within tasks, experimental testing indeed revealed significant differences between certain profiles. For a given directional task, significantly higher RIDE risk was observed under the contradirectional profile but not the ipsidirectional profile. This result was likely due to the turning strategy adopted by the participants (Fig. 5). In preparing for a turn, they tended to anticipate the turn by executing a wider arc—bringing themselves closer to the contradirectional wall—prior to executing the turn. Under most circumstances (i.e., bilateral, ipsidirectional, or no impairment), this would be a reasonable driving plan and would not cause significant

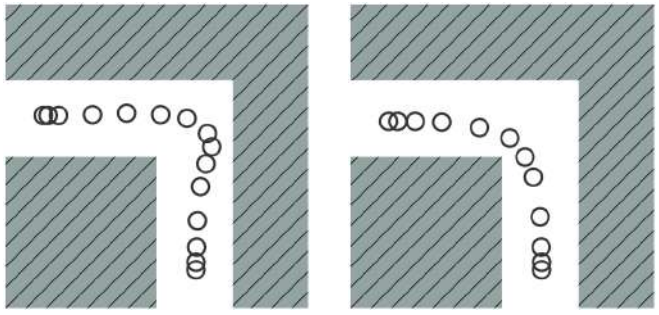

TABLE II
INTER-TASK COMPARISONS FOR STOCHASTIC AND DETERMINISTIC METRICS

	Metric	Profile	Left Turn Task		Right Turn Task		
			Mdn	(IQR)	Mdn	(IQR)	p
Stochastic	RIDE Risk	Unimpaired	0.29	(0.06–0.38)	0.28	(0.06–0.37)	.844
		Bilateral	0.49	(0.13–0.54)	0.17	(0.04–0.29)	.219
		Unilateral Left	0.29	(0.09–0.41)	0.87	(0.65–0.97)	**.031***
		Unilateral Right	0.75	(0.64–0.94)	0.17	(0.08–0.35)	**.031***
Deterministic	Driving Duration (s)	N/A	9.00	(8.25–10.50)	9.50	(9.00–10.00)	.655
	Joystick Variability (°)	N/A	7.02	(6.79–8.62)	7.11	(5.28–9.08)	.844

Abbreviations: * ($p < .05$), IQR (interquartile range), Mdn (median), N/A (not applicable), RIDE (Robotic Individualized Driving Evaluation)

risk. However, under a contradirectional assessment profile, this wider trajectory (Fig. 5a) represents a significantly increased risk of colliding with the contradirectional wall. The stochastic model developed in this study accounted for this context via the given assessment profile. If the driver had instead taken a more direct line to the corner (Fig. 5b), the ipsidirectional profile would instead have yielded the highest RIDE risk. This profile-based approach enables clinicians to perform standardized assessments that account for impairment context. Furthermore, the robotic assessment could be performed in clients' homes and communities to provide targeted risk assessments of their daily environments. Thus, RIDE could serve as a clinical decision support tool to assess clients' needs within individual and environmental contexts.

Stochastic models can leverage context to extract more meaning from deterministic metrics. However, stochastic assessment has yet to be used for power mobility, although it has been used in the related field of power seating [26]. In conventional wheelchair seating practice, seating pressures are measured to screen for pressure ulcer risk. Since conclusive thresholds for pressure ulcer formation have yet to be determined [27], stochastic gradient descent has been used to predict pressure ulcer risk by integrating interface pressure measurements with clinical context (i.e., pressure ulcer history) [26]. In the present study, stochastic modeling was also used to assess risk via contextual profiles. It was hypothesized that the deterministic metrics would not detect significant differences between PWC driving tasks, whereas the stochastic RIDE model—given context via assessment profiles—would detect significant differences.

(a) Representative (b) Hypothetical

Fig. 5. Representative and hypothetical trajectories for the left turn task. (a) A representative trajectory from one driving trial, in which the participant anticipated the turn by executing a contradirectional arc. (b) A hypothetical trajectory, in which the driver takes a more direct path around the corner.

Between tasks, experimental testing indeed revealed significant differences in stochastic metrics but not deterministic ones. This result highlighted the contextless nature of traditional measurements. For example, a more direct turning trajectory (Fig. 5b) may not be ideal in all contexts, despite being superior by deterministic measurements (e.g., lower driving duration and joystick variability). Consider a PWC user, Alice, with advanced cervical dystonia. Her chin tends to point down toward her right shoulder, causing her field of vision to be rotated rightward. Even with seating adjustments and physical therapy, her postural condition will unlikely resolve in the near future. Thus, her reduced leftward perception constitutes a unilateral-left impairment. For Alice, the more direct trajectory (Fig. 5b) represents a significantly increased risk of collision with the corner. The more roundabout trajectory (Fig. 5a)—despite its higher driving duration and joystick variability—would represent a more optimal decision. The RIDE model would account for Alice's condition and could complement deterministic metrics to provide a more contextual, client-centered assessment.

Beyond assessment, training is needed to address identified barriers. For example, trainees of the Wheelchair Skills Training Program have seen improvements in PWC driving performance [28]. However, the improvements were modest and transient. To boost efficacy, robotics-based stochastic assessment may be able to identify personalized hotspots for more targeted training. This computational approach could also reveal hidden risks. For example, for wheelchair seating, stochastic modeling revealed potential underappreciation of the coccygeal region in predicting pressure ulcer risk [26]. For PWC driving, stochastic modeling could reveal analogous insights on previously underappreciated risks and barriers. Furthermore, because RIDE leverages a robotic wheelchair, the training could potentially occur remotely. Robotic assessment could allow PWC users to continue self-paced training at home so that skill improvements could be better retained over time.

There were limitations to this study. In terms of system design, all obstacles were treated equally. Future work should distinguish between different obstacle types and their respective threat levels. In terms of experiment design, the sample size was small. Future work should include more participants so that more diverse driving strategies and trajectories can be observed. Additionally, the study participants did not present

with disabilities since this was a preliminary test of the robotic system and assessment profiles. Future work will assess the drivers, so the sample should include people with disabilities. Lastly, only two driving tasks were included. Future work should include a higher quantity and variety of tasks, especially to test the bilateral and ipsidirectional profiles.

VI. CONCLUSION

The RIDE model brings a personalized approach to power mobility clinical practice. It represents a novel use of robotic wheelchairs: stochastic assessment of PWC driving. In contrast to deterministic metrics, this stochastic approach accounts for individual and environmental differences. Clinicians can use configurable RIDE profiles to perform standardized assessments that account for impairment context and, in turn, provide more targeted training to enhance functional independence in PWC users.

Integration of a Gripper-Equipped Humanoid Social Robot for EEG-Monitored Action Observation Paradigms

Anh T. Nguyen, *Member, IEEE*[1], Hao Zhang[2], Tian Tan[2], Mohammad Abrar[1], Yuxin Zhang[3], and Michelle J. Johnson, *Member, IEEE*[4]

***Abstract*— Action Observation (AO) therapy leverages the mirror neuron system (MNS) and may support motor recovery in neurorehabilitation. In this study, we integrated Flo v2, a humanoid robot equipped with grippers and object detection system, into an AO therapy paradigm with electroencephalography (EEG) monitoring. Flo v2's enhanced design enables the execution of upper-limb actions, either transitive (involving object interaction such as grasping a cup) or intransitive (gesture-based without object manipulation such as waving). The robot control is synchronized with EEG recording to facilitate the investigation of cortical responses during AO tasks. We also conducted a case study to assess of the upgraded robot system's feasibility. Three healthy participants observed and imitated robot-performed actions, where the robot actor was in person or on videos. Exploratory analyses of EEG signals examined sensorimotor mu event-related desynchronization (ERD) during video-based and in-person AO tasks. Results indicated stronger responses during bimanual and transitive AO in the in-person settings. However, individual variability in cortical responses was evident, with one subject showing less pronounced ERD patterns, and that comparisons of mu ERDs across different types of action in video-based AO settings were inconsistent among subjects. Flo v2's enhancements demonstrated its feasibility as a tool for robot-mediated AOE therapy and highlighted potential for further neurorehabilitation research.**

I. INTRODUCTION

Action observation (AO) therapy enhances upper-extremity motor function in individuals recovering from neurological conditions like stroke [1]. It leverages the mirror neuron system (MNS), which activates during the observation and execution of motor acts, facilitating motor learning through motor cortex and parietofrontal region activation [2], [3]. MNS activation supports cortical reorganization, aiding motor recovery in stroke survivors [4]. EEG can measure cortical responses during AO to assess motor recovery through sensorimotor mu rhythm (8–13 Hz) suppression [3], [5], [6].

Factors such as the human-like appearance of the agent and types of actions in visual stimuli during AO affect neural responses in the MNS [7]. Several studies used different types of robots, such as robotic arms [8], [9] and humanoid robots [10], [11] in AO paradigms and analyzed the MNS responses to actions performed by robots versus by humans [12]. The MNS shows varying responses to human and robot actions, with generally stronger activation for human agents in simple movements [8], [13], [14]. However, complex and goal-oriented actions elicit similar MNS responses to both agents, particularly in the parietal and premotor regions [15], [16], [17], [10]. These findings suggest that the potential use of robots for neurorehabilitation such as AO therapy. Regarding the concept of transitivity during AO, transitive actions involve interaction with objects in the peripersonal space (e.g., grasping a ball), while intransitive actions are simple hand-arm movements that do not involve objects (e.g., waving). Human MNS typically displays greater responses in frontal and parietal MNS and motor cortex to transitive than intransitive actions [18], [19]. EEG studies indicate that MNS responses to transitive actions of the human hand induce greater mu suppression in the C3 channel compared to intransitive actions [20].

Although the neuromodulatory effects of transitivity in human actions have been widely studied, only a few studies have explored this concept in the context of observing robot actions. Gazzola et al. identified significant differences in fMRI activity in the premotor and parietal areas when observing transitive versus intransitive robot arm movements [8]. However, an EEG study by Oberman et al. found no such effect of object versus non-object robot arms actions using mu suppression in C3 and C4 [9]. These mixed results highlight the need for further research to clarify how different types of robot-performed actions influence cortical responses. Furthermore, previous studies examining transitivity have primarily utilized robot arms rather than full humanoid robots. Compared to simpler robot arms, robots embodying a human-like form can perform complex, full-body movements that more closely resemble human motor patterns, potentially leading to stronger neural responses during AO. This highlights a gap in understanding how actions performed by humanoid robots influence MNS activation during AO.

The Flo robot, a custom-designed humanoid social robot developed in the Rehabilitation Robotics Lab at the Univer-

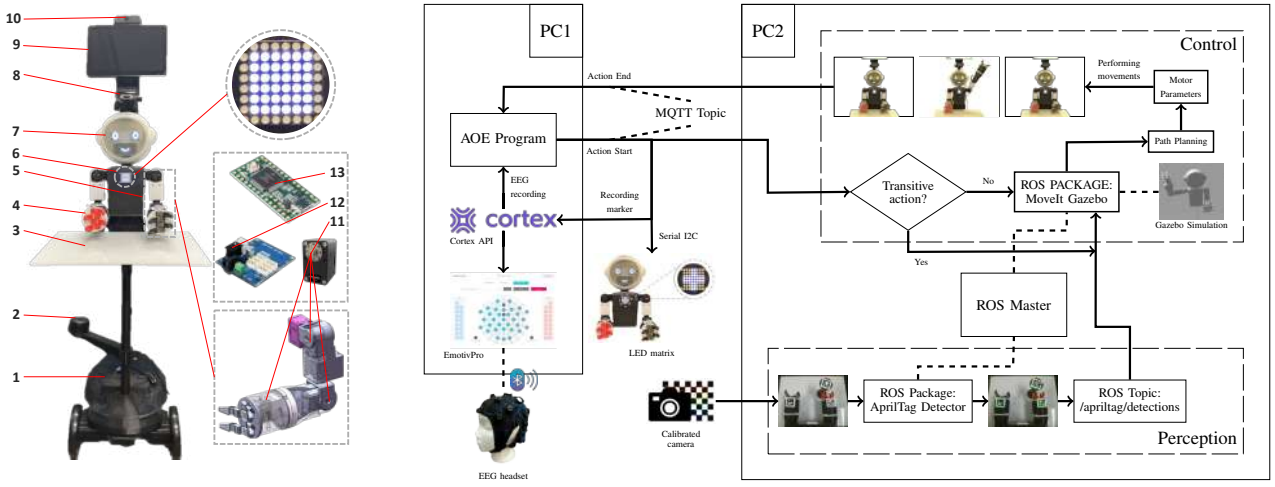
sity of Pennsylvania, features an expressive facial interface and articulate upper limbs to demonstrate upper extremity tasks [21], [22]. Initially designed as part of a telerehabilitation system, Flo enables remote interaction between clinicians and patients while facilitating demonstration of rehabilitation activities [23]. Previous studies found Flo effective in comparison to traditional telepresence method [24] and has potential use for exploring MNS activation during AO tasks [11]. This proof-of-concept paper presents the latest advancements in Flo robot (Flo version 2), aimed at improving its suitability for AO therapy, and a case study to assess the use of upgraded system in AO paradigms and investigate the neurophysiological effects of observing various robot actions using EEG.

II. FLO V2: ENHANCEMENTS FOR AO THERAPY

A. Design Objectives

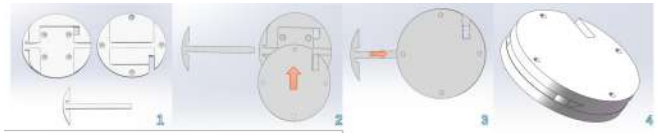
The improvements aimed to provide Flo with a more human-like appearance and movement capability, optimizing its potential to engage patients effectively. Specifically, the design sought to increase the robot's ability to perform both transitive and intransitive actions. The addition of an automated object detection and grasping system aimed to streamline its manipulation with objects. These advancements collectively aim to create a reliable, user-friendly platform that aligns with the therapeutic needs of AO therapy, potentially supporting motor recovery after stroke through enriched and interactive robot-mediated therapy.



Moreover, Action Observation and Execution (AOE) program was developed to integrate EEG recording with real-time robot control, allowing precise synchronization between observed actions and recorded brain activity. This integration enables the examination of cortical responses to robot-assisted AO therapy. Fig. 1(a) shows the Flo v2 system hardware set-up and Fig. 1(b) shows control of the robot integrated with the EEG-monitored AOE experiment. Details of the robot's development, including hardware and software specifications, are available in our GitHub repository.

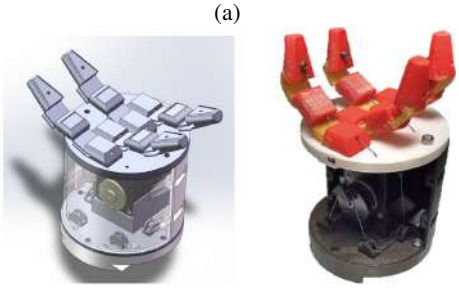
B. Hardware Developments

1) Humanoid Arms and Grippers: Each arm offers four DYNAMIXEL-driven DOF in Fig. 1(a), closely resembling basic human joint configurations. The lower arm section accommodates a quick-change mechanism in Fig. 2(a) that simplifies gripper swaps. Inspired by the Yale OpenHand project [25], each gripper employs a single motor and a fishing-line tendon system in Fig. 2(b) to flexibly grasp common household objects.



2) Face and Chest LED Matrix System: Flo v2's LED system includes a 16×8 matrix for the mouth, two 8×8 matrices for the eyes, and an 8×8 chest matrix, maintaining the interactive design of the previous version [21]. A Teensy 3.2 microcontroller integrated with ROS enables real-time facial expression adjustments via serial communication. The LED matrices are embedded in a translucent black urethane screen for effective light transmission and contrast while concealing internal components.

The chest LED matrix is of the same type as used in the AOE program (described in section II-E), capable of displaying predefined patterns such as a fixation cross,



(a) (b)

Fig. 1: a) The Flo v2 robotic system includes: 1. Ohmnilab base; 2. LIDAR; 3. Tray; 4. Gripper; 5. Arm; 6. Chest LED matrix; 7. Face LED matrices; 8. RGB Camera; 9. Ohmnilab screen; 10. Ohmnilab camera; 11. DYNAMIXEL motors; 12. U2D2 Power Hub; and 13. Teensy 3.2. (b) The software architecture follows a step-by-step flow. Initially, the AOE program on PC1 starts an action, triggering the system workflow. If the action is identified as a transitive action involving an object on the tray, PC2 utilizes data provided by the perception module, specifically AprilTag detections, to plan and control the robot to execute the action. If the action is not transitive, it will be performed by the robot without additional planning for grasping. Simultaneously, PC1 controls the chest LED matrix, synchronizing with the AOE experiment to provide precise markers on EEG recording linked to the subject's actions.

Fig. 3: Automated grasping system: (a) Side view showing the camera's vision range indicated by the red dotted lines; (b) Camera view displaying detected AprilTags.

a triangle, a square (Fig. 1(a)) , or remaining in an off state. These visuals provide supplementary feedback, further enhancing Flo v2's expressive capabilities.

3) Telepresence Base: The social robot Flo v2 is mounted on the Ohmnilab telepresence robot, which can be controlled using ROS and equipped with both a camera and LIDAR sensor for remote-controlled navigation and obstacle detection.

C. Automated Grasping and Object Detection System

1) Tray and Camera Setup: Flo v2 is capable of performing automated grasping actions, which allows Flo v2 to perform more actions. To achieve this, Flo v2 is equipped with a 42.4 cm × 32.3 cm tray used for placing objects that need to be grasped. An RGB camera positioned 43 cm above the tray offers a top-down view, enabling precise identification of the objects' locations for grasping.

2) AprilTag System: Each object placed on the tray is fitted with a 2.4 cm × 2.4 cm AprilTag. The AprilTags serve as visual fiducial markers, allowing the camera system to detect and identify the objects' positions. This setup, shown in Fig. 3(a), ensures that Flo v2 can efficiently locate and grasp objects autonomously. Figure 3(b) shows the arrangement of April Tags on each gripper and on an object.

3) Object Localization and Grasping Process: Object localization and grasping in Flo v2 involve detecting AprilTags attached to objects using a top-mounted RGB camera. Once the object is identified and its position determined, the coordinates are transmitted to the control system. Using the ROS framework, the robot plans a path to accurately position its gripper, ensuring precise object grasping with real-time adjustments for reliable manipulation.

D. Software Development and System Architecture

The software architecture is illustrated in Fig. 1 (b).

1) Robot Control System: We import the Unified Robotic Description Format (URDF) model of the robot into the Gazebo simulation environment, perform path planning and collision detection through ROS Noetic MoveIt, and convert angle data of each joint into motor data and send it to each motor via USB. While driving the real-world robotic arm, arm motion is also represented in the Gazebo simulation.

2) Visual LED Control System: To implement visual markers during the AOE experiment, we utilized a Teensy 3.2 microcontroller programmed via the Arduino IDE. The microcontroller was designed to control the patterns of the chest LED matrix, including a fixation cross, a triangle, and a square. These patterns serve as visual stimuli, synchronized with the EEG recording. Serial communication using I2C protocol was established between the Teensy and the AOE program, enabling real-time control of the chest LED. The program sends commands through a serial interface to the microcontroller to display or turn off specific patterns.

3) Camera Calibration and AprilTag Detection: To localize the real robot arm end-effector and determine the 6-DOF position of various objects (e.g., a cup, a dumbbell, a hairbrush), camera calibration is first performed using a checkerboard pattern with a size of 8x6 inner corners and each square measuring 0.0245 meters to obtain intrinsic parameters, such as the focal lengths f_x and f_y, and the principal point coordinates c_x and c_y. This is achieved using the `camera_calibration` package in ROS [26].

After camera calibration, we use the ROS package `apriltag_ros` [27] to detect AprilTags attached to the objects. This package identifies the AprilTags in the scene and publishes their 3D pose (position and orientation), as well as their respective IDs, enabling accurate positioning and tracking of the tagged objects.

To further calculate the physical distance D from the camera to the detected tag, we developed a custom ROS package named `apriltag_detector`. This package uses the intrinsic camera parameters obtained from the calibration process. According to the pinhole camera model, the distance is calculated by $D = (f \times s)/w$, where f represents the focal length, s is the actual size of the AprilTag, and w is the perceived width of the tag in the image (measured in pixels). The `apriltag_detector` package then publishes the final 3D coordinates, pose, and calculated distance of the detected tag to a ROS topic (`/apriltag/detections`). These data are subsequently used in the robot control system for manipulation tasks.

E. AOE Experiment Program

The AOE experiment program is designed to facilitate the execution of a series of robot actions while recording EEG data using the Cortex API [28]. The program initiates by establishing a connection to the Cortex service and creating a recording session (Fig. 1(b)). During the session, markers are injected at specific points to annotate events, such as the presentation of stimuli or the execution of actions. The Cortex API is used to manage the recording session, inject markers, and handle session-related callbacks.

In parallel, the program utilizes the MQTT protocol to communicate movement commands to the robot's control system. Each action in the sequence is randomized, and the corresponding movement number is published to a predefined MQTT topic. This enables the robot to receive real-time movement instructions synchronized with the experimental protocol. The program includes a simple GUI for controlling the experiment and offering visual feedback to the operator. Overall, the integration of the Cortex API and MQTT allows for precise synchronization, facilitating the coordination between EEG data recording and robotic control.

F. Specifications and Performance Testing

1) Gripper Payload Testing: The payload capacity of Flo v2's gripper was measured in two directions: along the gripper's axis (horizontal) and perpendicular to it (vertical). An NLB-500 analog force gauge was used for both measurements. For horizontal force, the gripper grasped a model object connected to the gauge via rope, and force was applied until detachment. For vertical force, the gripper held the object while downward force was applied until detachment. The average payload capacities, calculated over five trials, were as follows: 328.34 g (horizontal) and 356.9 g (vertical) for the left gripper, and 259.0 g (horizontal) and 326.3 g (vertical) for the right gripper.

2) Range of Motion and Capabilities: To determine the workspace, we used the robot's URDF model to generate approximately 20,000 reachable points for each arm. These points were then validated using MoveIt to ensure they were free of collisions with the robot itself or the environment. The collision-free points were visualized as a point cloud in RViz, providing a clear representation of the arm's spatial capabilities. The robot arm's modified DH parameters are shown in Table I. Figure 4 shows the robot arm's configuration with coordinate frames (X_i, Y_i, Z_i) established according to the modified DH parameters in Table I, along with key dimensions between joints.

The workspace of Flo v2's arms, shown in Fig. 5, represents the spatial extent of reachable points for each arm. The workspace accommodates a range of unimanual and bimanual actions. Unimanual actions include intransitive movements such as overhead arm raise and waving, as well as transitive actions like lifting objects or using tools. Bimanual actions include intransitive tasks such as clapping or synchronous shoulder movements, as detailed in Table II. This study focused on unimanual transitive and intransitive actions, with bimanual intransitive actions included for comparison. Bimanual transitive actions were not intentionally excluded but were beyond the study's scope.

Joint i	θ_i(Angle)	d_i(along z_{i-1})	a_i(along x_i)	α_i(around x_i)
1	θ_1	40 mm	0 mm	0
2	θ_2	0 mm	0 mm	$\pi/2$
3	θ_3	117 mm	0 mm	$-\pi/2$
4	θ_4	0 mm	0 mm	$\pi/2$
End-effector	–	151.14 mm	0 mm	0

TABLE I: Modified DH parameters of the robot arm

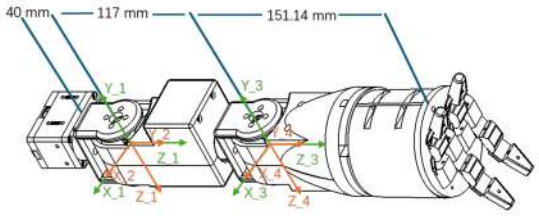

Fig. 4: Modified DH parameters and robot arm coordinates

Fig. 5: Visualization of the Flo v2 robot's arm workspace from front, side, and top views, with white dots indicating reachable points and range of motion for various actions.

Arm Configuration	Action Type	Action Examples
Unimanual	Intransitive	Overhead arm raise, Forward punching, Waving, Shoulder abduction/adduction
	Transitive	Lifting a dumbbell, Drinking from a cup, Using a hairbrush
Bimanual	Intransitive	Clapping, Synchronous and Alternating shoulder abduction/adduction, Alternating forward punching

TABLE II: Types of action the robot can perform.

3) System Limitations and Future Upgrades: Despite the robot's capability to autonomously grasp objects, the current system requires manual placement of objects onto the tray. Furthermore, during intransitive actions, objects on the tray may obstruct the robot's movements, necessitating manual removal of the objects. To address these limitations, we plan to upgrade the tray system by enabling it to lower when objects are not required, thereby preventing interference, and raise when objects are needed for grasping. This improvement aims to achieve fully automated object grasping and seamless operation in all action types.

In addition, the Flo v2 system currently relies on two separate PCs to manage its operations: one for controlling

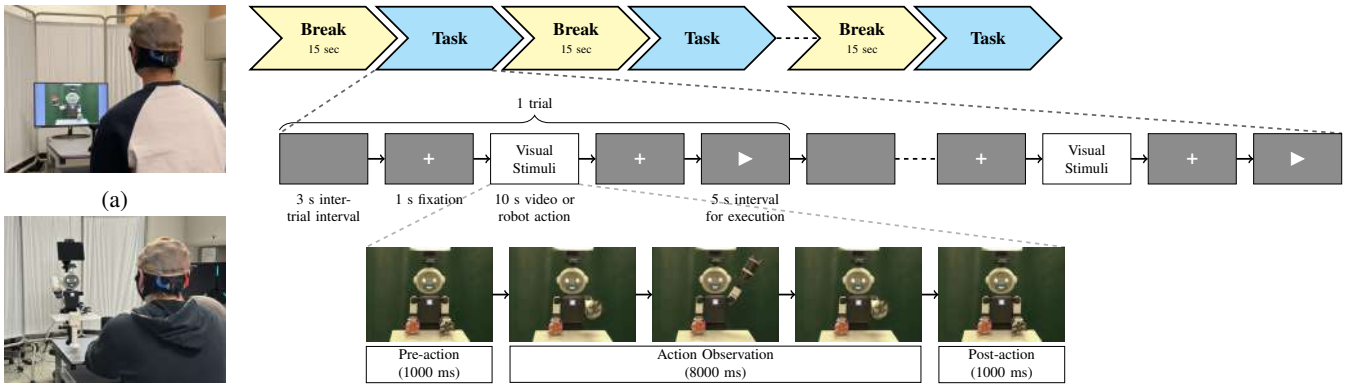

Fig. 6: Experimental setup of (a) video-based and (b) in-person robot AOE experiments. (c) Block design of AOE experiments.

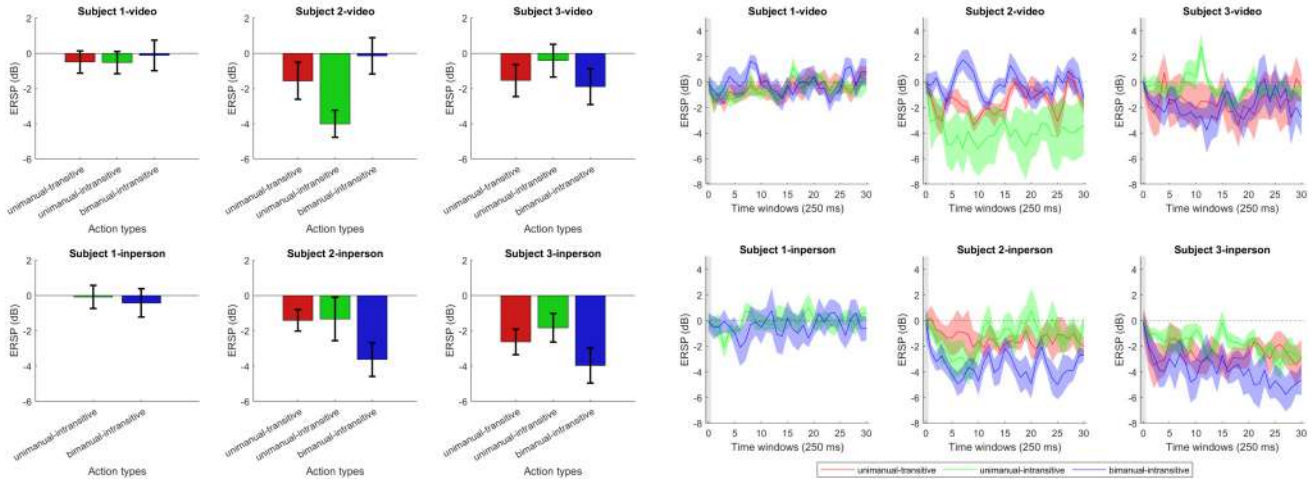
the robot and another for handling EEG recording and data synchronization. This setup increases complexity, introduces potential latency in data communication, and complicates portability and deployment in new environments. To address this, we plan to containerize the entire system using Docker, which will enable the deployment of all required software on a single PC through modular ROS Docker containers.

III. EVALUATING FLO V2 IN AO THERAPY

A. Experimental Design and Protocol

This case study recruited three right-handed participants, ages 23 to 24, with no history of neurological or psychiatric disorders, to explore the neurophysiological effects of observing various robot-performed actions on the mirror neuron system (MNS). This study was approved by the University of Pennsylvania Institutional Review Board (IRB No. 830126) on June 29, 2021.



Participants completed two experiments in order: a video-based and an in-person robot action observation and execution (AOE) experiment. In the video-based experiment (Fig. 6(a)), pre-recorded videos of actions performed by the Flo v2 robot were presented as visual stimuli using the open-source software PsychoPy[29]. In the in-person experiment (Fig. 6(b)), the Flo v2 robot performed actions directly, with the LED matrix on its chest indicating task stages, and the system was administered by the aforementioned AOE program. For both experiments, participants observed 10-second arm actions of different types (i.e., seven unimanual actions for each arm and four bimanual actions, see Table II) consisting of a 1000 ms stationary pre-action, an 8000 ms action observation interval, and a 1000 ms stationary post-action. Each stimulus was repeated four times and presented in a counterbalanced block design (Fig. 6c), each block contained a sequence of trials. Each trial began with a 1000 ms fixation cross, followed by the stimulus, another 1000 ms fixation cross, and a 5000 ms action execution interval indicated by a triangle shape. The video-based experiment included six blocks of 12 trials each. In the in-person experiment, the first six blocks featured the 12 intransitive actions including four unimanual actions for each arm and four bimanual actions, and the final six blocks each featured one of the six transitive actions (i.e, two for each arm).

To control for perceptual differences between 2D and 3D settings, participants were positioned 150 cm away from the monitor or robot. Videos were recorded in an allocentric perspective using an APS-C camera with a 30 mm focal length (equivalent to a 45 mm full-frame focal length, close to the ”normal” human perspective of 50 mm [30]) and displayed full-screen on a 27-inch monitor, approximating the size of the in-person robot (40 cm height). Before the experiments, participants received training on AOE tasks with sample videos. They were instructed to focus and keep their hands still while observing the fixation cross and the videos, and later mirror the observed actions during the execution phase.

B. EEG Data Acquisition and Processing

The EEG data were recorded using the Emotiv EPOC Flex system (Emotiv Inc., San Francisco, U.S.A.), equipped with 32 Ag-AgCl electrodes arranged according to the International 10–20 system. EEG data acquisition was managed through Emotiv Pro software, which facilitated real-time communication with the PsychoPy platform during the video-based experiment and with the AOE program during the in-person experiment via the Cortex API.

Off-line pre-processing and analysis were conducted using EEGLAB toolbox [31] in MATLAB. EEG data were filtered (1–40 Hz) and channels with artifacts (sudden shifts, excessive noise, or voltage amplitude) were visually removed. The data were re-referenced to the average, interpolating removed channels, and cleaned with Independent Component Analysis (ICA) to eliminate muscular, ocular, or cardiac artifacts. Data segments were created with epochs starting at the onset of visual stimuli, rejecting those with amplitudes exceeding 100 μV. To calculate the event-related desynchronization (ERD), fixation cross intervals were used as the baseline. Time-frequency analyses were conducted for all trials, assessing the sensorimotor mu (8-13 Hz) ERDs relative to baseline power, averaged across action types and channels (C3 and C4), separately for condition, and experiment.

(a) Mean ERD values during AO

(b) Individual ERD time courses during AO

Fig. 7: Mean mu ERD values and time courses during AO tasks for each condition, including three action types (unimanual transitive, unimanual intransitive, and bimanual intransitive) and two experiments (video-based and in-person robot).

C. Results

For the included EEG data across experiments (video-based and in-person robot), an average of $87.89 \pm 6.89\%$ of AO epochs were retained after preprocessing. The Bluetooth connection between EEG headset and PC1 during collection of EEG for transitive action stimuli during the in-person experiment for Subject 1 was disrupted by environmental electromagnetic interference, leading to missing data on transitive robot actions.

Overall, all subjects showed ERDs in mu band, indicated by negative values of event-related spectral perturbation (ERSP), during AO across all conditions (Fig. 7(a)), and patterns of mu ERDs were consistent across the time course of the task (Fig. 7(b)). Subject 1 showed less visible ERD patterns compared to others. Examining the Power Spectral Density (PSD) in the alpha range (8–13 Hz) of this subject also found flatter and less defined patterns compared to others. Among the other two subjects, except for the data from Subject 2 during video-based AO, data from Subject 2 during in-person AO and data from Subject 3 during both AO conditions showed the strongest mu ERDs for bimanual actions and stronger mu ERDs induced by observation of unimanual transitive actions compared to unimanual intransitive ones.

D. Discussion

The Flo v2 robot was able to perform transitive actions, which is an upgrade from Flo's previous version. The integration with the AOE program to facilitate EEG acquisition and real-time synchronization with robot actions helped conduct EEG-based investigation of cortical responses during robot-performed AOE tasks. The case study demonstrates the feasibility of integrating Flo v2 into AO paradigms. All subjects exhibited mu band ERDs; however, there was variability among participants, in which one subject displayed less pronounced ERD patterns than the others. The pilot results in other two subjects revealed that the strongest values of mu ERD were observed during the observation of bimanual actions for both subjects in the in-person experiment. This finding aligns, in part, with Vuckovic et al.'s EEG study, which demonstrated that motor execution of a bimanual task elicited significantly stronger mu ERD compared to unimanual tasks [32]. While Vuckovic et al. focused on motor execution, our study extends this understanding to the domain of action observation, suggesting that observing bimanual actions may engage similar sensorimotor processes as those activated during their execution. Comparing the effects of unimanual transitive and intransitive actions, the latter induced stronger mu ERDs in both Subject 2 and 3 particularly in the in-person experiment. This agrees with findings from the previous EEG study [20] as well as the meta-analyses of functional neuroimaging studies on MNS activation [18], [19]. However, these findings were limited to the in-person experiment; the video-based experiment showed variability in mu ERDs among subjects (e.g., Subject 2 showed the strongest mu ERD for unimanual intransitive actions, while Subject 3 showed the strongest mu ERD for bimanual actions). To validate these findings and investigate the efficacy of these systems in clinical populations, larger sample sizes are essential for further research. Additionally, future studies could incorporate test-retest analysis to assess EEG response reliability across sessions and utilize insights on neural predictors of human-robot interaction [33] to create personalized rehabilitation protocols that adapt to individual cognitive and neural profiles.

ACKNOWLEDGMENT

We thank the National Institutes of Health for funding this research through grant F31-HD102165. Additionally, we appreciate Michael Sobrepera and Ajay Anand for their contributions to the robot system development.

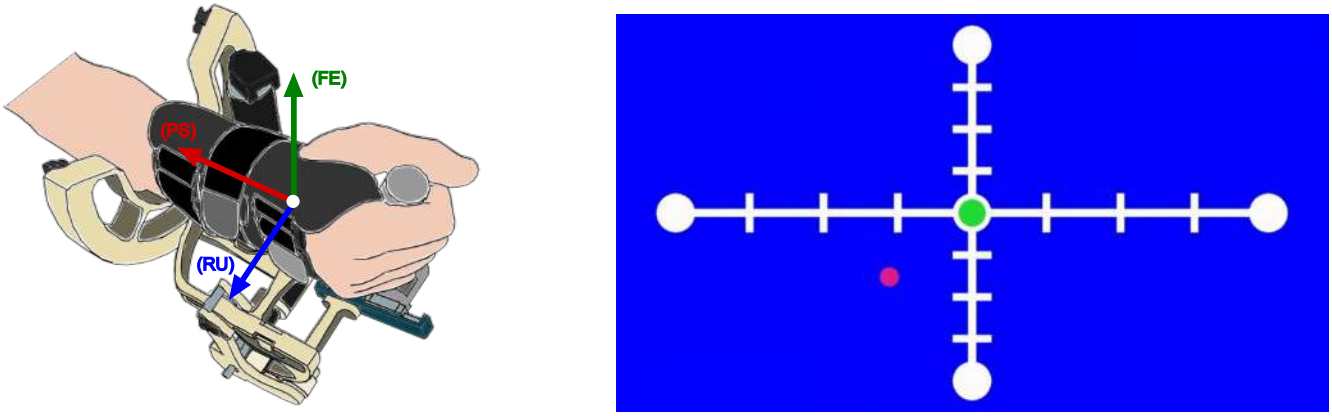
***Abstract*—Movement smoothness is a commonly employed metric of motor impairment in stroke patients due to a strong correlation with Fugl-Meyer Assessment score, and because it can be assessed with functional-oriented tasks like wrist pointing. Robotic assessments of wrist-pointing tasks typically use targets located at fixed points in the workspace, which can exceed the range of motion (ROM) of stroke patients who exhibit severe motor impairment. We hypothesize that movement smoothness assessed based on movements that do not reach visual targets may conflate assessment of movement smoothness with ROM. We propose that scaling the locations of wrist pointing targets for wrist flexion-extension and radial-ulnar movements from a ROM assessment will better reflect movement characteristics. In this paper, we analyze wrist-pointing movements for fixed and ROM-scaled target locations. We evaluate wrist-pointing performance in both conditions for 8 neurologically-intact participants whose wrist ROM was constrained with a wrist brace simulating ROM deficits present after stroke. Results show that failing to reach targets during wrist pointing has a significant negative impact on movement smoothness. Additionally, scaling target placement to ROM increases the proportion of targets reached while producing practically equivalent movement smoothness to successfully reached fixed target locations. These findings support incorporation of ROM-scaled target placement into movement smoothness assessment.**



***Index Terms*—exoskeleton, movement smoothness, robotic assessment, stroke rehabilitation.**

I. Introduction

Stroke is the leading cause of long-term disability. In the United States, 9.4 million people are estimated to have had a stroke, cumulatively costing 56.5 billion dollars. By 2030, it is projected that another 3.4 million adults in the US will have had a stroke [1]. Rehabilitation is important to reduce impairment and restore quality of life and independence in the stroke population. Objective motor impairment assessments are useful tools to assess motor recovery after stroke and to determine therapy protocols that have the potential to promote rehabilitation. Robotic assessments of motor impairment provide an objective basis for assessment through precise measurement of kinematic and dynamic quantities of movement [2]. Comparatively, clinical assessments typically rely on a series of clinician-evaluated ordinal scales that require specialized training to administer. Further, these assessments can introduce subjective variability in evaluations between clinicians [3]. Despite the benefits of robotic assessment and rehabilitation, which are often performed in tandem [4], they remain underutilized in rehabilitation [5], [6]. One reason could be the potential that robotic measures of motor impairment, such as movement smoothness, have poor construct validity. In other words, the tasks used to assess movement smoothness could mischaracterize the observed motor impairment such as if movement smoothness was impacted by range of motion (ROM), limiting the ability of these metrics to accurately quantify motor impairment.

Movement smoothness is a commonly used metric in robotic assessment of upper limb functionality [2]. Prior work suggests that movement smoothness increases with stroke recovery as sub-movements become blended [7], and movement smoothness has been shown to positively correlate with clinical assessments of stroke [8], [9]. Tasks for assessing movement smoothness typically consist of goal-directed movements performed through planar reaching or point-to-point movement. These assessments typically use either fixed placement of targets, or they scale the placement of targets according to an individual's range of motion (ROM). Across prior studies, there is a lack of consistency in implementation of fixed or scaled targets during robotic assessment. The impact of the decision to fix or scale the placement of targets on movement smoothness remains unexplored in the literature. Understanding the impact of fixed and scaled targets on movement smoothness is the first step toward improving assessment of motor impairment by determining which paradigm provides smoothness measurements that are more strongly correlated with motor recovery.

We hypothesize that using a fixed placement of targets in the robot's workspace that may exceed an individual's ROM could conflate assessment of their movement smoothness with ROM. ROM impairment in the upper limb is a frequent motor deficit of in movement disorders such as stroke [10]. If an individual is unable to reach all fixed placement targets during goal-directed movements, the assessed movement smoothness may not accurately reflect their movement characteristics. This coupling would negatively impact the construct validity of movement smoothness assessment since its intent is to gauge motor coordination. We additionally hypothesize that scaling target placement to an individual's

(a) (b)

Fig. 1: (a) In the study, neurologically-intact participants donned a wrist brace to simulate the ROM deficits common to stroke survivors. The image shows the neutral wrist position of the OpenWrist robotic device, which has 3 serial revolute joints aligning with the anatomical degrees of freedom (DOF) passing through the wrist: pronation-supination (PS), flexion-extension (FE), and radial-ulnar (RU) deviation. In the current study, only FE and RU axes were used for the wrist pointing task. (b) Participants view a series of target locations and their current location on a computer monitor. The red circle is the participant's current location, computed from the FE and RU joint angles of the OpenWrist. The current target location is indicated by a green circle. During wrist pointing, users made goal directed movements by visually overlapping the red circle representing their wrist orientation with the green circle representing the target position.

ROM could decouple ROM from assessment of movement smoothness by ensuring that targets lie within an individual's reachable workspace.

In this study, we evaluate the aforementioned hypotheses to determine the effects of these two target placement methods on the construct validity of movement smoothness assessment. To this end, we conduct an experiment where neurologically-intact individuals perform wrist ROM assessments and wrist pointing tasks in a wrist and forearm exoskeleton, the OpenWrist [11]. Participants perform these tasks with and without a wrist brace donned to simulate the ROM deficits of stroke survivors. The choice to use neurologically-intact individuals wearing a wrist brace limits additional motor deficits, such as poor coordination, that frequently accompany stroke and could confound movement smoothness assessment [10]. To evaluate these hypotheses, our experiment addresses three aims: First, we seek to quantify the effect of constraining wrist motion with a wrist brace. Second, we quantify the percent of successful (complete) target acquisitions with a wrist brace donned with and without ROM-scaled target placement. Third, we quantify the effect of target location on movement smoothness measured via spectral arc length (SPARC). The outcomes of this experiment are used to inform guidelines for the creation of future movement smoothness assessments.

II. Methods

We conducted a series of experiments to assess the effect of limited range of motion on movement smoothness when performing goal-directed reaching movements with the wrist. Neurologically-intact participants performed point-to-point reaching movements using the Rice OpenWrist [11] to move a cursor on a screen to various target locations. Participants used both wrist flexion-extension (FE) and radial-ulnar (RU) deviation to reach targets. We constrained movements using a wrist brace, and we varied the mapping of the user's range of motion to the various target locations. Our dependent variable was movement smoothness, which was quantified by the metric spectral arc length (SPARC) [7].

A. Participants

Eight neurologically-intact participants (5 female, 3 male) with an age range of 20-30 years old ($\mu = 25.8$ yr, $\sigma = 3.5$ yr) with limited or no experience with wrist pointing tasks were enrolled in the experiment. Participants were right-hand dominant or ambidextrous (7 right-handed, 1 ambidextrous). Each participant completed the experiment and provided informed consent in compliance with Rice University's Institutional Review Board, protocol number IRB-FY2023-48.

B. Apparatus

The device used in this study was the OpenWrist, a serial manipulator for wrist rehabilitation and assessment [11]. This exoskeleton contains three revolute joints that facilitate three degrees of freedom of wrist movement: forearm pronation-supination (PS) (locked during this experiment), wrist flexion-extension (FE), and wrist radial-ulnar (RU) deviation (Fig. 1a). An additional linear slider on the hand grip allows for passive movement to abate joint misalignment. Prior studies on the movement impedance of the OpenWrist have validated it as a measurement device when using spectral arc length to assess movement smoothness [12]. Control of the OpenWrist and measurement of joint angles were executed using C++ and a Q8 USB data acquisition device (Quanser) running at a sampling rate of 200 Hz. Wrist FE and RU deviation joint angles were measured with a resolution of 0.0094º and 0.0070º respectively, using Broadcom HEDL-5540 A11 optical encoders on each of the Maxon DC motors driving each joint. Velocity of each joint was estimated through the Q8's instantaneous velocity

estimator. The OpenWrist has a wrist FE ROM of 1.2217 rad (70º) in flexion and 1.1345 rad (65º) in extension, along with a RU ROM of 0.6109 rad (35º) in radial deviation and 0.6981 rad (40º) in ulnar deviation.

To mitigate misalignment of participants' anatomical wrist joint axes with the OpenWrist, the device orientation was adjusted for each participant. Participants were instructed to maintain comfortable standing posture while the OpenWrist's height was adjusted via a standing desk to rest the participant's elbow on the OpenWrist's elbow support with both shoulders level. Afterwards, the participants were guided to adjust their position in the OpenWrist to achieve neutral forearm pronation-supination, 90 degrees of elbow flexion, and slight shoulder abduction. To limit deviation in grip or forearm position during the experiment, the hand and forearm of each participant was secured to the OpenWrist with self-adhering medical tape. Alignment of the participant and device joint axes was maintained through verbal feedback aimed at minimizing compensatory movements throughout the experiment.

To visually guide ROM assessment and wrist pointing, a graphical user interface (GUI) was used to display FE and RU deviation joint angles (Fig. 1b). Output from the optical encoders was scaled by a constant factor to map FE and RU deviation to the x and y axes, respectively.

C. Task Description

Participants were asked to manipulate the OpenWrist handle to move the cursor on the screen. The tasks comprised an assessment of their ROM and an evaluation of movement smoothness (measured with SPARC) as they completed wrist pointing movements to various targets in the workspace.

1) ROM Assessment: The purpose of ROM assessment was to capture the maximum and minimum joint angles of each participant in wrist flexion-extension (FE) and radial-ulnar (RU) deviation. Assessment consisted of 2 blocks, the first to assess FE ROM and the second RU deviation ROM. Each block was comprised of 3 trials, each with a duration of 20 seconds. Participants began each trial with their wrist in a neutral position (0º FE, 0º RU deviation). During each trial, participants were asked to sweep back and forth as far as they could in the FE or RU direction while the other DOF was held in a fixed location (via active PD control on the joint). Absolute minimum and maximum joint angles during the trial blocks were selected for each joint axis.

2) Wrist Pointing: The purpose of the wrist pointing tasks was to measure the completion or incompletion of each goal-directed wrist movement along with movement smoothness. Assessment consisted of 3 identical blocks of 40 trials of wrist pointing movements. The number of blocks and trials was determined from pilot testing to provide a sufficient number of trials for data analysis while mitigating mental and physical fatigue. Participants began each block with their wrist in a neutral position (0º FE, 0º RU deviation) and targets on the GUI then alternated between being placed away from neutral and returning to neutral. They were instructed to acquire each target within 6 seconds by moving directly to the visual target. If targets were acquired within 6 seconds, the trial was counted as complete and the next target appeared. Conversely, if a target was not acquired within 6 seconds, the trial was counted as incomplete and the next target appeared. The 6 second time window was determined from pilot testing to provide ample time to reach targets while minimizing buildup of fatigue in participants trying to reach targets outside of their wrist ROM.

D. Target Location Scaling

For the wrist pointing with fixed target locations, target positions were distributed within a square 2D coordinate space extending 0.4 rad (22.9º) in the positive and negative FE and RU deviation axes. During ROM-scaled target placement phases, the target locations used in fixed target placement were scaled according to minimum and maximum joint angles in FE and RU deviation. To calculate the position of the ROM-scaled targets, the fixed placement target positions were scaled to 75 percent of minimum and maximum joint angles assessed during the brace-on phase for ROM assessment (1).

$$\theta_{scaled} = 0.75 \cdot \theta_{fixed} \cdot \frac{0.8}{\theta_{max} - \theta_{min}} + \frac{\theta_{max} - \theta_{min}}{2} \quad (1)$$

The 75 percent scaling was chosen to limit changes in movement smoothness resulting from increased stiffness experienced close to wrist ROM limits with the brace donned.

E. Experiment Design

The experiment consisted of two phases of ROM assessment (R) that varied the brace-on condition (B1-on or B0-off) and four phases of wrist pointing (W) that varied the brace-on condition (B1-on or B0-off) and target placement method (S-scaled or F-fixed) to address our three aims.

To address our first aim, ROM assessment was conducted in two conditions, one with the brace on (RB1) and one with the brace off (RB0), to determine the effect of the wrist brace on ROM. Wrist pointing was conducted with the wrist brace off (WB0F) and wrist brace on (WB0S) to determine the effect of the wrist brace on movement smoothness, measured via SPARC. Additionally, the wrist brace-on condition of ROM assessment was used to determine the appropriate scaling factors for target placement during wrist pointing. To address our second aim, we quantify the number of targets achieved in the brace-on condition during wrist pointing with both ROM-scaled (WB1S) and fixed (WB1F) target placements. To address our third aim, we evaluate movement smoothness for four different conditions. First, we evaluate the effect of target location on SPARC (WB0S vs. WB0F). Then, we evaluate the effect of target completion on SPARC (WB1S vs. WB1F).

The phases and conditions of the experiment were presented in four different orders (O1, O2, O3, and O4) in a counterbalanced manner to mitigate the effects of training on the average performance of each section across the participants (see Table I). Participants were evenly distributed among the 4 experiment orders. Counterbalancing between

the brace-on (B1) and brace-off (B0) wrist pointing conditions was not implemented due to observed difficulties during pilot testing in reproducing ROM limitations due to donning and doffing of the wrist brace. Prior to starting the experiment, participants completed a familiarization period for wrist pointing tasks comprised of one WB1S block and one WB1F block. A short break was provided between phases 3 and 4 to minimize participant fatigue.

TABLE I: Experiment Phase Orders

Order	Brace On			Brace Off		
	1	2	3	4	5	6
O1	RB1	WB1S	WB1F	RB0	WB0S	WB0F
O2	RB1	WB1F	WB1S	RB0	WB0S	WB0F
O3	RB1	WB1S	WB1F	RB0	WB0F	WB0S
O4	RB1	WB1F	WB1S	RB0	WB0F	WB0S

[R-ROM assessment, W-Wrist pointing, B1-Brace on, B0-Brace off, S-scaled target locations, F-Fixed target locations]

Brace-on ROM assessment was implemented first for each order since the ROM value for constrained wrist pointing movements was needed to calculate the ROM-scaled target placement. To minimize brace donning and doffing, all brace-on conditions were conducted first, followed by all brace-off conditions. This approach served to address observed issues with ROM measurement reproducibility during pilot testing after repeat donning and doffing of the wrist brace.

F. Data Analysis

Movement smoothness for each of the individual wrist pointing trials was calculated using SPARC [7]. While many metrics to quantify movement smoothness exist, SPARC performs favorably in simulations of harmonic disturbance, change in movement duration and distance, and measurement noise [13]. SPARC calculates movement smoothness as the negative arc length of the Fourier magnitude spectrum within a selected frequency range:

$$SPARC = -\int_0^{\omega_c} \left[\left(\frac{1}{\omega_c} \right)^2 + \left(\frac{d\hat{V}(\omega)}{d\omega} \right)^2 \right]^{\frac{1}{2}} d\omega \quad (2)$$

where $\hat{V}$ is the normalized Fourier magnitude spectrum of the velocity profile (3), and ω_c is the cutoff frequency (4) with a max of 10 Hz.

$$\hat{V} = \frac{A(\omega)}{A(0)} \quad (3)$$

$$\omega_c \triangleq min\ \{w_c^{max}, min\ \{\omega, \hat{V}(r) < \overline{V}\ \forall\ r > \omega\ \}\ \} \quad (4)$$

As movements become less smooth, the number of the peaks in the normalized Fourier magnitude spectrum increase. These additional peaks indicate more distinct sub-movements and increase the magnitude of the negative arc length.

Statistical analysis of the practical equivalence of movement smoothness distributions was performed using a Region of Practical Equivalence (ROPE) test [14]. To conduct this test a ROPE was defined. Any difference in measurment falling within the ROPE was considered negligible. We selected ROPE values to be 0.2 times the standard deviation of the test data, assuming that an effect size of ≤ 0.2 is small or negligible, based on recommendations from Cohen [14]. We used a 95% credible interval for these tests.

Statistical comparison of the difference in movement smoothness distributions was performed with a Mann-Whitney U test [15]. A p-value less than 0.05 was chosen as the standard for establishing significance.

III. Results and Discussion

We analyzed wrist ROM in FE and RU deviation with and without the wrist brace, achievement of targets during wrist pointing, and movement smoothness measured with SPARC during wrist pointing. These data highlight and address our three aims. First, we quantify the effect of restricting wrist motion with a wrist brace. Second, we quantify the effect of scaling target placement on successful target acquisition during wrist pointing with a wrist brace donned. Third, we quantify the effect of target location and wrist motion constraint on movement smoothness.

We compared wrist ROM in FE and RU deviation assessed during RB0 (brace on) and RB1 (brace off). Then, we compared the effect of donning the wrist brace on movement smoothness during WB1S and WB0S. The data presented in Table II suggest that the wrist brace was effective in constraining wrist motion.

TABLE II: Mean ROM for Wrist FE and RU Deviation

	FE Min	FE Max	RU Min	RU Max
RB0	-0.474 rad	0.574 rad	-0.428 rad	0.496 rad
RB1	-0.842 rad	0.962 rad	-0.727 rad	0.563 rad

It should be noted that some participants saturated the ROM of the OpenWrist during ROM assessment, preventing discernment of the actual amount by which the wrist brace reduced ROM.

The effect of the wrist brace on movement smoothness was evaluated using the distribution of movement smoothness for complete target acquisitions during WB1S and WB0S as shown in Fig. 2. Incomplete target acquisition trials were omitted from the comparison, since we hypothesized that movement smoothness would be altered for trials in which the targets were not successfully acquired.

Mean SPARC values for the wrist brace on versus off conditions were similar, but the distribution of SPARC values for these two conditions were significantly different with a p-value less than 0.001. Therefore, while the wrist brace effectively constrained wrist movements, there was a significant difference in movement smoothness between the conditions.

Next, we evaluated the effect of target placement scaling on the percent of successful target acquisitions during wrist pointing (WB1F vs. WB1S), with results presented in Fig. 3. The mean percentage of target locations reached during fixed and ROM-scaled target location wrist pointing was 92.3 % and 98.2 %, respectively. For some participants, the ROM

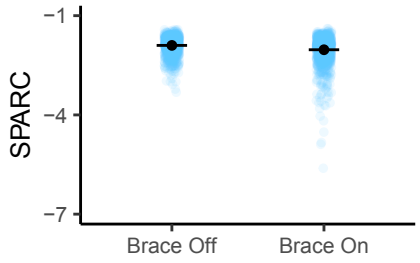


Fig. 2: SPARC values for successful target acquisition movements during WB1S and WB0S. Mean values of SPARC for brace off and brace on target acquisitions were -1.899 and -2.073, respectively.

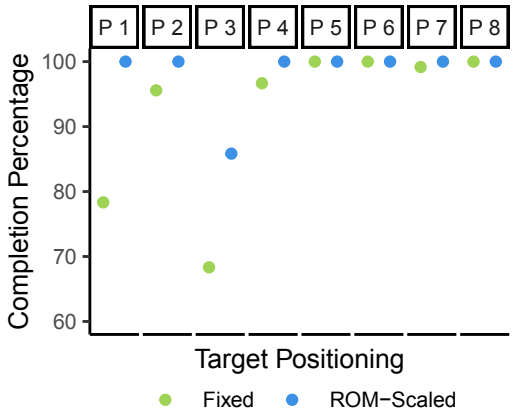

Fig. 3: Percentage of targets reached during WB1F and WB1S for each participant (P1 to P8). P1 and P2 completed the experiment in order O1, P3 and P4 in O2, P5 and P6 in O3, and P7 and P8 in O4 (Table I).

constraints imposed by the brace during both conditions were insufficient to prevent complete target acquisition of any targets. However, scaling target location to ROM improved the percentage of targets reached for participants who were unable to acquire all fixed location targets and had not saturated the mechanical constraints of the OpenWrist.

One participant (P3) exhibited incomplete target acquisitions despite implementation of ROM-scaled target locations. It was noted during the experiment that the proportion of their ROM in combined wrist FE and RU deviation (diagonal movement) to their assessed wrist ROM along the FE and RU axes was lower than other participants. Differences in the shape of their wrist ROM and that of the average wrist ROM defined by Crisco, et. al [16] are likely responsible for their 85.3 % target completion during WB1S. Even with scaled target locations, the corners of the rectangular bounds of the target pattern (as seen in Fig. 4) could exceed their wrist ROM. It is possible that saturation of the mechanical ROM of the OpenWrist by some participants limited additional cases of wrist ROM shape mismatch. Failure to acquire targets due to wrist ROM shape mismatch could be minimized by scaling a target pattern that more closely reflects the wrist ROM defined by Crisco, et. al [16]. Alternatively, replacement of both the FE and RU ROM assessments with a circumduction task that captures a continuous wrist ROM profile could be used to map target placement to a personalized wrist ROM.

To examine the effect of both target locations and ROM-scaling on task completion, the location and number of target incompletions during WB1F and WB1S were evaluated. Sample results for participant 1 are shown in Fig. 4.

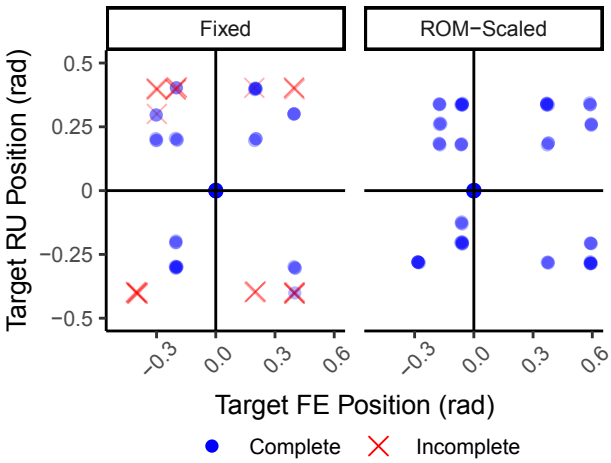

Fig. 4: 3 blocks of 40 trials each are plotted for both wrist pointing conditions. Participant 1 reached 78.3 % of fixed target locations and 100 % of ROM-scaled target locations.

For wrist pointing with fixed target locations, there was a higher proportion of task incompletion for target locations that were farther from the center (diagonally located). When wrist pointing was performed with scaled target locations in both the FE and RU directions, there was an increase in the number of successful target acquisitions.

Finally, we compared the effect of scaling target locations on movement smoothness calculated with SPARC (using data from WB0F and WB0S). The distribution of SPARC measures from successful (complete) target acquisition trials is shown in Fig. 5.

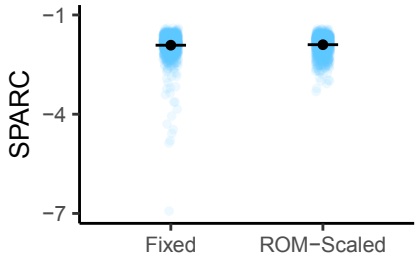

Fig. 5: Mean values of SPARC for target acquisition of fixed and ROM-scaled target locations were -1.914 and -1.899 respectively.

Using the ROPE (region of practical equivalence) test, we showed that the two distributions were practically equivalent when targets where successfully acquired. Thus, during wrist pointing, movement smoothness measured from ROM-scaled

target locations can be used in place of movement smoothness measured from fixed target locations.

To compare the effects of target incompletion on movement smoothness, the distribution of movement smoothness measured from complete and incomplete target acquisition during WB1S and WB1F are shown in Fig. 6.

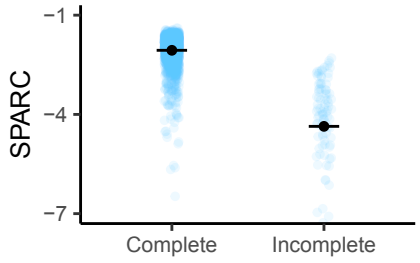

Fig. 6: Mean values of SPARC for complete and incomplete target acquisition were -2.062 and -4.361 respectively.

Differences in movement smoothness distributions were assessed with a Mann-Whitney U test, resulting in a p-value of 0.008 which met the criteria for statistical significance. This supports our hypothesis that the use of goal-directed movements with target locations placed outside of an individual's workspace conflate assessment of movement smoothness with ROM.

Based on our findings, we propose that movement smoothness assessments should implement target locations that are scaled to an individual's ROM. Given that assessments for determining ROM are common among robotic assessments of upper limb functionality [2], the barrier for implementing ROM-scaled target locations is relatively low. Additionally, we recommend that the pattern of targets used for goal-directed movements should reflect the shape of the average individual's ROM. Future work should investigate whether improvements in the construct validity of movement smoothness assessments from ROM-scaled target locations improves how well movement smoothness tracks functional recovery.

IV. Conclusion

Movement smoothness is a commonly used metric for gauging motor impairment during robotic assessments of upper limb functionality employed in rehabilitation. Heterogeneity of placement methods for target locations in goal-directed movements used in movement smoothness assessment calls into question the effect of target location. In this paper, we evaluated the effects of target location and completion on movement smoothness and target completion with and without ROM-scaled target locations. Neurologically-intact individuals donned a wrist brace to simulate ROM-limitations of individuals with stroke, limiting the additional motor deficits that frequently accompany stroke. The wrist brace was found to be effective for constraining wrist ROM in FE and RU deviation, but imposed slight, significant changes in movement smoothness. As expected, we found that failure to reach targets due to ROM limitations had a significant effect on movement smoothness, worsening the construct validity of movement smoothness assessment. Scaling target locations with ROM increased the proportion of targets acquired, while producing practically equivalent movement smoothness to complete target acquisition of fixed target locations. Based on these findings, we conclude that target locations for movement smoothness assessments should be scaled according to an individual's ROM.

Modeling and Estimation of Stiffness Imposed by Cable-based Exosuits

Randheer Singh[1] and Vineet Vashista[2]

Abstract— **Cable-based exosuits are one of the prevalent choices for rehabilitation, among others. These exosuits are redundant in nature and are capable of imposing a desired joint torque along with a specific impedance simultaneously due to redundancy. The exosuit imposed impedance majorly depends on the geometric routing of the cables and tension in cables. Therefore, the resulting stiffness and damping imposed onto humans could be different from what is intended for a musculoskeletal system of generalized anthropometry. Thus, modeling and estimating the impedance imposed by a cable-based exosuit is of utmost importance for the design and development of efficient and effective rehabilitation exosuits. The current work developed a framework to estimate stiffness imposed by a passive cable-based exosuit onto a human arm. To test the framework, an experiment was conducted on two participants, and the joint space and task space stiffness was estimated using the developed framework. The results indicate that during the design of routing, the geometry is more important than the cable tension. Furthermore, for the same cable routing, the imposed stiffness differed in magnitude for both participants. The developed framework can be even more beneficial in the design of complex and nonintuitive cable routing.**

I. INTRODUCTION

The human musculoskeletal system enables the desired motion of a limb by planning the trajectory and generating the necessary joint dynamics (i.e., torques and impedance) [1]. However, musculoskeletal disorders arising from neural and motor disability can potentially compromise this capability [2], [3]. Rehabilitation, by applying external dynamics to the disabled limb, is one of the most conventional approaches to improve motor and neural control. Recently, robot-based rehabilitation has also shown potential for the motor recovery of disabled limbs, along with conventional physiotherapy [4]–[8]. The robot imposes predefined dynamics onto the targeted limb, mimicking a physical interaction similar to a physiotherepist.

The rehabilitation robots typically apply force and torque either depending on the limb's task space trajectory or based on a particular joint's biological reference torque depending on body weight. Similarly, in other cases, the dynamics is imposed based on joint kinematics to impose a predefined impedance on the particular joint [4], [5], [7], [9]–[11]. The two categories of robots, rigid link and cable-based exosuits [12], are the most widely used for rehabilitation. The cable-based exosuits are redundant and can impose diverse impedances onto human limbs for the same joint torque due to redundancy. The imposed stiffness and damping could vary due to the different anthropometry of the user, the type of cable routing, the magnitude of tensions in the cables, and the impedance of the cable passive elements [13].

Furthermore, depending on the physiological parameters, each human perceives the imposed dynamics differently since the segment lengths would result in different moment arms. Eventually,the resulting stiffness and damping imposed onto humans could differ from what is intended for a musculoskeletal system of generalized anthropometry. Moreover, the type of imposed dynamics plays an important role since humans adapt differently when subjected to the same magnitude of external torques, but different impedances (i.e., stiffness and damping) are imposed [14]–[16]. Therefore, estimating the imposed external dynamics as impedance during a physical interaction is vital for designing efficient and effective rehabilitation solutions. However, modeling exosuit-imposed dynamics as impedance has not been fully explored, and very little work has been done to estimate the imposed external dynamics as impedance [17] during the physical interaction of the human arm.

The objective of the current work was to develop a framework to model and estimate the exosuit imposed stiffness and map it to the human arm anatomical joints. To achieve this, a passive exosuit is used to apply different force fields onto the arm during planar motion. The exosuit is capable of altering the imposed dynamics by allowing to have different routings of the cables. Further, an experiment was performed on two participants to test the developed framework, and the imposed stiffness was quantified and mapped onto the arm anatomical joints.

II. METHODS

The current study aims to model and estimate the dynamics imposed by a cable-based exosuit during physical interaction tasks. A passive exosuit is used to achieve it, which applies force on the arm segments that eventually result in joint torques and impedance onto the arm. It is worth noting that throughout the remainder of the article, the impedance should only be understood as the imposed stiffness by the exosuit as damping and inertia are ignored due slow movement and low weight of the exosuit.The imposed stiffness by the passive exosuit onto the human arm was estimated by utilizing a redundant system stiffness formulation to model the imposed stiffness [13]. Human experiments were performed with a passive exosuit to mimic a physical interaction task for the human arm.

A. Experimental Setup

The passive exosuit contains a table-based platform that consists of mounted grooved pullies through which the cables are routed. A typical steel cable is connected at one end onto the human arm through a polypropylene brace and passes over the pullies. The cable is connected to a spring and a constant weight at the other end, as shown in Fig.1. The cable routings are used in four configurations: C1, C2, C3, and C4, as depicted in Table I. The system resembles a passive exosuit since the cables can be routed in any of the configurations mentioned in Table I. The kinematics is recorded using the motion capture system (vicon, UK), and the external force exerted by the cables during the interaction trials is recorded using the load cell sensors (Futek, USA).

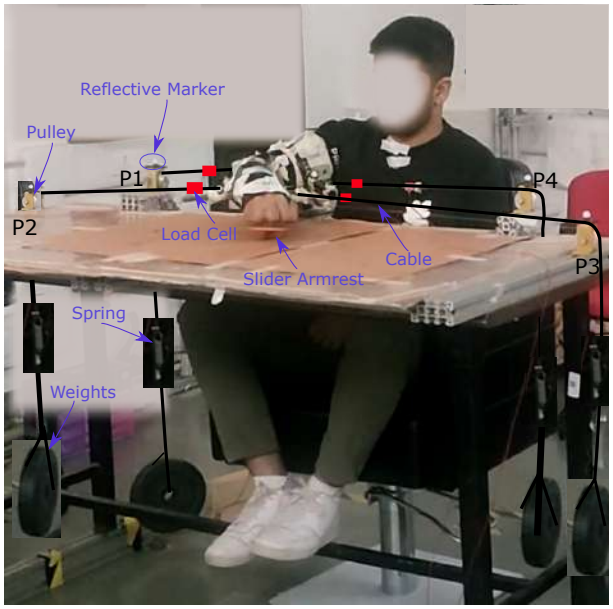

Fig. 1. A representative picture of the participant for configuration C1. The cables attached to the arm brace pass through a pully and eventually terminate with a spring in series holding a weight. Also, load cells are connected in series to measure the cable tensions.

The cable routings are chosen to impose diverse stiffness on the human arm, as shown in Fig. 2. The two of the routings, C3 and C4, are single-joint intervention routings, and the other two, C1 and C2, are multijoint routings, as shown in TableI.

TABLE I

CONFIGURATION DEFINITION BASED ON THE CABLES USED IN THE EXOSUIT EMULATOR

Configuration ID	Cables used	Affecting Joints
C1	All	both
C2	only 2 and 3	both
C3	only 1 and 2	only Shoulder
C4	only 5	only Elbow

B. Imposed Dynamics Modeling

The mathematical formulation of the imposed stiffness is modeled assuming the exosuit is a serial chain multibody system having two serially connected rigid links. The link lengths are assumed equal to the arm limb segments and the joints coincide with the arm joints. The cables, along with the springs, are considered actuators of this redundant system. In the remainder of the article, the exosuit manipulator refers to a two-link serial chain cable-driven manipulator. The dynamics of such a system can be derived using the Lagrangian approach [18], [19].

$$\frac{d}{dt}\Big(\frac{dL}{d\dot{\theta}_i}\Big) - \frac{\partial L}{\partial \theta_i} = \tau_i, i = 1, ..., n \tag{1}$$

Where L represents the Lagrange, θ_i is the generalized coordinate, and τ_i is external joint torque at i^{th} joint. Now, the joint torques generated at i^{th} joint by j^{th} cable having a tension, T_j, can be represented by Eq. (2).

$$\tau_i^c = \Big(\hat{l}_j \cdot \frac{\partial \vec{r}_j}{\partial \theta_j}\Big) T_j, where \;\; \vec{l}_j = \vec{M}_j - \vec{r}_j \tag{2}$$

M_j in Eq. (2) represents the pulley position, r_j represents the location of connection point of j^{th} cable on i^{th} link, and T_j represents the force applied by the j^{th} cable. Now, for the current system *m* cables and *n* joints, the mapping between joint torques and cable tension is given by Eq. (3).

$$\underbrace{\begin{bmatrix}\tau_1\\ \tau_2\\ \vdots\\ \tau_n\end{bmatrix}}_{\tau} = \underbrace{\begin{bmatrix}(\hat{l}_1 \cdot \frac{\partial \vec{r}_1}{\partial \theta_1}) & (\hat{l}_2 \cdot \frac{\partial \vec{r}_2}{\partial \theta_1}) & \cdots & (\hat{l}_m \cdot \frac{\partial \vec{r}_m}{\partial \theta_1})\\ (\hat{l}_1 \cdot \frac{\partial \vec{r}_1}{\partial \theta_2}) & (\hat{l}_2 \cdot \frac{\partial \vec{r}_2}{\partial \theta_2}) & \cdots & (\hat{l}_m \cdot \frac{\partial \vec{r}_m}{\partial \theta_2})\\ \vdots & \vdots & \vdots & \vdots\\ (\hat{l}_1 \cdot \frac{\partial \vec{r}_1}{\partial \theta_n}) & (\hat{l}_2 \cdot \frac{\partial \vec{r}_2}{\partial \theta_n}) & \cdots & (\hat{l}_m \cdot \frac{\partial \vec{r}_m}{\partial \theta_n})\end{bmatrix}}_{A} \underbrace{\begin{bmatrix}T_1\\ T_2\\ \vdots\\ T_m\end{bmatrix}}_{T} \tag{3}$$

$$\tau = AT \tag{4}$$

The term τ is a $n \times 1$ column vector representing joint torques imposed by the passive exosuit during the interaction, and T is a $m \times 1$ column vector representing cable forces of the exosuit. Notably, for the current analysis, m depends on the configuration and has values 4, 2, 2, 1, respectively, for the configurations C1, C2, C3, and C4.

Since the task is planar, for simplifying the data representations, the imposed joint stiffness is represented only for shoulder elevation (ElvAngle) and elbow flexion/extension (EFE) degrees of freedom, resulting in a two 2×2 matrix in the joint space. For the remainder of the article, the shoulder will refer to the shoulder elevation degree of freedom. The elbow will refer to the elbow flexion-extension degree of freedom, and the stiffness should be interpreted as the exosuit imposed stiffness.

$$\begin{bmatrix}d\tau_s\\ d\tau_e\end{bmatrix} = \begin{bmatrix}K_{SS} & K_{SH}\\ K_{ES} & K_{EE}\end{bmatrix} \begin{bmatrix}d\theta_s\\ d\theta_e\end{bmatrix} \tag{5}$$

$$d\tau = \mathbf{K}_{\theta \mathbf{Exo}} d\theta \tag{6}$$

$\mathbf{K}_{\theta Exo}$ is an exosuit imposed multi-joint stiffness matrix that relates the imposed joint torque, $d\tau$, and angular deflection, $d\theta$. Elements K_{SS} and K_{EE} in Eq. (5) represent the imposed

shoulder and elbow joint stiffness. From the relation between A and τ in Eq. (3), we get Eq. (7). Further, using Eq. (6), Eq. (7) can be re-written as in Eq. (8).

$$d\tau = (dA)T + A(dT) \tag{7}$$

$$\mathbf{K}_{\theta\mathbf{Exo}} d\theta = (dA)T + A(dT) \tag{8}$$

$$dT = k_c dl \tag{9}$$

The cable stiffness can be expressed as in Eq. (9). Here, *dl* is a differential change in cable length resulting due to changes in cable tension, *dT*. k_c is a $m \times m$ diagonal cable stiffness matrix holding the spring stiffness values of each cable, k_c, along the diagonal. Subsequently, k_c for each spring can be estimated experimentally.

$$dl = -A^T(d\theta) \tag{10}$$

$$\mathbf{K}_{\theta\mathbf{Exo}} d\theta = (dA)T - Ak_cA^T d\theta \tag{11}$$

$$\mathbf{K}_{\theta\mathbf{Exo}} = \underbrace{\left[\frac{dA}{d\theta_1}T \quad \frac{dA}{d\theta_2}T \quad \cdots \quad \frac{dA}{d\theta_7}T\right]}_{\kappa_d} - \underbrace{Ak_cA^T}_{\kappa_c} \tag{12}$$

Equation 10 presents the relation between changes in cable length. *dl*, with change in joint angles, $d\theta$. By using Eq. (10) and (9), Eq (7) can be re-written as Eq. (11). Further, dividing both sides by $d\theta$ results in the expression for the imposed joint stiffness of the modeled multibody system as in Eq. (12). The matrix κ_d represents the effect of the rate of moment arm and cable tensions, and κ_c represents the effect of the spring stiffness and geometry on the overall joint stiffness $\mathbf{K}_{\theta\mathbf{Exo}}$ respectively.

The resistance required at the joints to resist this external perturbation can be written by equation (13),

$$dF = \mathbf{k_x} dx \tag{13}$$

using the virtual work principle as in Eq. (14), the endpoint force and the corresponding joint torques can be related.

$$\tau = \mathbf{J^T} F_{ext} \tag{14}$$

Where $\mathbf{J}$ is the exosuit manipulator Jacobian and F_{ext} is the external force at the endpoint of the exosuit manipulator. Subsequently, the task space stiffness of the model can be written using the Jacobian transformation from joint space to task space as represented in Eq. (15).

$$\mathbf{K}_{\mathbf{xExo}} = J^{\propto T}\left[\mathbf{K}_{\theta\mathbf{Exo}} - (\frac{\partial J^T}{\partial \theta})F_{ext}\right]J^{\propto 1} \tag{15}$$

$$\mathbf{K}_{\mathbf{xExo}} = \mathbf{J}^{\propto\mathbf{T}}\left[\mathbf{K}_{\theta\mathbf{Exo}}\right]J^{\propto 1} \tag{16}$$

For the case of no external force, F_{ext}, on the manipulator, the imposed task space stiffness of the arm model can be obtained from Eq. (16)

The passive exosuit system had springs in series along with the constant weight. The stiffnesses of the springs were estimated by hanging the weight and measuring the corresponding deflection. The passive exosuit cables 1, 2, 3, 4, and 5 have spring stiffness of $550, 460, 460, 550, 275$ N/m, respectively.

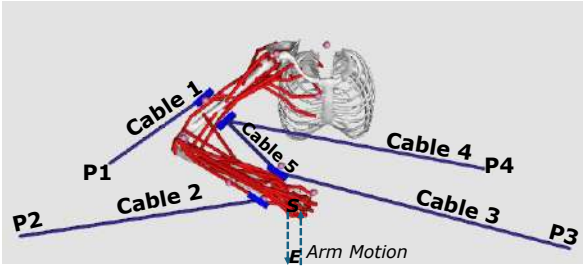

Fig. 2. The cables of the exosuit are modeled as muscles in OpenSim 4.1 to estimate the three-dimensional moment arm matrix and its derivative.

C. Estimation of Cable Moment Arms

An upper limb musculoskeletal model has been used to estimate the three-dimensional moment arms of the exosuit cables onto the arm anatomical joints and their derivatives during the task [20]. The flow of the data is depicted in Fig 3. A generic model is scaled used to estimate the joint kinematics of the arm using the standard inverse kinematics tool available in OpenSim [21]. During the experiment, the pulley position,and the point where the cables connect to the human arm were also recorded using reflective markers to determine cable force direction. Also, the cables were modeled as muscle and added to the scaled musculoskeleton model using an XML editor to estimate the approximate moment arms during the motion and are depicted in Fig.2. Only moment arms were estimated, and no dynamic analyses were performed in the OpenSim tool.The moment arms are extracted from the OpenSim 4.1 using the MATLAB (MathWorks, Natick, Massachusetts, USA) API method [22]. Also, the derivatives of the moment arm are numerically computed using a custom Matlab script using the central difference formula. Once these two quantities are computed, the structure matrix A and the derivative of the structure matrix with the joint coordinates $\frac{dA}{dq_i}$ are determined, and eventually, the three-dimensional imposed joint stiffness can be evaluated from the equation (12).

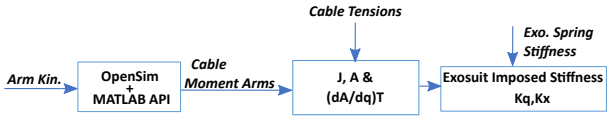

Fig. 3. The flowchart explaining the process to estimate exosuit imposed stiffness from the experimental data

D. Experimental protocol

The experiment was conducted on two healthy male participants (mean age: 28 years; weight: 67.5 kg; height: 171 cm). Participants were informed about the experimental procedure and signed a written consent form approved by the Institute Ethics Committee of the Indian Institute of Technology Gandhinagar (Identifier number: IEC/VV/2021/013) before participation. The participants were asked to sit in the chair, torso was firmly fixed to chair to avoid compensatory movement.Participant was instructed to trace a straight line

drawn on the table (to maintain uniformity of motion across participants) while the passive exosuit was connected to the human arm, as depicted in Fig 2. All the configurations were used in a random sequence, with different configurations in each trial, resulting in a total of four trials for each participant. The cable routing used for each configuration is depicted in Table I. The participants were instructed to trace a marked straight line on the table, reach the end point E, and return back to the starting point S as shown in Fig. 2 constituting a lap. Five such laps were performed by each participant, and the data was analyzed only for the third lap of each trial for each participant.

III. Results

All the trajectory samples are normalized and represented in a 0% to 100% range, as shown in Fig 4, where 0% is at the start of the trajectory, 50% is at the point E (fully extended arm) in Fig. 2, and 100% refers to the reaching back to the start point. The estimated joint stiffness and task space stiffness imposed by the passive exosuit onto the human arm at a single point (i.e., the $50\%^{th}$ Trajectory corresponding to point E in Fig. 2) for both the subjects and all the configurations are represented in Tables II and III, respectively.

TABLE II

Joint stiffness imposed by the passive exosuit onto the human arm. The values are at the 50% of the trajectory

	P1 :$K_{\theta Exo}(Nm/rad)$	**P2:** $K_{\theta Exo}(Nm/rad)$
C1	$\begin{bmatrix} /209.7240 & /101.3796 \\ /101.7724 & /53.6666 \end{bmatrix}$	$\begin{bmatrix} /106.2269 & /58.7875 \\ /57.2850 & /33.0859 \end{bmatrix}$
C2	$\begin{bmatrix} /185.7969 & /102.1495 \\ /102.3850 & /56.4579 \end{bmatrix}$	$\begin{bmatrix} /100.0407 & /60.8073 \\ /59.1132 & /35.3615 \end{bmatrix}$
C3	$\begin{bmatrix} /17.6669 & /0.0000 \\ /0.0000 & /0.0000 \end{bmatrix}$	$\begin{bmatrix} /6.0788 & /0.0000 \\ /0.0000 & /0.0000 \end{bmatrix}$
C4	$\begin{bmatrix} /0.0000 & /0.0000 \\ /0.0000 & /1.9121 \end{bmatrix}$	$\begin{bmatrix} /0.0000 & 0.0000 \\ 0.0000 & /2.6704 \end{bmatrix}$

The element $(1,1)$, $(2,2)$ and diagonal terms of the joint stiffness matrix denoted in Table II represent the shoulder elevation angle and elbow flexion-extension and coupling terms, respectively. Similarly, the elements $(1,1)$, $(2,2)$ and diagonal terms of the task stiffness matrix denoted in Table III represent the lateral and anterior-posterior(Ant-Post) and coupling terms, respectively. As expected during the single joint intervention configurations, $C3$ and $C4$ have no coupling terms in the imposed joint stiffness matrix; however, the imposed task space matrix has coupling terms for the same.

The joint stiffness can be divided into two components κ_C and κ_D representing the effect of cable tensions and geometry, respectively, as defined in the equation (12). The contribution of the cable tensions is much less as compared to the contribution of the geometry of the cable routings, as shown in Fig.4(a)-(f). This is due to the fact that dA/dq terms have very little magnitude, and even a higher magnitude of the cable tensions would result in less contribution to total joint stiffness as compared to the κ_C.

TABLE III

Task stiffness imposed by the passive exosuit onto the human arm. The values are at the 50% of the trajectory

	P1 :$K_{xExo}(N/m)$	**P2:** $K_{xExo}(N/m)$
C1	$\begin{bmatrix} /20.4199 & 114.4939 \\ 88.2816 & /19.9199 \end{bmatrix}$	$\begin{bmatrix} /36.6288 & 14.7282 \\ /3.4024 & 51.2419 \end{bmatrix}$
C2	$\begin{bmatrix} /5.5510 & 81.4191 \\ 61.0320 & 26.6057 \end{bmatrix}$	$\begin{bmatrix} 18.3495 & /20.1117 \\ /35.3627 & 58.6005 \end{bmatrix}$
C3	$\begin{bmatrix} /40.2956 & 18.4938 \\ 15.8039 & 10.8469 \end{bmatrix}$	$\begin{bmatrix} /33.5169 & 27.6373 \\ 28.7943 & /6.1885 \end{bmatrix}$
C4	$\begin{bmatrix} /30.1460 & 16.7266 \\ 16.7266 & /8.9128 \end{bmatrix}$	$\begin{bmatrix} /66.2173 & 38.7086 \\ 38.7086 & /22.0125 \end{bmatrix}$

The configurations C1 and C2 have four cables and two cables attached, respectively, but impose a similar magnitude of joint stiffness. Even though the C1 configuration has four weights attached to the arm as compared to C2, where only two weights are attached to the arm. Configuration C2 also imposes higher task space stiffness as compared to C1 for both participants in either direction, as shown in Fig. 5(a)-(f). This is due to the reason that in configuration C1, cables 1 and 4 are connected to the upper arm and do not have a larger moment arm, resulting in less contribution to the imposed joint stiffness, as shown in Fig. 4.

The single joint intervention routings (C3 and C4) do not impose coupling on the joints directly, as shown in Figs. 4(c) and (d); however, the task space stiffness contains coupling terms due to the coupled nature of the cartesian kinematics, as shown in Figs. 5(c) and (d). Hence, the participant perceives a coupled force field in task space during the task, even during the single joint intervention configurations (i.e., C3 and C4) were not intended to be coupled physically.

IV. Discussion

The primary objective of this study was to develop a computational framework for estimating the stiffness imposed by a cable-based exosuit onto human arm during physical interaction and map it to arm anatomical joints. The framework was successfully implemented and tested on two participants to analyze the role of geometrical stiffness κ_c and cable tension κ_d in determining joint stiffness. The results indicate that geometrical stiffness contributes more significantly to total joint stiffness than cable tension [13], and that imposed impedance varies based on user anthropometry. These findings demonstrate the effectiveness

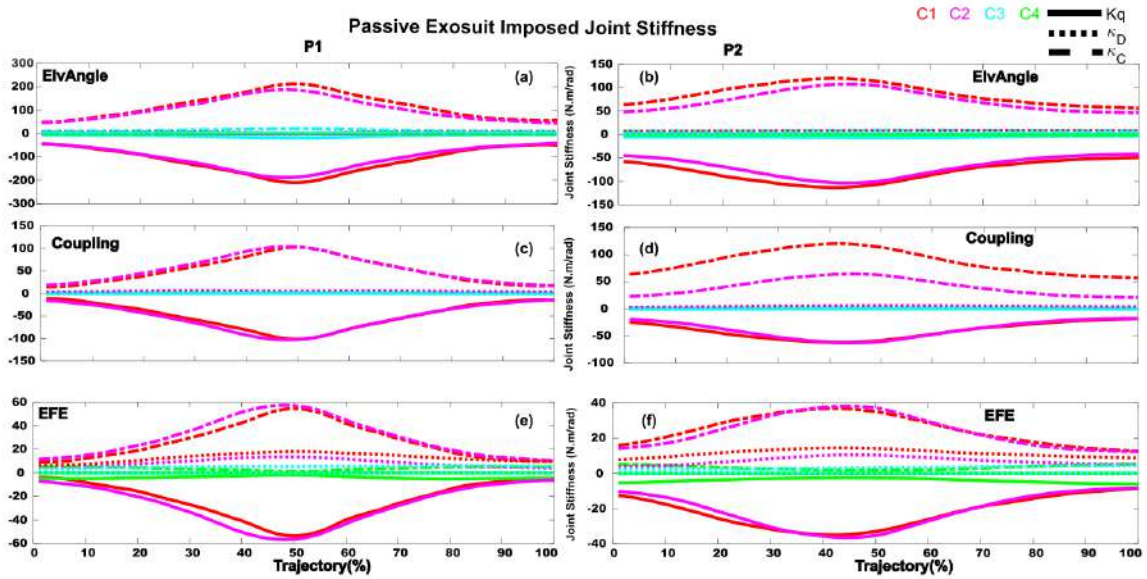

Fig. 4. Imposed joint stiffness by the passive exosuit onto the human arm. The values of κ_C are plotted using the dashed line, and the values of κ_D are represented using the dash-dot line. The configurations are denoted by the color of the configuration ID (i.e.,$C1, C2, C3$ and $C4$). The total joint stiffness is plotted using the solid line.

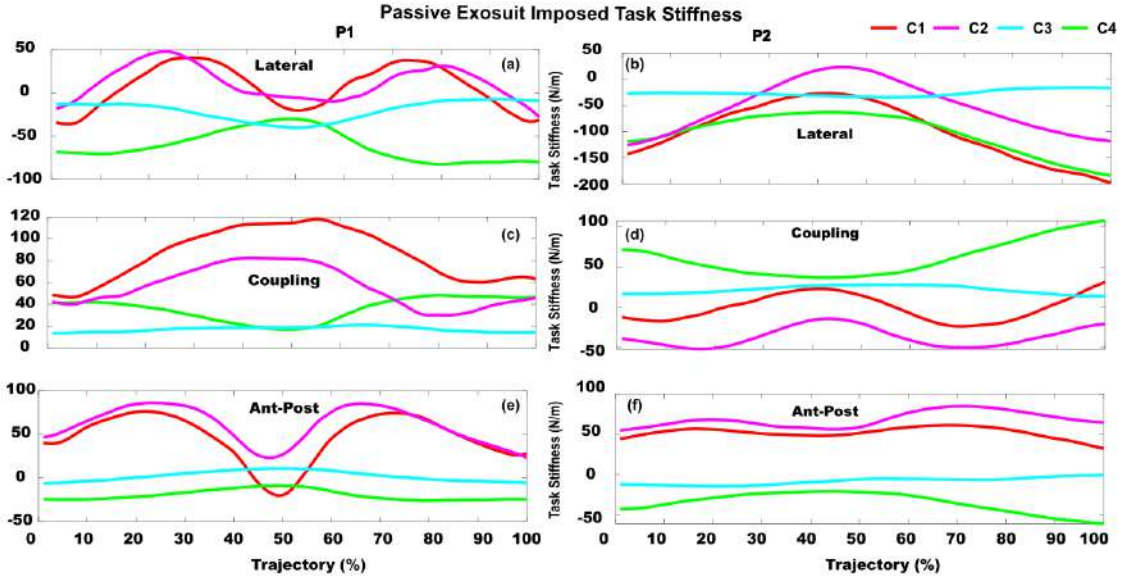

Fig. 5. Imposed task space stiffness by the passive exosuit onto the human arm. The configurations are denoted by the color of the configuration ID (i.e.,$C1, C2, C3$, and $C4$). The total task space stiffness is plotted using the solid line.

of the developed framework in quantifying exosuit-imposed stiffness changes.

The results show that configuration C2 imposes more stiffness in task space than C1, even though during the C1 configuration, the applied weight on the arm is double that of C2. This would probably be due to the cable tension having very little contribution to joint stiffness and cable routing having a larger effect on the imposed stiffness. So, Configuration C2 could potentially be a better option for imposing more stiffness in cartesian space. This also indicates that during the design of cable-based exosuits, the geometric routing should be given priority over the cable tensions.The single joint intervention routings do not impose coupling on the joints, as shown in Figs. 4(c) and (d); however, the task space stiffness has coupling terms due to the coupled nature of the cartesian kinematics, as shown in Figs. 5(c) and (d). The force field perceived by the participant would be of a coupled nature. This is important from a rehabilitation paradigm design perspective because the participant would react to the imposed dynamic

depending on what the participant perceives in the task space.

The framework also maps the stiffness imposed by the exosuit onto the arm anatomical joints . This mapping helps interpret the interaction force field in terms of imposed impedance. The results indicate that for identical configurations for participants 1 and 2, the exosuit imposed different joint stiffness on the arm joints .The difference would mean that the shoulder would be stiffer for P1 as compared to P2 during the same trajectory and the same exosuit, and if this were not to be taken care of, it would potentially result in different adaptions among the users [13], [17]. This would even strengthen the notion that the dynamics to be imposed onto participants by any cable-based exosuit should be modeled beforehand for all the participants and rehabilitation/intervention paradigms should be designed accordingly.Additionally, this framework holds significant potential for rehabilitation applications. Understanding how users perceive task-space stiffness is essential for designing motor training interventions that are tailored to individual needs. The ability to account for variations in stiffness due to geometric and anthropometric differences ensures that exosuits can be personalized to person spacific and joint specific inverventions.By accounting for variations in stiffness resulting from both geometric and anthropometric differences, the framework enables personalized exosuit designs that can be tailored to individual-specific and joint-specific rehabilitation interventions.

The framework was tested on only two participants, limiting the generalizability of the findings and future studies should include a larger and more diverse sample . Additionally, the framework was evaluated on passive exosuits with simple cable routings, and its application to active exosuits with dynamic control mechanisms remains unexplored. Future research should focus on integrating the framework into real-time control systems to enable dynamic, impedance-informed adjustments, enhancing human-exosuit interaction and performance [13].

Learning-based Estimation of Forward Kinematics for an Orthotic Parallel Robotic Mechanism

Jingzong Zhou,[1,†] Yuhan Zhu,[1,†] Xiaobin Zhang,[1,†] Sunil Agrawal,[2] and Konstantinos Karydis[1]

***Abstract*— This paper introduces a 3D parallel robot with three identical five-degree-of-freedom chains connected to a circular brace end-effector, aimed to serve as an assistive device for patients with cervical spondylosis. The inverse kinematics of the system is solved analytically, whereas learning-based methods are deployed to solve the forward kinematics. The methods considered herein include a Koopman operator-based approach as well as a neural network-based approach. The task is to predict the position and orientation of end-effector trajectories. The dataset used to train these methods is based on the analytical solutions derived via inverse kinematics. The methods are tested both in simulation and via physical hardware experiments with the developed robot. Results validate the suitability of deploying learning-based methods for studying parallel mechanism forward kinematics that are generally hard to resolve analytically.**

I. Introduction

Cervical spondylosis, a common source of neck pain caused by degenerative changes that start in the intervertebral discs, has been significantly affecting people over 30 years of age [1]. A study in testing the efficacy of intermittent cervical traction in patients with chronic neck pain has shown that 26% to 71% of the adult population experience an episode of neck pain in their lifetime [2]. Although neck pain has been reported to lead to a lesser degree of disability compared to back pain, the quality of life of patients is still severely affected by chronic symptoms [3]. To mitigate the long-term impact, effective management is thus crucial. Typical medical management includes pharmacological and rehabilitation components, with physical therapy playing a pivotal role for the latter [4]. A randomized clinical study that involved 60 patients with neck pain lasting for at least six months revealed that patients receiving physical therapy demonstrated greater improvement in pain relief and functional outcomes than those solely with drug treatment [5]. Controlled clinical trials have substantiated that extension traction as part of cervical spine rehabilitation can improve patients' quality of life [6]. To enhance accessibility and convenience, an assistive wearable neck brace presents a promising alternative for therapy. Such a device could offer patients consistent treatment and minimize the need to visit the hospital frequently.

Traction exercise neck braces, developed as a treatment for cervical spondylosis, aim to adjust the cervical vertebra structure to alleviate related neck pain [7]. Because of spatial restrictions in the head-neck region, parallel robots are particularly well-suited to deliver appropriate motion support while employing a compact structure. A notable example is a three-chain parallel robotic neck brace whereby each chain contains three joints (two revolute [R] and one spherical [S]) arranged in series (RRS) [8]. This design provides an assist-as-needed moment around the head-neck area, ensuring both safety and efficacy in a head movement training task [8]. Similarly, a study of a three degree-of-freedom (DoF) neck brace used a three-chain-RPUR parallel mechanism,[1] which was developed to relieve pain in the cervical spine by delivering an upward traction force [9].

However, operating a parallel robot can pose great challenges because of the complexity of its forward kinematics [10] and the often-times complete absence of closed-form analytical solutions. The intricate geometry and highly nonlinear dynamics of such robots result in non-unique solutions in most cases [11]. Although numerical solvers are commonly employed, their computational inefficiency may limit more widespread applicability, especially when in need to perform online computation on edge hardware [12]. Further, the solution of forward kinematics is often attained indirectly by solving inverse kinematics first and then inverting them locally, as demonstrated in studies with a two degree-of-freedom spatial parallel mechanism [13]. Motivated by these challenges, our work aims to employ data-driven methods to solve the forward kinematics based on solutions obtained from inverse kinematics.

One data-efficient yet powerful learning-based family of methods for robotic systems is Koopman operator theory, which has been gaining attention owing to its capacity to enable real-time learning and support data-driven control [14]. The Koopman operator is not nearly as data-intensive as most other machine learning techniques and takes much less time to train, making it a suitable candidate method for hardware with lower computation capabilities and requiring a higher update frequency. Koopman operator theory, along with methods to estimate the operator from data (such as the Extended Dynamic Mode Decomposition with control (EDMDc) [15]), has been applied in the modeling and control of various robotic systems [16]. Notable examples include the modeling and control of a tail-actuated robotic fish [17], trajectory control for micro-aerial vehicles [18], dynamics estimation for spherical robots [19], and model extraction for soft systems [20]. Koopman operator theory

[1] Recall that P stands for a prismatic joint and U for a universal one.

has also been applied to the trajectory tracking control of a three-soft-fingered mechanism for zero-shot grasping [21].

Deep neural networks provide a promising alternative to capture the non-linear relationship between the inputs (in the joint space) and the outputs (in the cartesian space) in forward kinematics [11], [22], [23]. The depth of deep neural networks can be flexibly adjusted, allowing different layers to capture varying levels of complexity in forward kinematics [24]. Some works have focused on deploying neural network-based methods for estimating the forward kinematics of various parallel mechanisms. For instance, Dehghani et al. proposed to solve the forward kinematics of parallel robot HEXA with a multilayer perceptron (MLP) [25], while Lee et al. used MLP as an estimator to capture the input-output relationship of the Stewart platform [26]. The Radial Basis Function (RBF) network was used in a hybrid robot for learning forward kinematics [12]. Prado et al. applied baseline neural networks to solve the forward kinematics of a wearable parallel robot [11].

In this paper, we first design and fabricate a three-chain Revolute-Revolute-Universal-Revolute (3-RRUR) parallel robot to provide traction support for patients who suffer from cervical spondylosis. The use of the RRUR structure for each chain is motivated by the need to enlarge the workspace compared to an earlier related work that used a Revolute-Prismatic-Universal-Revolute (RPUR) structure [13]. The inverse kinematics is first solved analytically (Section II) to generate data which are in turn used to train two distinct learning-based methods considered herein. Then, forward kinematics is estimated using the Koopman operator (Section III) and a recurrent neural network (RNN; Section IV). Extensive testing in simulation and via physical experiments (Section V) demonstrate the feasibility of both learning-based methods and offer insights as to when one method might be preferred over the other. This work provides a key step toward porting data-driven methods into robotic orthotics and establishes a basis for more Koopman operator-based methods to be investigated within this context. The contributions are summarized as follows:

- A 3-RRUR parallel robot is designed to support patients who suffer from cervical spondylosis. The physical and kinematics models are described in detail.
- Two data-driven methods, the Koopman operator and an RNN, and an analytical method, are deployed to solve the forward kinematics in simulation. To the best of the authors' knowledge, this is the first attempt to utilize the Koopman operator on a 3-RRUR parallel robot.
- A physical prototype of the parallel robot is fabricated and tested in the real world with the analytical method.

II. Analytical Kinematic Analysis

A. Physical Structure of the 3-RRUR Parallel Robot

The physical structure of the developed parallel robot is shown in Figure 1. The robot is composed of three chains. A kinematic description of each chain is shown in Figure 2. The joint centers in each chain are represented as S_i, K_i, Q_i, and E_i, $(i = 1, ..., 3)$ for joints $R_{1,i}$, $R_{2,i}$, U_i, and $R_{3,i}$, respectively. Each chain has five DoFs and provides one constraint to the end-effector frame, P. In total, the end-effector frame has three independent DoFs, which can be controlled by three rotary motors located on the first revolute joint of each chain, attaching them to the base plate characterized by frame O. In each chain, the axes of the first two revolute joints and one axis of the universal joint are chosen to be perpendicular to the plane in which the chain operates. The intersection of the other axis of the U_i joint and the axis of the third revolute joint $R_{3,i}$ is denoted by point A_i. Intersection points A_1, A_2 and A_3 form an intermediate plane. With the particular choice of geometric constraints, A_1 and A_3 stay in the same plane XZ ($^OA_{1y} = 0$, $^OA_{3y} = 0$), while A_2 stays in plane YZ ($^OA_{2x} = 0$).

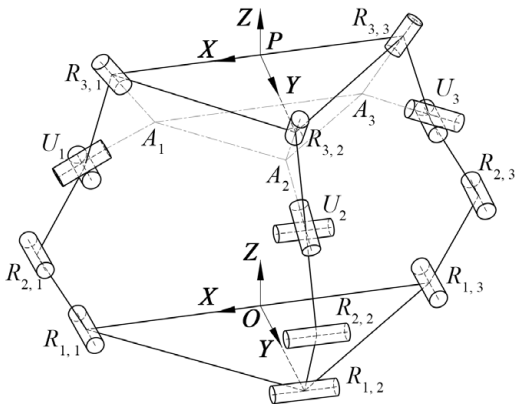

Fig. 1. Diagram of the developed 3-RRUR parallel robot.

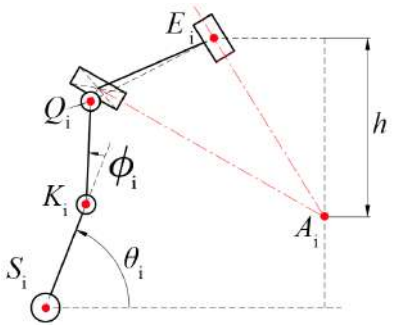

Fig. 2. Chain structure diagram of 3-RRUR parallel robot

B. Inverse Kinematics

Since the end-effector has three DoFs that can be independently controlled, we choose those DoFs that are directly related to head-neck motion as input to inverse kinematics. The three main head orientations to be supported by the mechanism are shown in Figure 3. The chosen DoFs are the z-translation, z_p, flexion/extension, β, and lateral bending, γ. The rest of the DoFs of the end-effector are accommodated based on the constraints once the aforementioned actuated DoFs obtain valid values. Here we choose Space-three 3-1-2 rotation matrix (1) to express the rotation between the base

Fig. 3. Description of three orientations of the head-neck aligned with the fixed base frame shown in Figure 1: (i) axial rotation, (ii) lateral bending, (iii) flexion and extension.

frame O and end-effector frame P, that is

$$R_O^P = \begin{bmatrix} s_\alpha s_\beta s_\gamma + c_\gamma c_\alpha & c_\alpha s_\beta s_\gamma - c_\gamma s_\alpha & c_\beta s_\gamma \\ s_\alpha c_\beta & c_\alpha c_\beta & -s_\beta \\ s_\alpha s_\beta c_\gamma - s_\gamma c_\alpha & c_\alpha s_\beta c_\gamma + s_\gamma s_\alpha & c_\beta c_\gamma \end{bmatrix} . \quad (1)$$

Each coordinate of A_i in the base frame can be written as

$${}^O A_i = [x_p, y_p, z_p]^T + R_O^P({}^P A_i) \ , \quad (2)$$

where $[x_p, y_p, z_p]^T$ represents the origin of the end-effector frame expressed in the base frame. Further, we have ${}^P A_1 = [r_A, 0, -h]^T$, ${}^P A_2 = [0, r_A, -h]^T$, and ${}^P A_3 = [-r_A, 0, -h]^T$. The axial rotation of the end-effector is equal to zero. Then,

$${}^O A_1 = \begin{bmatrix} x_p \\ y_p \\ z_p \end{bmatrix} + R_O^P({}^P A_1) = \begin{bmatrix} x_p + r_A c_\gamma - h c_\beta s_\gamma \\ y_p + h s_\beta \\ z_p - r_A s_\gamma - h c_\beta c_\gamma \end{bmatrix} \quad (3)$$

$${}^O A_2 = \begin{bmatrix} x_p \\ y_p \\ z_p \end{bmatrix} + R_O^P({}^P A_2) = \begin{bmatrix} x_p + r_A s_\beta s_\gamma - h c_\beta s_\gamma \\ y_p + r_A c_\beta + h s_\beta \\ z_p + r_A s_\beta c_\gamma - h c_\beta c_\gamma \end{bmatrix} \quad (4)$$

$${}^O A_3 = \begin{bmatrix} x_p \\ y_p \\ z_p \end{bmatrix} + R_O^P({}^P A_3) = \begin{bmatrix} x_p - r_A c_\gamma - h c_\beta s_\gamma \\ y_p + h s_\beta \\ z_p + r_A s_\gamma - h c_\beta c_\gamma \end{bmatrix} \quad (5)$$

where h and r_A are design constants of the parallel robot; h stands for the distance between plane $A_1A_2A_3$ and plane $E_1E_2E_3$, while r_A stands for the radius formed by circle $A_1A_2A_3$. Considering the geometry constraints, the x-translation, x_p, and y-translation, y_p, are expressed as

$$x_p = h c_\beta s_\gamma - r_A s_\beta s_\gamma \ , \quad (6)$$

$$y_p = -h s_\beta \ . \quad (7)$$

To solve for the joint variables θ_i and ϕ_i for each chain, we use

$$||{}^O Q_i(\theta_i, \phi_i) - {}^O E_i||^2 = l_{Q_i E_i}^2 \ , \quad (8)$$

$$||{}^O Q_i(\theta_i, \phi_i) - {}^O A_i||^2 = l_{Q_i A_i}^2 \ . \quad (9)$$

where $l_{Q_iE_i}$ and $l_{Q_iA_i}$ are design constants of the parallel robot, and ${}^O Q_i(\theta_i, \phi_i)$, $i = 1, ..., 3$, represent the joint coordinates in the base frame.

C. Forward Kinematics

Three sets of equations (each containing two functions f_1 and f_2) can be found after resolving the inverse kinematics. We can write these as follows (detailed expressions of those equations can be found in the appendix).

$$f_1(\theta_i, \phi_i, z_p, \beta, \gamma) = 0 \text{ and } f_2(\theta_i, \phi_i, z_p, \beta, \gamma) = 0 \ . \quad (10)$$

The unknown variables now are ϕ_1, ϕ_2, ϕ_3, z_p, β, and γ. Concerning the safety during the usage of the mechanism, we do not expect the mechanism to have "inward" or "elbow up" postures ($\theta_i < 90°$). Therefore, we are only interested in the solutions with $\theta_i > 90°$ from the inverse kinematics. Thus, those solutions from inverse kinematics should match the forward kinematics. Further, θ_i joint values obtained from the inverse kinematics, when sent as input to forward kinematics, should produce the same end-effector pose as in the inverse kinematics. To circumvent the complex procedure of solving the forward kinematics directly, data-driven approaches are introduced in the following sections.

III. Koopman-based Kinematics Estimation

A. Koopman Operator Overview

The Koopman operator efficiently learns the system's dynamics by lifting the original states to a latent space and capturing the flow of the lifted states (observables) with a finite number of linear functions. For an unforced system $x_{t+1} = f(x_t)$ with flow $\Phi(t, x)$ and complex-valued observables $\varphi \in \mathcal{F}$, the continuous time Koopman operator $\mathcal{K} : \mathcal{F} \to \mathcal{F}$ is defined as $(\mathcal{K}\varphi)(\cdot) = \varphi \circ \Phi(t, \cdot)$. Being linear, the Koopman operator can be characterized by its eigenvalues and eigenfunctions. A function ϕ is an eigenfunction of $\mathcal{K}$ if $(\mathcal{K}\varphi)(\cdot) = e^{\lambda t}\phi(\cdot)$, with λ being the corresponding eigenvalue [27]. The time-varying observable $\psi(t, x) = \mathcal{K}\varphi(x)$ is the solution of the PDE [28],

$$\begin{matrix} \frac{\partial \psi}{\partial t} = \mathcal{L}_f \psi \\ \psi(0, x) = \varphi(x_0) \end{matrix} \ , \quad (11)$$

where x_0 is the initial condition for the unforced system and $\mathcal{L}_f$ is the Lie derivative with respect to f.

A vector-valued observable $\mathrm{g}(\cdot)$ may be expressed in terms of Koopman eigenfunctions ϕ_i as $\mathrm{g}(\cdot) = \sum_{i=1}^{\infty} \phi_i(\cdot) v_i$, where v_i denote the Koopman modes. Koopman modes are obtained from the projection of the observable on the span of Koopman eigenfunctions. Then,

$$\mathcal{K}\mathrm{g}(\cdot) = \mathcal{K} \sum_{i=1}^{\infty} \phi_i(\cdot) v_i = \sum_{i=1}^{\infty} \mathcal{K}\phi_i(\cdot) v_i = \sum_{i=1}^{\infty} \lambda_i \phi_i(\cdot) v_i \ . \quad (12)$$

B. Implementation

Herein, the Koopman operator is utilized to learn the mapping from the motor angles, $\theta_1, \theta_2, \theta_3$, to end-effector angles β and γ, and translation z_p. The x- and y-translations can be then computed by (6) and (7). Suppose there are M sets of motor angles and corresponding end-effector poses. Let $X = [x_1, x_2, ..., x_M]$ denote the M motor angle states, where $x_j = [\theta_{j1} \quad \theta_{j2} \quad \theta_{j3}]^T, j = 1, 2, ..., M$, and

$Y = [y_1, y_2, ..., y_M]$ denote the corresponding M end-effector poses, where $y_j = [\beta_j \quad \gamma_j \quad z_{pj}]^T, j = 1, 2, ..., M$. For the lifting function design, which plays a crucial part in approximating the true system propagation model, we set

$$\begin{aligned}\Psi(x_j) =&(1, \theta_{j1}, \theta_{j1}^2, \sin\theta_{j1}, \cos\theta_{j1}) \otimes \\ &(1, \theta_{j2}, \theta_{j2}^2, \sin\theta_{j2}, \cos\theta_{j2}) \otimes \\ &(1, \theta_{j3}, \theta_{j3}^2, \sin\theta_{j3}, \cos\theta_{j3}) \ ,\end{aligned} \tag{13}$$

where $\otimes$ stands for the Kronecker product. Note that this is a minimal dictionary. A larger dictionary consisting of more complex operations may increase prediction accuracy at the expense of increasing complexity. Construction of the dictionary is out of the scope of this paper; we refer the interested reader to [29] for a detailed analysis of how to construct such a dictionary based on an underlying system's kinematic information. The Koopman operator can be numerically approximated from data using EDMDc [15]. It entails the minimization of the total residual between the prediction and ground truth in the Koopman state, i.e.

$$J = \frac{1}{2}\sum_{j=1}^{M}(\Psi(y_j) - K\Psi(x_j))^2 \ . \tag{14}$$

This least-squares problem 14 can be solved by truncated singular value decomposition (SVD) as

$$K \triangleq G^{\dagger}A \ , \tag{15}$$

where

$$G = \frac{1}{M}\sum_{j=1}^{M}\Psi^*(x_j)\Psi(x_j) \tag{16}$$

$$A = \frac{1}{M}\sum_{j=1}^{M}\Psi^*(x_j)\Psi(x_{j+1}), \tag{17}$$

with $\dagger$ denoting the pseudoinverse and $*$ denoting the conjugate transpose operations, respectively.

With K in (15), the following equations are obtained

$$\begin{cases} v_n = (w_n^* B)^T \\ \lambda_n \xi_n = K\xi_n, \\ \varphi_n = \Psi\xi_n \end{cases} \tag{18}$$

where ξ_n is the n-th eigenvector, w_n is the n-th left eigenvector of K, and B is the matrix of appropriate weighting vectors so that $x = (\Psi B)^T$. By plugging expressions (18) back to (12) we can then describe the evolution of the system using the estimated Koopman operator.

IV. RNN-based Kinematics Estimation

A. RNN Overview

RNNs are a class of deep neural networks designed for sequential data processing and temporal modeling. Unlike feedforward networks, RNNs have a recurrent structure that allows information from previous time steps to be recorded and used in the current computation. This is achieved through feedback connections in the hidden layers, enabling RNNs to capture dependencies over time. The hidden state h_t at time step t is updated using $h_t = f(W_h h_{t-1} + W_x x_t + b)$ where f is a nonlinear activation function, W_h and W_x are weight matrices, x_t is the input, and b is the bias. In the context of solving the forward kinematics of parallel robots, RNNs offer a distinct advantage due to their ability to model the inherent dependencies between joint variables and the resulting end-effector poses.

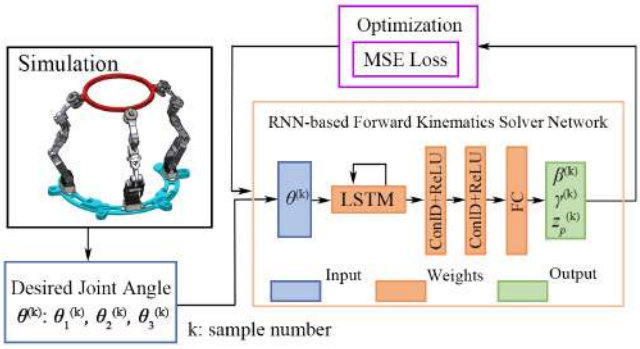

Fig. 4. The RNN-based architecture considered herein.

B. Implementation

The employed RNN architecture is shown in Figure 4. The *RNN-based Forward Kinematics Solver Network* module receives the three motor angles as inputs and outputs the flexion angle (β), lateral bending angle (γ), and the z-translation (z_p) of the end-effector. Training data were generated using the analytical inverse kinematic solver. The inputs and outputs from the analytical inverse kinematic solver were flipped and fed into the network.

V. Experimental Testing and Results

Validation and testing were formulated into two parts; simulations and physical experiments. Simulations aim to assess the accuracy of predicting the end-effector pose from the active joint variables using the Koopman operator-based and RNN-based estimators. To establish a ground truth for validation, a trajectory of end-effector positions and orientations was generated from inverse kinematics. This trajectory serves as a benchmark to evaluate the performance of both methods. A dataset consisting of 248,790 samples was created for training. A distinct set of 802 samples was used for testing. Simulations with the Koopman Operator and the RNN-based estimator (including training and testing) were performed on an Intel Core i7-11800H processor @2.3GHz with RTX3060 Mobile GPU with 6GB of VRAM.

Results for the Koopman operator-based and RNN-based estimator are shown in Figures 5 and 6, respectively. It takes just 28.08 sec to train the Koopman operator. The average MSE in predicted trajectory positions is 3.24 (base units in mm), while the average MSE in predicted trajectory orientations is only 0.06 (base units in deg). The RNN was trained for 50 epochs with a total training time of 455.55 sec. The model achieved a trajectory translation MSE of 0.0062 (base units in mm) and orientation MSE of 0.0035 (base units in deg). Additionally, the testing performance yielded an $\mathbf{R}^2$-score of 0.9974, indicating a high level of accuracy

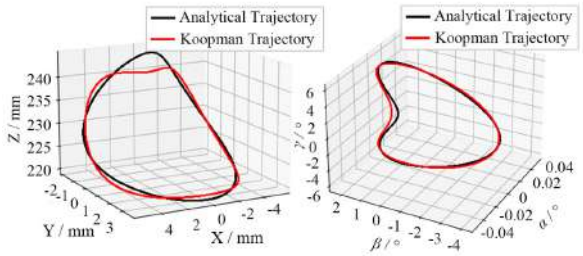

Fig. 5. Predicted end-effector position (left) and orientation (right) in simulation using the Koopman operator-based estimator.

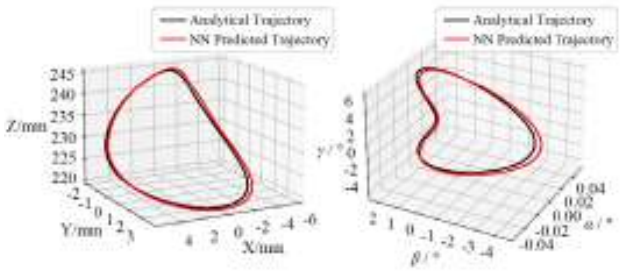

Fig. 6. Predicted end-effector position (left) and orientation (right) in simulation using the RNN-based estimator.

in the model's predictions. Overall, both methods' feasibility was shown in the simulated testing.

When comparing the two methods, we observe a notable trade-off between accuracy and computational efficiency. The RNN-based method achieves a significantly lower trajectory prediction error compared to that estimated via the Koopman operator. However, this improved performance comes at the cost of computational efficiency since the RNN-based method requires approximately 10 times more training time to reach this level of accuracy. This highlights a critical consideration in selecting the appropriate method based on the specific requirements of accuracy and computational efficiency in practical applications. Deviations from the desired trajectory were observed in the predicted position (Figure 5). However, the overall trajectory form is maintained. In addition, the prediction accuracy depends to a certain extent on the selection of the Koopman dictionary; a more extended dictionary could help rectify this.

Physical experiments considered the same ground truth trajectory as in the simulation testing. The latter was applied to the fabricated 3-RRUR parallel robot prototype (Figure 7). End-effector frame $E_1E_2E_3$, base frame $S_1S_2S_3$, and link $S_iK_iQ_iE_i$ $(i = 1, ..., 3)$ are 3D-printed with PLA basic material (Bambu Labs). Joints S_i are formed by LX16A bus servomotors. Joints K_i, Q_i, E_i are revolute joints formed by binding barrels with 304 stainless steel phillips head and deep groove ball bearings. The physical trajectory data were captured by an 8-camera Optitrack motion capture system at 100Hz. Key dimensions of the prototype include: $r_A = 85.04\,\text{mm}$, $r_S = 141\,\text{mm}$, $r_E = 120\,\text{mm}$, $h = 48.51\,\text{mm}$, $l_{Q_iA_i} = 66.56\,\text{mm}$, $l_{Q_iE_i} = 85.06\,\text{mm}$, $l_{K_iS_i} = 83.925\,\text{mm}$, $l_{K_iQ_i} = 83.925\,\text{mm}$, $l_{E_iA_i} = 59.76\,\text{mm}$.

Results of the captured trajectory and desired trajectory are shown in Figure 8. The overall trajectory trend was followed by the feedforward trajectory computed analytically. However, deviations and, at times, large offsets were observed as well. Two likely sources caused these errors. First, differences in assumptions used in the mathematical model and the real physical prototype (for instance the geometry constraints of A_i) cannot be fully achieved because of the deformation of each link. Second, fabrication errors, especially those causing friction in the revolute joints and collision of links on each chain $S_iK_iQ_iE_i$, can all contribute to cumulative errors in the end-effector motion.

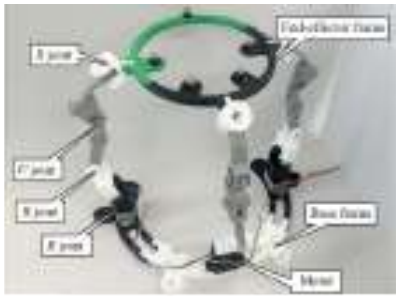

Fig. 7. Fabricated prototype of the proposed 3-RRUR parallel robot. In each chain, the first R joint that is connected to the base frame is actuated via a servomotor, whereas all other joints are passive and forced to move as determined by the geometry constraints.

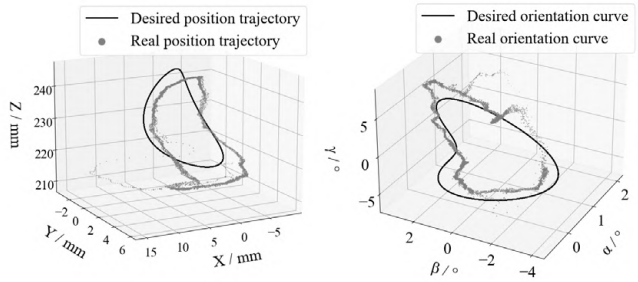

Fig. 8. Comparison between desired trajectory and the experimentally-obtained one collected via motion capture.

VI. Conclusion

A 3-RRUR parallel robot was designed as a means to provide traction support for patients who suffer from cervical spondylosis. To address the challenge in forward kinematics analysis associated with the parallel mechanism structure, an analytical method for solving inverse kinematics, which can often be solved directly in contrast to forward kinematics, was studied to generate a dataset for data-driven model training. Then, a Koopman operator-based method and an RNN-based method were introduced to resolve the forward kinematics of the robot. The prediction accuracy from the RNN-based estimator is noticeably higher than that of the Koopman operator, while the Koopman operator can be much more quickly and easily deployed and updated online, without the need for large computational resources. Lastly, a fabricated prototype of the proposed 3-RRUR parallel robot was designed to validate the results of the same trajectory presented in the two data-driven methods. This work offers a basis to support porting data-driven methods into robotic orthotics. Future directions of research include online model learning via the Koopman operator to control the mechanism,

as well as design and fabrication improvements to make the motion of the physical prototype smoother.

ACKNOWLEDGMENT

The authors would like to thank Dr. Zhichao Liu for offering his assistance with the experiments.

APPENDIX

We list below the closed-form expressions for the forward kinematics of the developed mechanism. Let r_E be the diameter of the circle spanned by points E_1, E_2, E_3 and r_S the diameter of the circle spanned by points S_1, S_2, S_3. The two kinematic constraints in chain $S_1K_1Q_1E_1$ are

$$f_1 : (a_{11} + z_{11})^2 + (a_{21} - z_{21})^2 = a_{31} \ , \qquad (19)$$

$$f_2 : (a_{41} + z_{11})^2 + (a_{51} - z_{21})^2 = a_{61} \ , \qquad (20)$$

where $a_{11} = x_p + r_E c_\gamma - r_S$, $a_{21} = z_p - r_E s_\gamma$ $a_{31} = l_{QE}^2 - y_E^2$, $a_{41} = x_p + r_A c_\gamma - h c_\beta s_\gamma - r_S$, $a_{51} = z_p - r_A s_\gamma - h c_\beta c_\gamma$, $a_{61} = l_{Q_1A_1}^2$, $z_{11} = l_{K_1S_1} c_{\theta_1} + l_{K_1Q_1} c_{\theta_1+\phi_1}$, and $z_{21} = l_{K_1S_1} s_{\theta_1} + l_{K_1Q_1} s_{\theta_1+\phi_1}$.

The two kinematic constraints in chain $S_2K_2Q_2E_2$ are

$$f_1 : (a_{12} + z_{12})^2 + (a_{22} - z_{22})^2 = a_{32} \ , \qquad (21)$$

$$f_2 : (a_{42} + z_{12})^2 + (a_{52} - z_{22})^2 = a_{62} \ , \qquad (22)$$

where $a_{12} = y_p + r_E c_\beta - r_S$, $a_{22} = z_p + r_E s_\beta c_\gamma$, $a_{32} = l_{Q_2E_2}^2 - (x_p + r_E s_\beta s_\gamma)^2$, $a_{42} = r_A c_\beta - r_S$, $a_{52} = z_p + r_A s_\beta c_\gamma - h c_\beta c_\gamma$, $a_{62} = l_{Q_2A_2}^2$, $z_{12} = l_{K_2S_2} c_{\theta_2} + l_{K_2Q_2} c_{\theta_2+\phi_2}$, and $z_{22} = l_{K_2S_2} s_{\theta_2} + l_{K_2Q_2} s_{\theta_2+\phi_2}$.

The two kinematic constraints in chain $S_3K_3Q_3E_3$ are

$$f_1 : (a_{13} - z_{13})^2 + (a_{23} - z_{23})^2 = a_{33} \ , \qquad (23)$$

$$f_2 : (a_{43} - z_{13})^2 + (a_{53} - z_{23})^2 = a_{63} \ , \qquad (24)$$

where $a_{13} = x_p - r_E c_\gamma + r_S$, $a_{23} = z_p + r_E s_\gamma$, $a_{33} = l_{Q_3E_3}^2 - y_E^2$, $a_{43} = x_p - r_A c_\gamma - h c_\beta s_\gamma + r_S$, $a_{53} = z_p + r_A s_\gamma - h c_\beta c_\gamma$, $a_{63} = l_{Q_3A_3}^2$, $z_{13} = l_{K_3S_3} c_{\theta_3} + l_{K_3Q_3} c_{\theta_3+\phi_3}$, and $z_{23} = l_{K_3S_3} s_{\theta_3} + l_{K_3Q_3} s_{\theta_3+\phi_3}$.

Assessing Personalized FES Patterns for Gait Rehabilitation in a Clinical Setting

Nicolas Feppon, Amine Metani, Samer Mohammed, *Senior Member, IEEE*

***Abstract*—Functional electrical stimulation (FES) for motor and neurological rehabilitation produces patient-dependent functional responses influenced by the individual's pathology and clinical profile. Given this inherent variability in patient responses, it is essential to personalize FES gait rehabilitation parameters to enhance the rehabilitation outcomes effectively. To optimize these parameters for gait neurorehabilitation, appropriate metrics are needed. In this preliminary case study, we assess if selected metrics can comprehensively evaluate the effectiveness of FES gait patterns with different degrees of personalization for specific post-stroke patients in the context of a clinical rehabilitation routine. These metrics do not only reflect the immediate orthotic effects, but also gait parameters that indicate rehabilitation progress and improved treatment outcomes. We analyzed data collected during rehabilitation of three post-stroke hemiplegic individuals with NeuroSkin, a multichannel textile FES system with embedded movement sensors and dry electrodes. We evaluated different stimulation patterns using metrics related to kinematic, spatio-temporal, postural, and asymmetry aspects of gait. Some metrics identified modest overall improvements between default and personalized stimulation patterns: walking speed (+0.63cm/s) and stride length (+0.41cm). However, patient-dependent analysis revealed substantial improvements which differed between patients across walking speed (+3.3cm/s), stride length (+4.7cm) and metrics reflecting asymmetry and postural control, as well as kinematic trajectories. We argue that these metrics should be integrated in FES-aided gait assessments. However, it remained difficult to identify which metrics should be primarily considered when optimizing an FES strategy, given heterogeneous improvements and limitations of the current framework.**

***Index Terms*—Functional Electrical Stimulation, Artificial Intelligence, Stroke, Motor Handicap, Neurological Rehabilitation, Neuroprosthesis, Personalized assistance**

I. Introduction

Functional Electrical Stimulation (FES) is used for motor rehabilitation following neurological injuries or diseases, such as stroke, spinal cord injuries or multiple sclerosis [1] [2]. To generate reliable functional movements, these systems must address various challenges, both related to the characteristics of FES and the redundancies of the neuromusculoskeletal system. Muscle fibers fatigue more quickly than with voluntary contractions induced by the central nervous system (CNS), and fatigue dynamics vary from patient to patient [1] [3]. Additionally, intensive FES can be painful, further limiting the intensity of muscle contractions. Electromechanical delay, which is the time between motor neuron activation and the initiation of muscle contraction [4], differs between patients. FES-induced movement is subject to variations in both muscle response and neural response [4]. Finally, inter-subject variability of nerves and motor points locations also limits the reproducibility of stimulation responses across patients. To address these variabilities, FES systems should be capable of adjusting to these characteristics, adapting parameters and timings of stimulation to each patient.

Stroke, a vascular cerebral injury that disrupts brain circuits due to impaired blood supply, often results in hemiplegia and gait impairments. FES therapies are widely used for post-stroke rehabilitation [5] and one of the highest priorities after stroke is gait rehabilitation. However, variability in patient conditions complicates the standardization of FES therapies, as the severity of gait deficits dictates rehabilitation options, and gait impairments vary based on the stroke's anatomic localization [6]. Factors such as fatigue, sensory function, and spasticity levels further influence rehabilitation protocols [7].

Human gait is a complex coordinated movement, which depends on an array of components to make it functional: support and forward propulsion of the center of gravity, balance of the center of gravity as it transitions between limbs, controlling knee and toe paths for toe clearance and foot placement and controlling coordination [8]. These components can also be categorized across dimensions, which have been found to explain most of gait's variability: Pace, Rhythm, Variability, Asymmetry and Postural control [9]. Gait analysis is used in rehabilitation to analyze gait impairments and measure rehabilitation outcomes. Spatiotemporal metrics of gait measure spatial and temporal differences between various gait events [10], while kinematic metrics measure displacements and trajectories of key anatomical points of interest. Gait phase represents the progression of the gait cycle, with 0% at heel strike, 60% at toe-off, and 100% at the next heel strike, providing a standardized framework for monitoring the cycle's progression. In neurorehabilitation robotics, the orthotic effect of the system on the gait is often evaluated using metrics from gait analysis: mean square error on joint angle trajectories [11], spatio temporal parameters [12] and walking speed [12] [13], and the clinically widespread 10-meter walk test [14] related to walking speed.

FES has demonstrated effects on high-level gait parameters, such as walking speed and spatiotemporal metrics, as well as physiological cost index in stroke patients [2] [15]. For

example, the review of Kottink et al., which evaluated orthotic effect after FES therapy, found an aggregate improvement of 0.13m/s in walking speed [15]. Street et al. found an orthotic effect of 0.10m/s [14]. These changes stem from FES-induced alterations in lower limb dynamics, as stimulation parameters directly influence muscle contraction patterns. The timing, profile, and amplitude of stimulation (referred to as "patterns" in this study) significantly impact gait kinematics, as evidenced through gait analysis metrics [16]. Given FES's role as a precision tool for inducing gait changes, reliable and precise evaluation metrics are crucial for determining optimal patient-specific modifications.

In the context of a long term rehabilitation, a rehabilitation system or therapy should not only produce an orthotic effect, but also a therapeutic one. FES aided therapy should aim to improve the patient's gait pattern, promoting better ambulation, autonomy, and general quality of life. FES is shown to have therapeutic effects [2], but the relationship between short-term robotic and FES interventions and long-term functional improvements remains unclear [17] and the therapeutic effect of FES remains not fully understood [1]. Individualized optimal pathways for gait improvement and rehabilitation using FES have yet to be established. However, it is necessary to have metrics which can evaluate instantaneous orthotic improvements of gait, but also indicate the best directions of orthotic changes for optimal rehabilitation. One way to do this is to evaluate the gait using metrics that are correlated with good rehabilitation outcomes. These can for example be found in literature-based predictors of rehabilitation outcomes. Good trunk control and balance as well as a greater range of motion of the hip at initial assessment are strong predictors of successful rehabilitation [18]. Additionally, walking speed is closely linked to quality of life and autonomy [19]. In stroke specifically, walking speed can serve as an indicator of the patient's clinical profile [14] and stage of rehabilitation.

Past studies have evaluated instantaneous orthotic effects of FES on patient's gait, as well as the long term therapeutic effects [14] [16] [2]. However, there is a need to evaluate FES patterns in the context of continued FES therapies, where a particular instantaneous orthotic effect can translate into different therapeutic effects over the long term. FES-aided gait should be evaluated continuously using an appropriate set of metrics to inform on how adequate a particular pattern is for the clinical profile of a patient, and how to optimize a FES-aided rehabilitation.

In this preliminary study, spatiotemporal metrics, metrics related to the gait dimensions of pace, asymmetry and postural control as well as kinematics will be evaluated on gait aided by different FES patterns. Spatiotemporal metrics will include gait speed, stance and swing durations, stride length and duration, double support duration and ratio. Asymmetry of swing phase and hip movement jerk will be evaluated as measures of asymmetry and postural control. Regarding gait kinematics, joint angle trajectories will be evaluated. This study conducts a preliminary evaluation of these metrics in post-stroke FES-aided gait, hypothesizing that they constitute essential parameters for characterizing the adequacy and efficacy of FES stimulation patterns for a specific patient. Through a series of three case studies, we evaluate a condition without stimulation and two conditions with a default and a personalized stimulation pattern using outcome measures that assess orthotic effects and measures wich are predictors of rehabilitation improvements. Through this analysis, we investigate the metrics' capacity to characterize gait enhancements. The condition with personalized stimulation is calibrated to be adapted to a patient's particular clinical profile and response to FES therapy.

II. Materials & Methods

We realized a retrospective analysis of the gait metrics data acquired by the Neuroskin device to compare the effects of different stimulation patterns. We compared the gait data of stroke patients with autonomous or assisted walking capacity under FES assistance provided by the Neuroskin device, across two stimulation conditions using gait analysis metrics.

Authorization to use the data was obtained from the National Commission for Data Protection and Privacy (CNIL: 22451530, MR-004). Patients were informed and gave their consent for data collection and analysis.

A. Experimental protocol

1) Functional electrical stimulation device: The commercial electrical stimulation device Neuroskin (Kurage, Lyon, France) was used for this study. Neuroskin integrates an 8 channels functional electrical stimulator (3F Fit Fabricando Faber, Belgrade, Serbia) [20], seven Inertial Measurement Units (IMUs, MikroE ICM-42688-P, Belgrade, Serbia) distributed on the back of the pelvis and the legs (3 on each leg: on the thigh, on the shank and on the foot), and Sateco SXTSC pressure sensors (Sateco AG, Schwerzenbach, Switzerland) integrated in a sole or shoe (4 sensors per side). Dry electrodes (Nanoleq, Rumlang, Switzerland) are integrated in a tight garment which is worn by the patient and connected to the stimulator. Electrodes are positioned on average motor point locations of patients, to induce contraction of 6 muscles or muscle groups on each leg: quadriceps, tibialis anterior, fibularis, gluteus maximus, hamstring and gastrocnemius. See Figure 1 for a depiction of the Neuroskin system.

Fig. 1. Neuroskin functional electrical stimulation device (Kurage, Lyon, France) with its main components

For a FES therapy session with Neuroskin, a practitioner first calibrates intensities for each muscle group individually, by selecting the stimulation for each muscle, increasing intensity, stimulating and going over this process until the patient feels discomfort. The last intensity is set as the maximum stimulation intensity. During the session, the device automatically stimulates patients as they walk, with timings based on the gait phase. The stimulation intensity is controlled as a percentage of the previously set maximal intensities, and can be adjusted globally throughout the session.

For all conditions, the default FES parameters for frequency and pulse width of the Neuroskin are used: frequency is set to 40Hz for all muscles, pulse width is set to 400 microseconds for quadriceps, gluteus and hamstrings, 250 microseconds for gastrocnemius, and 200 microseconds for tibialis and fibularis.

2) Data collection: We collected data from 1 minute walking bouts, on level ground, at a self-selected comfortable speed, under 3 different conditions:

1) walk without stimulation,
2) walk with stimulation using default stimulation patterns,
3) walk with stimulation using personalized stimulation patterns

"Default stimulation patterns" refers to the default stimulation algorithm of Neuroskin without personalization, "personalized stimulation patterns" refers to the condition with personalized gait phase prediction of Neuroskin and with stimulation parameters set by an expert. These modalities are detailed in section II-B.

The maximal stimulation intensities for each muscle were calibrated according to the recommended usage guidelines for Neuroskin in FES therapies (see section II-A1). For each patient, the session began with the condition without stimulation. The order of the subsequent conditions was specific to each patient: 1-2-3 for patient 1, 1-3-2 for patient 2, and 1-3-2 for patient 3. Before beginning the first of the two stimulation conditions, the patient walked for a period with stimulation controlled by the Neuroskin stimulation algorithm, to become accustomed to the stimulation levels. During this time, the stimulation intensities were gradually increased for all muscles (as described in section II-A1) to the maximum level acceptable for the patient. This stimulation intensity was then selected for all stimulation conditions and is reported in Table I for each patient. The two modalities used in the personalized stimulation condition are described in the section II-B2. For the first of these modalities, a configuration change was necessary to switch between the default and personalized gait phase prediction models, and involves using data from the patient's gait over 10 consecutive steps in a straight line without stimulation, which is then used for finetuning of the gait phase prediction model. Secondly, a physiotherapist adjusted the stimulation parameters (intensity and timing in gait phase domain) to further optimize the patient's walking pattern. To accomplish this, the patient walked for a few minutes while the physiotherapist modified the relevant parameters. Once an optimal configuration was identified, the personalized stimulation condition was conducted. The chosen parameters are reported in Table I.

TABLE I
INCLUDED PATIENTS WITH HEMIPARETIC SIDE AND DETAILS OF STIMULATION PARAMETERS USED.

Patient number	**Time since stroke, Hemiparetic side**	**Patient information (Gender, Age, Weight)**	**Stimulation intensities for default stimulation condition**	**Stimulation timings[1] and intensities for personalized stimulation condition**

[1] Stimulation timings are given as beginning and end of stimulation, expressed as a percentage of predicted gait phase.

Distance markers were placed at 0 and 10m on the ground. For each condition, the patient started from behind the first marker, and was asked to walk straight, passing both distance markers. After reaching the second marker, the patient was asked to turn around and walk back to the first marker. The time was recorded each time the patient passed a marker.

3) Participants: 3 chronic stroke patients were included in this preliminary study. These patients were undergoing rehabilitation with the Neuroskin in their usual rehabilitation location in France. They were stimulated only on their paretic side. Detailed information for each patient, along with the stimulation parameters, is provided in Table I. In the third column, stimulation intensities for the default stimulation condition are given. The default stimulation timings for this condition are given in Figure 2. The final column of Table I describes the parameters (intensities and timings) for the personalized stimulation condition. "quad" stands for quadriceps, "hams" for hamstring, "tib" for tibialis, "gas" for gastrocnemius, "glut" for gluteus and "fib" for fibularis.

4) Metrics & data processing: Metrics reflecting spatiotemporal, kinematic, postural and asymmetry aspects of gait were computed to assess the gait resulting from the stimulation patterns. Kinematic metrics were computed: hip, knee and ankle joint angle trajectories were calculated using the algorithms described below and range of motion of the hip was computed. Following spatiotemporal metrics were computed: walking speed, cadence, stance and swing time and ratio, and double support time and ratio). Metrics related

to postural control and asymmetry were also calculated: asymmetry in swing phase duration and hip movement jerkiness. Cadence, stance and swing durations were calculated from gait events (heelstrike and toe-off) which were detected using a threshold-based method on signals from pressure sensors. Joint angles were calculated from the IMU data with the use of the Versatile Quaternion-based Filter algorithm [21] for IMU orientation estimation and Quaternion Management Toolbox [22]. They were segmented into single gait cycles using the heelstrike events. Walking speed was calculated with the distance marks and the recorded time. Stride length was calculated using the distance, and the number of strides extracted from gait events. Asymmetry was calculated as a measure of right and left swing phase duration discrepancies, as defined in the work of Rössler et al. [23]. Postural sway jerkiness was used as a measure of trunk control and calculated as defined in the work of Kim et al. [24]. Parts of the conditions where there was no straight walking were excluded from the analysis.

B. Stimulation conditions

1) Stimulation with default stimulation patterns: The stimulation is controlled by an algorithm developped by Kurage. In this algorithm, a neural network predicts the gait phase percentage from IMU data (gyroscope and accelerometer data) in real time. The gait phase percentage represents the gait cycle and is 0 at heel strike, and increases from 0 to 100 in a gait cycle. The neural network was trained on a dataset of 193 stroke patients. The default stimulation rules are predefined and indexed on the real time predicted gait phase percentage (Figure 2). The default stimulation was used in the second condition of the experimental protocol, named "default stimulation patterns".

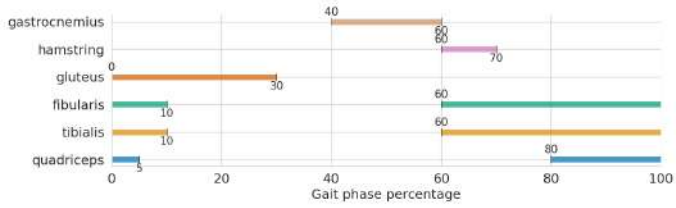

Fig. 2. Default stimulation rules used in the Neuroskin device for the 6 targeted muscle groups. Stimulation is applied based on gait phase percentage. The color bars show when stimulation is active for each muscle.

2) Stimulation with personalized stimulation patterns: In the condition "personalized stimulation patterns", two functionalities were used for personalizing the stimulation patterns: personalization through finetuning of the gait phase prediction model to the patient and when needed as assessed by an expert physiotherapist, the change of FES parameters (timings expressed as a percentage of gait phase and intensities). These modalities are explained below.

The gait phase real time estimation can be adapted to the user's specific gait by finetuning of the gait phase prediction model to the data recorded on the gait of the patient. This allows to better predict gait phase and therefore more accurately time stimulation based on the defined percentages of stimulation, but it does neither affect the stimulation intensities nor the beginning and end percentages.

Finetuning is a common method in Deep learning to leverage the paradigm of transfer learning, where a neural network is firstly trained on a large corpus of data, with underlying characteristics and subsequently trained again on data on a different task. The goal with this procedure is reducing training time and improving accuracy by limiting overfitting. An example of this adaptation, for patient number 1 is shown in Figure 3. In part (a) of this figure, the predicted gait phase percentage (in %) is shown in relation to normalized real gait cycle duration (in %). The solid line represents the median predicted gait phase percentage values, with the shaded areas indicating the first and third quartiles. The dashed line represents the gait phase percentage detected by gait events, which is the target for the neural network prediction and can be considered the true gait phase percentage. In part b, the default muscle stimulation rules based on the predicted gait phase percentage are shown, with the lower and upper quartiles for the beginning and end of stimulation shown in lighter shades. Here, we can observe that the start and the end of stimulation in gait cycle duration for each muscle are not accurate (comparing to the default stimulation rules in Figure 2, the median beginning of stimulation is off target for most muscles, maximally by 11% for gluteus), and there is considerable variability (mean interquartile range across muscles is 9.3%). We are able to compare values of beginning and end of stimulation in gait cycle duration and predicted gait phase because the dashed line representing true gait phase is linear in this case. In parts c and d where the personalized stimulation is used, we observe that the gait phase estimation is more accurate (maximal offset for median beginning or end is 3%) with reduced variability (mean interquartile range is 2.7%). As a result, stimulation is more accurately timed, closer to the defined start and end gait cycle percentage values and with smaller variability.

The second modality used in the personalized stimulation condition was expert adaptation of FES parameters. The FES system also integrates functionalities to manually change the following parameters: timings of the stimulation rules for each muscle in gait phase domain (as a percentage), impulse width for each channel and frequency for bilateral pairs of muscles. This procedure is useful for further adapting stimulation patterns to suit individual patients or specific exercises, using the expert knowledge of medical staff and physiotherapists. In this study, the timings in gait phase domain and intensities of stimulation were adapted.

III. Results

We analyzed the metrics described in Section II-A4 across all conditions and patients. Mean results and standard deviations are given in Table II. Metrics showing most important variations are shown in Figure 4, which displays patient-specific outcomes relative to normative ranges (green bands), taken from [23] and [24]. Overall patient responses did not

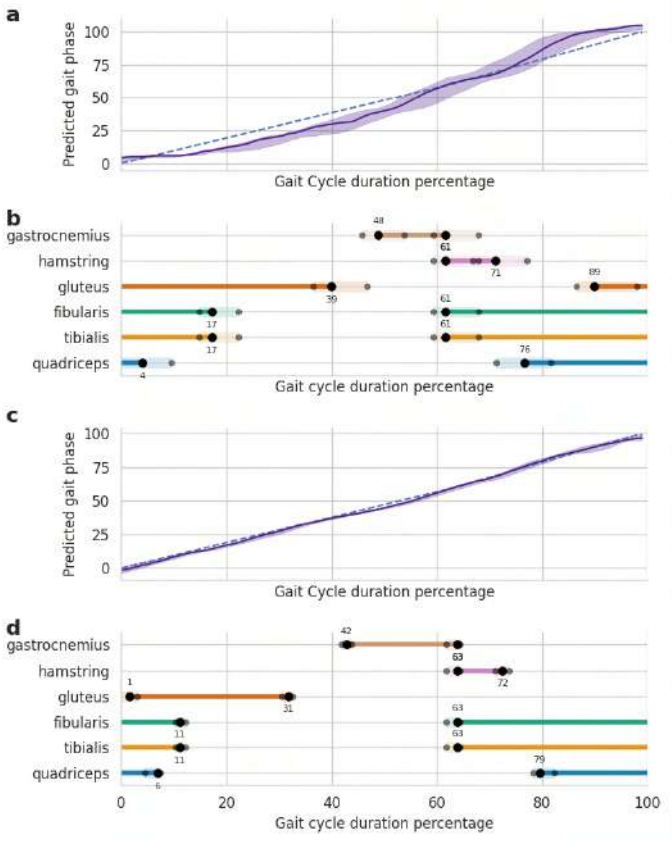

Fig. 3. Stimulation patterns personalization through finetuning for patient 1. **a.** Gait phase estimation using Kurage default stimulation shown in violet as a percentage of gait cycle, against normalized gait cycle duration. The dashed line represents true gait phase percentage as calculated using gait events. **b.** Median muscle stimulation rules with the default stimulation patterns, applied based on gait phase percentage. Quartiles are shown in shaded colors **c.** Gait phase estimation using Kurage personalized stimulation model shown in violet as a percentage of gait cycle, against normalized gait cycle duration. **d.** Median muscle stimulation rules for personalized model, applied based on gait phase. Quartiles are shown in shaded colors.

show substantial trends of metric variations between conditions when considering the mean. However individual patient responses analysis indicates heterogeneous results between no stimulation, default stimulation, and personalized stimulation conditions.

To facilitate understanding results in a clinical context, clinically relevant changes are given for following metrics: the minimal clinically important difference (MCID) for stroke patients is 10cm/sec for gait speed [25] and 5.81° for hip ROM [26]. For other spatiotemporal metrics and to the best of our knowledge, MCID values have not been established yet in the literature, therefore minimum detectable change (MDC) values are given. MDC values are 8.58 for cadence and 11.96 cm for stride length [27]. To the best of our knowledge, MDC or MCID values for asymmetry in gait phase duration and hip movement jerkiness have not been established. Firstly, the conditions without stimulation and with default stimulation are compared. The comparison revealed improvements in asymmetry (-2.6%), walking speed (+2.59cm/s), and stride length (+5.16cm), but with considerable standard deviations across patients: 4.2%, 7.5cm/s and 9.5cm respectively. Double support ratio (+2.7%) and postural sway (+14.77$cm^2 * s^{\propto 5}$) increased, with standard deviations of the difference between the conditions of 1.2% and 19.8$cm^2 * s^{\propto 5}$ respectively. This indicates deviation from double support ratio normative values and reduced trunk control, respectively. However, increased double support ratio may indicate increased stability. The increased postural sway is primarily attributed to patient 1, who also exhibits important gait asymmetry under stimulated conditions. It should be noted that this patient was only stimulated on the ankle dorsiflexor muscles.

Personalized stimulation yielded modest additional improvements in walking speed (+0.63cm/s) compared to default stimulation, with a standard deviation of 2.34cm/s. Hip range of motion on the left hemiparetic patient increased by 3.44° from default to personalized stimulation, which is an increase of 12% or reduction of 30% of the gap to healthy values. Postural sway and double support ratio continued to increase further away from normative values. Other spatiotemporal parameters remained largely unchanged between all conditions (maximum variations for individual patients: cadence ±1 step/min; stance duration ±0.04s; swing duration ±0.02s; stride duration ±0.02s). Hip range of motion for the right side hemiparetic patients also did not show substantial changes (±1,54°).

Kinematic trajectories improved between conditions without stimulation and with default stimulation mainly for 2 patients, correcting the main gait deficit of each patient, with an additional improvement for one patient with personalized stimulation. Individual patient responses on evaluated metrics varied substantially across conditions. Given this heterogeneity, patient-level analysis provides additional meaningful insights.

Patient 1 had right-side hemiplegia and exhibited ankle dorsiflexion impairment. Dorsiflexor stimulation improved swing phase ankle dorsiflexion and reduced compensatory knee flexion through enhanced ground clearance, resulting in improved walking speed and stride length. The timing of hip flexion aligned better with normative values. However, asymmetry increased with stimulation. The personalized stimulation condition improved further plantarflexion at toe-off and further enhanced walking speed (+3.3cm/s, +4.7%), though gait asymmetry (+11.4%) and postural sway (+44$cm^2 * s^{\propto 5}$, +45.5%) continued to increase.

Patient 2 presented with left hemiplegia, characterized by impaired ankle dorsiflexion with phase delay and a beginning of genu recurvatum, evidenced by minimal knee flexion during stance phase (Figure 6). The patient exhibited a compensatory strategy by throwing his leg forward which resulted in a slight phase lead in knee angle trajectory. Default stimulation application slightly resolved the knee flexion phase lead, contributing to improved gait symmetry, as can be seen on Figure 4. However, there was no substantial improvement in ankle joint trajectories, and a decrease in walking speed (-6.5cm/s, -12%). For the personalized stimulation condition, the physiotherapist increased stimulation intensity and advanced onset timing for hamstring stimulation to address both the knee

TABLE II
RESULTS ON ALL METRICS ACROSS STIMULATION CONDITIONS[1]: MEAN AND STANDARD DEVIATION

Condition	Without stimulation	Default stimulation	Personalized stimulation
Cadence (steps/min)	**49.0** (8.89)	48.33 (6.81)	48.0 (7.55)
Left stance duration (s)	0.98 (0.19)	**0.98** (0.15)	1.00 (0.15)
Right stance duration (s)	**0.73** (0.14)	0.76 (0.11)	0.78 (0.16)
Left swing duration (s)	**0.36** (0.02)	0.35 (0.02)	0.35 (0.05)
Right swing duration (s)	0.27 (0.1)	**0.28** (0.09)	0.27 (0.1)
Mean stance duration (s)	**0.86** (0.16)	0.88 (0.12)	0.9 (0.15)
Mean swing duration (s)	**0.37** (0.06)	0.36 (0.05)	0.35 (0.06)
Left stance ratio (%)	**72.5** (3.79)	73.5 (2.65)	74 (1.53)
Right stance ratio (%)	72 (5.51)	**72** (4.36)	74 (6.66)
Stride duration (s)	**1.23** (0.2)	1.24 (0.17)	1.25 (0.2)
Double support duration (s)	**0.48** (0.12)	0.51 (0.09)	0.53 (0.11)
Double support ratio (%)	**38.33** (4.5)	41.0 (3.0)	42.33 (4.6)
Walking Speed (cm/s)	49.18 (12.5)	51.77 (17.1)	**52.39** (18.9)
Mean stride length (cm)	60.09 (14.8)	65.24 (26.0)	**65.65** (26.0)
Range of motion left hip (deg)	29.26	28.17	**31.61**
Range of motion right hip (deg)	28.38 (1.4)	**29.73** (0.21)	28.41 (0.01)
Asymmetry swing (%)	19.38 (11.0)	**16.78** (13.7)	17.86 (22.4)
Postural sway jerkiness (cm^2/s^5)	**54.97** (43.8)	69.74 (37.9)	80.81 (63.7)

[1] Reported values in the table are mean values and standard deviation is shown in brackets. Metrics concerning one specific side were calculated only on hemiparetic sides. Standard deviation is not given for left hip ROM, since there is only 1 patient. For each metric, the closest result to normative values across the three conditions is shown in bold. Normative healthy values are taken from [23] and [24].

flexion phase advance and genu recurvatum. Personalized stimulation improved slightly further knee flexion phase lead which translated to an improved hip range of motion (+12% or reduction of 30% of the gap to healthy values) and maximal hip flexion angle, yielding additional symmetry improvements (-3.6% in asymmetry or reduction of 34% of the gap to healthy values), but did not show other meaningful improvements in ankle movement control. The small improvements on this patient with stimulation conditions could be due to the fact that the speed of this patient was initially quite high with a short stride length, making FES orthotic changes smaller due to delays in neuromuscular responses.

Patient 3, a chronic stroke patient with right-side hemiplegia, presented ankle dorsiflexion impairment and gastrocnemius spasticity, leading to excessive plantarflexion during swing and toe-off phases (Figure 5). The patient compensated with exaggerated knee flexion to achieve ground clearance, resulting in gait asymmetry and right stance instability. Default stimulation patterns improved swing phase dorsiflexion. These modifications yielded enhanced walking speed (+2.2cm/s, +6.3%) and reduced asymmetry (-2.3%, reduction of 46% of the gap to healthy values) through improved heel strike (Figure 4). The personalized stimulation patterns incorporated parameter adjustments done by the physiotherapist: reduced gastrocnemius stimulation to mitigate spasticity, advanced timing of quadriceps and tibialis anterior activation and extended hamstring stimulation duration. This parameterization resulted in a slightly reduced knee flexion, sign of less ground clearance necessity, and improved slightly dorsiflexion angle at toe off, as seen on joint angle trajectories. This manifested in increased stride length (+4.7cm, +9.3%) and better postural control (-12.5$cm^2 * s^{\propto 5}$, getting into healthy values range).

These results indicate that the metrics showing improvement from default to personalized stimulation differ from patient to patient: for some patients, there was an improvement on asymmetry (patient 2 getting closer to normative healthy values with -3.6%, patient 1 getting into the range of healthy values) and postural control (patient 3 getting into healthy values range) and walking speed decreased or stagnated (-2.6cm/s for patient 2, stagnation for patient 3), and for others, the inverse occured (increase of asymmetry and postural sway, with increase in walking speed, +3.3cm/s or +4.7%, for patient 1). In this situation, it is difficult to identify what is the more relevant metric to consider for FES pattern optimization. However, the most relevant and informative assessed metrics in this preliminary study were walking speed, stride length, kinematic analyses and hip ROM and metrics reflecting postural sway and asymmetry, which all give information on the possible rehabilitation improvements of patients. Especially, we see that metrics revealing macro-level dimensions of gait like pace, asymmetry and postural control were as important as more precise measures of kinematic changes, which can explain changes in macro-level measures of gait.

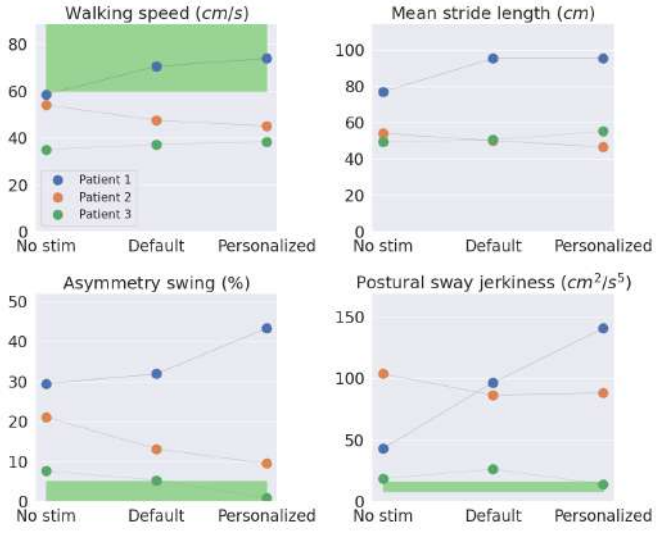

Fig. 4. Changes in gait metrics across stimulation conditions, on most relevant metrics. Green areas represent normative healthy values. For mean stride length, the normative values are above the chart. For postural sway, a pathological gait is generally indicated by a higher hip movement jerk than a healthy gait. Normative healthy values are taken from [23] and [24].

IV. DISCUSSION

Although a small improvement in gait speed and left hip range of motion was found when comparing default stimulation to personalized stimulation, no clinically significant overall improvement was observed across metrics. It is important to note that this study evaluates immediate orthotic

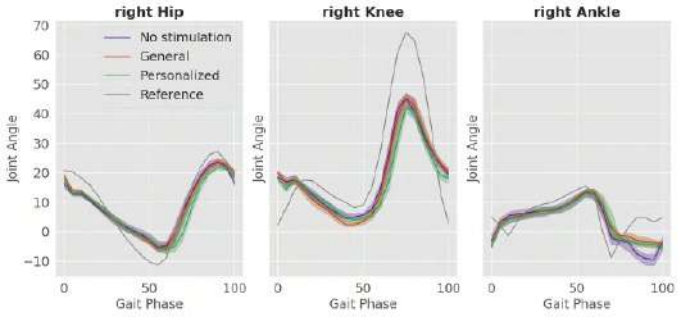

Fig. 5. Joint angles for all conditions of stimulation for patient 3. Only paretic side is shown. The median is shown in plain color, and translucid colors show the lower and higher quartiles. The reference of joint angles trajectory is shown in grey.

effects, while clinically significant improvements may emerge over the course of prolonged FES therapy. For example, we observed that improvements in gait kinematics for patient 2 did not translate to increased walking speed when evaluating the orthotic effect, but could eventually translate to improvements along a therapy. Individual analysis revealed different patient-specific gains, with small additional improvements with personalized stimulation, which was specifically tailored to address each patient's primary gait impairment, subsequently impacting other gait metrics.

This preliminary study shows small improvements due to personalized FES on gait, and while not being clinically meaningful overall, some patient-specific improvements can be noted. These discrepancies between patients indicate the need for a more general framework to understand how improvements manifest for some patients on some metrics but not for others. This framework needs to better take into account the clinical profiles and current rehabilitation status and needs of patients, to inform on which aspects of gait should be primarily improved. It is possible that optimal rehabilitation for some patients may require improvements in certain metrics while accepting temporary degradation in others to facilitate overall gait enhancement. Evaluation of gait in the light of more theoretical frameworks of gait, like biomechanical frameworks of gait would be useful. These open questions relate to gaps in the understanding of poststroke recovery [28].

Our selection of metrics and their implications merits a more detailed discussion. Walking speed, while commonly used, represents a macro-level measure that does not describe the qualitative aspects of gait within gait cycles and patients may increase speed with a more pathological gait. Walking speed should therefore not be the sole metric for FES-aided gait evaluation. Additionally, the use of reference trajectories for joint angles presents another methodological challenge, especially for stroke patients, as there is no universal optimal gait pattern [29]. This could introduce bias when evaluating patients' gait against standardized references.

While these preliminary results suggest that the chosen metrics are relevant for evaluating different FES stimulation patterns, and that personalized stimulation can enhance gait patterns beyond default stimulation, several limitations should be noted. Firstly, the current personalization process only influences stimulation timings within the gait cycle by small percentages and does not account for the muscle response to stimulation, so orthotic differences can be expected to be small. Additionally, the expert setting of FES parameters is constrained by time limitations, and high inter-operator variability, which could result in suboptimal and heterogeneous parameterization. This highlights potential future directions. There is a clear need for automated, more detailed parameterization of FES patterns. Secondly, the retrospective analysis done in this preliminary study limits the possibilities in terms of applied FES patterns and evaluated metrics: in a clinical context, no specific intervention could be planned, which limited the design of this preliminary study.

All the aspects discussed above show that this preliminary study, while showing promising results, requires extension to a larger prospective patient population and the evaluation of additional metrics relevant to FES-based gait rehabilitation, while better taking into account clinical profiles of patients and embedding them in a clinical gait rehabilitation framework. Further work in this direction is currently in progress.

V. Conclusion and Perspectives

This study evaluated FES in gait rehabilitation for three post-stroke patients, comparing gait parameters under three conditions: non stimulated gait, default FES-assisted gait, and personalized FES-assisted gait. The personalized stimulation condition incorporated patient-specific parameter adjustments by an expert physiotherapist, as well as finetuning of the stimulation algorithm. Analysis revealed modest improvements in speed, stride length, and asymmetry between non stimulated and default stimulation conditions, while the transition from default to personalized stimulation showed a small mean speed improvement. However, individual patients exhibited notable improvements across distinct metrics, indicating that therapeutic responses vary according to each patient's clinical profile, specific gait impairments, and individual-optimal rehabilitation pathways. Future research should validate these findings through a larger prospective cohort study to integrate FES-aided gait evaluation into a comprehensive clinical rehabilitation framework, later potentially enabling exploration of

AI-based methods for dynamic parameter adaptation tailored to individual patient profiles and clinical needs.

ACKNOWLEDGMENT

The authors gratefully acknowledge the physiotherapists Marwan Al Khoury and Nikola Babic for their FES parameters optimization in personalized stimulation conditions, Baptiste Moreau for code support, MD. Hybrid Actuation Paradigm in Back-Assist Exoskeleton for Symmetric Loading Conditions - A Feasibility Study

Arpeet Dhal[1], Teja Krishna Mamidi[1], Vineet Vashista[1*]

***Abstract*— The mandates of safety standards in manual material handling tasks have spurred the development and commercialization of many back-assist exoskeletons. These devices prevent back pain injuries by redistributing the applied loads, reducing the effort and fatigue in heavy and repetitive loading tasks. The majority of them employ passive and active actuation paradigms. The passive ones are known for better transparency and energy efficiency, while the active ones provide a higher degree of assistance and quickly adapt to task severities. The present work investigates the feasibility of a hybrid actuation paradigm for load-carriage under symmetric loading conditions. The preliminary results suggest that the proposed modifications to an existing passive exoskeleton effectively economize energy expenditure and improve adaptability.**

quasipassive, exoskeleton, load-carriage, hybrid actuation.

I. Introduction

Low back pain due to manual material handling tasks is a common problem in occupational settings [1], [2]. Specifically, lifting performed using wrong postures or heavy loads and repetitively was reported to be the primary cause of this ailment [3]. In order to ensure safety and promote preventive measures, guidelines, including recommended lifting weight limits [4], and techniques [5] were formulated. Further, personal protective equipment such as back braces and exoskeletons are promising alternative solutions, but assessment of their benefits is still ongoing [6].

Many back-assist exoskeletons were developed in the past for commercial and research purposes [7]. Among these, the *passive* devices provide assistance by redistributing the biomechanical energy over a lifting cycle using mechanical restoring elements [8]. In contrast, the *active* ones use an external energy resource such as electric, hydraulic, and pneumatic actuators to augment human effort [9].

Although passive devices are lighter, energy-efficient, and cost-effective, they have limited adaptability to task and environment variability. Hence, the current work explores the benefits of hybrid actuation paradigms [10], wherein external energy resources are only employed to alter the mechanics of passive exoskeletons. In particular, the passive Back-ASsist Exosuit (BASE) proposed in [11] was considered for improvement.

[*]Vineet Vashista is the corresponding author.

The preliminary studies with the BASE emulator involved finding the appropriate design to minimize muscle effort, reduce the device-to-body forces, and improve comfort for squat lifting/lowering tasks [12]. The limitations of this recommended design considered for mitigation in this work include the following. Eliminate manual adjustments of stiffness bands to match task severity. Alleviate the device-to-body forces on the shoulder during the pretension of the stiffness band. Therefore, in the current study, the following modifications are made to transform the passive device into a hybrid one for enhanced transparency and adaptability.

- An algorithm to detect different phases of the lifting cycle was developed using a thigh-mounted IMU.
- Inclusion of control and actuation units to attain the desired cable tension profiles during the phases of pre-tension and release (see Section III-B) while adapting to the task severity and reducing the device-to-body forces on shoulders.
- A load-bearing element was introduced to support the reaction forces from stretching the stiffness band and reduce the energy expenditure of the actuator.

The proposed phase detection algorithm is unique as it only uses the data from a single gyroscope's axis and bio-signatures for classification. In the past, multiple sensors with learning techniques were used for such purposes [13], [14]. Further, research incorporating hybrid actuation paradigms in back-assist exoskeletons is very limited [15].

The rest of the paper is organized as follows. The details pertinent to the passive and hybrid back-assist exoskeletons are presented in Sections II and III, respectively. Section IV presents the preliminary results and discussions. Finally, the conclusions are presented in Section V.

II. Passive Exoskeleton

The optimal configuration for the moment arm of the BASE emulator from [12] is adopted in this work to demonstrate the mechanics of the passive exoskeleton. Its design, different phases of the lifting task, and the profile of device-to-body force on shoulders during a typical lifting cycle are described first. It is then followed by the motivation to explore a hybrid paradigm for better user comfort and adaptive assistance.

As depicted in Fig. 1(a), the passive exoskeleton comprises Taylor's back brace with an additional base plate to mount the lever arm at a specific orientation. An inextensible nylon strap attached at the shoulders connects the load cell with another strap passing over the lever arm. Subsequently, the

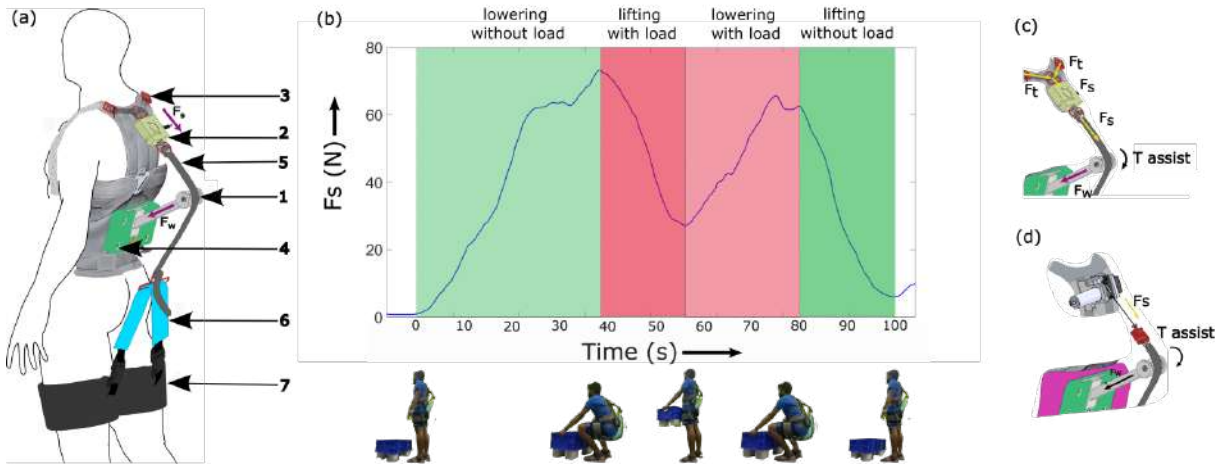

Fig. 1. (a) Schematic of a passive back-assist exoskeleton. 1: Moment Arm, 2: S-beam Load Cell, 3: Taylor's Brace, 4: Fixture for Moment Arm, 5: Non-extensible Cable, 6: Stiffness Band, 7: Thigh Straps, (b) Variation of assistive force F_s with different phases of the task involving lowering and lifting with/without load, (c) An inset depicting the shoulder straps balancing the assistive force F_s in a passive configuration, (d) An inset showing the actuator unit balancing the assistive force F_s in the hybrid design.

nylon strap is coupled with an elastic stiffness band clipped to the thigh braces.

The working principle of the exoskeleton is as follows. Initially, as the person donning the exoskeleton starts to squat, the stiffness band stretches, storing the kinetic energy till the lowest position. Later, when the person starts to stand with/without the load, the potential energy stored in the stiffness band augments the motion to reach the highest position, thereby reducing muscle efforts [8]. Also, it provides an alternative path for load transfer from the shoulders to the thighs through the mechanical components, reducing the joint loadings.

As shown in Fig. 1(b), a complete cycle of the task would involve a sequence of four phases, namely, lowering without load, lifting with load, lowering with load, and lifting without load. The forces F_s measured by the load cell would gradually increase when lowering and decrease when lifting due to the extension and shortening of the stiffness band, respectively. Further, as depicted in depicted in Fig. 1(c), these forces would create an assistive moment T_{assist} about the lumbosacral joint and the device-to-body forces including the tensile forces F_t at the shoulder and the compressive force F_w at the lumbosacral joint [12].

The modulation of assistance to match varying task severity could be achieved by replacing the elastic band with a higher/lower stiffness band or manually increasing/decreasing the pretension after donning. In the former approach, frequent donning and doffing are needed to meet the needs of dynamic task severity scenarios. In the latter, along with discomforting and unnecessary device-to-body interactions (e.g., shoulder pull) when standing, manual interruptions with frequent adjustments are warranted. Hence, in the current study, the modulation of assistance is attempted using a hybrid actuation paradigm, ensuring transparency and energy-efficient modifications.

III. Hybrid Exoskeleton

The modifications to the design of the passive exoskeleton are elucidated first. Next, a gait event detection algorithm is described using the signature of the sagittal plane angular velocity of the right thigh during lifting tasks. Finally, the control architecture, followed by preliminary results, is presented.

A. Design

The hybrid exoskeleton additionally features actuation, locking, and control units.

1) Actuation Unit: This unit modulates the assistive forces by adjusting the pretension of the stiffness band to ensure transparency in the phases of non-intervention and achieve the desired levels of assistance during interventions. Hence, it alleviates the need for manual interruptions to change the stiffness band and accounts for changes in the task severity to some extent. Further, as shown in Fig. 1(d), it replaces the nylon straps connected to the shoulders in the passive exoskeleton. Consequently, the device forces, i.e., reaction force, will now be distributed through Taylor's brace instead of being concentrated at the shoulders, enhancing the user's comfort.

A Faulhaber BP4 3274 BLDC motor with a built-in encoder and a custom pulley attached to its shaft constitutes the actuator unit, as depicted in Fig. 2(b). The two-stage custom pulley has a drum for winding and unwinding the cable next to a pawl for engaging and disengaging with a ratchet of the locking mechanism described below.

2) Locking Unit: In order to conserve energy expenditure of the portable exoskeleton and promote passive transparency, the actuation unit is only used when the required assistive forces are minimal, i.e., in the initiation of lowering and termination of lifting. In the remaining phases of the task, the assistive load is transferred to a load-bearing element through the pawl and ratchet mechanism.

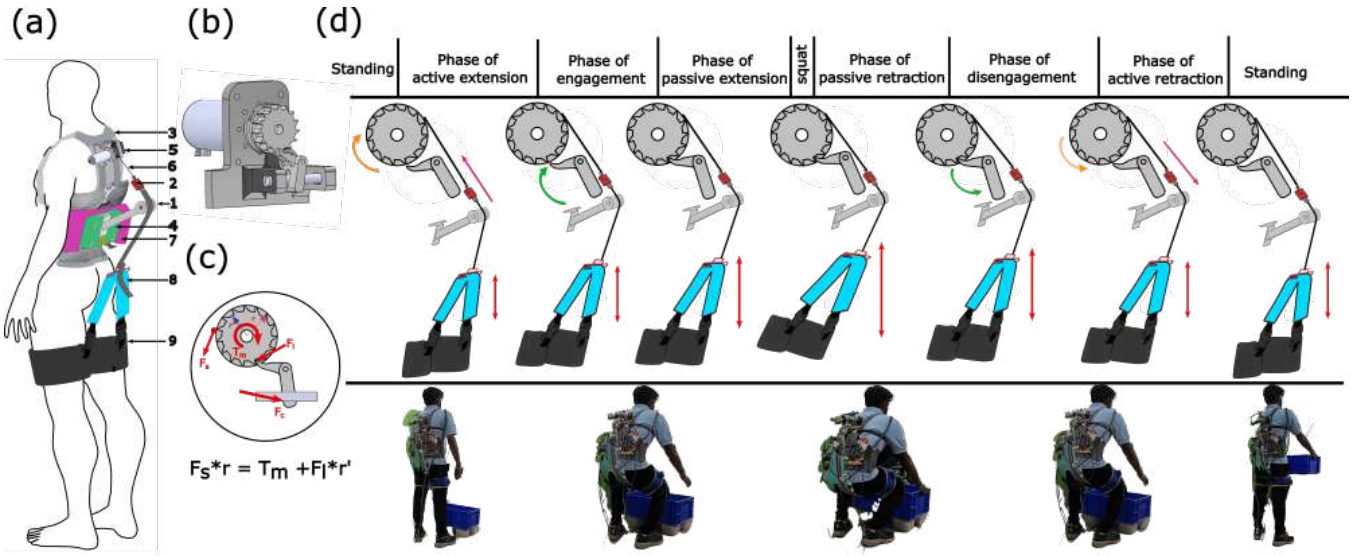

Fig. 2. (a) Schematic of a hybrid back-assist exoskeleton. 1: Moment Arm, 2: S-beam Load Cell 3: Taylor's Brace, 4: Fixture for Moment Arm, 5: Actuator Unit, 6: Inextensible Cable, 7: Control Unit, 8: Stiffness Band, 9: Thigh Straps, (b) Actuation and locking units, (c) An overlay of forces acting on different elements (including the load-bearing element) when engaging the pawl. (d) A classification of different phases of the load carriage cycle to aid in designing the control inputs. The actuator's rotation is denoted in orange, the servo's rotation in green, the cable movement in purple, and the extent of stiffness band deflection in red.

The ratchet forms the distal part of the custom pulley in the actuation unit. It was designed to engage with the pawl and transfer the load to a load-bearing element (a steel rod fixed to the motor mount) when required. The pawl is attached to an MG995 metal gear servo motor for engagement and disengagement with the ratchet at the appropriate phases using position control. Since the servo cannot support the loads experienced during the task (shown in Fig. 1), the pawl engages with the load-bearing element. As depicted in Fig. 2(c), a pawl extension makes contact with a steel rod, preventing it from moving further even when the cable pulls the ratchet to rotate anti-clockwise, acting as an anchor to support deflections of the stiffness band. Eventually, the load-bearing element would transfer the reaction forces to the back brace. Hence, with this design, the energy the BLDC motor requires to maintain the pulley position is economized. The forces experienced by the ratchet F_l can be determined from the assistive force F_s and the torque applied by the actuator T_m using the relation specified in Fig. 2(c). Subsequently, this information can be used to choose the appropriate dimensions of the load-bearing element.

3) Control Unit: The NI myRIO micro controller forms a central component that integrates the inputs from an Adafruit BNO085 IMU and an S-beam load cell to control actuation and locking at appropriate gait cycle phases. Apart from these, the control unit includes a motor motion manager and a load cell amplifier.

B. Load-carriage Phase Classifier

The signature of variations in the angular velocity of the thigh (ω_t) in the sagittal plane was used to detect different phases of the load-carriage task [16]. One of the axes of the gyroscope in an IMU, aligned with the front axis, is used for this purpose. The IMU is mounted on the thigh brace using an elastic strap. The data was collected with a sampling frequency of 200 Hz, and a moving average window of 100 samples was used to alleviate the noise.

The zero crossings and peaks of the signature determine the transition between phases. In order to avoid false detection of zero crossings, a threshold ϵ_t, i.e., a value close to zero (30 deg/s), was used in this work. The choice of ϵ_t predominantly depends on the sensor's sensitivity to small variations of the thigh motion in a static posture and is typically independent of the user. The peaks (p_i) and valleys (v_i) are identified by instances where a change in the sign of slope, i.e., $\dot{\omega}_t$, occur. As shown in Fig. 4, the following phases are detected in a sequence.

- Phase 1 $[\epsilon_t < \omega_t < \omega_t(p_1)]$: As the wearer squats without load, the angular velocity increases and reaches a local maximum.
- Phase 2 $[\omega_t(p_1) < \omega_t < \epsilon_t]$: As the wearer continues squatting without load and rests near the ground, the angular velocity decreases from a local maximum to zero.
- Phase 3 $[-\epsilon_t > \omega_t > \omega_t(v_1)]$: As the wearer picks up the load and starts lifting, the angular velocity decreases from zero to a local minimum.
- Phase 4 $[\omega_t(v_1) > \omega_t > -\epsilon_t]$: As the wearer continues moving and stands with the load, the angular velocity increases from a local minimum to zero.

The wearer would squat, leave the load, and stand up to complete one cycle. Hence, the detection of Phases 5-8 is similar to that of Phases 1-4 mentioned above.

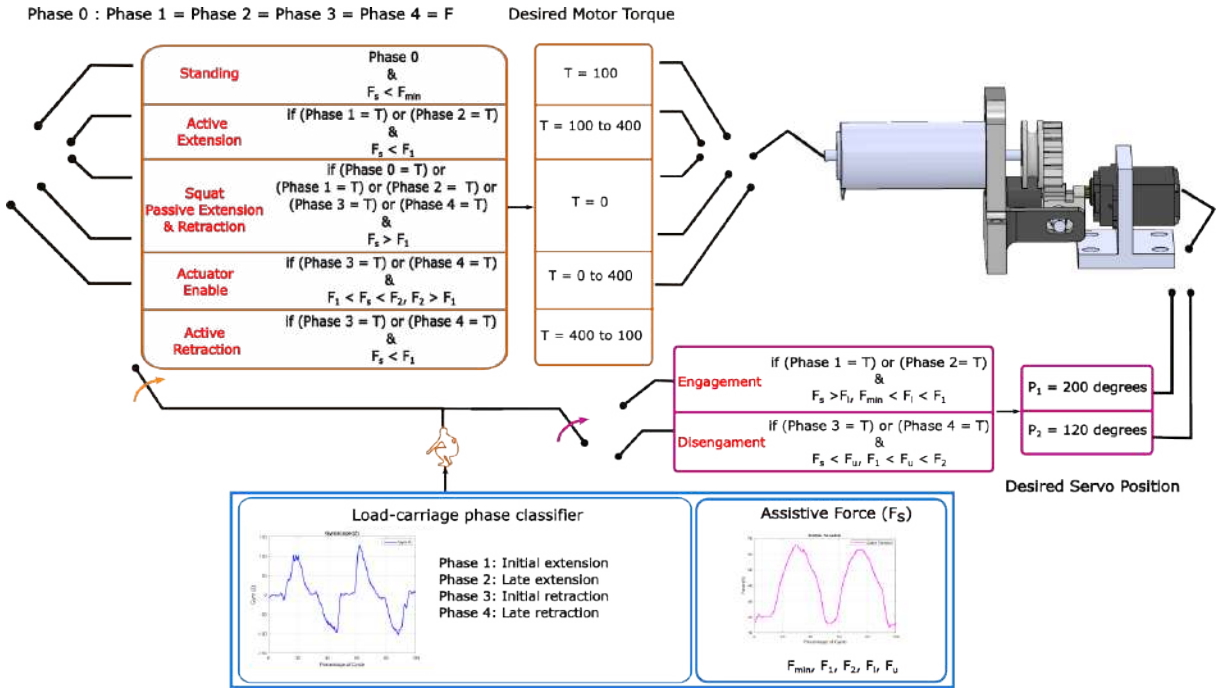

Fig. 3. Schematic of the control inputs to the actuators based on the phases of load-carriage task and the assistive force.

C. Control Architecture of Hybrid Exoskeleton

The phases identified from the signature of ω_t in Section III-B and the values of assistive force F_s, the engagement, and release of the locking unit and operation of the actuator unit are performed using the algorithms shown in Fig. 3. As shown in Fig. 2(d), a typical load carriage task would undergo the following phases twice in a cycle.

- Standing: A wearer is ideal in an upright posture.
- Phase of Active Extension: As the wearer starts to squat, the actuator starts applying the torque in a controlled manner to reach the desired assistive force.
- Phase of Engagement: As the assistive force increases beyond a specified threshold, the servo motor engages the pawl, and the actuator shuts off.
- Phase of Passive Extension: As the wearer continues squatting, the stiffness band expands with the assistive forces supported by the load-bearing element.
- Squat: A wearer halts in the squatting posture.
- Phase of Passive Retraction: As the wearer moves up, the stiffness band restores and the load-bearing element continues to support the assistive force.
- Actuator Enable: As the assistive force reduces beyond a threshold, the actuator is enabled to be ready with the necessary supporting torque.
- Phase of Disengagement: Once the actuator is enabled, the servo motor disengages the pawl, and the actuator supports the assistive force to prevent the slackness before reaching the upright posture.
- Phase of Active Retraction: As the wearer moves up, the actuator gradually reduces the assistive force to a minimum value.

In this work, the high-level control involves determining the desired motor torques and servo positions based on the inputs from IMU and load cell. The low-level torque control is governed by a PI controller of the motion manager using the feedback of motor input current and the servo positions through pulse width modulation. A typical variation of the desired control inputs during a load-carriage cycle is shown in Fig. 4.

IV. Results and Discussions

The developed exoskeleton was tested in two modes: passive and active. The details of the pilot studies with one male participant (31 years, 167 cm height, and 73 Kg weight) and their outcomes are presented below. The participant was informed about the experiment and signed a written consent approved by the Institute Ethics Committee of the Indian Institute of Technology Gandhinagar (Identifier number: IITGN/IEC/2023-24/71).

1) Passive: The purpose of this study is to demonstrate that the proposed locking unit is effective, i.e., it is capable of supporting the assistive force. For this purpose, first, the actuator achieves an assistive force of 20 N. Subsequently, the pawl is engaged, and the actuator is disabled. The pawl is kept engaged when the wearer performs the load-carriage task with a 10 kg payload.

The variation of the assistive force F_s and the actuator torque T are depicted in Fig. 5. It can be seen that the assistive force is non-zero, and its variation is similar to that of the passive exoskeleton in Fig. 1(b), indicating no slippage during the task. Also, with effective locking, the actuator does not draw current to support the assistive force.

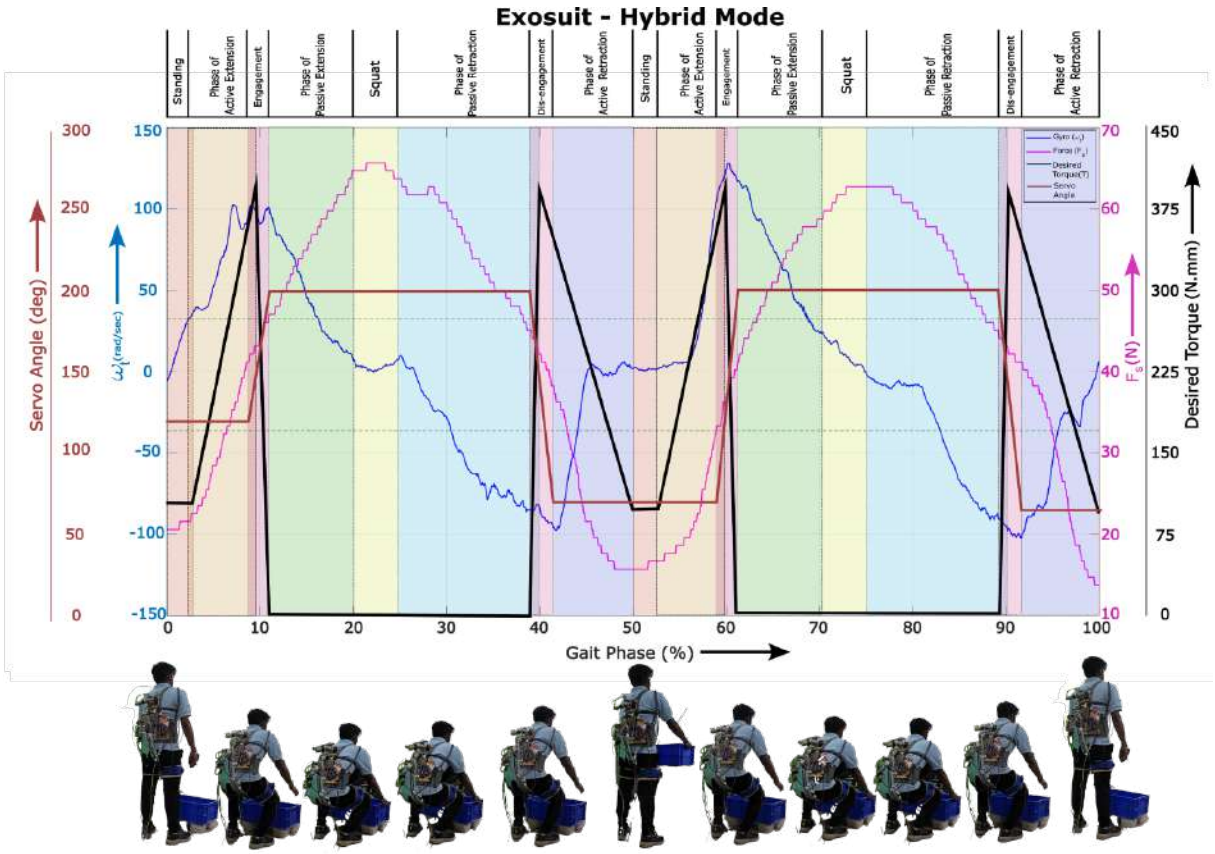

Fig. 4. A depiction of desired actuation torques and servo positions for typical variations of the thigh's angular velocity and assistive force during a load-carriage cycle.

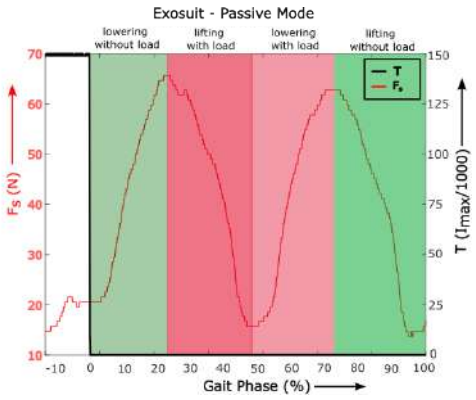

Fig. 5. Changes in the assistive force during a load-carriage gait cycle when the pawl is engaged with the ratchet and the load-bearing element.

2) Active: The typical torque requirements of an actuator to support the assistive forces in a gait cycle were investigated in this study. For this purpose, the actuator's shaft was ensured to be stationary using position control. Subsequently, the wearer was asked to perform the load-carriage task with a 10 kg payload.

As depicted in Fig. 6, the measured actuator torque varies in proportion to the assistive load. For an initial pretension of 20 N, the peak torque requirement is 80% of the rated torque, i.e., 0.65 N-m. Such loads on the actuator could be avoided with the proposed hybrid actuation strategy. Further, the zero crossings of ω_t match with the local minimum and maximum values of the assistive loads, indicating that the standing and stooping postures are identified correctly.

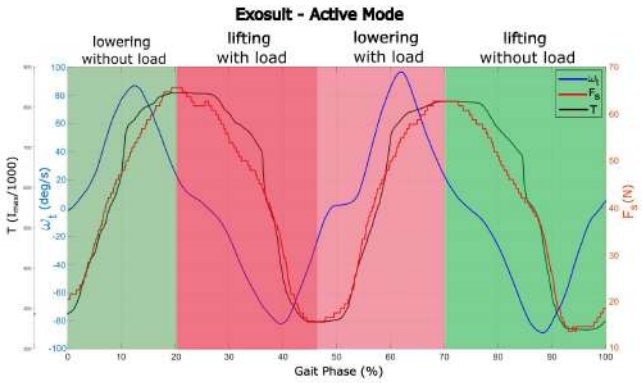

Fig. 6. Changes in the torque requirement, assistive force, and angular velocity for the load-carriage cycle when the actuator acts as a stationary anchoring point.

In essence, this work features a simple and effective classifier to detect different phases of the load-carriage task

as opposed to the ones in the past [13], [14], often requiring multiple sensors and learning-based classifiers. The proposed classifier is tested for squat lifting tasks and may not work for the cases of stooping involving minimal thigh movement. In such cases, the input to the classifier could be changed to signatures of cable tension from the load cell or angular velocity from an additional sensor placed on the trunk.

Although increasing the force F_s would increase the assistive moment at the lumbosacral joint, it would also amplify the device-to-body forces [12]. It is unwarranted to subject the participant to such forces when assistance is not required, e.g., the pretension during standing in the passive designs. Therefore, the proposed hybrid design avoids such scenarios by gradually increasing the assistive forces only when the participant starts lowering, i.e., the phase of active extension. Further, the electrical energy consumption of the actuator is kept minimal by transferring the load to the load-bearing element once the desired pretension is achieved.

Hence, the proposed hybrid design improves the user's comfort by reducing unnecessary device-to-body forces while providing the required assistance in an energy-efficient manner when compared to the active and passive paradigms [6]. These improvements were realized by the appropriate design of the actuation unit and the introduction of the locking unit. In the current work, only a qualitative and limited quantitative assessment were performed. A full-scale study with multiple participants are to be performed to establish the robustness of these units.

V. Conclusions

The feasibility of using a hybrid actuation paradigm in back-assist exoskeleton for symmetric loading conditions in squatting load-carriage tasks is investigated. An existing passive exoskeleton, BASE, is considered for improvement in this study. In order to improve user comfort, an actuation unit was developed to avoid unnecessary device-to-body forces at the shoulder and modulate the provided assistance to match the task severity. A locking unit was introduced to conserve the energy expended by the actuator and exploit the advantage of passive transparency. Further, a load-carriage phase detection algorithm is developed to provide appropriate control signals to the actuation and locking unit. In the present work, different components of the proposed actuation paradigm are examined. In the near future, experiments, including longitudinal studies, are yet to be conducted to comment on the efficacy of the proposed actuation paradigm.

Development of a Soft, Spring-like Finger Tendon Exo-Glove Design with a Four-Output Cable-Driven Linear Servomechanism

Lauren Gan[1], Oscar Vazquez[1], Nicholas Dalton[3], Zhuwei Qin[2], Xiaorong Zhang[2], and David Quintero[1]

***Abstract*—Powered hand exoskeletons offer a viable solution to improve the quality of life for individuals experiencing hand paralysis caused by cardiovascular diseases (e.g., stroke). While hand rehabilitation exoskeleton gloves aid in regaining hand functionality, enabling users to perform a variety of active daily living tasks for independent living remains challenging. This paper presents the Rehabilitative Tendon Actuated Control Hand Exo-Glove, a lightweight, soft exo-glove that uses spring-like finger tendons driven by four actuated rack and pinion transmission for finger flexion and extension. Force validation experiments measured fingertip forces during actuation, with average values of 4.95 N (thumb), 4.66 N (index), 6.61 N (middle), and 3.89 N (ring). The exo-glove achieves a maximum hand grasping force of 21 N, an open/close grasping time of 1.2 seconds, and successfully handles objects up to 450 g. These performance metrics meet healthy hand grasping criteria while offering a lighter and more affordable solution compared to other exo-gloves with large, complex set of actuator design components.**

I. INTRODUCTION

Millions of Americans experience mobility impairment, particularly in the hand or arm, from musculoskeletal disorders to cardiovascular diseases such as stroke [1]. Hand impairment weakens finger muscle movements and disrupts biomechanical coupling, limiting hand grasping capabilities [2]. Effective hand rehabilitation requires consistent and repetitive therapy, which has been shown to improve hand function and strength [3]. A Powered hand exoskeleton (e.g., exo-glove) is a rehabilitation device designed to assist with hand grasping using motorized actuators to control finger flexion and extension, combined with sensors for intelligent control. In general, exo-gloves implement force or position control schemes, using sensors such as electromyography [4], electroencephalogram [5], or force myography [6] to detect user grasping intent. However, exo-gloves face significant challenges due to their reliance on wearable sensors. Sensor placement, calibration, and signal interference can compromise accuracy and responsiveness, especially in dynamic, real-world environments.

In recent years, soft robotic approaches in exo-glove designs have significantly reduced device weight and improved user conformity compared to rigid, heavier mechanisms that are overly constrained [7]. Manufactured from complaint and flexible materials, soft exo-gloves adapt comfortably to the hand's musculoskeletal structure, making them practical for daily use. Soft exo-gloves typically use one of two actuation methods for hand manipulation. The first relies on pneumatic or hydraulic systems, where fluidic chambers with ridges expand from air or hydraulic pressure to control finger movement [8]. The second approach uses tendon or cable-driven actuation, routing cables through soft material straps and Teflon tubing to reduce friction during force transmission [9], [10]. Typically, Bowden cables are commonly employed for a push-pull linear motion along the fingers to adjust joint displacement. A notable contribution in cable-driven, soft exo-glove designs is the Exo-Glove Poly (EGP) II in [11], a polymer-based design with cable routing along both the dorsal and palmar side of the hand. The EGP II only supports three-finger actuation for the thumb, index, and middle finger in grasping objects. Although limited to three digits, the EGP II and similar designs highlight the potential of cable-driven soft exo-gloves in rehabilitation, suggesting that further investigation in different design alternatives can improve hand grasping and enhance user dexterity.

This paper presents the Rehabilitative Tendon Actuated Control Hand (REACH) Exo-Glove, a novel polymer-based, tendon-driven exo-glove designed to improve hand conformity and multi-finger functionality. Conventional cable-driven, soft exo-gloves often experience structural deformation from forces exerted by the actuator transmission [12]. The REACH Exo-Glove addresses this issue using a cable-driven linear servo actuation system that delivers strong holding force and independent finger actuation for various grasping tasks. The design introduces two key innovations. First, the exo-glove features a flexible crisscross membrane, manufactured from thermoplastic polyurethane (TPU) material, which conforms to the finger with a low profile and functions similarly to a scissor-lift mechanism, allowing efficient elongation. Second, the exo-glove incorporates a lightweight servomechanism with a custom-built four rack and pinion linear drive system, fabricated through additive manufacturing. This replaces heavier, off-the-shelf direct drive linear actuators. Theoretical kinematics and force analyses confirmed that the REACH Exo-Glove

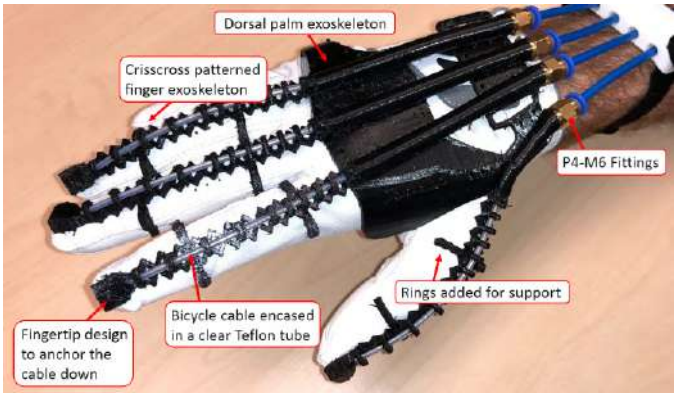

Fig. 1. REACH Exo-Glove design features a crisscross pattern, flexible cable routing structure from additive manufacturing malleable material, to enhance finger flexion. Ring anchors along the middle and proximal phalanges support the routing, ensuring efficient tendon movement.

achieves the required cable travel for producing hand flexion and extension while generating sufficient fingertip forces for grasping objects. Experimental measurements validated these findings by comparing the exo-glove's range of motion and fingertip forces to the desired specifications. A preliminary user study further evaluated the exo-glove's performance, assessing its ability to perform multi-finger grasping tasks with objects of various shapes and sizes.

II. REACH EXO-GLOVE DESIGN AND FINGER FORCE MODELING

A. Design Overview

Assistive exo-gloves must enable users to pinch and grasp objects of various shapes and sizes, while remaining comfortable, easily movable, and capable of generating sufficient force for flexion and extension. The design goals for this exo-glove include cable-driven flexion and extension actuation, full hand open/close grasping in under 4 seconds, and ability to manipulate objects of varying weights and diameters [13]. For activities daily living (ADLs) and hand rehabilitation, each finger should produce a target force of up to 5 N [14]. Full hand grasping force between 10-15 N is satisfactory for essential ADLs [15], though some existing exo-gloves exceed these values [16], [17]. Based on these benchmarks, the REACH Exo-Glove was designed to deliver approximately 5 N per finger, achieving a combined grasping force of over 20 N.

The REACH Exo-Glove actuates finger flexion and extension to enhance hand movement performance. To ensure proper alignment and user comfort, the exoskeleton body is sewn onto a lightweight spandex golf glove with breathable mesh (FINGER TEN Men's Golf Glove). The tendon-drive system positions actuators remotely, reducing the on-hand weight and improving wearability. This design prioritizes both rehabilitation and assistive applications, while maintaining user comfort. Additive manufacturing techniques (i.e., 3D printing) was employed to accelerate production, allow easily modified design components for different users adjustments,

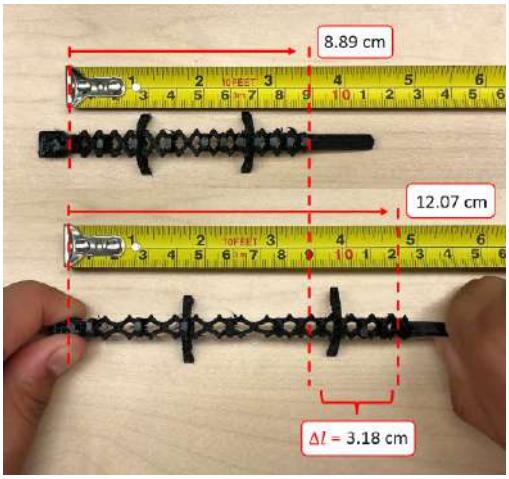

Fig. 2. The crisscross design along the finger body mimics a scissor mechanism, enabling spring-like actuation with up to 35% elongation, achieving 3.18 cm of extension during flexion.

and reduce the weight of the system. This was utilized for the finger tendon design (Fig. 1) and the custom rack and pinion gear train design (Fig. 3).

B. Elastic Finger Body and Cable Actuation Design

In Fig. 1, the exterior finger body design features a crisscross pattern at the base to enable vertical extension and compression. This structure is made from TPU material (85A NinjaFlex), which reduces costs while maintaining favorable properties for flexion and extension. This novel tendon design incorporates complaint, spring-like flexibility, as demonstrated in Fig. 2, allowing the structure to retract toward its equilibrium distance. Further, the semi-circular rings positioned on the middle and proximal phalanx provide additional support, ensuring the cable remains in a designated linear path for proper actuation parallel to the fingers. Loops extend from the crisscross base to guide the cabling. To minimize friction, a thin Teflon tube (4 mm outer diameter, 2 mm inner diameter) is placed along the finger body, trimmed to length, and slid over a 1.5 mm diameter Bowden cable. The Bowden cable provides the necessary strength and stiffness for push-pull actuation from the linear servomechanism. The cable is then threaded through the loops and anchored at each fingertip by crimping an end cap, which is securely sewn to the box-like fingertip structure and the glove. As the cable transitions from the sheath and routed through the dorsal palm exoskeleton (see Fig. 1), the cable is held in place using a crimp, that is then mounted to the connectors (PC4-M6 straight fittings) onto the servobox. The dorsal palm body mounting structure is made from TPU material and designed to naturally conform as a contour fit to the hand. This brace design is fabricated separately from the finger actuators, but integrates into the exoskeleton through sewn connections. Holes (1.5 mm in diameter) are distributed throughout the exoskeleton to facilitate this assembly.

C. Gear Transmission and Servobox

The finger flexion and extension entailed a back-drivable push-pull effect of the singular cable by way of linear motion. To provide the linear travel for the cable-driven mechanism, a rack and pinion actuator servobox was designed using polylactic acid polymer (PLA) material. The weight for the servobox is 704±2g, which includes four sets of a two-stage 2:1 gear train system, one gear transmission for each servo motor to actuate the thumb, index, middle, and ring finger independently. The little finger is not independently actuated, i.e. there is no servo motor designated for this finger. This is reasonable to exclude a dedicated actuator system for the little finger as for the human hand muscular structure [18], the ring and little share intertwined tendons. As observed during the execution of most grasping tasks, the little finger is excluded from having independent motion. For the motor selection, we opted for a higher torque servo motor (FT6335M, 360°, 35 kg/cm rated torque, 7.4V), which is 55 x 20 x 43 mm (L x W x H) and weighs 67±1g. Each independent actuated finger has its servo motor connected to the rack and pinion. The gear train comprises a spur, pinion, and linear rack, with motion transmitted from the servo motor pinion gear (see Fig. 3).

The gears used in this system are spur gears with full-depth involute-shaped teeth. The following values were chosen based on tooth system: 20° pressure angle and 1.5 mm module. Gear pitch diameters were kept below a size of 50 mm to ensure the overall size of the servomechanism would remain small for a compact servobox. Gear 3 is the pinion gear which makes it the largest gear in the system to ensure the linear travel of the rack is enough for flexion. Once the number of teeth and pitch diameters for spur gears have been selected and checked with consistent pitch circle values, gear ratios, and interference, force analysis is carried out.

The free-body diagram illustrating the gear train and the forces acting on each gear is depicted in Fig. 4. Numbering for gears begin at 1 while the shafts are denoted with the alphabet, starting with a, while F and T correspond to force and torque. Subscripts indicate the force or torque of one object against another, e.g. F_{a1} is the force of shaft a against gear 1 (spur pinion). Superscripts indicate whether the force is in the tangential or radial direction [19]. As the force we are concerned with is the force of the rack, the output force will be the value of F_{34}, as it is the pinion force transmitted to the rack. Recall, all diagonal forces must be resolved into tangential and radial forces, as seen with F_{32}, where the angle is equivalent to the pressure angle, ϕ. The rack gear is made to be as long as necessary; the length of the rack is simply dependent on the circumference of the pinion gear, therefore it is found through the simple equation $2\pi r$ and then multiplied by the control angle ratio to 360°, representing one full revolution, to get the linear travel.

The force exerted by the rack comes out to be:

$$F^t{}_{34} = \frac{2T_{b3}}{d_3} \tag{1}$$

where $F^t{}_{34}$ is the tangential force of the rack (gear 4) as it transmits the force acting on the pinion (gear 3), T_{b3} is the torque of shaft b against the pinion, and d_3 is the pinion's pitch diameter. This comes from the transmitted load equation, where the transmitted load W_t is set equal to the tangential force F^t. The tangential force is the important to recognize here as using the radial component would not be accurate because it transmits no power; thus $F^t{}_{34} = F_{34}$. F^t can be plugged into the equation for torque and W_t, where $T = (d/2)W_t$. As for working out the free-body diagram, the torques and forces acting upon the gears were calculated through first working out gear 1. Since gear 1 is the input from the motor, the gear will share torque and RPM values based on the motor used. Also, gears 2 and 3 share the same shaft, so T_{3b} is equivalent to T_{b4} where T_{3b} is solved using the equations for transmitted load and torque. After assigning measurements to the respective gears and referencing equations modeling gear force relations, F_{34} is estimated to be 9.23 N.

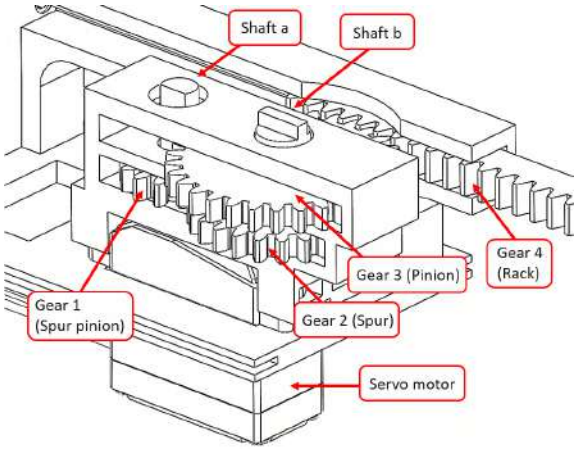

Fig. 3. Rack and pinion gear train attached to servo motor to translate rotary motion to linear motion to actuate the Bowden cables for flexion and extension.

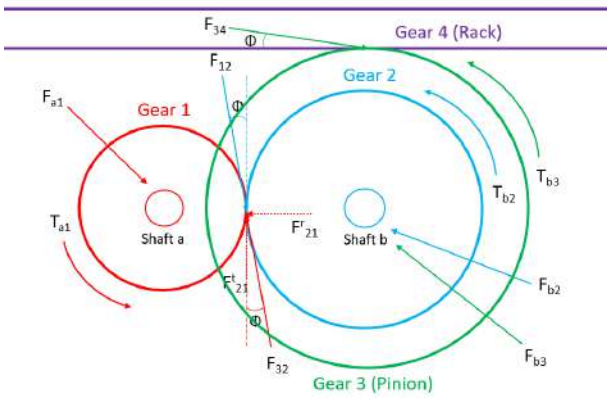

Fig. 4. Diagram of gear force resolutions per gear. Gear 1 (spur pinion) drives gear 2 (spur), where gear 2 and gear 3 (pinion) share the same shaft, and gear 4 (rack) shares the same force output as gear 3.

D. Force Estimation Using Kinematics

Kinematic calculations to estimate force were carried out a total of four times, one per actuated finger. The process of obtaining the force and torque at the fingertips is outlined as follows. The input torque at the servo spline is given by the relationship $T = k_t i(t)$, where k_t is the motor torque constant, and $i(t)$ represents the load current with respect to time as measured by the current sensors. There are four INA219 DC current sensors being used, one for each servo motor, to continuously monitor load current. This measured current is directly related to the torque generated by the servo motor. To account for the interaction between the motor and the rack and pinion, the linear force exerted by the rack is derived from the torque and can be expressed as:

$$F_{\text{rack lin}} = \frac{k_t i(t) N}{r_s} \tag{2}$$

where N is the total gear ratio of the system and r_s is the radius of the servo spline.

The linear force $F_{\text{rack lin}}$ of the rack is equal to the input force applied to the actuation cable, which is routed to the finger tip. As the cable travels through a Teflon tube, friction between the cable and the tube becomes a factor, reducing the effective force transmitted to the joints. Therefore, the output force from the cable, $F_{\text{cable out}}$, is adjusted for the frictional losses and can be expressed as:

$$F_{\text{cable out}} = \frac{k_t\, i(t)\, N}{r_s} - \mu_{\text{PTFE}}\, m_c\, g \tag{3}$$

with μ_{PTFE} representing the coefficient of friction for Teflon tubes (0.05-0.1 range). m_c refers to the mass of the cable and g is the gravitational constant. (9.81 m/s^2).

Once the force has been adjusted for friction, it is transmitted through the cable to the fingertip. To estimate the force at the fingertip, we modeled the fingers as a 2-link rigid body for the thumb and a 3-link rigid body for the index, middle, and ring fingers. In this model, measured joint angles were incorporated to approximate the finger's trajectory as the cable force flexed the finger, ultimately transmitting force to the fingertip. The metacarpophalangeal (MCP), proximal interphalangeal (PIP), distal interphalangeal (DIP), and interphalangeal (IP) joints were measured while a subject wore the glove as it was actuated to its maximum closing position. Based on the adjusted output force and the finger joint configuration, the fingertip force was then computed. Using geometric forward kinematics, the force at the fingertip, F_{tip}, is represented as:

$$F_{\text{tip}} = F_{\text{cable out}} \qquad _i = 1^n \ \cos\theta_i \tag{4}$$

where θ_i is the angle at a specific joint i, and k corresponds to the number of joints involved in finger flexion. As the cable moves the finger joints, the force is transferred sequentially through the joints, decreasing slightly based on the cosine of the angle θ_i at each joint. These angle reductions reflect the mechanical advantage (or disadvantage) of each joint as the finger moves through its range of motion.

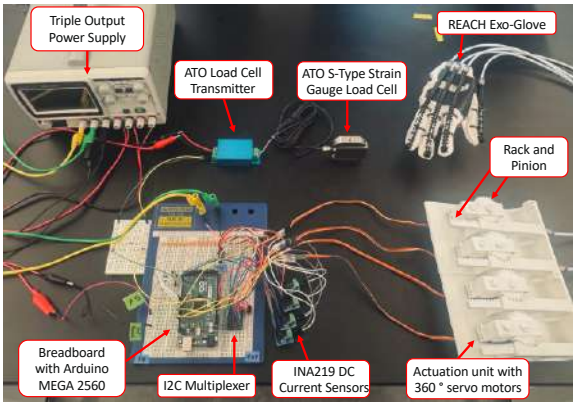

Fig. 5. Overall testing setup, where currently the prototype is actuated using a benchtop servobox connected to the microcontroller.

By summing the forces applied at each joint, we can approximate the force exerted by the finger. This iterative computation builds on the output force at each joint, which is influenced both by the cable's frictional losses and the joint angles, providing an estimate of the total force transmitted to the fingertip during actuation.

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. Experimental Hardware Setup & Protocol

The derived kinematic equation was implemented in the system and validated through the experimentation that was approved by the Institutional Review Board (IRB) at San Francisco State University. Fig. 5 shows the experimental hardware setup of the power source supplying 7.4 V, 24 V, and 5 V to the high-torque servo motors, the INA219 current sensors, and the ATO load cell transmitter, respectively. The tests utilized an Arduino Mega 2560 microcontroller to control the servo motors and measure the sensor readings measurements. During bench-top testing, the actuators housed in the servobox are placed on a table beside the user as tasks are performed. For each test, three trials were carried out, with data recorded during three phases: (1) Rest - a single finger moved from a fully open rest position to a closed position by servo actuation, (2) Press - the finger maintained a fully closed position while pressing on a load cell for five seconds, and (3) Rest - the finger returned from the fully closed position, back to the open resting position. During testing, the subject placed a single finger over the load cell, keeping their wrist and palm flat on the table and fully relaxed for the entire process.

B. Fingertip Force Experiment Validation

The results shown in Fig. 6 compare the forces applied to the load cell by each finger to the predicted force for the thumb, index, middle, and ring fingers. The load cell measurements serve as the ground truth, capturing the actual compression forces, while the predicted forces are derived from a kinematic equation implemented in the control system. This comparison validates the accuracy and consistency of the force prediction algorithm. The load cell forces have smaller standard deviations across all fingers, indicating greater consistency in the

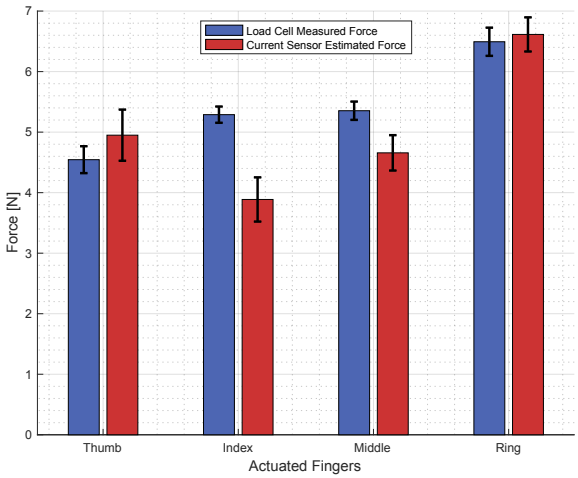

Fig. 6. Validation of Force Estimation Algorithm Using Measured Load Cell Forces as Ground Truth References Compared to Predicted Forces Across Individually Actuated Fingers for Five Trials Each .

measured data compared to the predicted forces. The thumb and ring fingers show the closest alignment between predicted and measured forces, with small absolute errors. Conversely, the index and middle fingers exhibit larger absolute errors, with predicted forces falling short the measured values. These results show the effectiveness of the prediction algorithm for certain fingers, as well as areas for further improvement.

Initially it was stated that a target of 5 N force per finger was desired. This goal was only achieved by the index, middle, and ring fingers, achieving measured forces of 5.29 N, 5.35 N, and 6.49 N, respectively. Overall, the ring finger produced the highest average force, while the thumb produced the lowest average force. The index and middle fingers exhibited similar average forces, indicating more consistent measurements. These results suggest that the load cell measurements provide reliable ground truth values for validation.

The ring finger maintained the highest average predicted force, aligning reasonably well with the measured force but showing a slightly higher standard deviation. Similarly, the thumb's predicted average force closely matches its measured value, but the standard deviation increases, indicating more variability in predictions. The index and middle fingers, however, show significant underestimations in predicted forces, with average values of 3.89 N and 4.66 N, respectively, and larger standard deviations of 0.37 N and 0.29 N. These predicted values fall short of the measured values for the index and middle fingers, which are 5.29 N and 5.35 N, respectively.

The observed discrepancies, particularly for the index and middle fingers, can be attributed to the cable routing and actuation mechanics. The cables routed over the fingers are fixed at the fingertips, creating a stiffer load for the servos to drive. However, this stiffness causes the index and middle fingers to twist as they flex forward during actuation. As a result, the fixed portion of the cable at the fingertips shifts, reducing the force pushing back against the servo motors. This reduction in force leads to a drop in the measured load

Fig. 7. The exo-glove grasped a variety of different sized objects and weights that include: a.) glue stick, b.) plastic ball, c.) hand sanitizer bottle, d.) plastic bottle, e.) aluminum bottle, and f.) spray bottle

TABLE I
AVERAGE FORCE APPLIED PER OBJECT

Object	Diameter (mm)	Weight (g)	Force (N)
Glue stick	20	16	9
Toy capsule	49	14	13
Hand sanitizer	51	119	18
Plastic bottle	64	408	19
Aluminum bottle	74	447	21
Spray bottle	35	119	–

current, which is directly used to estimate fingertip forces. Therefore the predicted forces for the index and middle fingers fall short of the actual measured forces from the load cell. This mechanical behavior highlights a key limitation in the current system design and explains the larger absolute errors observed for these fingers. Addressing variability across fingers. Could prob be written better. Also considering length, the index and middle fingers were more prone to cable stiffness as the cable is required to actuate along a longer distance. Traveling within the housing tube, greater friction force is present compared to the thumb.

Pinch and grasping tests were conducted to assess the forces applied to objects ranging from 20 to 74 mm in diameter and

weighing $\leq$ 450 g. For objects requiring a full-hand grasp, such as the hand sanitizer, plastic bottle, aluminum bottle, and spray bottle, the motors were actuated to the closed-hand position. The glue stick and toy capsule required a two-finger and three-finger pinch, respectively. Therefore, only the servo motors for those fingers were actuated to the closed-hand position. Because of this, the finger placement was dependent on the shape of the object being held. As it can be seen in Fig. 7, object f, the spray bottle, was unsuccessful. Despite providing sufficient force, the glove was not able to provide the required range of motion to grasp the spray bottle's neck. There was an approximate 10 mm gap between the glove and the bottle's surface, so it can be assumed that the minimum diameter an item must be for successful grasping is over 45 mm. Table I presents the diameter, weight, and average force per object.

IV. CONCLUSION

This paper introduces the REACH Exo-Glove, a proposed assistive exo-glove with four finger independent control. The fingers flex and extend by translating servo motors' rotary motion into linear travel in this tendon-drive approach. The glove implements a finger exoskeleton body designed for optimal flexion/extension and a servobox printed using PLA due to its low density. In efforts to advance the system proposed within this paper and upon conducting further research, the glove is planned to be integrated with additional sensors, such as to provide haptic feedback, or precise finger positions via inertial measurement unit sensors. Additional experiments on the glove's grasping will be conducted with a closed-loop control scheme and a variety of objects to determine the force required to grasp a variety of common household items. While the ergonomic design attempts to minimize strain, further redesigns will be carried out to simplify the glove's assembly process and improve user experience. The main priority of this project lies within making the glove more functional and available for future testing and research. The results obtained support the validity of using additive manufacturing for actuator design. Although the glove currently lacks a control interface and has yet to be integrated with all desired sensors, this four finger exo-glove provides a promising functional device that can allow for expansion in the biomedical engineering research field with the current lack of information about exo-gloves with this exact methodology approach.

Variable Power Assistance Robotic Manipulation System for Upper Arm Rehabilitation

S. M. Mizanoor Rahman, *Member, IEEE*

***Abstract*—We present a 1DOF power assist robotic system that can be used by stroke patients for upper arm rehabilitation. An object can be tied with the power assist robotic system, and a human patient can lift the object vertically up and lower it down continuously. The power assist robotic system provides power assistance to the human in lifting and lowering the object. The amount of power assistance could be changed, which could change the haptically perceived heaviness of the object and vice versa. Therefore, the stroke patient could adjust the perceived heaviness of the object at different stages of rehabilitation progress considering the abilities of the patient to lift and lower the object with the assist system at different stages of rehabilitation. We developed a model to quantity power assistance levels and implemented a psychophysical method to compute power assistance for different perceived heaviness of the object. In an experiment, we evaluated the performance of the power assist robotic system based on a novel evaluation scheme using healthy subjects. The results showed that the subjects were able to realize the variations in the power assistance levels due to variations in the perceived heaviness of the object. The human-robot interaction (HRI) evaluation results showed satisfactory interactions between human subjects and the power assist system. The proposed device can be used by stroke patients for free motion upper arm rehabilitation, which can improve their quality of life (QoL).**

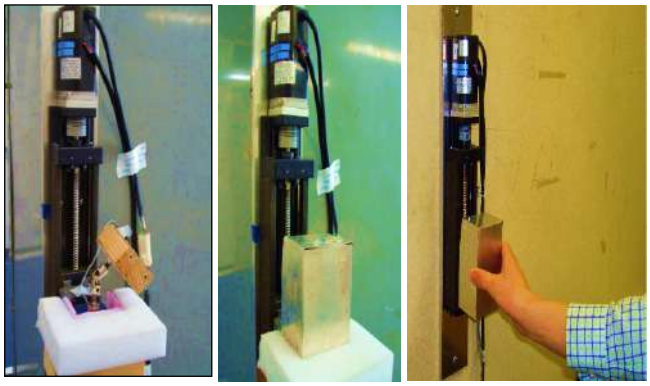
I. INTRODUCTION

Stroke patients are encouraged to receive training using rehabilitation devices, especially robotic devices to fully or partially recover the impacts of stroke [1]. The literature shows separate robotic devices for upper arm and lower arm rehabilitation [2]-[3]. For upper arm rehabilitation, it seems to be important that the robotic rehabilitation devices that provide power assistance to stroke patients may be more effective for rehabilitation training compared to the robotic rehabilitation devices that do not provide power assistance to the patients [4]. This is because the power assist devices can reduce burdens of the users/patients and augment their capabilities and performance [4]. Therefore, the use of power-assisted robotic rehabilitation devices, especially devices for upper arm rehabilitation received attention and priority [5]. However, most of the state-of-the-art power assist devices for upper arm rehabilitation are wearable, and the patients may need to bear the weight of the devices [6].

S. M. M. Rahman is with the Mechanical Engineering Program at The Pennsylvania State University, 120 Ridge View Drive, Dunmore, PA 18512, USA (e-mail: mrahman@psu.edu; Tel.: +1-570-963-2588).

We believe that a power assist robotic device that allows stroke patients to manipulate objects freely may be more advantageous and effective for robotics-based upper arm rehabilitation. However, the literature does not show such a free manipulation type power assisted robotic rehabilitation device for the upper arm.

We also believe that changes in power assistance levels through changes in the perceived haptic heaviness of the manipulated object may impact the rehabilitation process significantly [7]. For example, a patient may need more power assistance at the initial stage of rehabilitation training because the patient does not have enough strength to manipulate a heavy object. On the other hand, the patient can gain strength after receiving rehabilitation training and then he/she may be able to manipulate comparatively heavier objects, i.e., he/she may need less power assistance. Therefore, we believe that investigation on such a variable power assistance system that can adjust the power assistance levels with the rehabilitation progress of patients could be a new research direction. However, such initiatives are not so evident in the literature. We proposed such a power assist robotic system for object manipulation for industrial load handling purposes [8]. However, its prospects for upper arm stroke rehabilitation were not investigated.



Therefore, in this paper, as a preliminary initiative, we proposed a simple 1DOF power assist robotic system that a stroke patient (here, healthy human subjects) could use to freely manipulate an object (lift an object up and lower it down) tied with the power assist system to receive power assistance at the time of rehabilitation training. We changed the power assistance levels and observed how the changes impacted the feelings and interactions of the patient (here, healthy human subjects) with the power assist system.

II. THE PROTOTYPE POWER ASSIST ROBOTIC SYSTEM

We developed a physical model of the power assist robotic system, as presented in Fig.1(a)-(c) [9]. This is a proof-of-concept prototype of the system. This is a 1DOF system that the patient could use to manipulate (lift and lower down) objects tied with the system for rehabilitation training. We used an AC servomotor with an encoder at its top, and attached it colinearly with a ball screw mechanism, and attached the entire system to a wall, as Fig.1 (a) shows. We used a load cell type force sensor to sense the force applied by the human/patient. We attached the force sensor to the ball nut of the ball screw system. Then, the force sensor was tied to one end of a universal joint. The other end of the universal joint was tied to a rectangular wooden

(resin) cube. This is shown in Fig.1(a). We then used an aluminum sheet (thickness: 0.0005m) to build a rectangular box with a cap by bending it. It was a small box with size 0.06 x 0.05 x 0.12m. Then, we placed the box through the wooden cube, which looked like as presented in Fig.1(b) [9].

Fig.1(c) shows how it looked like when a patient (a human subject) grasped the object and lifted it up and lowered it down with the system [9]. The ball screw output the linear motion of the object from the rotary input motion of the servomotor. The object (box) could be placed on a foam to protect it from possible vibration to be generated when the box would touch the bottom surface (Fig.1(b)). The self-weight of the object was negligible, which was 0.016 kg. The object was manipulated with the power assist system, and we named it 'power-assisted object (PAO)'. The power assist system was connected to a computer through interfaces. This was the configuration of the prototype power assist system used in the experiments, as follows.

(a) (b) (c)

Fig.1 Different steps of constructing the physical power assist robotic system model.

III. DYNAMICS AND CONTROL OF THE ASSIST SYSTEM

Based on the physical model shown in Fig.1(c), we derived a simple dynamics model for lifting and lowering an object with the power assist robotic system as presented in (1). In (1), f_a denotes the linear force applied by the actuator (servo motor), f_h denotes the linear force applied onto the object by the human user (the patient), F denotes the force that can be generated due to the friction in the mechanical drive (ball screw) system, m denotes the mass value of the object that we may use in the control system of the power assist system (virtual mass) for the object to be manipulated with the assist system, g denotes the gravitational acceleration, K denotes the viscosity of the mechanical drive or ball screw sliding mechanism, and x_d can be used to denote the desired linear displacement of the object manipulated with the power assist robotic system, which we call the 'desired displacement' [9].

$$m\ddot{x}_d + K\dot{x}_d + mg + F = f_h + f_a \tag{1}$$

We want that patients should manipulate objects with the power assist system freely. By free manipulation, we here mean that the hand of the user (patient) may not need to be tied with the object during manipulation of the object with the power assist robotic system. Therefore, considering the free motion dynamics [9], we can ignore the actuator or motor force (it exists, but human patient may not realize it), viscosity, friction and any other types of disturbances to keep the model in (1) simple. This assumption results in a new and simpler dynamics model of the power assist robotic system as presented in (2).

$$m\ddot{x}_d + mg = f_h \tag{2}$$

Our experience shows that the weight of an object visually perceived by a human differs from the weight of the same object perceived haptically by a human user if the object is manipulated with a power assist robotic system [9]. This happens because a power assist robotic system reduces the haptically perceived wight of an object [9]. A human user (patient) may not be able to realize this difference, and as a result the human may apply an incorrect force to the object to manipulate it with the power assist robotic system. The chance of such an error in human force programming is higher in the beginning of the use of the power assist robotic system by patients because the patients are not familiar with the exact behaviors of the system.

This erroneous force application can seriously impact the motion of the assist system, which may cause injuries and accidents to the patients [9]. As an attempt to mitigate this effect, a psychophysical hypothesis is adopted that the mass parameter used in the inertial force in (2) may be different from the mass parameter used in the gravitation force in (2), which results in a newer dynamics model as shown in (3). For (3), we use the assumptions that $m_1 \neq m_2 \neq m$, $m_1 \ll m, m_2 \ll m, m_1\ddot{x}_d \neq m_2 g$. We derived a simple admittance type feedback position control of the power assist robotic system for object manipulation by patients based on (3), as shown in Fig.2. This control is simple, but it is a novel control method in the sense that it reflects patient psychology in term of potential mismatch between the visual and haptic weight perceptions of the manipulated object [9].

$$m_1\ddot{x}_d + m_2 g = f_h \tag{3}$$

IV. MODEL TO COMPUTE POWER ASSISTANCE

We propose a computational model as in (4) to compute the power assistance amount for lifting and lowering an object with the developed power assist robotic system, shown in Fig.1. In (4), *PAA* stands for power assistance amount, and *PAW* stands for power assisted weight or haptically perceived heaviness of object manipulated with the power assist robotic system for an arbitrary value of m_2 [9]. As the model shows, it is expected that changes in m_2 mainly change the *PAA* because the changes in *PAW* also depend on m_2.

$$PAA = m_2 - PAW \tag{4}$$

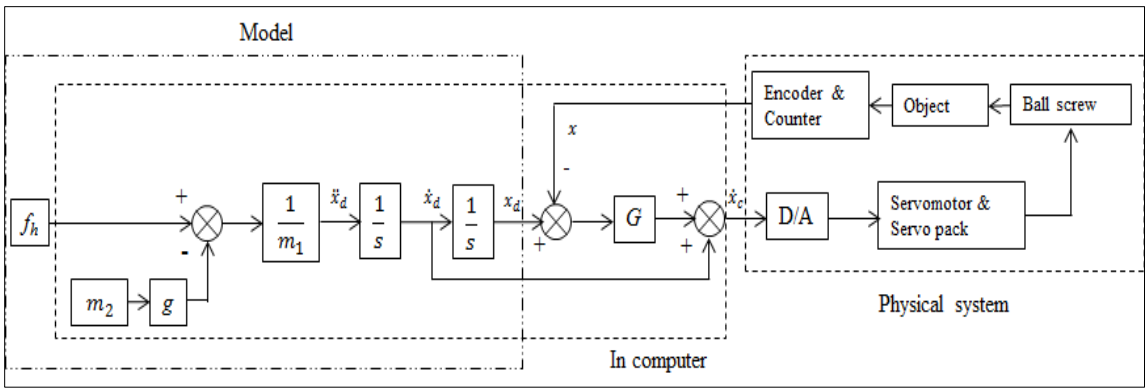


Fig.2 The admittance type feedback position control system for the power assist robotic system for object manipulation. Here, G denotes feedback gain, x is the actual displacement, x_d is the desired displacement, x_c is the commanded displacement, D/A is digital to analog converter [9].

V. EXPERIMENTS

A. Subjects

We recruited 24 human subjects (15 engineering graduate students, 9 engineering undergraduate students; 22 males, 2 females) to conduct the experiments. The ages of the subjects were from 21 years to 34 years with mean 24.39 years and standard deviations ± 4.63. The subjects received written instructions of the experimental procedures. The procedures were also verbally explained to each subject separately. We collected written consent from each student (subject) for their voluntary participation to the experiments. The study plan was approved by the ethical committee of the university. The subjects did not report major health problems. Therefore, the subjects were considered as healthy subjects.

B. Experiments Design

We conducted two independent experiments using the healthy subjects we recruited. In the first experiment (Experiment 1), we investigated whether the human subjects could feel the changes in power assistance provided by the power assist robotic system and the amount of strength the subjects needed to manipulate the object with the power assist system for each level of power assistance. In the second experiment (Experiment 2), we investigated human subjects' physical and cognitive interactions with the power assist robotic system for different levels of power assistance provided by the power assist robotic system. We believe that those investigations were very necessary for the power assist robotic system for its suitability as an upper arm free motion rehabilitation device for stroke patients. It was necessary to use actual stroke patients in clinical trials to evaluate the proposed rehabilitation device. However, unavailability of stroke patients motivated us to use healthy subjects to evaluate the proposed design in lieu of stroke patients. We believe that the results obtained through using healthy subjects would help prove the effectiveness of the proposed device in principle, which could tell about the prospect of the device for its potential use by actual stroke patients [1].

C. Experimental Procedures

For Experiment 1, we implemented the proposed admittance type feedback position control system (as presented in Fig.2) using MATLAB/Simulink. We selected the ode4 solver (Runge-Kutta; fixed-step) with the sample time (fundamental) as 0.001s. We see in the computational model in (4) that m_1 values have no influences on the power assistance provided by the system though m_1 values were observed to influence the system kinematics such as velocity and accelerations of the assist system [9]. Therefore, we used an arbitrary value m_1=0.50 in the control system in Fig.2 because such a value was observed producing the optimal kinematics of the assist system [10]. We see in (4) that m_2 values can influence the computed values of power assistance and we found in our previous research that m_2 values influenced haptically perceived weights and power assistances [10]. Therefore, we selected a combination of m_2 values heuristically (based on our experiences with the proposed assist system), which is presented in Table I.

Table I: The m_2 values selected to be used in the control system

m_2 values (kg)										
0.1	0.15	0.20	0.25	0.50	0.75	1.0	1.25	1.5	1.75	2.0

At the time of the experiment, we randomly selected a m_2 value from the set of values given in Table I and used the value to implement the control system shown in Fig.2. We then randomly selected a human subject. The human subject lifted the object tied with the power assist robotic system and lowered it down and again lifted it up and then released the object. Then, the subject lifted different reference weights (known weights) separately using the dominant hand and in this way compared the perceived haptic weight (heaviness) of the object manipulated with the power assist robotic system with that of the reference weights, and thus psychophysically estimated the perceived haptic weight of the object manipulated with the power assist robotic system [10]. This weight was named "power-assisted weight or *PAW*" of the object manipulated with the power assist system for that value of m_2. In this procedure, we conducted the experiment for each value of m_2 shown in Table I for

each of the 24 subjects separately. Each subject also subjectively rated how much hand strength he/she needed to manipulate the object with the power assist system for some selected values of m_2 such as 0.1kg (the lowest value), 1.0kg (the moderate value) and 2.0kg (the highest value) using a 7-point Likert scale, where 1 indicated the least amount of strength needed and 7 indicated the most amount of strength needed to manipulate the object [11]. We here believe that the lower the needed strength, the higher the assistance provided by the system.

For Experiment 2, we repeated Experiment 1 procedures as the above for all subjects. However, we used only 3 values of m_2 such as 0.1kg (the lowest value), 1.0kg (the moderate value) and 2.0kg (the highest value). At the end of the manipulation of the object with the power assist system, each subject responded to a set of questionnaires regarding assessing his/her interactions with the power assist system for object manipulation. We developed the questionnaires reflecting relevant human-robot interaction (HRI) criteria and each subject evaluated each of the HRI criteria using a 7-point Likert scale, 1 being the least favorable HRI and 7 being the most favorable HRI [12]-[13]. The physical HRI (pHRI) criteria [13] that we used were adaptability (how the human subjects were adapted his/her grasp configurations and grasp locations on the object) [14], coordination (how the human subjects maintained a balance between the forces they applied to the object for its manipulation and the resulted motion or kinematics of the manipulated object) [15], safety (how safe the human subjects felt when manipulating the object with the power assist system) [16], ease of use (how easy it was for the subjects to manipulate the object) [17], naturalness (how normal or natural the subjects felt when manipulating the object with the power assist system freely) [18], and intuitiveness (whether the human subjects were intuitive and enthusiastic in using the system for potential future manipulation of objects) [19].

We also used cognitive HRI (cHRI) criteria to assess the cognitive HRI of the human subjects [13]. Two cHRI criteria were the human subject's trust in the device for its intended application [20], and the subject's situation awareness at the time of object manipulation using the power assist system [21]. The subjects assessed those two criteria separately using the Likert scale [11], [13]. Another measure of cHRI was the cognitive workload of subjects for grasping and manipulating the object [22]. Each subject completed the NASA-TLX to report his/her cognitive workload [22]. All the subjects participated in Experiment 2 separately.

VI. EXPERIMENTAL RESULTS

A. Results of Experiment 1

We used the m_2 value and the mean of the corresponding *PAW* value to calculate *PAA* for each m_2 value using (4). The results are shown in Table II. The results in Table II show that the *PAW* values were almost 40% of the m_2 values [10]. This empirical relationship reveals that the power assist robotic system can reduce the haptically perceived heaviness of the manipulated object to approximately 40% of the true weight (m_2 value) of the object. The obtained results can be interpreted in such a way that the power assistance amount (*PAA*) is the amount of reduction of the true weight of the object due to the contribution (assistance) of the robotic system [9]. This can mean that more reduction in the weight haptically perceived by the user can result in more power assistance amount, and vice versa. Higher amount of power assistance should be the usual expectation of the users. The results thus prove that the human subjects can feel or realize the changes in the power assistance provided by the power assist robotic system through changes in the haptic weights.

Table II: Different m_2 values, the corresponding *PAW* values, and the computed *PAA* values

m_2 (kg)	*PAW (kg)*	*PAA (kg)*
0.10	0.04	0.06
0.15	0.06	0.09
0.20	0.08	0.12
0.25	0.10	0.15
0.50	0.20	0.3
0.75	0.30	0.45
1.0	0.40	0.6
1.25	0.50	0.75
1.50	0.60	0.90
1.75	0.70	1.05
2.0	0.80	1.2

Fig.3 shows that the human subjects needed to apply more hand strength (hand power) to manipulate the object with the power assist robotic system when the true weight (m_2 values) increased, and vice versa. The human users, especially stroke patients may not possess a high amount of hand strength at the early stages of rehabilitation. However, stroke patients can recover gradually and thus can apply more hand strength gradually and thus the stroke patients can manipulate heavier objects and obtain higher amount of power assistance gradually. Thus, this device can help stroke patients pursue a gradual rehabilitation process adjusting with the need of the power assistance amount of the system at different stages of rehabilitation progress [1].

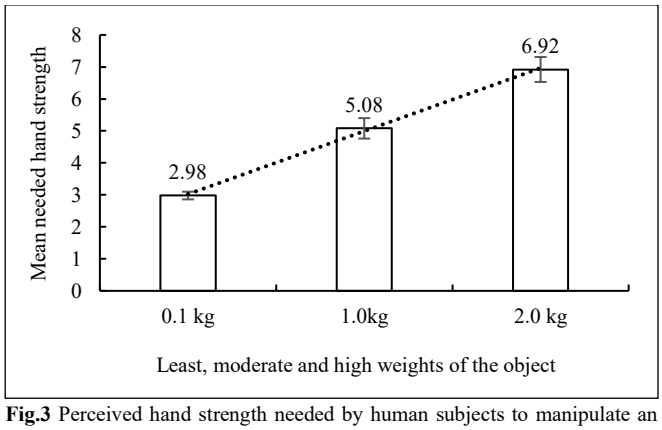

Fig.3 Perceived hand strength needed by human subjects to manipulate an object with the power assist system for different virtual weights of the object. Here, the less strength needed to manipulate the object is considered as the better.

B. Results of Experiment 2

We analyzed the displacement profile and the velocity profile for a trial for manipulating the object with the power

assist robotic system by a human subject for the m_2 value equal to 0.10kg, which showed that smooth displacement and velocity were generated when manipulating the object with the power assist robotic system. The smooth kinematics indicated that the power-assisted manipulation was safe for the users because unsafe manipulation could generate severe vibrations that could make the kinematics unsmooth or fluctuating [10].

Fig.4 shows the pHRI assessment results for different m_2 values (least, moderate and highest values) [13]. The results show that the pHRI effectiveness was the highest for the least m_2 value, and it decreased as the m_2 values increased. It happened probably due to the reason that the higher m_2 values increased the haptically perceived weights that reduced the pHRI. Therefore, an optimum m_2 value would need to be determined for optimal rehabilitation experience [10]. We conducted an analysis of variance (ANOVA) for the results presented in Fig.4, which showed that variations in the pHRI scores between the subjects were statistically nonsignificant (p = 4.82, p>0.05). However, variations in the pHRI scores between different m_2 values were statistically significant (p = 0.00039, p<0.05).

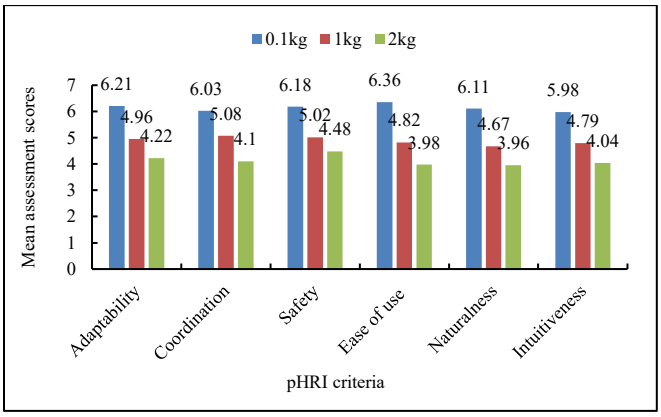

Fig.4 The pHRI assessment results for different m_2 values (kg).

Fig.5 shows the cHRI (trust, situation awareness) assessment results for different m_2 values (least, moderate and highest values). Like the pHRI results, the cHRI results also show that the cHRI effectiveness was the highest for the least m_2 value, and it decreased as the m_2 values increased. It happened probably due to the reason that the higher m_2 values increased the haptically perceived weights that reduced the cHRI effectiveness [13]. Especially, higher haptic weights for greater m_2 values might force the human subjects to concentrate more on adapting and coordinating with manipulation complexities caused by higher perceived weights and corresponding unfavorable kinematics of object manipulation [14]-[15], which might reduce human trust in the assist system as well as lower situation awareness [20]-[21]. It means that the humans needed to pay more attention to manipulating the object for higher haptic weights. As a result, humans were not able to be highly aware of the entire working environment. We conducted an analysis of variance (ANOVA) for the results presented in Fig. 5, which showed that the variations in cHRI scores between the subjects were statistically nonsignificant (p = 6.33, p>0.05). However, the variations in cHRI scores between different m_2 values were statistically significant (p = 0.00687, p<0.05) [13].

Fig.6 shows the cHRI (cognitive workload) assessment results for different m_2 values (least, moderate and highest values) [22]. The results show that the cognitive workload was the least for the least m_2 value, and the cognitive workload increased as m_2 values increased. Note that least cognitive workload is the best [22]. Those results might occur because the human subjects needed more efforts and physical and mental demands when the haptic weights increased, and the corresponding kinematics became more unfavorable when m_2 values increased. Human subjects had more pressure on maintaining time and performance for unfavorable kinematics due to higher m_2 values that caused frustration [23]. All those situations increased the cognitive workload for increased m_2 values [22]. We conducted an analysis of variance (ANOVA) for the results in Fig. 6, which showed that variations in cognitive workload scores between subjects were statistically nonsignificant (p =18.48, p>0.05). However, variations in cognitive workload scores between different m_2 values were statistically significant (p = 0.000824, p<0.05) [13], [24].

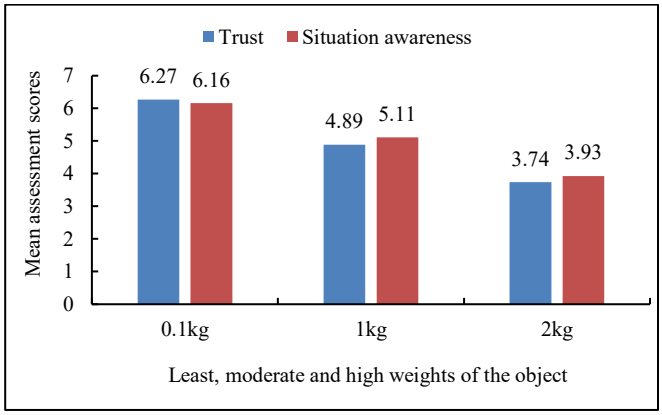

Fig.5 The cHRI (trust and situation awareness) assessment results for different m_2 values.

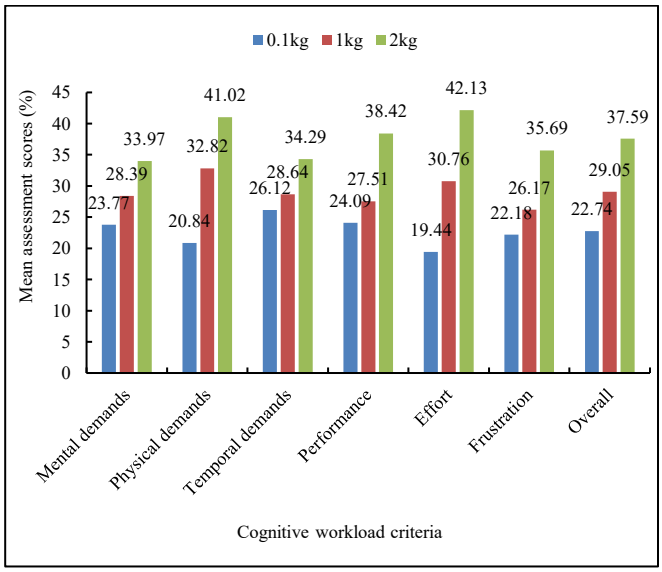

Fig.6 The cHRI (cognitive workload) assessment results for different m_2 values (kg).

VII. CONCLUSIONS AND FUTURE RESEARCH

We developed a 1DOF simple and small power assist robotic system so that stroke patients could manipulate an object tied with the power assist system freely, which could facilitate their free motion rehabilitation training by providing variable power assistance in object manipulation. We also applied a psychological cue (weight perception) to adjust the control of the system following psychophysical approaches to enhance safety and adaptability of the assist device for stroke patients. The evaluation results show that the device can provide variable power assistance at different conditions, which can help stroke patients adjust the power assistance amount with their hand strengths at different stages of rehabilitation progress. We also evaluated the effectiveness of interactions of healthy subjects with the device and the results show that the interactions were effective and satisfactory. Those results using healthy subjects indicate the possibility that similar results may be obtained if the device is used by stroke patients.

In the future, we will derive more advanced control methods that can further enhance safety and adaptability of the system for stroke patients. We will conduct a clinical study using stroke patients to verify and validate the results that we obtained herein using healthy human subjects.

ACKNOWLEDGMENT

The author conducted the experiments when the author was with Mie University, Tsu, Mie, Japan. The author expresses his thanks to Mie University for the support he received at that time for this research.

Research Ethics Statement:

The author followed necessary ethical principles while working with the human subjects for this research. Informed consent was received from the subjects.

EPIC-Tech - Engineering and Physiotherapy Interdisciplinary Collaboration with Technology: A case study

Camila Shirota, Jacquelin Donovan, Catherine Cave, Sami A. Kaab, Alejandro Melendez-Calderon

Abstract— **We present a case study investigating the impact of integrating a novel rehabilitation device (Andago) into physiotherapy services of a public hospital in Australia. A 3-month baseline of usual therapy was compared to a 3-month trial which involved an implementation team consisting of a physiotherapist and a rehabilitation engineer supporting a new rehabilitation device being used in clinical practice. Therapists were free to use the Andago for therapy. The patient progressed from non-ambulatory during baseline to walking with single-person assistance by trial end. There was a higher proportion of therapy dedicated to walking when comparing baseline to trial phases, and when comparing Andago and usual therapy within the trial phase. However, therapists reported increased perceived strain and fatigue during Andago-assisted sessions. Therapist engagement with the Andago was moderate, with the device utilized in approximately one out of five sessions per week. The implementation team enabled safe and supported uptake of the novel device which was valued by the case study participant and their therapist. Findings suggest the Andago's potential to enhance gait training but highlight the need to address usability challenges and staff burden to optimize integration and adoption in clinical practice. We believe this can be addressed by better integration of clinically-oriented engineers in the delivery of rehabilitation services.**

I. Introduction

Rehabilitation technologies have the potential to support the delivery of therapy. Electromechanical gait training devices in combination with physiotherapy increase the chance of regaining independent walking ability for patients after stroke [1]. However, the adoption of rehabilitation technologies in clinic is still limited [2, 3]. Many factors affect the clinical adoption of rehabilitation technologies [4], including training requirements, limited technical support, difficulty in evaluating different technology-based options when initial investment is high, and a history of technology not meeting the needs of patients and therapists. Although clinical physiotherapists already manage many of these issues, it is typically not within their scope of practice. In contrast, these issues are within scope of rehabilitation engineers, who can play a crucial role in addressing these challenges. For instance, they can collaborate with therapists to translate clinical goals into technology-enabled training programs, allowing therapists to focus on patient care without the added concern of adjusting and operating a variety of devices. They can also establish robust technical support to ensure therapists have access to assistance when needed, reducing the burden of limited support and high training requirements. Furthermore, engineers can facilitate the evaluation of different technology-based options by conducting thorough assessments that consider clinical/user needs and technical specifications. They can help therapists make informed decisions, even when faced with high initial investments (e.g., device cost). Lastly, by actively engaging with both patients and therapists during the design and implementation phases, engineers can ensure that the technologies developed truly meet the needs of end-users, addressing the historical issues of technology not aligning with the reality of service delivery. A collaborative approach where rehabilitation engineers become an integral part of clinical rehabilitation teams, could foster more effective and efficient adoption of technologies. Fortunately, new models of cooperation between rehabilitation stakeholders [5, 6] are gaining ground and demonstrating positive outcomes.

Our goal is to establish a targeted approach to implementing new technology in rehabilitation services–which is currently fragmented and does not fully exploit potential synergies across disciplines (e.g. physical therapy and clinical rehabilitation engineers). An alliance between rehabilitation engineers and therapists could address some of the challenges in clinical adoption of technology, resulting in better rehabilitation outcomes for patients. To test this concept, we pilot the introduction of a novel device to the therapy team within a public hospital. Here, we describe the protocol for our study, and elaborate on the journey of one case study–with the purpose of discussing insights into the factors that can facilitate successful technology adoption in an inpatient rehabilitation hospital.

II. Methods

The selected device for this pilot trial was the Andago (Hocoma, Switzerland)–a medically-certified robotic device that provides adaptable body weight support to allow users to

J. Donovan and C. Cave are with the Princess Alexandra Hospital, Metro South Health, Australia

S.A. Kaab was with The Hopkins Centre, Griffith University, Australia, and the School of Electrical Engineering and Computer Science, The University of Queensland, Australia

A. Melendez-Calderon is with the School of Electrical Engineering and Computer Science, and the School of Health and Rehabilitation Sciences, The University of Queensland, Australia; and the Jamieson Trauma Institute, Metro North Health, Queensland, Australia (alej.melendez@uq.edu.au)

practice standing, balance and walking tasks safely in overground conditions. The Andago has been assessed for usability and acceptance in inpatient neurorehabilitation populations [7-9], and the short set-up times and overall high satisfaction by patients and therapists suggest it is a promising adjunct to conventional overground gait therapy. Thus, it provides an ideal use-case to test the overall concept of a therapist-engineer alliance more broadly, with decreased concern for the usability of the technology itself being a confounding factor [10].

The Andago was a novel device for the rehabilitation services involved in this study, and unknown to the physiotherapy clinicians other than those on the research team (JD and CC). Research team members (CS, JD, CC, AMC) were trained to operate the device, in a train-the-trainer model.

A. Participants

The study took place at the Geriatric and Rehabilitation Unit and the Brain Injury Rehabilitation Unit of the Princess Alexandra Hospital (Brisbane, Australia). Inclusion criteria for patient participants included being an inpatient over 18 years of age; eligible to use the Andago (<2.00 m and <135 kg); eligible for standing, stepping, and/ or overground gait and balance training with need for bodyweight support or falls prevention mechanism; and adequate English, cognition and communication skills (or legal guardian) to provide consent. The study was approved by local ethics committees (HREC/2023/QMS/99869, GU Ref No: 2024/024). All participants provided consent prior to study enrolment. Participants were enrolled in the study as they became eligible to participate (e.g., became inpatients or started gait training), and exited the study as they were discharged from hospital or at the end of the study period(s).

B. Protocol

The study was split into two phases of 12 weeks: a baseline and a trial phase, with 8 weeks in between. In the baseline phase, patients followed treatment as usual. Within the clinical settings of this study, the included services aim for at least one physiotherapy session of 60 min per day for every inpatient. In the trial phase, the treating team had access to an Andago as an option to be used as part of therapy. The Andago was available for use as part of a clinic that was offered for 4-half days/ week, organized and staffed by an implementation support team of one advanced physiotherapist and one rehabilitation engineer (both from the research team). Bookings were available for 45-60 min, and limited to 2x/ week per patient due to patient numbers and clinic capacity. Andago sessions were led by the patient's treating therapist, who could refer to the implementation team members for support as needed (e.g., clinical reasoning, device operation, troubleshooting). The implementation support team further managed scheduling, communication with clinical teams, therapist training, ensured the device was ready for use (e.g., charging, cleaning between patients, storage), and overall safety during use.

C. Data collection and analysis

Patient demographics–such as age, condition, and date of admission–were collected at study entry. To compare the effect of therapy during the study phases, we chose assessments and outcome measures that were familiar to and routinely used by the clinical teams and thus more easily integrated into the patient workflow. Patient outcomes were collected at study entry and exit, including functional measures (i.e., Functional Ambulation Category - FAC, a global summary of physical function using the Clinical Outcome Variables Scale - COVS [11], a summary of staff physical assistance required for several mobility tasks including transfers and walking, 10-meter walk test and quiet balance measures).

As part of the study, the participating patients' treating physiotherapist documented every therapy session. This included the number and experience of staff that delivered the session (junior – new graduates, senior, and advanced – e.g., specialists and leads of clinical service teams); estimates of the amount of time spent standing, stepping, walking, and total exercise time. Standing, stepping and walking were recorded as discrete items, for example, standing time did not include any time associated with stepping or walking tasks. Therapists also recorded the estimated number of sit-to-stands and steps, and distances walked; the levels of physical strain and fatigue perceived by staff to deliver each session; and any factors that might have impacted therapy. Physical data sheets were given to therapists every Monday and collected every Friday.

During the trial phase, research team members also documented every Andago session. Similar to the usual therapy session documentation, it included the number and experience of staff who delivered the session; estimates of the amount of time spent standing, stepping, walking, and total exercise time; the number of sit-to-stands and steps, and distances walked; and the levels of physical strain and fatigue of staff to deliver each session. Total exercise time and walking distance were taken as measured by the Andago. Patients and clinicians were invited to semi-structured interviews at the end of the trial phase to provide their perspectives as participants in this study.

We separated session data between days with and days without therapy, to understand what affects the delivery of regular therapy. All session data were averaged across the session types (i.e., baseline, trial without Andago, and trial with only Andago). We used these data to better understand what types of activities are completed during therapy sessions, staffing utilized and service delivery-related outcomes (e.g., number of sessions delivered, session duration). To compare sessions between study phases while minimizing external factors, we identified 2 participants who were enrolled in both phases of the study. We selected the longest enrolled participant for this case study.

III. Results

This case study is about a 60-year-old male (1.75 m, 71.5 kg), who had multiple strokes over the course of one admission (right MCA followed by meningitis and a right cerebellar stroke over 5 weeks). He had type-2 diabetes, vasculitis, hypertension, and gastro-oesophageal reflux disease comorbidities. He was admitted to rehabilitation 3.5 weeks after his second stroke. When admitted to the physiotherapy service, he had 4 mobility goals for discharge: transferring (e.g., from bed to chair) independently, standing

independently at a rail for 5 min, walking with a mobility aid (e.g., walker, walking stick) and assistance of 1 person for 20 m, and accessing the community with a wheelchair and assistance of 1 person. This patient joined the baseline phase (36 days post-last stroke) for its last 7 weeks, the trial phase for the full 12 weeks, and was discharged a few weeks later. The patient's outcomes improved throughout these periods (TABLE I.); notably, he was unable to walk at baseline entry and progressively improved to require the assistance of only 1 person at exit of the trial phase.

[a]number and type of assistance required: SBA=stand-by-assist (i.e., patient is not touched but person is nearby in case of e.g., loss of balance or safety risk); A=assist; -=unable.

[b]Clinical Outcome Variables Scale, from 13 (lowest) to 91 (highest) physical function.

[c]Functional Ambulation Category, from 0 (requires 2+ assistance) to 5 (independent) walking ability.

During the baseline study phase, a total of 39 sessions were documented. 6 sessions were not delivered due to public holidays (n=4), staffing issues (n=1), or other therapies (n=1). 4 sessions were affected by other therapies (n=2), medical procedures (n=1), or staffing issues (n=1), resulting in shorter sessions. 7 extra therapy sessions (i.e., second therapy session for the day) were delivered by physiotherapy assistants.

During the trial study phase, 63 sessions were documented. 13 sessions were not delivered due to public holidays (n=1), patient doing other activities (such as discharge planning, n=4), staffing issues (n=2), patient issues (n=2), other therapies (n=2), and not specified (n=2). 24 sessions were shortened by other therapies (n=18), other activities (n=3), Andago (n=2), and staffing issues (n=1). 14 sessions were with the Andago only.

On average, during the baseline phase on days where therapy was delivered, the patient received 65.2 min of therapy, with approximately 1/3 of the time spent on gait-related activities (Fig. 1). During the trial phase, therapy lasted 42.0 min on average per day, with increased portions focused on gait-related training (39% without Andago and 66% in Andago-only sessions). There was a decrease in standing time and repetitions, a slight increase in stepping time with increased number of steps, and a clear increase in walking time and walked distances between the baseline and trial phases, and sessions without and with the Andago.

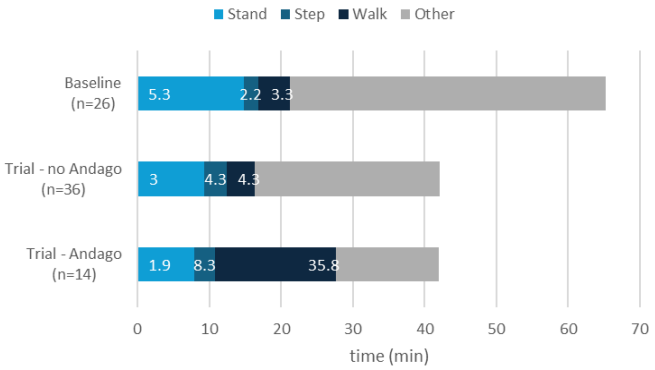

Figure 1. Breakdown of physiotherapy sessions: average dose and intensity of activities per therapy day. Numbers inside bars indicate number of sit-to-stands, number of steps, or distances walked (in m).

Baseline sessions required, on average, 1.5 staff per session to deliver therapy (Fig. 2), while trial phase sessions required approximately 1.2 staff with or without the Andago. Trial sessions had relatively more senior staff. Note that the Andago implementation team had dedicated advanced physiotherapists.

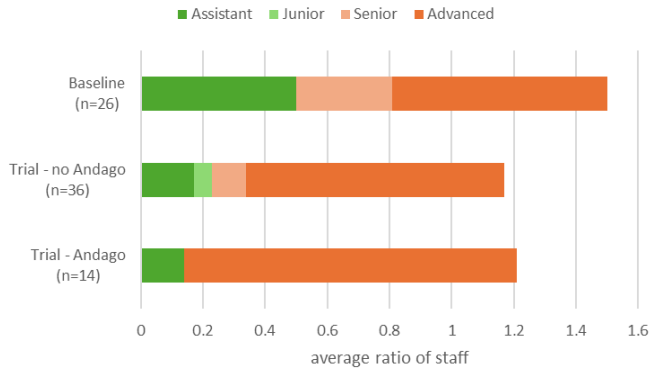

Figure 2. Staff required to deliver therapy (n=number of sessions): average number of staff and their level of experience per session.

Staff perceived baseline phase sessions (Fig. 3) more straining than trial sessions overall (average 1.36) and similarly fatiguing (average 0.94). Andago sessions were associated with the highest perceived strain and fatigue, and trial phase non-Andago sessions with the lowest strain and fatigue.

Regarding the patient's and therapist's perspectives, based on preliminary analysis of the interviews, the case-study patient stated that the Andago helped him balance, he felt more in control, and he was able to do more with the Andago than when free walking with his therapist. The therapist was initially unsure about the suitability of the device to the patient but saw therapeutic and psychological benefits once initiated, they found implementation staff support allowed them to focus on the patient during Andago sessions, and the implementation team were able to support the service more widely by providing expertise to address issues with other existing technologies that were otherwise not being used.

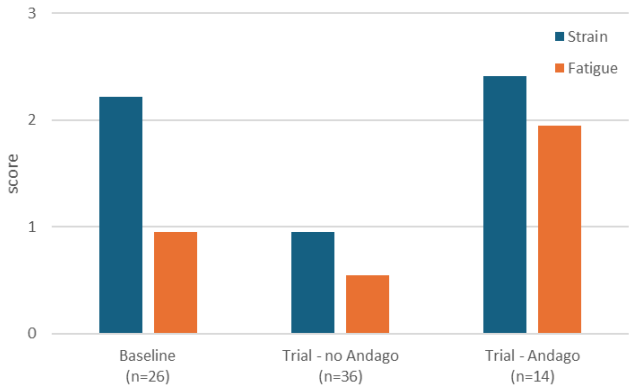

Figure 3. Staff perceived strain and fatigue delivering sessions. Scale from 0 (least) to 10 (most).

IV. Discussion

This case study illustrated the potential benefits of integrating a novel rehabilitation technology, in this case the Andago, into routine inpatient neurorehabilitation care in a model supported by a clinician and a rehabilitation engineer. Specifically, the patient was able to increase the amount of walking training compared to usual care sessions. During the trial phase, the amount of walking was remarkably higher in sessions using the Andago compared to without; but this came at the expense of staff perceiving higher strain and fatigue to deliver therapy.

Despite the expectation that a body-weight support device would decrease the physical demands of gait-related training on therapists, the treating therapist perceived it to be more physically straining and fatiguing than usual therapy. The most likely reason for this result was the much larger number of steps and walking distance achieved within the device compared to usual therapy, in combination with the physical build of the device impacting on the therapist's access to the patient's leg and preferred methods of facilitation. Although the Andago is not counter-indicated for patients that require leg facilitation to walk, this may have negatively impacted therapists' perceptions of the device. With further time and use, therapists may be able to develop different strategies to facilitate leg movements in less straining and fatiguing ways. Furthermore, it is possible that gait-related (and thus most physically strenuous) activities were mostly reserved for the Andago sessions, which is supported by the increased walking times and distances in these sessions when compared to sessions without the Andago. Despite the treating therapist's increase in fatigue and strain, the overall physical assistance of a second person for therapy reduced. In particular, as described by the therapist in a post-trial interview, during Andago training the second assistant was required to do very limited manual handling compared to their requirements completing similar gait tasks without the Andago. It could be that less overall staffing during Andago sessions resulted in higher strain and fatigue for each individual therapist. Although strain and fatigue scores were overall low (< 2.5 out of 10), the increased perceived physical effort could keep therapists from using devices. Indeed, usability issues are often cited as barriers to the adoption of technology in clinical settings.

Many of the changes observed in this study are due to the patient's improvement during their inpatient stay. For example, the length of therapy sessions and number of staff decreased between the baseline and trial phases, which could reflect more resources (in the form of staffing and extra sessions) afforded to this patient during the baseline phase due to his high level of functional impairment, which was not needed in the trial phase as he improved. This is supported by a higher proportion of the trial sessions dedicated to gait-related activities, which also shifted from standing to walking. This difference is even more evident when comparing concurrent trial phase sessions with and without the Andago, suggesting the device was not only appropriate and useful for this patient, but also enabled higher intensity gait intervention provision as reported in [9].

As a first pilot study of the EPIC-Tech model, we were interested in whether and how much therapists would engage in using a new piece of technology as part of their therapy. As such, therapists were able to decide whether their patients would benefit from the device (Andago), and schedule its use accordingly. For this case study in particular, the treating therapist chose to use it for roughly 1 session out of 5 in a week rather than the 2 that were available to them. This could be due to competing workload demands and challenges aligning with Andago clinic times from the treating therapist, who also had managerial responsibilities. This highlights an organizational obstacle to device implementation, which requires more careful consideration should we expect increased adoption and use of ever more complex devices.

Despite best intentions to deliver at least 1 physiotherapy session per day, many sessions were missed or shortened due to other activities. Notably, issues were mostly at the organizational (e.g., staffing and other therapies), and patient (e.g., prioritization of other activities) levels [3, 12]. We believe that the presence of the dedicated therapist and rehabilitation engineer to support the use of the novel device avoided the appearance of issues related to technological factors (e.g., usability, technical issues). Notably, the device was always set up for every clinic, any device errors that occurred during sessions were quickly resolved on-the-spot, and no sessions needed to be modified due to device-related issues. Such practical issues are rarely considered in research studies but are critical in implementation of technologies into clinical practice, and should be further studied.

A. *Limitations and future work*

While this is only a single case study, we aimed at reporting clinically relevant insights into how rehabilitation technologies may impact therapy delivery. Our team has collected data from 25 participants, and is in the process of fully analyzing the pooled data. In our ongoing analysis, we will not only examine the service delivery outcomes and Andago training data, but also incorporate patient and staff experiences from semi-structured interviews, as well as discussing key considerations such as workflow integration and organizational readiness.

V. Acknowledgment

Authors acknowledge Mr. W Mitchell for his valuable contributions to this research, as a colleague researcher and as a consumer representative; and Dr. R Bell, Director of the

Brain Injury Rehabilitation Services at the Princess Alexandra Hospital for supporting this study.

***Abstract*—In the field of wearable robotics, assessing physical human-exoskeletons interaction (pHEI) is of critical importance in the development of wearable assistive devices. However, in the early stages of development of such devices, involving human testing could raise safety and ethical concerns. To address those limitations, we developed an active dummy leg named Leg Replica. Yet, the realism for pHEI was not adequate when mimicking soft-tissue behavior (compression and shear). The work presented here focused on identifying synthetic soft tissue simulants to enhance the fidelity of the Leg Replica, resulting in responses under compressive and shear stresses similar to those observed in human subjects.**

A novel approach is proposed in this work as a testing method for mechanical characterization of compressive and shear stresses of human soft tissues that is coherent with the specific application of wearable lower limb exoskeletons. The testing methodology was applied to 10 human subjects as well as the Leg Replica enhanced with three different platinum-catalyzed silicone material of varying hardness and thickness. One of the tested materials, with a thickness of 3 cm, demonstrated a mechanical behavior under compression and shear stresses comparable to that observed in human tissue. This study demonstrates the ability of the proposed methodology to objectively benchmark the adequacy of the Leg Replica combined with a new tissue simulant to mimic the biomechanical behavior of the human leg.

I. Introduction

Robotic assistive devices such as lower extremity exoskeletons have been developed for the past four (4) decades, but only in the last 10–15 years they have received a great interest both from the scientific and industrial community. Such devices can range from different target contexts: healthcare, industrial, and consumer applications [1]. This rapid development of such wearable devices led to an increased number of available options seeking to reach the market [2].

In a previous work from our group, the critical problem faced by the community regarding the lack of a systematic benchmarking framework to quantitatively assess and compare these technologies was pointed out [3], which is crucial when considering any device to reach the market [4].

To fill this gap, a sensorized robotic dummy limb of a human leg (hereon referred to as Leg Replica) was developed and fabricated to provide a standard and reproducible test-bed that can be used to study multiple aspects of physical human-exoskeletons interaction (pHEI) without the need of involving human individuals, particularly in the initial phases of the development of wearable robotic assistive devices. Details of the Leg Replica can be found in [5]. A benchmarking methodology to study pHEI based on the Leg Replica was recently proposed [3], in which a soft silicon layer was placed between the exoskeleton and the dummy leg rigid outer shells to mimic human soft tissues. The presence of a soft layer between the Leg Replica and the exoskeleton is not only to reduce noncontact area resulting from the rigid outer shells (made of ABS thermoplastic polymer), but also to guarantee that the Leg Replica itself serves as a realistic benchmarking platform for testing wearable lower-limb assistive devices. Indeed, the ability of the soft tissue simulant to follow the movements imposed by the exoskeleton without slippage is a crucial requirement to ensure high fidelity of human soft tissue mechanics and an effective evaluation of the exoskeleton performance. In our previous work, the mechanical properties associated with the soft tissue composition found in the human leg were obtained using a 1.3 cm-thick layer of a platinum-catalyzed silicone (EcoFlex OO-30™, Smooth-On Inc., Macungie, PA, USA).

The work presented here aimed to identify a synthetic

This work was supported by the research initiation grants to Lecturers "ALECTORS-2023" as described in the agreement CG/2023/08/07, of October 25, 2023, of the UPC Governing Council and also by the project EXOSAFE, awarded by the COVR European Project under grant agreement No. 779966.

simulant material that would improve the human likeness of the Leg Replica regarding human soft tissues in terms of mechanical behavior when wearing an exoskeleton. In the process of selecting the synthetic simulant, a novel application-oriented testing method for mechanical characterization of the overall compressive and shear stresses of the thigh has been developed. The specific procedures originated from the consideration that proper development and characterization of synthetic simulants (material + thickness), followed by comparisons with human tissue properties, can be challenging. Additionally, this process requires specialized knowledge and potentially collaboration with experts in the field, and it is application-specific. The proposed tests aim to provide a basic characterization that is compatible with the aim of measuring the exoskeleton mechanical load to the human leg consisting of compression and shear stresses applied to the human soft tissue by the cuffs and straps used to secure wearable lower limb exoskeletons around the human leg. Without a detailed knowledge of the material's intrinsic properties, our goal was to find a synthetic material that would behave, at macroscopic level, like human tissue under compression and also how much displacement the simulant would allow in response to tangential forces oriented longitudinally without any slippage of the straps. To our knowledge, no similar characterization tests have been reported in the literature.

This approach was necessary because, on the market, there are many commercially available materials labelled as skin tissue simulants, however the properties required to replicate tissue behavior vary based on the specific application. Consequently, a material that effectively simulates tissue behavior for one application might not perform as well in another. It is crucial that material selection is carried out through tests tailored to the specific application context.

The paper is structured as follows. Section II describes the methodology adopted for this evaluation. Then, results are presented and discussed in Section III and Section IV, respectively. Section V offers concluding remarks from the work presented.

II. Materials and Methods

The main aim of this work is to characterize the mechanical properties of human soft tissues at the macroscopic level, with a focus on the specific application of mobility assistive devices such as exoskeletons. This characterization is a necessary step to find the requirements for a soft tissue layer to be added to an existing Leg Replica [5] and make it an effective benchmarking device to emulate the human leg for wearable exoskeleton R&D and to investigate pHEI. Therefore, in this section, an application-specific method is presented that aims to characterize the mechanical properties of human limbs in the context of wearable lower-limb exoskeletons. Specifically, the method includes two tests to characterize the macroscopic compressive (1) and shear (2) stresses of the thigh. These tests are conducted both on the Leg Replica thigh together with the simulant material and on a sample of 10 human subjects to establish a reliable comparison. Moreover, as the Leg Replica was designed as a left side leg, all testing procedures were conducted on the left leg of human subjects.

A detailed description of these tests is provided later in subsections II-B and II-C.

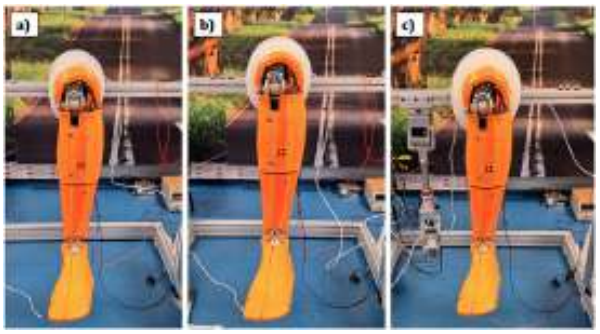

Fig. 1. Sample materials applied on the Leg Replica thigh. The different thicknesses for each of the three materials included in the present work: (a) 1-cm, (b) 2-cm and (c)-3 cm.

A. Experimental procedures

Ten (10) healthy subjects (6m; 4f) were enrolled in the study. All participants provided written informed consent prior to enrollment. The study protocol was approved by CSIC's Ethics Committee (approval 185/2023). The human research was conducted ethically in accordance with the World Medical Association Declaration of Helsinki. From each subject, anthropometric and demographic measurements were taken including: age (24$\pm$3 years; mean$\pm$1SD), height (172$\pm$6 cm), weight (63.2$\pm$7.6 kg), BMI (21.4$\pm$2.1 kg/m^2), leg circumference at the strap (interface) location for the shank (29.7$\pm$2 mm), for thigh at the Distal location (43.4$\pm$3 mm) and at the Proximal location (52.4$\pm$4 mm). BMI was calculated based on subjects' height and weight [6].

Three sample materials were selected for testing on the Leg Replica: the previously used Ecoflex OO-30™ [3], a softer variant from the same product line, Ecoflex OO-10™, and an even softer version created by adding 10% by weight of Silicone Thinner™ to Ecoflex OO-10™, referred to as OO-10T. Ecoflex OO-30™ and OO-10™ have a hardness of 00-30 and 00-10, respectively. Hardness is not available for the OO-10T material. Each material was produced in three different thicknesses: 1, 2, and 3 cm resulting in a total of nine (9) samples. Each sample was placed onto the Leg Replica's thigh segment, as shown in Fig. 1. For both Compression and Displacement tests, all human participants and the Leg Replica wore identical leggings for consistency in the measured outcomes of these experiments. The leggings composition consisted of polyester, polyamide, and elastane.

B. Compression test

The assessment of the static compression that is exerted by the straps on the soft tissue was indirectly estimated by measuring the torque required to secure the exoskeleton strap to the thigh and the consequent reduction in the perimeter of this securing strap.

A torsional dynamometer (STS103, Sealey Ltd, Bury St Edmunds, England) was used to indirectly measure the

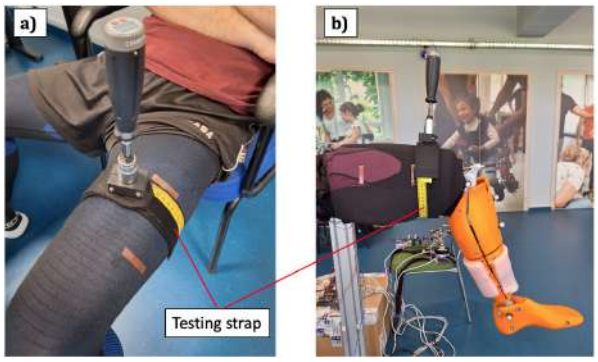

Fig. 2. Compression tests setup on a) Human thigh ("Proximal" location) and b) Leg Replica thigh ("Distal" location)

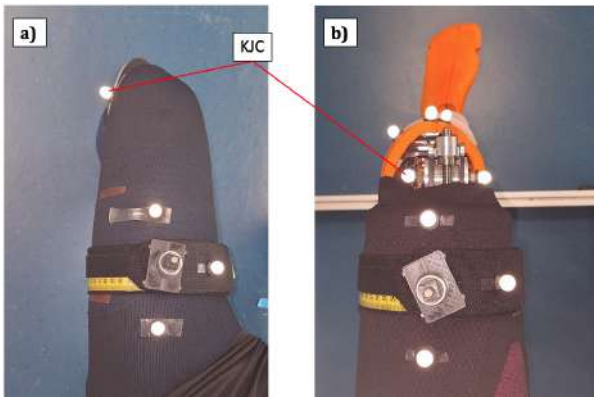

Fig. 3. Displacement test setup on a) human thigh ("Proximal" location) and b) Leg Replica thigh ("Distal" location). Location of the KJC is highlighted.

compressive forces applied to the leg tissues by measuring the torque required to turn the BOA dial used to tighten the strap around the leg. A custom adapter transfered the torque from the dynamometer to the dial. This provides an indirect estimation of the compressive mechanical characteristics of the human soft tissues in the thigh, which in turn represents the reference for the Leg Replica + soft tissue simulant.

The experimental protocol for compression testing included the steps described below. Human participants were instructed to keep their muscles as relaxed as possible during the whole experimental procedure. The first step is to identify the subjects' knee joint center of rotation (KJC). The second step is to apply adhesive tape markers along the longitudinal axis of the thigh, at distances of 125 mm ("Distal") and 239 mm ("Proximal") from the KJC. The placement of these tapes allowed the correct positioning of the straps with respect to the KJC for applying the compression stresses on the thigh. These distances correspond to the locations of the attachments (cuffs and straps) along the thigh segment of the exoskeleton used in [3]. The testing strap, consisting of a 5-cm wide strap (QuickFit Strap 2" (50mm), with BOA® dial, Click Medical LLC, Steamboat Springs, USA, OK1420-130-05) to which a conventional sewing measuring tape, was attached to determine leg circumference and changes in circumference resulting from the compression. The third step requires fitting the strap tightly around the thigh to ensure a snug fit while minimizing compression of the underlying tissue (see Fig. 2 for details). To ensure a snug fit, preliminary tests established a minimum threshold torque of 0.20 Nm corresponding to the reference baseline state of zero tissue compression. This normalization was intended to ensure estimation of mechanical properties of the leg soft tissues under compression only. The fourth step started after reaching the 0.20 Nm value, and in this step the strap was gradually tightened using the dynamometer in increments of 0.05 Nm. At each increment, tightening was paused to measure and record the reduction in circumference due to the compression. Tightening stopped when reaching a maximum torque value of 0.60 Nm to prevent discomfort and any pain suffered by the volunteers. Steps 3 to 4 of this procedure were performed for a total of three times in both the distal and proximal locations on all 10 human subjects, as well as on the Leg Replica with the three synthetic tissue simulants described earlier II. The number of runs per body site was limited to three to prevent fatigue while ensuring enough repetitions to account for intra-subject variability.

C. Displacement test

The second test consisted in the evaluation of the maximum displacement permitted by the soft tissues in the thigh. This evaluation was conducted by applying shear stress along the thigh's longitudinal axis. As for the Compression test, participants were instructed to keep their muscles as relaxed as possible. The first and second steps are identical to those of the Compression test, including the identification of the subjects' KJC and placement of adhesive tape markers at the Proximal and Distal locations (see II-B).

The longitudinal position of two (2) reflective markers was included in this test:

A reference marker placed on the subject's KJC (visible in Fig. 3) was assumed as static during the procedure.

The second marker was placed in the middle of the testing strap's width to measure the maximum displacement allowed by the tissue softness with respect to the KJC. This marker is referred to as "interface marker".

The other two markers shown in Fig. 3 were not included in the protocol of this test.

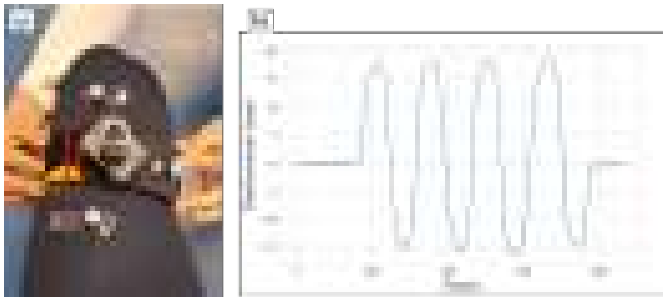

Fig. 4. Detail of the tangential motion applied to the testing strap. In a) the red arrow show the directions of the motion when applying the tangential force. In b) the relative displacement of the interface marker placed on the strap with respect to the KJC is shown over time [frame] for subject 8 in the Proximal location during the 5th run of the test.

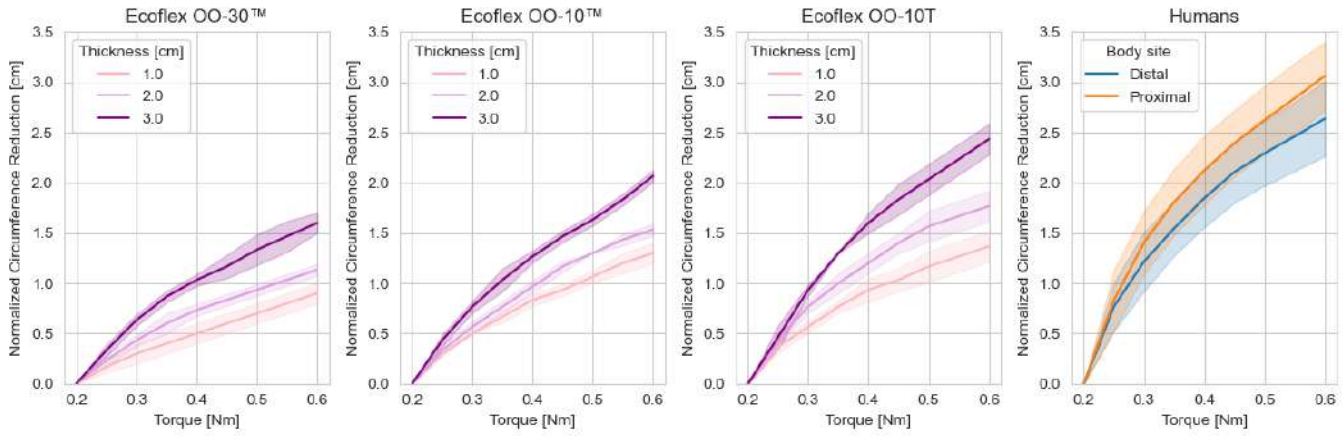

Fig. 5. Circumference reduction-Torque characteristics extracted for each material (OO-30, OO-10, OO-10T) and the considered thickness (1.0, 2.0, or 3.0 [cm]) combining the two locations in the first three plots; and for humans at both distal and proximal location in the fourth plot. Shaded areas represent the standard deviation calculated on different trials for the Leg Replica and different subjects for human tests.

This setup is illustrated in Fig. 3 for both human subjects and the Leg Replica. In the third step, the strap was tightened around the thigh using the dynamometer until a torque value of 0.60 Nm was reached. Preliminary testing determined that this value prevents discomfort for the large majority of individuals while preventing sliding of the strap during the test. The fourth step, consisted of manually displacing the strap from its resting position until the maximum displacement was reached along the longitudinal direction of the thigh (see Fig. 4 for details). The motion consisted of applying a shear stress to the strap first towards the proximal direction, then towards the distal direction, and finally returning it to the resting position. This alternating motion was repeated four times (Fig. 4b)). The experimenter ensured that the strap moved along the thigh with no occurrence of slippage between the strap and the thigh. The fourth step was performed for a total of five (5) times, always starting and ending in the resting position for both the Proximal and Distal locations.

Marker displacements relative to the KJC were recorded using an optoelectronic motion capture system (VICON, Oxford, UK) with a sampling rate of 100 sample/s and accuracy of 0.2 mm. This test was carried out on both human subjects and the Leg Replica. Quantifying the maximum displacement permitted by the soft tissue in the human thigh allowed an estimation of the shear mechanical characteristics under similar conditions to when an exoskeleton is strapped around the leg and in turn represents the reference characteristics for the Leg Replica + soft tissue simulant.

D. Data analysis

The normalized circumference reduction with respect to the dynamometer torque reading estimated the compression of the soft tissue under the strap. The normalized circumference reduction was defined as the difference between the circumference reduction of the thigh at any particular torque reading minus the circumference reduction measured at 0.20 Nm (zero-compression). Therefore, it always starts from 0 cm, and it increases as the applied torque increases.

The displacement metric developed to characterize the response to shear stress was based on the position of the interference marker with respect to the KJC marker along the thigh's longitudinal direction (see Figs. 3 and 4 for details). The position was normalized by the distance at rest. The displacement was estimated as maximum range using the 4 peaks in both directions (distally and proximally) and these were referred to as absolute maximum and minimum displacements allowed by the soft tissue at each location. Some variability across cycles can occur and to avoid bias in the results the 4 peaks were not averaged across cycles.

The statistical analysis performed on the results of human testing were carried out using Python within the DataSpell environment. The Shapiro-Wilk normality test was performed to confirm the normality distribution assumption, justifying the use of ANOVA and T-tests for determining the significance of subject-specific factors. Paired T-tests were performed to test a significant effect of the strap location along the thigh. For the weight, height, and circumference at rest (no strap) the Pearson correlation analysis was performed to evaluate the correlation between the results and factors related to body size. The α-value=0.05 was used to test for significance.

III. Results

A. Compression test

The behavior of the human soft tissues in response to compression is shown in Fig. 5. In this figure, the Normalized Circumference Reduction is plotted vs the applied torque to the BOA dial. It can be seen that, in general, the behavior of the reduction is larger at the Proximal location than in the Distal (closer to the knee joint). This difference resulted to be significant ($p<0.05$) for torque values greater than 0.25 Nm. Therefore, the results from the two locations can't be combined, and have to be treated separately, specifically regarding any further analysis aimed at evaluating the statistical influence of the other factors. However, this is not the case for the soft tissue simulant and that is why there is no distinction of body site, but only the material and its thickness. The

effect of gender on compression was tested using an ANOVA and no significant effect of gender was found ($p>0.05$) for both locations. The Person correlation analysis performed on weight, height, and the circumference at rest (no strap) showed weak correlation with values always less than 0.5 and in most cases close to 0 across all the torque values and the two locations. Age did not show to be correlated, as the Pearson-coefficients ranged between 0.04 and 0.31.

When the performance of the simulants is compared to that of the human tissues, all simulants exhibited a greater compression stiffness than the human reference, which reached a Normalized Circumference Reduction of 2 to 3.5 cm at 0.6 Nm. The only sample that achieved this level of reduction was the Ecoflex OO-10T with a thickness of 3 cm, which reached a circumference reduction of 2.5 cm. Additionally, this simulant consistently exhibits the highest circumference reduction and closeness to the human values, followed by Ecoflex OO-10™, with Ecoflex OO-30™ showing the least reduction across all thicknesses (see Fig. 5).

B. Displacement test

In Fig. 4-b) a sample data of the motion resulted from the shear stresses applied is provided. Displacement results were averaged across repetitions and for the humans also across subjects (are provided in (Fig. 6). Minor differences were observed between the displacement results at the Proximal and Distal locations on the Leg Replica. Consequently, the results for soft tissue simulants are presented according to varying thicknesses, while for human subjects, the results are separated by location. The key findings of the displacement test are collected in this figure, illustrating the maximum range of motion of the interface marker. In general, the displacement was significantly higher at the Proximal than the Distal location ($p<0.05$). Therefore, the results from the two locations had to be treated separately and any further analysis evaluating the statistical influence of the other factors should be performed separately. The correlation analysis performed on weight, height, the circumference at rest (no strap), and age showed weak correlation with values between 0.13 and 0.27 in magnitude across all repetitions and the two locations.

The average displacement of the interface marker in humans was about 2.6 cm and 1.6 cm at the Proximal and the Distal location, respectively. On the Leg Replica, the Ecoflex OO-10T being the softest and most compliant among the three material types, it is the only material that allowed displacement ranges comparable to. It is worth noting that the Ecoflex OO-10T consistently exhibited the highest displacement range, followed by Ecoflex OO-10™, with Ecoflex OO-30™ showing the smaller displacement across all thicknesses.

IV. Discussion

The present study aimed to address the challenge of characterizing the overall (macroscopic) behavior of soft tissues in human and dummy limbs. Specifically, the replication of human tissue behavior by means of a rigid dummy leg in combination with a layer of synthetic soft tissue simulants

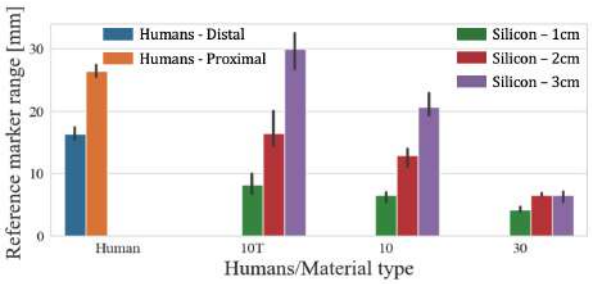

Fig. 6. Bar plots showing the average displacement results of the interface marker at the Distal and Proximal locations for the 10 subjects and also for each simulant material (OO-30, OO-10, OO-10T) for the three different thickness values (1, 2, or 3 [cm]). Error bars represent 1 SD.

was set forth. Addressing properly this task requires systematic testing of materials under various conditions plus assessing human soft tissue characteristics is inherently challenging. Moreover, the existing literature describing human soft tissue behavior under external stress shows high variability depending on body location, age, sex, and training level of individuals. Taking these aspects into account, we designed general tests that capture key macroscopical mechanical characteristics highly related to the effects of a wearable exoskeleton attached to a limb. The primary effects identified were the degree of tissue compression and the natural limit of skin displacement under the effect of shear stress. These tests are not intended to provide an exhaustive and precise analysis of the materials considered, but rather to establish benchmarking methods and metrics tailored to the use case of an exoskeleton strapped to a limb.

In section III it has been presented the outcomes of the compression and displacement tests to assess the mechanical properties of soft tissues at two locations (Proximal and Distal) of the thigh segment. Results included the application of the proposed methodology to human volunteers and also to the Leg Replica with each of the three synthetic tissue simulants and each of the three different thicknesses.

The compression test results in humans, Fig. 5, illustrate an upward trend of the Normalized Circumference Reduction at both locations. This indicates that as torque increases, the reduction in circumference also increases. This is expected because higher torque generally implies greater compression of the tissue. Additionally, results showed that the tissue behavior was found to be significantly different between the Distal and the Proximal locations. Specifically, the proximal site consistently shows a greater reduction in circumference compared to the distal site at all torque levels. This suggests that the proximal body site is more compressible, which is expected in humans due to differences in tissue composition and in the volume of soft tissue surrounding the bone at the two locations. The proximal site, being thicker and fleshier, is expected to be more compressible as supported by the data. Thus, the increased compressive effects at the proximal site are consistent with its anatomical characteristics and the expected physiological response to higher torque levels (see Fig. 5). Lastly, the curves exhibit an almost asymptotic behav-

ior, which aligns with expectations. Initially, tissues compress more easily, but as the compression (torque) increases, tissues approach their maximum compression limit. Therefore, further increases in torque yield minimal additional compression. This effect would be even more pronounced with higher torque values, but ethical limitations prevented testing beyond certain compression levels.

In the compression test results, the comparison of performance between the three simulants and the human tissue showed a strong influence of the simulant thickness across all three materials. As thickness increased from 1 to 3 cm, an increase in Normalized Circumference Reduction was observed for the same torque (see Fig. 5). Hence, in general, for the three synthetic simulants included in this study, increasing thickness enhances compressibility. Among all material types and levels of thickness, the 3-cm Ecoflex OO-10T combination emerged as the only candidate to achieve compression values comparable to those observed in human tissues. Even though human tissue exhibited greater compression characteristics than the tested simulants for the three levels of thickness, the 3-cm Ecoflex OO-10T is the only one for which the displayed curves almost coincided with those of the human tissue. Therefore, it can be concluded that the 3-cm Ecoflex OO-10T combination is a suitable simulant for mimicking human soft tissue compressive behavior when applied to the Leg Replica. It is worth noting that thickness was limited to 3 cm to maintain the overall size of the Leg Replica within the range of average human leg circumference. Additionally, an excessive thickness of the soft tissue simulant layer would hinder exoskeleton mounting. Considering the trend in the data presented, a higher thickness would have allowed to obtain results overlapping with those obtained in human testing.

When considering the results obtained from the displacement test and comparing the performance of the three simulants with the outcomes of the human testing, the influence of the thickness on the displacement for the simulant materials is evident for all three simulant materials (see Fig. 6). As thickness increases from 1 to 3 cm, all materials showed an increased displacement range. Additionally, the results indicated that the human displacement range at the Proximal location was matched only by the OO-10T material with a 3 cm thickness, while at the Distal location, a smaller displacement range was observed in humans, and it could be achieved by a minimum 2 cm layer of the OO-10T and a 3 cm layer of EcoFlex OO-10™.

Concluding, it has to be acknowledged that the simulant thickness is much lower than the overall thickness of the thigh, for example. However, this work tried to verify the feasibility of replicating the mechanical behavior observed in human when wearing an exoskeleton by simply adding a layer of soft tissue simulant.

V. Conclusions

The research presented here focused on identifying and testing materials to enhance the human likeness of the Leg Replica, enabling better benchmarking of lower limb exoskeletons. The aim was to replicate the behavior of human soft tissues under compression and shear stresses, simulating conditions similar to those when an exoskeleton is attached to the human leg. To achieve this, a new application-oriented testing methodology was developed and proposed. It provided a way to assess mechanical properties of the human leg that are meaningful for benchmarking wearable exoskeletons by including compression and displacement tests simulating conditions resulting from exoskeleton straps. Three different platinum-catalyzed silicone materials of varying hardness and thickness were tested using this methodology when placed around the rigid Leg Replica, and their performance was compared to human results. The performance of all three materials, met or exceeded human tissue results in some cases. Among them, the Ecoflex OO-10T was the most effective, particularly in the 3 cm thickness, achieving similar results to those of humans. This material closely matched human soft tissue behavior in both tests, highlighting the importance of both material properties and design parameters (e.g. thickness). These findings contribute positively to the development of benchmarking systems like the Leg Replica for evaluating exoskeleton designs. The Ecoflex OO-10T placed on the Leg Replica enables more accurate testing of human-exoskeleton interactions, enhancing reliability and performance validation.

In conclusion, while remarkable progress was made, further refinement is needed to fully replicate human tissue behavior. Future investigations should identify materials with better performance; extend testing of a wider age range; include movement disorder individuals; and investigate materials that mimic the complex properties of human tissues (i.e. anisotropy and viscoelasticity). Improved materials replicating these characteristics would significantly enhance benchmark devices like the Leg Replica even further.

Prosthetic Control by Learning: A Multi-Agent Cooperative Game Framework

Haofei Hou, Wenduo Zhu, Lecheng Ruan, and Qining Wang, *Senior Member, IEEE*

***Abstract*—Lower-limb powered prostheses traditionally rely on structured, phase-based controllers designed for specific movement patterns, limiting their adaptability to diverse human motions. This paper presents that powered prosthetic control is a cooperative multi-agent game between the human user and the prosthetic device, as both agents must coordinate their actions actively and adapt their policy reciprocally for successful prosthetic motions. Based on this insight, we develop a model-free reinforcement learning framework that enables the prosthesis to adapt to diverse human movement patterns through cooperative policy learning. Preliminary results in the simulator demonstrate that our framework can generate human-like motions across both walking and complex tasks, establishing the effectiveness of viewing prosthetic control through the lens of multi-agent cooperation. This work opens new possibilities for developing more intuitive and versatile prosthetic systems that naturally synchronize with human movement intentions.**

***Index Terms*—Powered Prostheses, Multi-agent Reinforcement Learning, Cooperative Game**

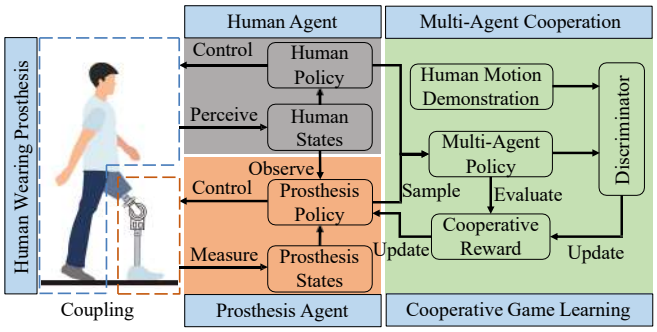

Fig. 1. **Framework.** Human wearing prosthesis can be regarded as a coupled system with two agents. The human agent has its own closed-loop controls, which runs independently but only observed. The prosthesis can be controlled, but the control goal is to achieve human-prosthesis collective optimality. By introducing the multi-agent game formulation, the prosthetic controller can be searched globally from a model-free reinforcement learning framework.

I. Introduction

Lower-limb amputation significantly impacts mobility and independence, affecting millions of people globally. Powered prostheses have emerged as a transformative solution, employing sophisticated controllers to restore natural movement patterns and enhance the quality of life [1]. Recent advances in control strategies have demonstrated remarkable improvements in walking efficiency and user satisfaction [2], [3], while expanded motion ranges and support for natural aperiodic movements have fostered improved body-prosthesis integration [4].

Traditional prosthetic control approaches primarily rely on phase-based methods, where the prosthetic follows predetermined trajectories or execution patterns based on walking gait thresholds [5], [6], which can be directly measured [7], [8] or indirectly estimated [9]. Representative frameworks include state machine control [10], [11], [12] and echo control [13]. Given their well-structured nature, research efforts have focused mainly on tuning control parameters and optimizing predetermined trajectories [14]. Recently, reinforcement learning has been successfully integrated into these frameworks for tuning structured prosthetic controllers, leading to improved control performance in prosthetic walking [15], [16], [17].

However, structured prosthetic controllers are inherently limited by their design for specific movement types. Since successful prosthetic control must comply with human motion, the interaction policy is typically embedded within the control logic and controller structure [18]. The explicit description of such human-prosthesis interaction remains challenging, which explains why existing works predominantly focus on periodic, symmetric motions like walking and running [19], [20]. Yet, the broader vision of rehabilitation engineering extends beyond walking capabilities to fully reconstruct mobility for individuals with disabilities. This necessitates prosthetic controllers that can adapt to diverse movement patterns rather than rely solely on well-structured policies for specific movements. This challenge parallels developments in bipedal robotics, where model-free reinforcement learning (RL) has been explored for policy generation in non-cyclic motions and universal control frameworks [5], [6], [21], achieving diverse movements and robust generalization [22].

Nevertheless, policy learning for complex prosthetic movements remains largely unexplored. A fundamental distinction between prostheses and bipedal robotics lies in the unique human-prosthesis relationship. Unlike fully autonomous systems with self-contained control objectives, prosthetic control involves continuous interaction with an independent, uncontrolled human agent. This interaction creates a dynamic environment where both the user and prosthesis must actively coordinate their actions through mutual force interactions to

achieve cooperative optimal performance, as shown in Fig.1. This inherent interdependence naturally frames the human-prosthesis system as a fully cooperative multi-agent game, where success depends on the synchronized actions of both agents.

In this paper, we present a novel framework that explicitly models the human-prosthesis relationship as a cooperative multi-agent game. We validated our framework on the left knee and ankle prosthetic control. Our approach leverages model-free RL to develop control strategies that accommodate diverse movement patterns. First-stage results demonstrate that the proposed framework can generate human-like motion across walking and complex tasks. Our results establish the effectiveness of viewing prosthetic control through the lens of multi-agent cooperation, offering a promising direction for developing more intuitive and versatile prosthetic systems.

Key contributions of this paper can be concluded in the following three aspects:

1) A formal characterization of prosthetic control as a cooperative multi-agent system.
2) A novel model-free reinforcement learning framework for prosthetic control on diverse movement patterns.
3) Validation of the framework's effectiveness across different movement patterns.

II. Methodology

A. Notations

The human-prosthesis coupling system is modeled with a markov decision process (MDP) [23], defined by a tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, r, \gamma \rangle$, where $\mathcal{S} = \mathcal{S}_h \times \mathcal{S}_p$ represents the system joint state space of human and prosthesis, $\mathcal{A} = \mathcal{A}_h \times \mathcal{A}_p$ is the joint action space of human and prosthesis, $\mathcal{T} : \mathcal{S} \times \mathcal{A} \to \mathcal{S}$ is the transition function, $r : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$ is the reward function, and $\gamma \in [0, 1)$ is the discount factor. At each time step t, the global state in the environment is s_t, state of human is represented by s_t^h, and the state of prosthesis is s_t^p,

$$s_t = \text{concat}(s_t^h, s_t^p) \in \mathcal{S}, \tag{1}$$

where $\text{concat}(\cdot, \cdot)$ represents the concatenation operation. The joint action a_t is executed in the environment. The human's action a_t^h is sampled from the policy $\pi^h(a_t^h|s_t)$.

$$a_t = \text{concat}(a_t^h, a_t^p) \in \mathcal{A}. \tag{2}$$

Human and prosthesis actions (states) are concatenated into a unified action (state) for the entire system. Joint action at iteration k is sampled from the joint policy $\pi_k = \pi_k^h \times \pi_k^p$. A key feature of a human-centric system is that the human model is observable but not directly controllable. Similarly, the prosthesis's action a_t^p is sampled from the policy $\pi^p(a_t^p|s_t)$. Collaboration is realized through the joint state s_t, joint action a_t, and joint reward r_t. The joint reward is defined as:

$$r_t = r(s_t, a_t) \in \mathbb{R}. \tag{3}$$

The reward is determined by the global state of the human-prosthesis system rather than being limited to the prosthesis's state.

The transition function obtained through simulation inherently models mechanisms such as the interactions between humans and prostheses (*e.g.*, motion constraints, and mechanisms). Through this modeling, we aim to enable RL strategies to learn the mechanisms of human-prosthesis interaction.

B. Human-Prosthesis Cooperative Game Model

The goal of the human-prosthesis coupled system is to collectively generate a satisfactory motion. When written in an optimization form, the whole coupled system can be optimized as

$$\max_{\pi} J(\pi) = \mathbb{E}_{s_0}[Q_\pi(s_0, a_0)], \tag{4}$$

where $Q_\pi(s_0, a_0)$ refers to the action value function of the whole system at the starting episode instance (s_0, a_0) and the notation $\mathbb{E}_x[f(x)]$ represents the expected value of $f(x)$ given the random variable x. However, as a cooperative game, we only have access to the control policy of the prosthesis π^p. Therefore, the reward function of the whole coupled human-prosthesis system needs to be optimized within the search for prosthetic control policy, as

$$\max_{\pi^p} J(\pi) = \mathbb{E}_{s_0}[Q_\pi(s_0, a_0)|\pi^h]. \tag{5}$$

This multi-agent cooperative game optimization can be investigated using the decomposed forms of the advantage function [23]. Define the state value function $V_\pi(s_t)$ as

$$V_\pi(s_t) = \mathbb{E}_{a_{t:\infty} \sim \pi}[\sum_{i=t}^{\infty} \gamma^{i-t} r(s_i, a_i)|\pi^h], \tag{6}$$

and action value function $Q_\pi(s_t, a_t)$ as

$$Q_\pi(s_t, a_t) = \mathbb{E}_{a_{t+1:\infty} \sim \pi}[\sum_{i=t}^{\infty} \gamma^{i-t} r(s_i, a_i)|\pi^h], \tag{7}$$

respectively. The advantage function can then be calculated as

$$A_\pi(s_t, a_t) = Q_\pi(s_t, a_t) - V_\pi(s_t). \tag{8}$$

The human-prosthesis system is then decoupled using multi-agent advantage decomposition and the sequential policy update scheme [23]. Define action value function for the human model $Q_\pi^h(s_t, a_t^h)$ as

$$Q_\pi^h(s_t, a_t^h) = \mathbb{E}_{a^p \sim \pi^p}[Q_\pi(s_t, (a_t^h, a^p))], \tag{9}$$

advantage function for the human model $A_\pi^h(s_t, a_t^h)$ as

$$A_\pi^h(s_t, a_t^h) = Q_\pi^h(s_t, a_t^h) - V_\pi(s_t), \tag{10}$$

and advantage function for prosthesis $A_\pi^p(s_t, a_t^h, a_t^p)$ as

$$A_\pi^p(s_t, a_t^h, a_t^p) = Q_\pi(s_t, a_t) - Q_\pi^h(s_t, a_t^h). \tag{11}$$

It is easy to know that multi-agent global advantage can be decomposed into two subsystem advantage functions as follows,

$$A_\pi(s_t, a_t) = A_\pi^h(s_t, a_t^h) + A_\pi^p(s_t, a_t^h, a_t^p). \tag{12}$$

We can also perform decomposition of the policy as

$$\begin{cases} L^h_{\pi_k}(\pi^h_{k+1}) = \mathbb{E}_{s,a^h\sim\pi^h_{k+1}}[A^h_{\pi_k}(s,a^h)] \\ L^p_{\pi_k}(\pi^h_{k+1},\pi^p_{k+1}) = \mathbb{E}_{s,a^h\sim\pi^h_{k+1},a^p\sim\pi^p_{k+1}}[A^p_{\pi_k}(s,a^h,a^p)], \end{cases} \tag{13}$$

where $L^h_{\pi_k}$ and $L^p_{\pi_k}$ are surrogate optimization functions of the two subsystems.

We can obtain from multi-agent trust region policy optimization (TRPO) theorem [23], [24] that

$$\begin{aligned} J(\pi_{k+1}) \geq J(\pi_k) + L^h_{\pi_k}(\pi^h_{k+1}) - C\mathrm{D}^{\max}_{\mathrm{KL}}(\pi^h_k,\pi^h_{k+1}) \\ + L^p_{\pi_k}(\pi^h_{k+1},\pi^p_{k+1}) - C\mathrm{D}^{\max}_{\mathrm{KL}}(\pi^p_k,\pi^p_{k+1}) \end{aligned} \tag{14}$$

holds universally, where

$$C = \frac{4\gamma \max_{s,a}|A_{\pi_k}(s,a)|}{(1-\gamma)^2}, \tag{15}$$

and KL-Divergence is defined as

$$\mathrm{D}^{\max}_{\mathrm{KL}}(\pi_k,\pi_{k+1}) = \max_s \mathrm{D}_{\mathrm{KL}}(\pi_k(\cdot|s),\pi_{k+1}(\cdot|s)). \tag{16}$$

Therefore, the prosthetic control policy can be updated by

$$\pi^p_{k+1} = \arg\max_{\pi^p}(L^p_{\pi_k}(\pi^h_{k+1},\pi^p) - C\mathrm{D}^{\max}_{\mathrm{KL}}(\pi^p_k,\pi^p)). \tag{17}$$

When assuming that the human policy evolves in a way for the human-prosthesis cooperation, *i.e.*, $L^h_{\pi_k}(\pi^h_{k+1}) \geq C\mathrm{D}^{\max}_{\mathrm{KL}}(\pi^h_k,\pi^h_{k+1})$, we can guarantee a monotonic improvement of the prosthesis policy as $J(\pi_{k+1}) \geq J(\pi_k)$.

C. Policy Update from Reinforcement Learning

Equ. 17 provides a theoretical optimization method, however, issues with convergence and computational cost make it challenging to solve. Therefore, we introduce the proximal policy optimization (PPO)-clip algorithm to perform reinforcement learning optimization [25].

We can get an estimator $\hat{A}(s,a)$ of the advantage function $A_{\pi_k}(s,a)$ by generalized advantage estimation (GAE) [24].

$$\hat{A}(s,a) = \sum_{i=0}^{T}(\gamma\lambda)^i[r_{t+i} + \gamma V(s_{t+i+1}) - V(s_{t+i})], \tag{18}$$

where T, λ, γ is trajectory horizon length hyper-parameter, GAE smoothing parameter and discount factor in MDP formulation. PPO optimizes the policy π^p_{k+1} by maximizing the PPO-clip objective [25].

$$\begin{aligned} \pi^p_{k+1} = \arg\max_{\pi_p} \Big\{ L^{\mathrm{PPO}}_{\pi^p_k}(\pi^p) = \mathbb{E}_{s,a\sim\pi_k}\Big[\min\Big(\\ \frac{\pi^p(a^p|s)}{\pi^p_k(a^p|s)}\hat{A}(s,a), \mathrm{clip}(\frac{\pi^p(a^p|s)}{\pi^p_k(a^p|s)}, 1\pm\epsilon)\hat{A}(s,a)\Big)\Big]\Big\}. \end{aligned} \tag{19}$$

To better learn human motion postures and dynamics and achieve more natural prosthetic control, we optimized the reward design to reflect human movements captured by motion capture.

Discriminator $D(s)$ is trained to predict whether a given state s is sampled from the human demonstrations $\mathcal{M}$ or generated by running the policy π [26]. The discriminator should result in a small score close to 0 for generated samples and a big score close to one for real samples from human demonstration. This is based on the assumption that real whole-body human motion demonstrates an upper bound for human-prosthesis cooperation.

With human motion prior (HMP) [26], reward function r_t can regularly updated as

$$r_t = -log\Big]1 - D_k(s_t)\big), \tag{20}$$

where $D_k(s)$ is the current discriminator.

The following objective is used to get updated discriminator

$$D_{k+1} = \arg\min_D \big\{-\mathbb{E}_{m\sim d_{\mathcal{M}}} log\big(D(m)\big) - \mathbb{E}_{m\sim d_{\pi_k}} log\big(1-D(m)\big)\big\}, \tag{21}$$

where $d_{\mathcal{M}}$ and d_{π_k} represent the probability of observing a state m in dataset $\mathcal{M}$ and when following policy π_k.

III. Simulation Setup

A. Environment

We established a human-prosthesis hybrid model in IsaacGym for verification of the control policy. The full-body model consists of 28 degrees-of-freedom (DoF): 14 DoF for the lower limb and 14 DoF for the upper body. The prosthesis is modeled as a four-DoF system, including 1 DoF for the knee joint and 3 DoF for the ankle joint: dorsiflexion-plantarflexion, inversion-eversion, and internal-external rotation.

The state vector s_t refers to the global state in Sec. II-A, which includes joint angles and global positions, joint angular velocities, linear velocities, and environmental interaction data (*e.g.*, ground contact forces). The action vector a_t specifies the target angles for all joints. A PD controller computes joint torques τ^m_t based on the target angles a_t:

$$\tau^m_t = g\cdot\left[k_p\cdot(a_t-\theta_t) + k_d\cdot(a_t-\theta_t)'\right]. \tag{22}$$

where τ^m_t is the motor output torque, g is the gear ratio, k_p is the stiffness (proportional gain), k_d is the damping coefficient (derivative gain), and θ_t is the current joint angle. These torques are applied to the joints based on the motor dynamics model as described in Equ. 23, while the IsaacGym physics engine simulates the system's transition function $\mathcal{T}$, updating the model's state accordingly by

$$\tau^m_t - \tau^l_t = J\cdot\theta''_t - k_d\cdot\theta'_t, \tag{23}$$

where τ^l_t is the load torque on the joint and J is the moment of inertia. Each episode is set to last up to 300 steps during training, with each step lasting 1/45 of a second.

B. Human Model and Demonstrations

We employ a human model π^h derived from AMP [26], a reinforcement learning-based bipedal controller, enabling dynamic and realistic simulations of human movements. This approach facilitates the study of complex control tasks. Human demonstrations are derived from motion capture data, rather than simulations, for both the human model and human motion prior, which are sourced from the Human3.6M dataset [27].

Since the specific mechanism of how the human adapts to the prosthesis is unknown, we train the human model firstly

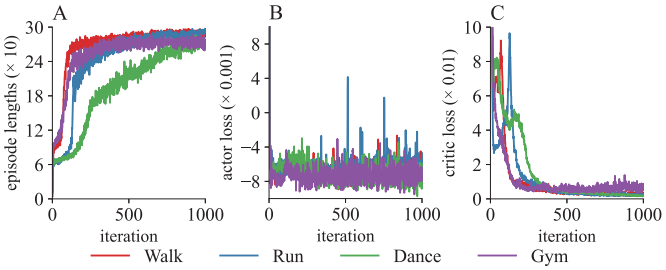

Fig. 2. **Learning Convergence.** The x-axis represents training iteration. (A) Episode length converges to approximately 300. (B) Actor loss stabilizes near zero. (C) Critic loss also approaches zero as training progresses.

and then freeze its parameters, *i.e.*, $\pi^h_{k+1} = \pi^h_k = \pi^h_0$. Therefore, it follows that $L^h_{\pi_k}(\pi^h_{k+1}) = 0 \geq C\mathrm{D}^{\max}_{\mathrm{KL}}(\pi^h_k, \pi^h_{k+1}) = 0$.

During the AMP training process for the human model, we also obtain a discriminator D_h, which serves as ground truth for analyzing the similarity between the actions of the human-prosthesis system and natural human motion.

C. Tasks and Metrics

We validate our method by testing the control of a left knee-ankle prosthesis across various tasks, including walking, running, dancing, and gymnastics. These tasks highlight the ability of our method to generate versatile and natural motion, which is demonstrated through detailed evaluations, analyses, and showcases.

The actions span a spectrum of complexity, from simple motions like walking and running to moderately complex activities like dancing and intricate movements like gymnastics. Walking involves a basic gait where one foot remains on the ground at all times while running features a quicker pace with phases where neither foot touches the ground. In the dance task, both hands are raised high, and the feet alternate ground contact while the body propels one foot to spin in the air for a full rotation. Gymnastics include high knee lifts, stretches, and balance-holding movements.

To validate our prosthetic control strategy (referred to as *Ours*), we use the human model (bipedal controller, referred to as *HC*) as our reference. The human controllers are trained to mimic the real motion of humans, thus conducting full cooperation of humans and prostheses. It performs similarly to the role of ground truth but is degraded to a certain extent as it is still a data-driven model, which only captures the distribution of human motion in a statistical sense.

We sampled 4,096 episodes and conducted two experiments: one tested the algorithm's generalization ability across various complex motions, and the other compared the system-generated motions from the perspective of gait symmetry with the human model to analyze the prosthetic controller's adaptability to humans. In the former experiment, we calculated the average normalized episode length ($\bar{T}_{\mathrm{n}}$), which measures policy robustness on different motions to prove our algorithm's generalization ability. In the ablation study, the mean discrimination score ($\sigma(\bar{D}_h)$) is calculated, which evaluates the similarity between the agent's motion and natural human behavior to show how our prosthetic controller can help people with disabilities achieve natural and human-like motion.

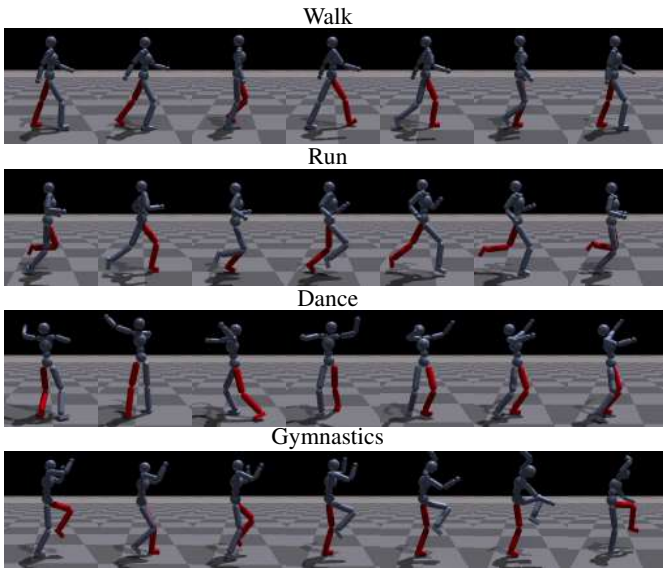

Fig. 3. **Showcases of the proposed prosthetic control.** The prosthetic control policy obtained from RL search can perform stable action in diverse types of motions, such as walk, run, dance, and gymnastics. The prosthesis part is represented in red in the simulation, including the left knee and left ankle.

TABLE I
EFFECTIVENESS TO PERFORM VARIOUS MOTION TASKS ($\bar{T}_{\mathrm{N}}$)

	HC	*Ours*
walk	99.2	96.7
run	98.8	98.4
dance	95.5	91.8
gymnastics	92.0	94.9

IV. RESULTS

A. Convergence

During the 1,000 training epochs, all networks, including the actor network (policy π^p_θ) and the critic network (value V_ϕ), successfully converged. The training losses and episode lengths stabilized and fluctuated within a small range, consistently approaching the specified maximum episode length. Detailed training metrics are shown in Fig. 2.

B. Generalization to Various Motion Tasks

As mentioned earlier, we trained a bipedal controller on the whole human model to mimic the real human motion, as a ground truth reference to our prosthetic controller. Tab. I presents the performance of our control policy across various motion tasks, in comparison with the mimic controller of real human motion. The results show that our proposed prosthetic control policy demonstrates comparable capability on various motion tasks, including periodic motions such as walking and running, and complex tasks like dancing and gymnastics. The average normalized episode length is

TABLE II
EFFECTS OF REWARD UPDATES (RU) ON SIMILARITY TO REAL HUMAN MOTION ($\sigma(\bar{D}_h)$)

	w/ RU	w/o RU
walk	20.5	16.1
run	15.2	11.2
dance	35.7	31.4
gymnastics	38.7	35.1

used to measure controller effectiveness. Unit difference in $\bar{T}_{\text{n}}$ indicates a performance reduction of only about 0.067 seconds in the whole trajectory, which has an almost negligible impact on performance in complex tasks. Key frames of the human-prosthesis system's motion were captured for visual demonstration, as shown in Fig. 3. These results, obtained without early stopping, highlight the system's stability and generalization across diverse types of motions.

C. Similarity to Human Motions

The reward updates in the proposed pipeline not only introduce a reference for the effectiveness of human-prosthesis cooperation but also create a chance to incorporate motion features of real human data as a prior in the policy search. Therefore, the proposed method shall have better similarity to normal human walking than the policy without reward updates. Such results are shown in Tab. II. It is easy to witness that when reward updates are removed, the motion diverges more from the real human motion reference. The policy search can easily get stuck in a local optimum focusing only on stability without coordinating with human motion. Some examples are demonstrated in Fig. 4. These results demonstrated the importance of human motion prior to helping our prosthetic controller achieve natural and human-like movements, and thus the effectiveness of incorporating reward updates in the pipeline.

V. DISCUSSION

The gait pattern of able-bodied individuals is often considered the ideal reference for amputees, as these patients typically aim to regain normal movement abilities [28]. Research has shown that imitating the gait of able-bodied individuals can significantly improve the mobility of amputees, reduce energy consumption, and lower the risk of secondary musculoskeletal injuries [29]. Some studies have designed 3-DoF ankle-foot prostheses and demonstrated that traditional 1-DoF transtibial prostheses, due to their limited degrees of freedom, tend to cause gait asymmetries and lack the ability to generate human-like motion [30], [31]. To achieve a gait more similar to that of a human, we hypothesize that an ankle prosthesis should possess motion capabilities akin to those of a human ankle.

Creating a universal model for individuals with disabilities is challenging because of significant gait variation between individuals and the impact of the prosthesis used. Our current model, based on the gait of an able-bodied individual with one leg amputated, partially captures the movement of individuals

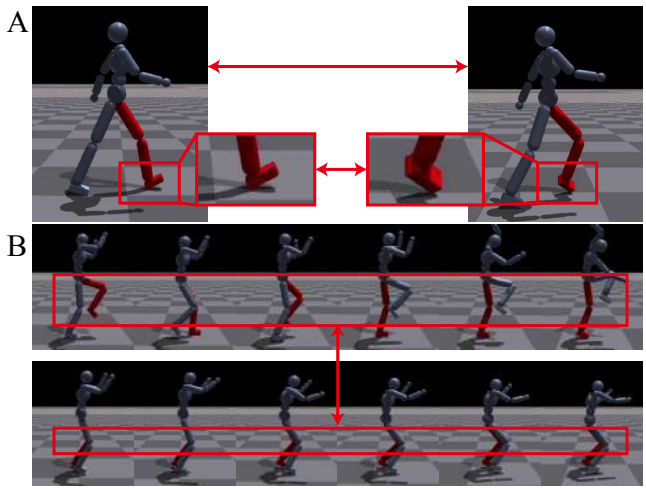

Fig. 4. **Effect of reward updates.** The reward updates in the proposed pipeline not only introduce a reference for the effectiveness of human-prosthesis cooperation but also create a chance to incorporate motion features of real human data as a prior in the policy search. (A) shows the anomaly of the ankle prosthesis joint arises when the reward update is turned off. (B) shows that the policy in gymnastics is stuck in a local optimum for stability, preventing the successful completion of the movement, when the reward update is turned off.

with disabilities. Our framework decouples the human model from prosthetic control, allowing for continuous refinement and customization. This flexibility offers the potential for better modeling of amputees as advancements in game modeling, musculoskeletal techniques, and new motion datasets emerge. In addition, several challenges may arise during implementation, including the variability of human motion, computational burdens, sensor accuracy, and system complexity.

For future work, we aim to improve the generalization of our method and implement our framework in real-world settings. The emergence of advanced musculoskeletal models [32], [33], high-performance sensors with enhanced accuracy [34], continuous advancements in prosthetic hardware [35], [36], and automated structural planning methods [37], [38] are progressively paving the way for practical applications. A significant challenge remains in regaining trust after unexpected movements, which could potentially be addressed through real-time environmental information acquisition to predict and prevent anomalous motions. Moreover, implementing motion constraints may help restore user confidence in the system's reliability and safety.

VI. CONCLUSION

This study models the human-prosthesis system as a multi-agent cooperative game, to capture the reciprocal adaptation nature of this human-robot hybrid system. We introduce a model-free RL on this formulation and enables the prosthetic control under complex and diverse movement patterns. The cooperative game model decouples prosthetic motion from human and thus provides an adaptive solution to non-cyclic complex motions such as dancing and gymnastics. The reward updating helps develop adaptive, personalized prosthetic

devices that better align with natural human movement patterns. These developments represent a significant step toward enhancing motor capabilities in individuals with mobility impairments and advancing the field of rehabilitation robotics.

Low-Rank Adaptation for Transformers in Dynamic Hand Gesture Recognition Using High-Density Surface Electromyography

Jirou Feng, Xingce Bao, Won Dong Kim, Kun Wang, and Jung Kim

***Abstract*— Dynamic hand gesture recognition (HGR) is critical for real-time prosthetics and neural robotics applications, where high-density surface electromyography (HD-sEMG) signals provide valuable insights into muscle activity. However, adapting machine learning models to new users while maintaining high accuracy and computational efficiency presents a significant challenge, mainly when dealing with individual variability in muscle signals. This study investigates the application of Low-Rank Adaptation (LoRA) in transformer-based models for dynamic HGR tasks. By incorporating LoRA into a pre-trained generalized transformer model, we explore its effectiveness in adapting to new subjects with varying rank values (r = 32, 64, 96) and different HD-sEMG signal window sizes (100 ms, 200 ms). Our experimental results demonstrate that LoRA achieves high accuracy during the dynamic phase of hand gestures and improves computational efficiency by reducing training parameter size. It is a promising solution for scalable and robust transformer-based systems in dynamic HGR. Furthermore, the ability to adapt quickly to new subjects with minimal retraining could make this approach particularly valuable for real-world applications.**

I. Introduction

Hand gestures offer a natural and intuitive way to facilitate communication, making them vital in human-to-human and human-to-machine interactions [1]. Hand gesture recognition (HGR) is crucial in developing advanced prosthetics, neurorobotics, and human-robot interaction (HRI), offering innovative and non-invasive control methods [2]. Surface electromyography (sEMG) signals are recorded non-invasively using sensors placed on the skin, detecting the electrical activity generated by the motor units of muscles [3]. These signals provide valuable information for decoding distinctive and consistent patterns, effectively classifying the user's motion intention. sEMG-based gesture recognition can be a real-time myoelectric control for bionic limbs [4], [5]. High-density surface electromyography (HD-sEMG) has garnered significant attention in recent years. It involves recording signals using a large number of electrodes arranged in a two-dimensional (2D) array. This dense electrode configuration captures muscle activity over time while providing a spatial (topological) representation of the underlying muscle group [6]. This wealth of information offers significant advantages over traditional bipolar sEMG, paving the way for next-generation neural interfaces with enhanced accuracy, sensitivity, and robustness [7].

Most existing studies primarily focus on the plateau phase of muscle contraction—a steady-state phase observed during highly controlled and instructed tasks, where the signal does not reflect dynamic contractions. Focusing solely on this steady segment limits temporal resolution, delays reactions, and increases the likelihood of misclassification during transient phases, thereby reducing the practicality and intuitiveness of the system. Dynamic hand gesture recognition leverages the benefits of electromechanical delay (EMD) [8] to predict hand gestures before their complete execution, enabling more proactive recognition during transitional phases.

sEMG-based HGR is commonly achieved through pattern recognition (PR), which typically involves two key stages: feature extraction and classification. Traditional machine-learning algorithms, such as linear discriminant analysis (LDA) [9], support vector machine (SVM), and k-nearest neighbors (kNN) [10] have been extensively explored in this context. For HD-sEMG, increasing the number of electrodes and gestures requires extracting more features, which increases the complexity of the feature extraction process. With the power of deep neural networks (DNNs), convolutional Neural Networks (CNNs) are among the most commonly used DNN architectures for HGR tasks, as HD-sEMG signals are often represented as HD-sEMG images [11], [12], [13]. While CNNs excel at extracting spatial features, they are less effective at extracting temporal features from sequential sEMG data. Recurrent Neural Networks (RNNs), such as Long Short-Term Memory (LSTM) networks, have been employed in recent studies [14], [15], [16] for capturing the temporal dynamics of sEMG signals. However, the sequential nature of LSTM's structure processes data step by step, leading to a time-consuming process.

Transformer neural network architecture introduces a self-attention mechanism to eliminate the need for recurrence or convolution [17]. This architecture enables parallel data processing and has widespread application in natural language processing and computer vision. Previous studies have introduced transformer-based models for HGR using both sparse sEMG [18], [19] and HD-sEMG signals [20], [21], achieving improved accuracy in decoding sEMG for hand movement classification.

The significant variability in sEMG signals between individuals makes it challenging for models to generalize

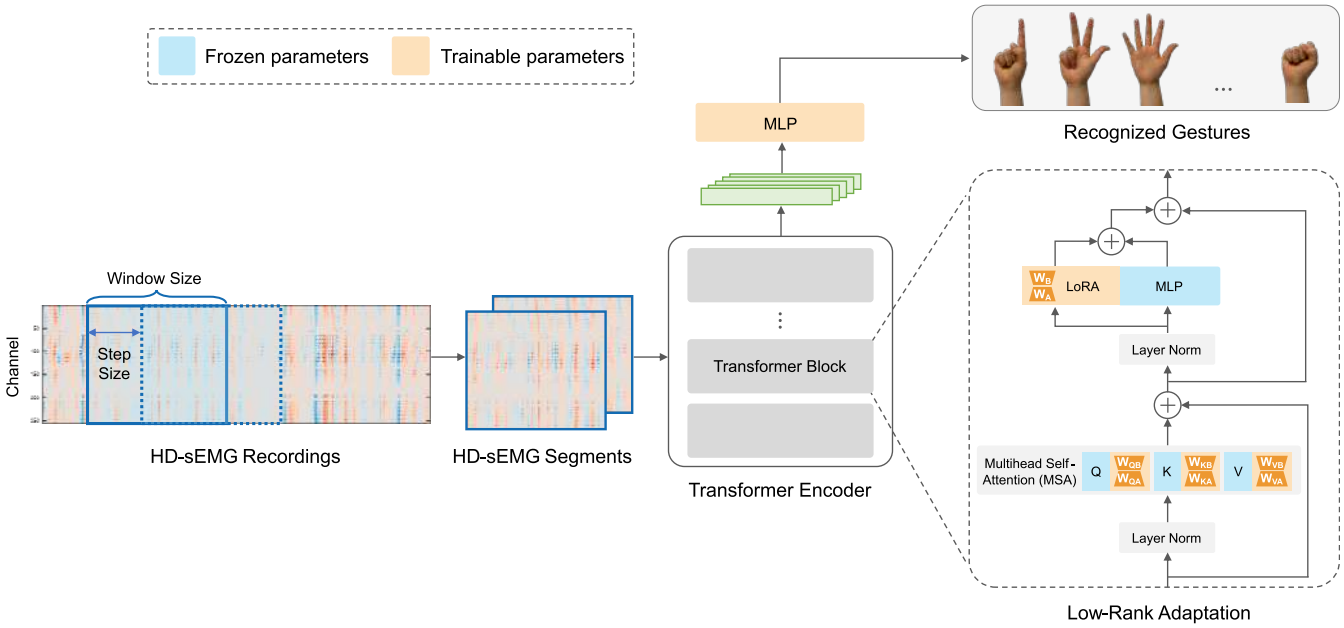

Fig. 1. Illustration of the Low-Rank Adaption (LoRA) of transformer models for hand gesture recognition using HD-sEMG signals

across subjects. Since each person's muscle structure and neurological activity can produce distinct sEMG patterns, directly applying a model trained on one subject to another typically results in poor performance. This variability necessitates using transfer learning to adapt the model to new subjects with limited data. The adaptation methods have gained traction, focusing on tuning only a small subset of parameters, reducing overfitting and computational burdens. One such method, Low-Rank Adaptation (LoRA) [22], optimizes only the low-rank matrices representing changes in the model's weight matrices, leaving the original weights unchanged. LoRA is computationally efficient and well-suited for transfer learning. Fig. 1 illustrates the LoRA of transformer models for hand gesture recognition using HD-sEMG signals.

In this paper, we are the first to investigate applying LoRA to transformers for HD-sEMG-based dynamic hand gesture recognition cross-subject transfer learning. We investigated the recognition accuracy on different ranks of LoRA and the effect of different window sizes of HD-sEMG signal segments. By leveraging pre-trained models and adapting them using LoRA, we can efficiently generalize across different subjects with minimal retraining. This approach reduces computational costs while maintaining acceptable recognition performance for a new user. It effectively solves HD-sEMG-based HGR tasks with diverse subjects and limited data.

II. Materials and Methods

A. HD-sEMG Datasets

In this study, we aim to evaluate the performance of LoRA of transformers on the dynamic phases of sEMG signals, a scenario relevant to real-world prosthesis control. We utilize the publicly available HD-sEMG dataset *Hyser*, precisely its pattern recognition (PR) sub-dataset, which includes 34 hand gestures covering various finger and wrist movements, as shown in Fig. 2(a). The PR dataset was collected from the right hand of 20 able-bodied subjects, consisting of 12 males and 8 females, with an average age of 26.55 ± 4.43 years. The HD-sEMG signals were recorded using four 8×8 electrode arrays, with two arrays placed on the extensor and flexor muscles of the subject's forearm, as shown in Fig. 2(b). A total of 256 channels of HD-sEMG signals were captured using the Quattrocento amplifier (OT Bioelettronica, Torino, Italy) at a sampling rate of 2048 Hz. Subjects were instructed to perform two trials for each gesture: three dynamic repetitions (a 1-second transition from hand resting to the target gesture) and a maintenance task (holding the gesture for 4 seconds). This study focuses on the dynamic transition phase for early gesture prediction, resulting in six repetitions per gesture. Fig. 2(c) presents an example signal plot from several representative channels, capturing the 1-second execution of a dynamic hand gesture. The *Hyser* PR dataset includes recordings from two sessions conducted on separate days. In this work, the variance of each subject on different days is not focused on; all experiments were conducted using data from session 1.

B. Signal Preprocessing

The PR dataset was processed with a 10–500 Hz 8th-order Butterworth band-pass filter and a notch filter to attenuate powerline interference at 50 Hz and its harmonic components up to 400 Hz. To enhance the quality of the recorded signals, outlier channels were identified using a threshold of 3 standard deviations from the root mean square of the signal and were replaced with the average values of the

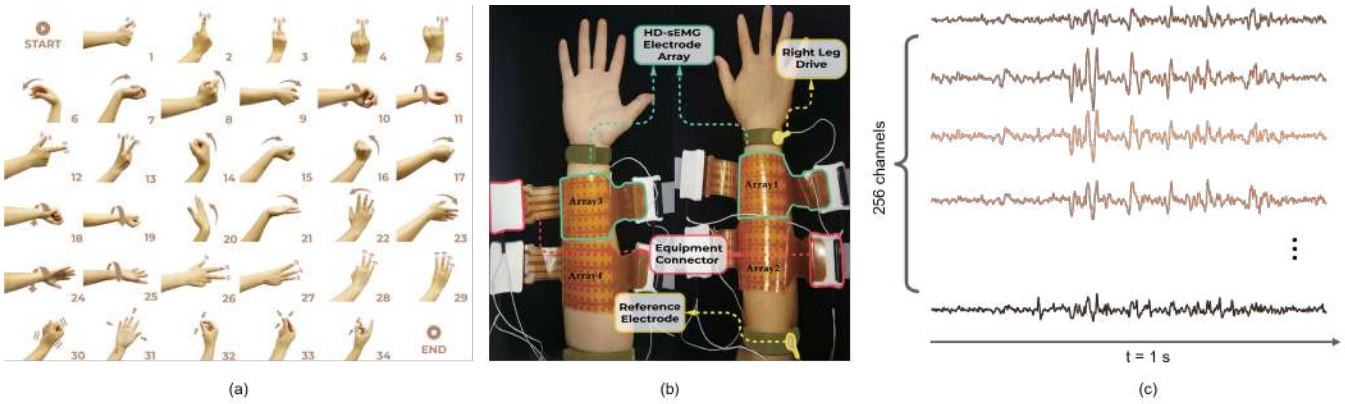

Fig. 2. *Hyser* pattern recognition (PR) dataset. (a) Involved 34 gestures, including finger and wrist movements. (b) HD-sEMG electrode array placement on the forearm. (c) Example plot illustrating recorded sEMG signals during a dynamic hand gesture. Images (a) and (b) are adapted from [23] under a Creative Commons license.

neighboring channels [24]. The initial 0.25 seconds of each 1-second signal were excluded to account for reaction time in each repetition. The z-score normalization was applied using the mean and standard deviation of the training data [25]. The signals were then segmented with a 100 ms (200 data samples) and 200 ms (400 data samples) sliding window and a 10 ms (20 data samples) stride, following commonly adopted standards from previous studies to meet real-time requirements.

III. Model Architecture

This section describes the transformer architecture that processes HD-sEMG signals for cross-subject transfer learning. The HD-sEMG segments are processed by a transformer encoder to capture temporal dependencies and contextual information. To facilitate efficient adaptation to new subjects, we apply LoRA, which allows model fine-tuning with minimal computational cost. For the final classification, an MLP head with a Softmax activation is used, and the model is optimized using cross-entropy loss to predict class probabilities. We will elaborate on these parts below.

A. Transformer Encoder

We utilize the original transformer architecture [17] and process the HD-sEMG signal segments, which are segmented into M overlapped windows. Each window represents a fixed-length signal segment with a slight overlap between consecutive windows to ensure continuity and capture temporal dependencies. These windows will be fed into transformers independently. Each input will have a size of $R^{N\times D}$, where N denotes the window length and D denotes the channel size.

The encoder consists of L stacked Transformer blocks that generate the contextualized encoding sequence $z_L \in R^{N\times D}$. Each block is composed of two key components:

- **Multihead Self-Attention (MSA):** This module applies a self-attention operation to the input z_{i-1} after normalization, followed by a residual connection:

$$z'_i = \text{MSA}(\text{Norm}(z_{i-1})) + z_{i-1}. \tag{1}$$

- **Multi-Layer Perceptron (MLP):** This module applies a feed-forward network to the output of the MSA after normalization, followed by another residual connection:

$$z_i = \text{MLP}(\text{Norm}(z'_i)) + z'_i. \tag{2}$$

In the self-attention mechanism, the queries Q_i, keys K_i, and values V_i are computed as:

$$Q_i = z_0 W_i^Q, \quad K_i = z_0 W_i^K, \quad V_i = z_0 W_i^V, \tag{3}$$

where W_i^Q, W_i^K, and W_i^V are learnable parameters. The attention output for each head is computed as:

$$\text{Attn}_i(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{D}}\right)V. \tag{4}$$

Finally, the outputs from all attention heads are concatenated and transformed using a learnable weight matrix $W \in R^{D\times D}$:

$$\text{MSA}(z_L) = [\text{head}_1, \ldots, \text{head}_L]W. \tag{5}$$

These operations work together to progressively refine the contextual information from the patches, ultimately producing the enriched embedding sequence z_L.

B. LoRA Adaptation

LoRA is an efficient method for adapting large pre-trained models to new tasks without updating the entire set of model parameters. Rather than fine-tuning all the parameters of a model, LoRA approximates the weight update with a low-rank decomposition. Specifically, the weight update ΔW is expressed as the product of two low-rank matrices A and B:

$$\Delta W = AB^T, \tag{6}$$

where $A \in R^{d\times r}$ and $B \in R^{r\times d}$, with r being a user-defined rank that is typically much smaller than d, the dimensionality of the weight matrix. This decomposition reduces the number of parameters that need to be updated, resulting in significant computational and memory savings.

The key idea behind LoRA is that the weight update ΔW can be introduced into the pre-trained weight matrix W_0 as follows:

$$W = W_0 + \Delta W = W_0 + AB^T. \tag{7}$$

This means that only the low-rank matrices A and B are trained during fine-tuning, which substantially reduces the number of parameters that need to be updated compared to traditional fine-tuning, where all parameters in W_0 are adjusted.

LoRA achieves this by introducing trainable low-rank matrices into specific parts of the model architecture, such as the attention layers in transformers. For instance, in the case of the self-attention mechanism, the attention weight matrices W_Q, W_K, W_V are adapted using LoRA. The update to the query, key, and value matrices in a self-attention layer can be written as:

$$W_Q = W_{Q0} + A_Q B_Q^T \tag{8}$$

$$W_K = W_{K0} + A_K B_K^T \tag{9}$$

$$W_V = W_{V0} + A_V B_V^T \tag{10}$$

where W_{Q0}, W_{K0}, W_{V0} are the original pre-trained weight matrices, and A_Q, A_K, A_V and B_Q, B_K, B_V are the learnable low-rank matrices for each respective weight matrix.

In this paper, we utilize LoRA to facilitate subject transfer learning for EMG-based models. When adapting to a new subject, LoRA allows us to update only the low-rank matrices A and B in the attention layers, enabling the model to efficiently learn the specific characteristics of the subject's data without the need for retraining the entire model. This approach minimizes computational overhead by focusing on low-rank updates while preserving the general knowledge from the pre-trained weights. As a result, LoRA enhances the model's ability to generalize to new subjects, making it a resource-efficient method for subject-specific adaptation in scenarios with limited computational resources. By leveraging LoRA, we can rapidly adapt to diverse subjects, ensuring that the model remains accurate and efficient even as the subject's data differs from the original training set.

C. Transfer Learning

Our transfer learning strategy employs LoRA for cross-subject model adaptation. As illustrated in Fig. 3, the approach comprises two stages: pretraining and calibration. During the pretraining stage, we aggregate data from multiple subjects to develop a generalized model. When introducing a new subject, we use LoRA to fine-tune the model with minimal parameter adjustments. This approach allows us to adapt the model to the new subject's specific characteristics efficiently, while maintaining the core knowledge from the initial training. This LoRA-based transfer learning strategy enables precise model customization with minimal computational overhead, ensuring effective learning across diverse datasets.

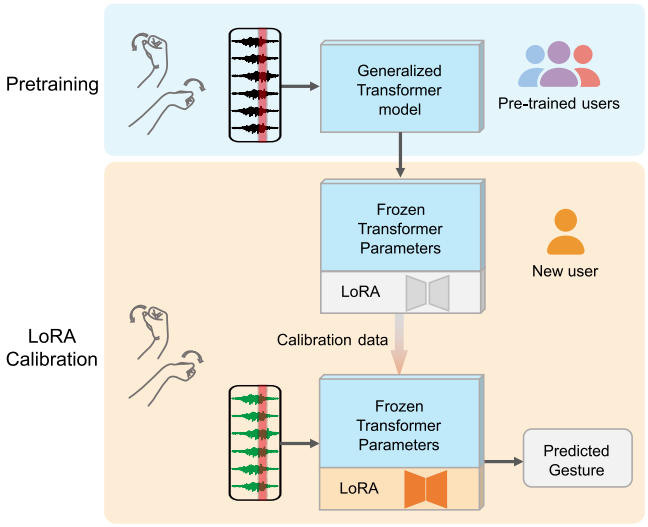

Fig. 3. Illustration of cross-subject transfer learning with LoRA

IV. Experiments and Results

A. Pre-trained Generalized Transformer Model

We employed subjects 1 through 10 to establish a generalized pre-trained model. The training set comprised repetitions $\{1, 2, 3, 4\}$, while repetitions $\{5, 6\}$ were the validation set to optimize the model's performance. All networks are implemented in Python, and computations are performed on an RTX 4090. Through hyperparameter tuning, the transformer encoder is configured with three layers (L = 3), each featuring an MSA with two heads, each of dimension 64. The MLP hidden layer size in the classifier is set to 128. Dropout rates of 0.3 are applied to both the classifier and the transformer encoder. The generalized model achieved an accuracy of 88.04% when trained on subjects 1–10 together.

To effectively assess the model's transfer learning capabilities, we used subjects 11 through 20 as new test subjects for transfer learning. For these subjects, we conducted experiments to analyze results from various combinations of calibration repetitions, specifically assessing the outcomes when using repetition sets $\{1\}$, $\{1, 2\}$, $\{1, 2, 3\}$, and $\{1, 2, 3, 4\}$. The test set remained consistent across all evaluations, utilizing repetitions $\{5, 6\}$ to ensure a standardized measure of the model's performance.

B. Evaluation of LoRA with Different Ranks

In the adaptation experiments, we first evaluated the performance of LoRA under different rank configurations. Table I presents the recognition accuracy (Acc.) and calibration time (Time) for different rank values ($\{32, 64, 96\}$) across varying calibration data sizes (1 to 4 repetitions). The results reveal distinct patterns regarding the impact of rank values and calibration data sizes on recognition performance and calibration time.

For recognition accuracy, higher rank values consistently yield better performance across all calibration data sizes. For example, with 4 repetitions, the accuracy increases from

TABLE I

TRAINABLE PARAMETERS AND AVERAGE RECOGNITION ACCURACY FOR 10 NEW SUBJECTS ACROSS VARYING RANK VALUES AND AMOUNTS OF CALIBRATION DATA (200 MS WINDOW SIZE).

Training Strategy		**Acc. [%] /Time [s]**	**Calibration Data Sizes**				**#Trainable Parameters**
			1 Rep	2 Reps	3 Reps	4 Reps	
LoRA (different Rank)	32	Acc.	50.53±6.18	61.54±6.99	67.71±7.02	75.76±6.79	295,330
		Time	69.9	127.4	187.5	234.0	
	64	Acc.	53.10±7.45	64.12±7.53	69.17±6.83	77.62±7.36	555,378
		Time	70.1	122.7	184.9	234.9	
	96	Acc.	54.12±8.47	66.38±7.46	72.27±7.10	80.29±6.46	811,426
		Time	68.1	124.3	184.4	239.2	
Subject-specific model without transfer learning		Acc.	58.50±13.63	63.35±14.23	69.25±13.73	72.18±12.17	929,122
		Time	52.31	98.49	147.12	181.99	

75.76% for rank 32 to 77.62% for rank 64, and further to 80.29% for rank 96. This improvement reflects the greater capacity of models with higher ranks to generalize from calibration data. Calibration time, on the other hand, is primarily influenced by the calibration data size rather than the rank value. For all ranks, the calibration time increases almost linearly with the number of repetitions, from approximately 70 seconds with 1 repetition to around 239 seconds with 4 repetitions. The minor variations in calibration time across rank values (e.g., 234.0 s for rank 32, 234.9 s for rank 64, and 239.2 s for rank 96 with 4 repetitions) suggest that the computational overhead associated with increasing rank is negligible in this context.

These results emphasize the importance of calibration data in improving accuracy while demonstrating that the time required for calibration is mainly independent of the rank value. Rank 64 offers a strong balance between accuracy and model complexity, achieving significant performance gains over rank 32 with only a moderate increase in trainable parameters. Although rank 96 achieves slightly better accuracy, the marginal improvement suggests diminishing returns, making rank 64 a practical choice for balancing performance and computational demands in real-world applications.

In Table 1, we also provide the results for individual subject-specific models without using LoRA. The results show that using a pre-trained model with LoRA, under the same training data size, can improve accuracy while reducing the training parameter size.

C. Evaluation of LoRA with Different HD-sEMG windows size

Figure 4 illustrates the recognition accuracy across different rank values ($r = 32, 64, 96$) and calibration data sizes (1 to 4 repetitions) for two HD-sEMG window sizes: 100 ms and 200 ms. The Wilcoxon signed-rank test was conducted in this study. Asterisks (*) are used to indicate statistical significance with respect to p-values: 1) $p > 0.05$ is considered not significant (ns); 2) * denotes $0.01 < p \leq 0.05$; 3) ** denotes $0.001 \leq p \leq 0.01$. Across all rank values and calibration data sizes, the recognition accuracy is consistently higher when using a 200-ms window compared to a 100-ms window. For instance, with $r = 96$ and 4 repetitions, the accuracy for the 200ms window reaches approximately 80.29%, whereas it is noticeably lower (around 75.38%) for the 100ms window. This pattern suggests that the 200 ms window provides richer temporal information, enabling the model to better capture relevant features for recognition tasks.

These results show the importance of window size in determining recognition performance. While a larger window (200 ms) generally yields better accuracy, practical considerations such as real-time constraints and computational overhead must be taken into account when selecting the appropriate window size for specific applications.

V. CONCLUSIONS

This paper presents an effective hand gesture recognition approach leveraging LoRA to enhance model adaptability

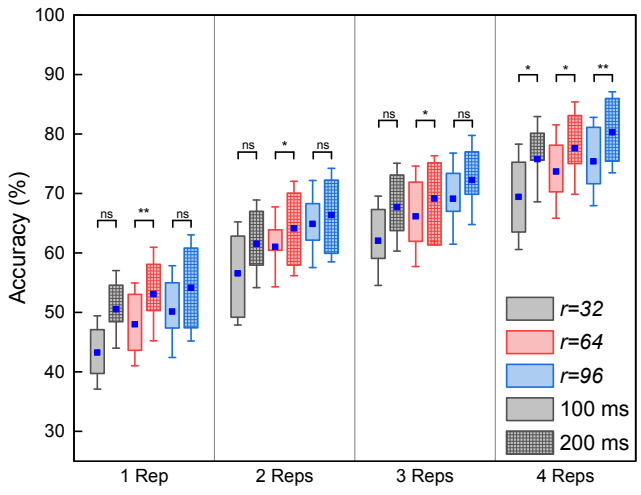

Fig. 4. Recognition accuracy boxplots of HGR performance for 10 new subjects with 100 ms and 200 ms HD-sEMG window size. Blue squares represent the average values.

for HD-sEMG signals. By aggregating data from multiple subjects during the pre-training phase, we developed a generalized model that efficiently customizes learning when introducing new subjects through the adjustment of a limited set of low-rank matrices. This method not only significantly reduces computational overhead but also ensures that the model rapidly adapts to new data characteristics, maintaining its efficiency and accuracy. Experimental results validate the reliability and flexibility of LoRA across different subjects, providing a strong foundation for future applications in gesture recognition, particularly in human-robot interaction and biomedical devices. The promising outcomes of this study position the LoRA approach as a valuable tool in advancing gesture recognition technology to meet increasing demands.

***Abstract*— The human-robot attachments (HRA) connecting humans to exoskeleton robots should facilitate user independence, efficient donning/doffing, maintain user-robot-kinematic alignment using interfaces that are sufficiently rigid, comfortable to wear, and (with the aid of the exoskeleton) accommodate dexterous human motion. This report presents a proof-of-concept comparison of an innovative self-aligning, size-adjustable HRA system designed for the upper arm. A novel discretely contracting orthosis adjusted by a dial ratcheting cable mechanism was fabricated from flexible and semi-rigid plastics to improve support and rigidity. Experiments comparing this new design to an existing rigid HRA design for the BLUE SABINO are conducted to characterize suitability in terms of ability to maintain kinematic alignment and to distribute interaction forces evenly on the user's arm. Piezoelectric force-sensitive-resistor sensors embedded in an elastic sleeve are used to measure human/orthosis interface forces at 8 Locations distributed on the circumference of the arm interface. Kinematic alignment was assessed for 5th-percentile female to 95th-percentile male sizes using 3D-printed mock arm cross sections. Laser alignment experiments found that the proposed device reduced arm center to orthosis center misalignment magnitude by up to 11.5 mm for 5th percentile male arm circumference vs. the existing design. Force measurements are inconclusive but indicate the potential to alter force distribution while being adequately adjustable and usable with repeatable settings.**

Keywords—human-robot interaction, orthosis design, rehabilitation robotics, compliant mechanism design.

I. INTRODUCTION

Stroke is a significant cause of physical disability, affecting approximately 1.3 million people annually [1]. Arm and hand impairments are the most common long-term consequence of stroke [2]. Traditional physical therapy is effective [3] but labor-intensive and expensive. Aging populations [4] and a limited supply of skilled therapists [5] have inspired the development of robotic solutions to decrease therapy labor requirements, investigate factors that promote recovery, and simultaneously assess and train users [6]–[10]. Research efforts have increasingly sought exoskeleton solutions that can simultaneously assist and train the upper limb and provide features such as gravity support and motion guidance [8], [11]. A growing body of evidence suggests that patient engagement is critical to recovery, with patients benefiting most from higher-intensity/longer-duration therapy and training protocols that continually adapt assistance according to patient performance [12]. Extended-duration therapies necessitate a design focus on the comfort and functionality of human-robot attachment systems to maintain users' motivation to undergo challenging therapy and work within clinical settings' inherent time constraints [13].

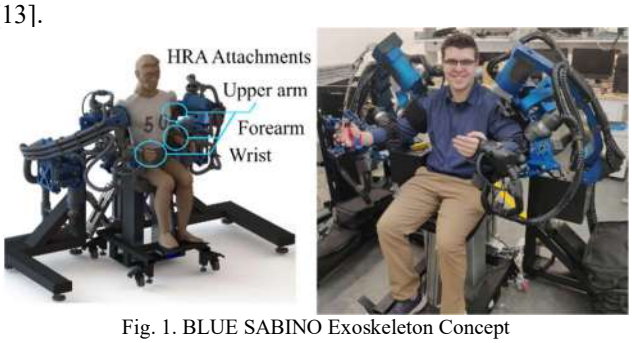

Fig. 1. BLUE SABINO Exoskeleton Concept

BLUE SABINO (BiLateral Upper-extremity Exoskeleton for Simultaneous Assessment of Biomechanical and Neuromuscular Output) (Figure 1) [14] is an 18-degree-of-freedom rehabilitative exoskeleton currently being developed at the University of Idaho. BLUE SABINO was developed with three HRA interfaces per arm, achieving size adaptability via 3D-printed sliding orthoses. However, kinematic misalignment between user and exoskeleton joints can still occur when users' arms are significantly above or below the 50th percentile. In addition, BLUE SABINO is intended to provide gravity assistance for users whose neurological impairment limits their ability to support the weight of their arm independently. In such cases, pressure at the orthotic interfaces can be concentrated, particularly around interface edges, and become uncomfortable. This is typically alleviated by including foam layers and large rounds on interface edges to distribute pressure, but foam inserts can reduce the precision of user-robot kinematic alignment. Furthermore, BLUE SABINO's primary force control uses force sensors between the HRA interfaces and the exoskeleton structure. The readings acquired by these sensors are affected by the rigidity of the HRA connection to the user. Therefore, consistency of exoskeleton measurements may be

influenced by the repeatability of donning aspects such as strap tensioning and user alignment. This project focuses on designing an alternate HRA system for devices like BLUE SABINO to improve kinematic misalignment, force distribution, and repeatability of orthosis securement to the upper limb.

II. Background

A. Compliance and Rigidity in HRA Systems

The dynamics of human-robot interaction must be designed to enable precise and repeatable control of interaction force and position [15]. Furthermore, human and robot joints should remain aligned during use since misalignment creates undesired interaction forces that can be uncomfortable or present a hazard to the user, depending on magnitude [16]. Stiff attachment constraints between the user and robot are desirable to facilitate high force transmission bandwidth, enforce alignment, and improve the accuracy of human joint angle estimation. On the other hand, some level of compliance in HRA is required. The complexity of human kinematics requires exoskeleton designs to approximate human's natural motion, meaning that even high-DOF devices inevitably suffer some degree of misalignment that is taken up in HRA [17]. Additionally, connection interfaces along the limb must account for the internal structure of the limb, including bony and fleshy areas, which change shape depending on joint positions. How to appropriately balance compliance vs rigidity in HRA connections remains an open question, so adjustable HRA devices that provide measurable and repeatable connection stiffness are needed.

B. HRA Designs State-of-the-Art

Traditional HRA designs use U-shaped cuffs and fabric straps to achieve size adjustability but often favor too much compliance, resulting in large or small users being poorly aligned with devices without significant care and attention from operators. Zimmerman et al. [18] proposed a design that included self-centering features, significantly improving reported user comfort and perceived device controllability. Simultaneously, growing attention is being placed on soft manipulators, including cable and pneumatically actuated components, to control force while manipulating objects precisely. Leveraging compliance in the design of HRA components for exoskeletons can enable improved control of the interfaces along with a better ability to align the user and exoskeleton joints. This is because a compliant orthosis can achieve far more adaptability in terms of geometry than a rigid shell. Further, compliance in the HRA can be designed to spread interaction forces more intentionally to enhance comfort and optimize overall rigidity.

III. Methods

A. Technical Requirements

To investigate the efficacy of a compliant HRA system design, a prototype orthosis was developed for the upper arm. Major design criteria were as follows:

1) Adjustability:

High-performance rehabilitative exoskeletons are multi-user devices, and it is therefore necessary to accommodate a large population range. The time required to fit devices to users by changing components or adjusting sizes in clinical applications should be limited. BLUE SABINO supports subjects sized approximately from the 5th-percentile female to 95th-percentile male; thus, the proposed orthosis design must accommodate at least this range. The corresponding diameter range for the upper arm is 70mm – 110mm [19].

2) Self-Centering:

Proper joint alignment enables repeatable human-robot interaction (HRI) measurement, essential to safe exoskeleton control [20]. On BLUE SABINO, the upper arm orthosis is located near the shoulder above the elbow. Angular alignment of the arm's long axis and center alignment on the upper-arms remote center of rotation locate the user's shoulder concerning the device, so the ability of the upper arm HRA to maintain this alignment is critical.

3) User Independence

Poor usability of assistive devices has been shown to lead to lower user acceptance rates and increased treatment abandonment [21], [22]. Patients who have suffered strokes often struggle to move their hands and limbs through small openings due to reduced motor control [3]. For this reason, the orthosis design should allow donning in a fully open configuration (rather than bypassing the arm through a closed loop) and have a method of securing and adjustment that can be easily performed with one hand.

4) Discrete Control/Repeatable

To optimize the balance between user comfort and attachment stiffness, the tightness of the orthosis must be quickly and incrementally adjustable. The design must allow fast and repeatable tensioning so that data collected over several sessions remains comparable and captures relevant information on user improvement rather than being overshadowed by misalignment effects. Finally, a readout of tension level is desirable to assist in repeatably setting (or adjusting) settings for desired patient comfort.

5) Comfortable

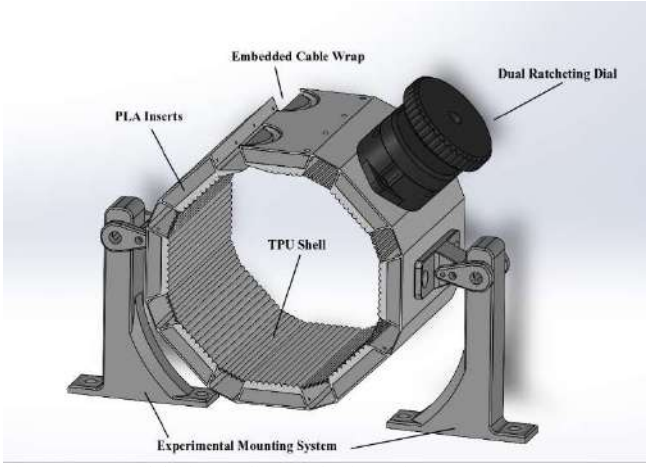
To enable extended therapy sessions, the orthosis must be comfortable for the user [23]. It's also vital that the HRA impedes patient movement as little as possible while using the exoskeleton [17]. Comfort is a subjective measurement, but objective measurements of force distribution from the orthosis can be used to evaluate comfort and transparency of the device.

B. Proposed solution

A cuff design has been developed with eight 3D-printed PLA linkages, connected in an octagon via a 3D-printed TPU outer shell (Figure 2). These linkages have cabling run through 4 channels, which are fed through a custom-made dual ratcheting dial. This outer shell maintains gaps between the linkages, so when the cabling is pulled, the walls of the

gaps are pushed inwards, and the mechanism contracts, reducing the overall diameter of the cuff.

The cuff is 100 mm long to adequately and comfortably distribute pressure on the upper arm. It can be opened, allowing donning/doffing without requiring a user to maneuver their arm through closed loops. It is secured via two cable loops, which wrap on embedded posts near the dual ratcheting system.



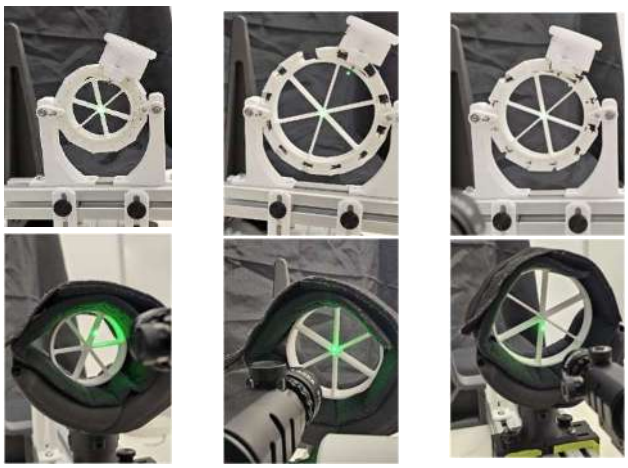


Fig. 2: CAD model of Compliant Orthosis Design

C. Experimental Evaluation

To establish initial evaluations of the prototype design, experimental comparisons are conducted with the prototype-compliant design and the present rigid shell orthosis from the BLUE SABINO exoskeleton. These tests evaluate 1) arm center to HRA center alignment, 2) Force distribution between the orthosis and user interface, and 3) volunteer-reported comfort while wearing each orthosis for a short time. Alignment data were collected with printed/molded arm mocks to facilitate direct center measurements. Force and comfort measures were collected from five healthy volunteers (one m, 4 f, ages 18 to 21). Participants provided written, informed consent, and tests were conducted according to protocol approved by the University of Idaho's Institutional Review Board (IRB #22-093).

1) Self-Centering Evaluation via Laser Scope

A laser alignment setup was constructed to measure the ability of orthoses to center a user's arm and differing diameter settings. The setup consists of a laser scope mounted in line with the orthosis. The orthosis was loaded with a mold-cast synthetic arm section, representing a 50th-percentile male bicep, with a marked center to which the laser was aligned. The orthosis was then loaded with circular 3D-printed pieces representing the 5th-percentile female (70mm diameter),
50th-percentile male (95mm diameter), and 95th-percentile male (110mm diameter) upper arms. The absolute planar distance between the marked center of these 3D-printed pieces and the laser point was measured to the nearest 0.1 mm using digital calipers (Fig 3).

Fig 3: Kinetic Alignment of Compliant (Top) and Solid Orthosis, using 5th (Right), 50th (Center), and 95th (Left) percentile cross section.

2) Force Distribution and User Reported Short Duration Comfort

a) Force Distribution

A testing apparatus arm band (Fig 4) containing an array of eight FlexiForce [24] piezoelectric sensors was created to measure the forces exerted at discrete points around the arm. The sensors were held in place by fabric loops to maintain equal spacing around the arm while the elastic arm band stretches to the accommodate diameter size variations as necessary (Fig 4).

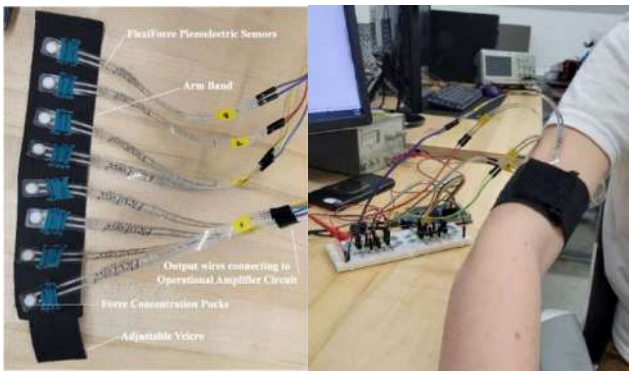

Fig 4. Arm Band FSR Testing apparatus with FlexiForce sensors while not worn (LEFT) and fit to a subject's upper arm (RIGHT).

Comfort was evaluated using this testing apparatus to measure pressure across the orthosis and identify high-pressure areas and overall pressure distribution. Participants wore the armband before donning the orthosis, and baseline force data was collected over 30 seconds. Once in the orthosis (Fig 5), force data was again collected over a period of one minute.

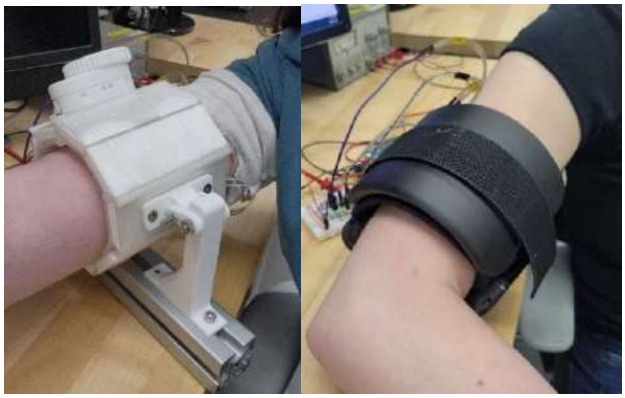

Fig 5. Participants secured in the prototype compliant orthosis (LEFT) and BLUE SABINO's solid orthosis (RIGHT) while collecting interaction force data.

b) Sensor Calibration and Data Processing

The piezoelectric sensors used generate a nonlinear output based on the force applied. Thus, calibration curves were generated for each sensor to map voltage readings to measured force. To this end, each sensor was incrementally placed under load using weights from 5 grams to 500 grams using a hanging force concentrator (Fig 6).

Fig 6. Sensor Calibration using hanging weight and force concentrator

The output voltages were recorded, and using MATLAB's "lsqcurvefit," a nonlinear least squares regression was applied to fit the a model of form :

$$y_N = p_1 e^{-p_2 x} + p_3$$

This model and the generated fit parameters provide a map that converts measured voltage readings from each sensor to force in (Newtons). The resulting calibrations were validated by applying various known weights and having MATLAB output the weights based on the corresponding calibration curve.

3) Comfort evaluation

Following the force distribution analysis, the patients were asked to evaluate the comfort of each orthosis using the Likert scale seen in Table 1. Patients were then encouraged to describe the comfort or discomfort further and what features they felt contributed to it and this feedback was also recorded.

TABLE I. COMFORT EVALUATION LIKERT SCALE

1	2	3	4	5
Very Uncomfortable	Somewhat Uncomfortable	Neutral	Somewhat Comfortable	Totally Comfortable

IV. RESULTS

Table II shows the misalignment measured from the laser scope to the center of the respective 3D printed section. The measurements are for the proposed flexible orthosis and the current solid design for 5th, 50th, and 95th percentile arm diameters.

TABLE II. MEASURED MISALIGNMENT

Device	**5th % (mm)**	**50th % (mm)**	**95th % (mm)**	**Average (mm)**
Flexible Orthosis	0.0	0.0	0.0	0.0
Solid Orthosis	11.5	2.7	10.3	8.2

Figures 7 and 8 illustrate forces measured during patient testing using the piezoelectric sensors on polar plots where 90 degrees (top) corresponds with the topmost point of the orthosis during experiments. The force between the points is estimated using MATLAB's "interp1" spline interpolation tool.

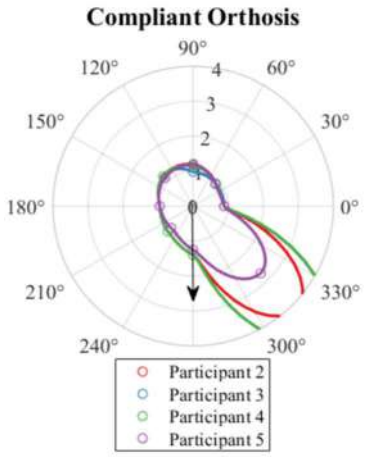

Fig. 7: Force Distribution for Compliant Orthosis

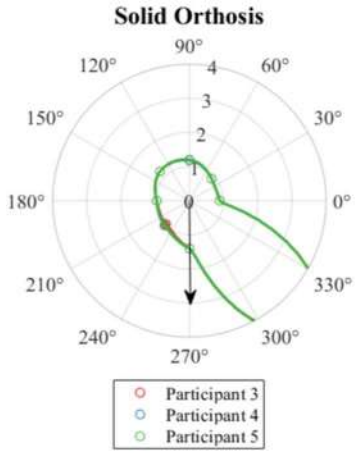

Fig. 8: Force Distribution for Solid Orthosis

Table III shows the results from the comfort evaluation using the Likert scale (Table I). The table includes participant data for solid and compliant orthoses and displays the total force measured and their arm circumference. Participant 1 had data recorded, but it was deemed unusable due to their arm size being under the 5th percentile.

TABLE III. CASE STUDY WITH 5 PARTICIPANTS

Participant	Upper arm diameter (mm)	Total Force (N) - Solid	Solid Orthosis Likert	Total Force (N) - Compliant	Compliant Orthosis Likert
2	76.4	N/A	3	11.75	4
3	89.1	12.64	4	12.48	4
4	87.5	12.68	4	12.65	4
5	90.7	12.68	N/A	9.93	N/A

V. DISCUSSION

The alignment comparison results demonstrate that the prototype design can better maintain proper center alignment across the necessary size range. Further testing with the prototype mounted to an exoskeleton is required to evaluate user-to-exoskeleton joint center alignment differences in a realistic application. The force distribution results are less conclusive, with both the solid and compliant designs achieving very similar levels of force and similar profiles. Indicating an issue with the data collection system. In both cases, FSRs under the arm experienced significantly more loading due to gravity, making it difficult to discern other differences. The comfort results are comparable to the current solid orthosis design. Still, some participants mentioned that the solid orthosis made the force concentrator bumps more noticeable than the compliant orthosis, indicating that the compliant orthosis.

VI. CONCLUSION

This project introduced a novel, compliant Human-Robot Attachment system for BLUE SABINO and other similar applications. A novel force testing apparatus and method of comparing orthotic systems has also been proposed through a proof-of-concept upper arm orthosis. The orthosis design proposed fulfills crucial requirements of adaptability from 5th to 95th percentile subjects, self-centering, independent usability, discrete control, and repeatability. These developments aim to further the work towards rehabilitative exoskeletons and highlight an often-overlooked feature of such systems.

VII. FUTURE WORK

The proposed HRA design will continue to be developed, with special care taken on the usability and comfort aspects of the design. Further design iteration is planned to and will consider the addition of a 3-point contact HRA using the developed compliant technology. It is planned to refine the force measurement systems for higher accuracy and develop a simple readout of the total force on the user. Further testing will be done to time the donning and doffing speed with untrained and trained participants to further determine independent usability. These HRA designs will then be applied to BLUE SABINO, and further testing will cover ADLs (Activities of Daily Living). Motion capture systems will be used on the exoskeleton to measure if/how the misalignment changes while in movement. If these orthosis designs are deemed successful and valuable for BLUE SABINO, they will be integrated across the other HRAs.

ACKNOWLEDGMENT

The authors would like to thank the University of Idaho Office of Undergraduate Research for awarding a Summer Undergraduate Research Fellowship to develop this project and to the DeVlieg Scholars Fund for supporting continuing work during the school year.

Structural Optimization of a Passive ExoNET for Forearm Supination

Valentino Wilson[1,2*], Partha Ryali[1,2], Leah O'Shea[1], Adith Srivatsa[1,2], Mac Camardo[1,2], Courtney Celian[1] and James L. Patton[1,2]

***Abstract*— Impairments in forearm supination are a common consequence of stroke, impeding essential activities of daily living and hand-object interactions. To address this, we present a forearm ExoNET—a novel, passive, wearable device designed to both assist and improve forearm supination for stroke survivors and others with movement deficits by generating clinician-defined, multijoint torque patterns using elastic actuators. Guided by torque deficit measurements from a custom-designed diagnostic device and driven by a mathematical model and structural optimization algorithm, the forearm ExoNET can be customized in real time to meet individual needs, providing configurations that deliver both assistive and therapeutic applied torque fields. Initial results demonstrate that the diagnostic device effectively identifies supination torque deficits in stroke survivors, while the optimization algorithm achieves strong predictive accuracy (R^2 = 0.987) in designing ExoNET configurations to counteract these deficits. These findings underscore the forearm ExoNET's potential to support active supination across the full range of motion, offering a low-cost, accessible solution with significant promise for improving upper-limb rehabilitation outcomes.**

I. INTRODUCTION

Forearm supination is essential for hand positioning during many activities of daily living, such as reaching, grasping, and manipulating objects. Reductions in forearm range of motion impair the ability to position the hand effectively [1] and diminish strength [2] during these tasks. After a stroke, individuals often experience motor impairments that compromise their ability to supinate the forearm, making tasks such as turning a doorknob, using utensils, or picking up objects challenging [3]. These impairments are part of broader sensorimotor deficits caused by stroke, which not only limit functional arm use but often result in compensatory strategies that lead to muscle imbalances and injury [4], [5]. Compounding these challenges, stroke survivors frequently exhibit abnormal joint coordination and altered muscle synergies across the upper limb [6], which can disrupt functional movement and limit precise motor control, further affecting forearm and hand positioning. Decreased arm use can exacerbate these challenges by leading to learned non-use, a vicious cycle of impairment that further diminishes muscle strength and gives rise to secondary effects such as contracture [7]. While large-scale arm therapy studies, such as the EXCITE [8] and ICARE trials [9], demonstrated improvements on clinical scores, substantial deficits persisted, particularly in resolving impairments that critically affect bimanual tasks—many of which depend on forearm supination. Therapeutic efforts to remediate the forearm and wrist, while promising, do not lead to recovery, thereby leaving many adults with life-long deficits [10].

Rehabilitation technology has predominantly focused on hand location rather than hand orientation [11], creating a significant gap in practical supination-supporting devices. Many existing solutions, such as the Bi-Manu-Track [12] and Haptic Knob [13], are large, non-wearable robotic systems, impractical for use during daily activities. While more portable options exist—such as the fabric-based helical actuator developed by Realmuto and Sanger [14] and the pneumatically powered sleeve by Park et al. [15]—they depend on external air supply systems, limiting real-world applicability. Other devices, such as the CRUX exotendon suit [16], use motors and a cable-driven system for active assistance but focus on general upper-limb augmentation rather than targeted supination support, lacking task-specific torque modulation. A more targeted solution is the guided double-rod active exoskeleton by Dezman et al. [17], which offers pronation/supination assistance in a compact form. However, such active devices rely on powered actuation—batteries, motors, and control algorithms—resulting in increased cost, complexity, and power dependence. Despite these advances, the field still lacks a system that is simultaneously wearable, inexpensive, lightweight, easy to use, and unintimidating for both users and clinicians.

The forearm ExoNET (Exoskeletal Network for Elastic Torque) presented here addresses these limitations and seeks to fill this critical gap. We present an alternative approach to motorized systems: the use of spring elements without a rigid skeleton. Such passive exoskeletal devices have excitingly been shown to assist walking [18] and running [19], but effective wearable units have yet to be developed for the forearm. The forearm ExoNET is a passive, wearable device designed specifically to support forearm supination by using a network of elastic actuators that can be configured to generate clinician-specified torque patterns. Instead of relying on software-based control, the ExoNET utilizes hardware-encoded torque generation, where actuator configurations are pre-programmed through structural optimization of material properties, geometry, and attachment points. This design enables targeted torque delivery while allowing the system to recycle energy efficiently, without the need for motors, controllers, sensors, or external power. The first realization

Research is supported by NIDILRR RERC Grant 90REGE0017.

of the ExoNET concept was the MARIONET (Moment Arm Adjustment for Remote Induction of Net Effective Torque), a device that modulates generated torque by adjusting the moment arm [20], [21]. This approach introduced a novel method for delivering torque to a joint, which has since been applied in various systems utilizing diagonal tension elements [21], [22], [23]. These applications include counteracting the effects of gravity during upper extremity reaching tasks [24], [25], [26] and supplementing muscle torque during gait [27], [28]. The forearm ExoNET represents the next evolution of this system, advancing the concept as a logical progression in its development.

The forearm ExoNET is configurable as both 1) an assistive orthotic that facilitates forearm supination and hand positioning for everyday tasks, and 2) a therapeutic device that strengthens supinator muscles and fosters motor coordination. The device can uniquely combine these functions by first providing resistance throughout the user's active range of motion, then transitioning to assistance upon reaching their movement limit (Fig. 1), thus encouraging active engagement while ensuring full supination. Prior research supports this approach, demonstrating that structured modulation of resistance during movement can enhance functional performance and facilitate motor learning [29]. To maximize its effectiveness, the ExoNET can be optimized to provide personalized support for each user's torque deficits. A custom-designed diagnostic tool measures a user's peak supination torque at multiple discrete angles, which are then compared to a neurotypical average to quantify these deficits. The arrangement of the elastic actuators is then tailored to meet each user's needs through a structural optimization model. Each tension element generates a sinusoidal torque profile that functions mathematically as a basis function, which can be linearly combined to achieve any desired torque profile through tuning via optimization [24].

By using passive elastic elements, the forearm ExoNET is lightweight, portable and safe to operate by a wide range of users. Its passive elastic actuators eliminate the need for complex controls, making the device simple and intuitive to operate. The simplicity of the device's design enables clinicians, care partners, and users to adjust its structure in real time. The ExoNET's passive design, simple construction, and user-centered approach make it affordable ($50 to manufacture) and accessible, reducing barriers to advanced rehabilitation technology and offering significant potential to enhance users' quality of life.

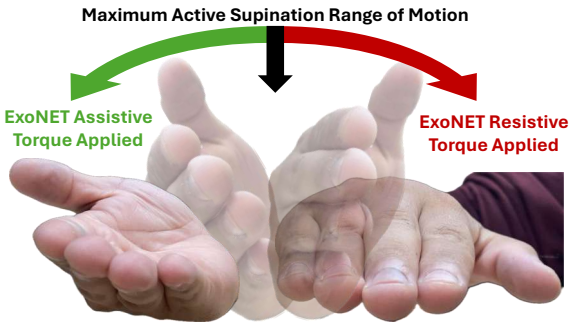

Fig. 1. Torque delivery mechanics of the forearm ExoNET. The device resists active supination and transitions to assistance at the maximum range. This dynamic response promotes muscle engagement while enabling full supination, highlighting its combined assistive and therapeutic capabilities.

In this paper, we outline the theoretical model of the forearm ExoNET, detailing the optimization algorithm for user-specific configurations, and present initial results demonstrating its potential for use in clinical settings.

II. METHODS

A. Device Actuation and Mathematical Representation

The forearm ExoNET can comprise two types of actuators—helical bungee cords and shutter springs—designed to create stable and unstable equilibrium states for controlled assistance and resistance during supination. The device's 3D-printed forearm and wrist bands, made of Thermoplastic Polyurethane (TPU), anchor the actuators to the body and are positioned distal to the elbow and proximal to the wrist, respectively. For simulation and optimization, the forearm is modeled as a frustum with elliptical cross-sections at the proximal and distal ends to accurately capture its tapered geometry. This representation enables precise modeling of actuator force vectors and torque generation.

1) Helical Bungee Actuator: The helical bungee actuator provides a stable equilibrium, offering consistent assistance or resistance across the full supination range (Fig. 2(g), blue curve). It is helically wrapped between the forearm and wrist bands (Fig. 2(a)) to optimize force transfer to the wrist through precisely oriented force vectors, thereby maximizing torque efficiency. The actuator is offset from the skin to enhance user comfort, and its length can be adjusted in real time to allow for fine-tuning of the applied torque magnitude to align with specific therapeutic objectives. This actuator can also be integrated with other types to balance stability and bias movement toward either assistance or resistance.

The actuator is mathematically modeled as a series of discrete spring segments along a helical path around the forearm (Fig. 2(e)). Each segment is treated as an individual spring with unique characteristics, allowing for variations in spring stiffnesses and resting lengths. This segmented approach provides a more accurate representation of the actuator's wrapping mechanics, enhancing the model's ability to simulate realistic behavior. The helical path of the bungee actuator is defined using parametric equations (1) that specify the positions of discrete points (nodes) along the helix. The helix is characterized by an average radius (r), axial distance between attachment points (h), number of helical turns (n), and angular change along the helix (u).

$$\begin{cases} x(u) = r\cos(u), \\ y(u) = r\sin(u), \quad u \in [0, 2\pi] \\ z(u) = \frac{h}{2\pi n}u, \end{cases} \tag{1}$$

To maintain this helical configuration, the actuator's trajectory is influenced by the height difference between the wrist and forearm attachment points ($h_{\text{w_mnt}}$, $h_{\text{f_mnt}}$) and their respective angular offsets ($\theta_{\text{w_mnt}}$, $\theta_{\text{f_mnt}}$), which define

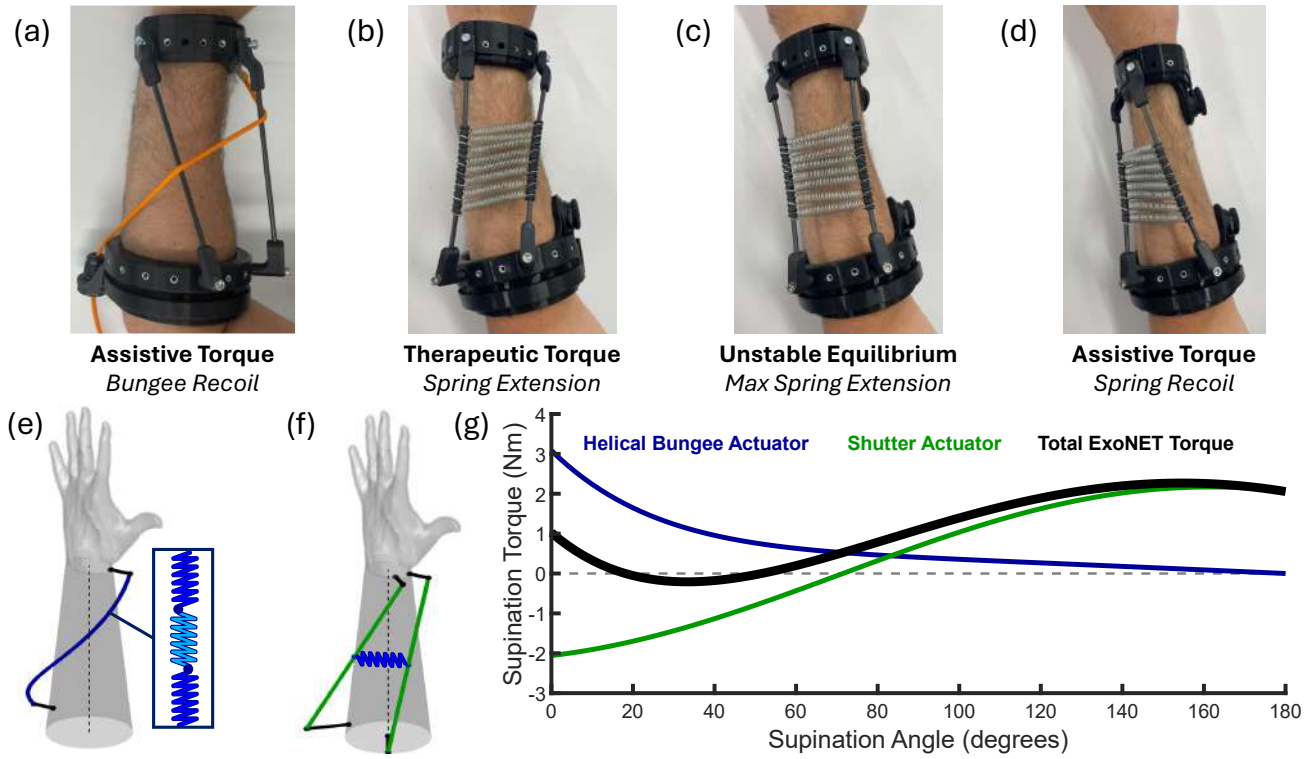

Fig. 2. Functionality of the forearm ExoNET actuators. (a) The helical bungee actuator, wrapped around the forearm, provides stable assistance across the full supination range. (b) Tension springs in the shutter actuator generate resistance within the user's active supination range. (c) The shutter actuator transitions from resistance to assistance, creating an unstable equilibrium. (d) Assistance is provided as supination exceeds the active range. (e) The helical bungee model consists of discrete spring segments, improving the accuracy of its wrapping mechanics and torque-delivering capacity. (f) The shutter actuator is modeled as rigid rods connected by an arbitrary number of tension springs. (g) Torque profiles for the helical bungee (blue) and shutter actuator (green) can be summed to create more complex torque profiles (black).

the rotational positioning of the bungee cord. These factors determine the actuator's wrapping trajectory, which is recalculated dynamically at each rotation step based on the updated attachment positions at the wrist and forearm. The helical pitch and number of turns are modulated by these attachment constraints, ensuring a structured, repeatable path rather than following the shortest straight-line route.

2) Shutter Actuator: Inspired by the mechanics of a camera shutter, the shutter actuator consists of two or more rigid fiberglass rods connected by tension springs. These rods function as mechanical extensions of the forearm, mimicking the behavior of the radius and ulna during supination while being offset with distinct origin and insertion points on the forearm and wrist band. Mathematically, the actuator is modeled as a system of rigid rods connected by tension springs, spanning between the forearm and wrist bands to reflect its physical configuration (Fig. 2(f)).

As the user initiates supination, the springs stretch, generating a resistive torque that increases with rotation (Fig. 2(b)). This resistance encourages muscle engagement, promoting active effort and progressive strengthening. However, the system exhibits a nonlinear torque response due to a mechanically encoded transition point. As supination progresses, the attachment geometry shifts the mechanical advantage of the springs, reaching a critical rotation angle at which the springs stop stretching and begin contracting instead (Fig. 2(c)). This reverses the torque contribution, causing the actuator to transition from providing resistance to offering assistance, facilitating the final phase of supination (Fig. 2(d)). This behavior arises from the nonlinear kinematic relationship between forearm rotation and spring extension, which is governed by the attachment locations and initial spring tension. The transition point represents a passive instability, where the effective moment arm changes sign, making further supination easier rather than harder. As a result, the shutter actuator seamlessly integrates resistive and assistive phases within a single motion, supporting both therapeutic strengthening and functional completion of supination (Fig. 2(g), green curve). While preliminary testing suggests that this approach is feasible, further controlled experiments are needed to quantify how this nonlinear torque profile influences rehabilitation outcomes.

B. Theoretical Model of Torque Generation

The core of the forearm ExoNET's functionality lies in the torque generated by each elastic actuator. The torque ($\boldsymbol{\tau}$) produced by each actuator is a product of the spring element's moment arm ($\boldsymbol{\rho}(\alpha)$) and force ($\boldsymbol{F}$):

$$\boldsymbol{\tau} = \boldsymbol{\rho}(\alpha) \times \boldsymbol{F} \tag{2}$$

The moment arm ($\boldsymbol{\rho}(\alpha)$) is governed geometrically by:

$$\boldsymbol{\rho}(\alpha) = \begin{bmatrix} 0 \\ 0 \\ L_{\text{forearm}} \end{bmatrix} - h_{\text{w_mnt}} \sin(\beta) \begin{bmatrix} \cos(\theta_{\text{w_mnt}} \pm \alpha) \\ \sin(\theta_{\text{w_mnt}} \pm \alpha) \\ \lambda \end{bmatrix} \tag{3}$$

and is a function of the actuator attachment point at the wrist ($h_{\text{w_mnt}}$), the wrist mount angle around the forearm's longitudinal axis ($\theta_{\text{w_mnt}}$), the wrist rotation angle (α), the fixed inclination angle of the forearm relative to the horizontal (β), and the fractional position of the attachment along the forearm length (λ). The spring force ($\boldsymbol{F}$) was initially modeled as a linear function using Hooke's Law but was later generalized to account for nonlinear elastic properties, thus improving accuracy in torque estimation. Given the inherent nonlinearity of the helical bungee, its force-displacement behavior was characterized experimentally using a load cell (Mark-10 Corporation, USA). Bungee cord samples were incrementally stretched while recording the applied force, generating tension-stretch curves to capture the actuator's nonlinear stiffness (Fig. 3). A smooth, differentiable function was fitted to the measured data to ensure accurate representation in the computational model. For compatibility with most optimization algorithms, this function was constrained to be C^2-continuous. This empirical characterization ensured that the torque predicted by our models was validated against real-world measurements obtained during benchtop testing.

Torque deficit profiles are often highly complex, making it impractical for a single spring or ExoNET element to produce the desired torque. However, by using combinations of ExoNET elements (where n represents the total number of elastic elements in the system), we can leverage their behavior as basis functions. This approach allows us to sum the torque profiles of each element to achieve complex, user-specific torque profiles:

$$\boldsymbol{\tau}_{\text{total}} = \sum_{i=1}^{n} \boldsymbol{\tau}_i \tag{4}$$

C. Diagnostic Tool

A custom-designed diagnostic tool is critical for assessing individual supination torque deficits, enabling precise customization of the forearm ExoNET to address each user's unique needs (Fig. 4). To establish a representative baseline, supination torque profiles are collected from neurotypical participants and averaged. This baseline serves as a reference for quantifying torque deficits in stroke survivors. The resulting individualized torque deficit profiles are then used as primary inputs to the structural optimization algorithm, guiding the ExoNET's configuration.

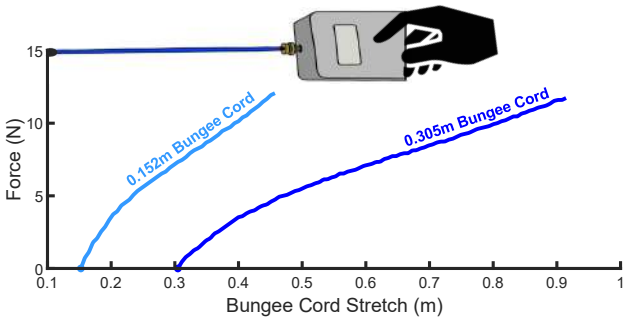

Fig. 3. Bungee cord tension-stretch relationship. (Top) Experimental setup where a load cell incrementally applies a controlled tensile force to the bungee cord. (Bottom) Experimentally derived tension-stretch curves for the same bungee cord at different resting lengths, demonstrating nonlinear elastic behavior. These data inform the computational model to ensure accurate torque predictions for ExoNET optimization.

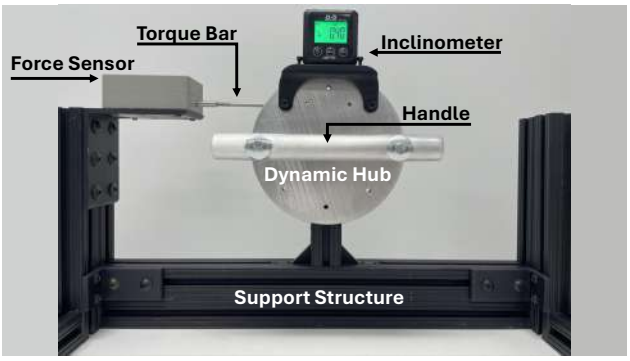

Fig. 4. Diagnostic tool user-specific supination assessment. The tool measures supination torque at discrete angles (0°, 45°, 90°, 135°, 180°) using the Dynamic Hub connected to a force sensor via the Torque Bar. When the Torque Bar is disengaged, the Dynamic Hub acts as a free-rotating disc, enabling active supination range measurement via a digital inclinometer. This data informs the forearm ExoNET optimization algorithm, tailoring torque assistance and resistance to each user's therapeutic needs.

The diagnostic device employs a Dynamic Hub connected to a force sensor via a Torque Bar to measure peak supination torque at multiple discrete angles (0°, 45°, 90°, 135°, 180°). Participants are instructed to exert their maximum supination effort at each angle, with the device recording peak torque output at each tested position. When the torque bar is disengaged from the hub, the system transitions into a free-rotating disc, allowing the measurement of the user's active supination range of motion. This dual functionality facilitates comprehensive assessments, including (1) manual muscle testing, quantifying the maximum torque the user can generate at multiple discrete angles across the full supination range, and (2) active supination range of motion, defining the functional range within which the ExoNET must operate effectively. To account for muscle synergies between pronation/supination ability and elbow flexion/extension, these tests are conducted at 0°and 90°of elbow flexion. The resulting data provides a quantifiable profile of the user's supination capacity and torque deficits through a structured, reproducible evaluation. This information serves as a foundational input for the ExoNET's optimization framework, ensuring that the device delivers targeted assistance or resistance where it is most needed.

D. Optimization Cost Function and Constraints

A multi-step constrained optimization algorithm was implemented to tailor the forearm ExoNET's design parameters for each user. The goal of this approach is to minimize the discrepancy between the user's specific torque deficit profile (desired torque) and the torque profiles generated by the ExoNET across the user's forearm range of motion (0-180°). The optimization adjusts variables such as number of actuators, actuator attachment points, spring stiffnesses, and other mechanical properties, ensuring that the ExoNET's

output precisely meets each user's therapeutic needs. The loss function (i.e., cost function) is defined as:

$$\arg\min \left(\sum_{\theta \in \Theta} \left[T_{\text{desired}}(\theta) - T_{\text{ExoNET}}(\theta, p) \right]^2 + Q \right) \quad (5)$$

where Θ denotes the discrete supination angles for torque measurements, $T_{\text{desired}}(\theta)$ is the desired torque from the user's measured torque deficit profile, and $T_{\text{ExoNET}}(\theta, p)$ is the torque generated by the forearm ExoNET at supination angle (θ) with the given parameters (p). Q is a regularization term that enforces soft constraints to ensure practical device configurations, as detailed below:

1) Number of Actuators Constraint: To encourage simpler and less cumbersome ExoNET designs, the optimization enforces a penalty term proportional to the number of actuators in the system:

$$Q_{\text{actuators}} = \lambda_{\text{actuators}} \cdot N_{\text{actuators}} \quad (6)$$

where $\lambda_{\text{actuators}}$ is a weighting factor that controls the impact of this penalty on the total cost.

2) Actuator Length Constraint: To promote safety and feasibility, actuator lengths are constrained within acceptable physical limits. If an actuator's length (L_i) exceeds its maximum allowed length ($L_{\max,i}$) or falls below its minimum allowed length ($L_{\min,i}$), a penalty is incurred:

$$Q_{\text{lengths}} = \lambda_{\text{lengths}} \sum_i \big[\max(0, L_i - L_{\max,i})^2 + \max(0, L_{\min,i} - L_i)^2 \big] \quad (7)$$

where λ_{lengths} is a weighting factor for length penalties, with squared terms imposing disproportionately higher penalties for larger violations.

3) Collision Avoidance Constraint: To prevent actuators from intersecting with the user's forearm (modeled as a frustum with elliptical ends), a penalty is applied when collisions are detected. The penalty is proportional to the degree of intersection:

$$Q_{\text{collision}} = \lambda_{\text{collision}} \cdot N_{\text{collisionPoints}} \quad (8)$$

where $N_{\text{collisionPoints}}$ is the number of points along the actuator that intersect the forearm, and $\lambda_{\text{collision}}$ controls the severity of the penalty.

The total regularization term (Q) is the sum of these individual penalties:

$$Q = Q_{\text{actuators}} + Q_{\text{lengths}} + Q_{\text{collision}} \quad (9)$$

E. Structural Optimization for Personalized Torque

The optimization process employs user-specific diagnostic data—including active supination range of motion and measured torque deficits—to define actuator configurations that minimize the loss function. This ensures the ExoNET delivers tailored assistance or resistance, enhancing user supination effectively. The model optimizes 70 design parameters used to configure the forearm ExoNET. These parameters can be broadly categorized into three groups: (1) actuator geometry, which includes attachment angles, distances, and the number of actuators; (2) spring properties, such as stiffnesses, resting lengths, and helical path characteristics; and (3) feasibility constraints, which ensure physical realism by preventing actuator collisions and enforcing practical attachment limits. Adjustments in actuator geometry modify moment arms, directly shaping the torque profile across the supination range, while spring properties influence the tension-stretch relationship and the magnitude of delivered torque. Collectively, these parameters drive the ExoNET's optimization process, ensuring the device is configured to address user-specific torque deficits. To address the complex, multimodal cost landscape, we implemented a stochastic optimization strategy, comprising two main phases.

1) Constrained Optimization with Multiple Initial Guesses: We used MATLAB's *fmincon* function within a custom loop to initiate multiple optimization runs from randomly generated initial parameter sets within defined bounds. This approach diversifies explored solutions and reduces the likelihood of the algorithm becoming trapped in local minima.

2) Simulated Annealing Refinement: After identifying the best solution from the initial runs, we applied a simulated annealing algorithm to further refine the actuator parameters. During each iteration, the parameters were perturbed, and the acceptance of the new configuration was determined by the Metropolis criterion [30] which follows a probabilistic rule for accepting worse solutions to escape local minima.

$$P_{\text{accept}} = \begin{cases} 1, & \text{if } \Delta C \leq 0 \\ \exp\left(-\frac{\Delta C}{kT}\right), & \text{if } \Delta C > 0 \end{cases} \quad (10)$$

Here, $\Delta C = C_{\text{new}} - C_{\text{current}}$ is the change in cost, k is the Boltzmann constant (set to 1 for normalization), and T is the current temperature. A random number between 0 and 1 determines acceptance based on P_{accept}, allowing occasional acceptance of worse solutions to escape local minima. The temperature (T) decreases according to a cooling schedule (e.g., exponential decay), gradually reducing the likelihood of accepting higher-cost solutions and enabling the algorithm to converge toward a global minimum.

F. Participant Characteristics and Neurotypical Baseline

The Northwestern University Institutional Review Board (Chicago, IL) approved this study (STU00218538) and served as the IRB of record. A reliance agreement was established with the University of Illinois Chicago research ethics authority (STUDY2023-1215). The study was conducted in accordance with the Declaration of Helsinki, with written informed consent obtained from all participants.

A single hemiparetic male with chronic stroke (more than 8 months), who is right-hand affected and dominant, was enrolled in the study. Baseline clinical outcome measures were collected, which included the Action Research Arm Test (ARAT, 25/57), Fugl-Meyer Upper Extremity (FMUE, 30/66), and Box and Blocks Test (BBT, unaffected hand: 35 blocks and affected hand: 20 blocks). The subject's supination capacity and torque-generating capability were assessed using the diagnostic tool, which measured active

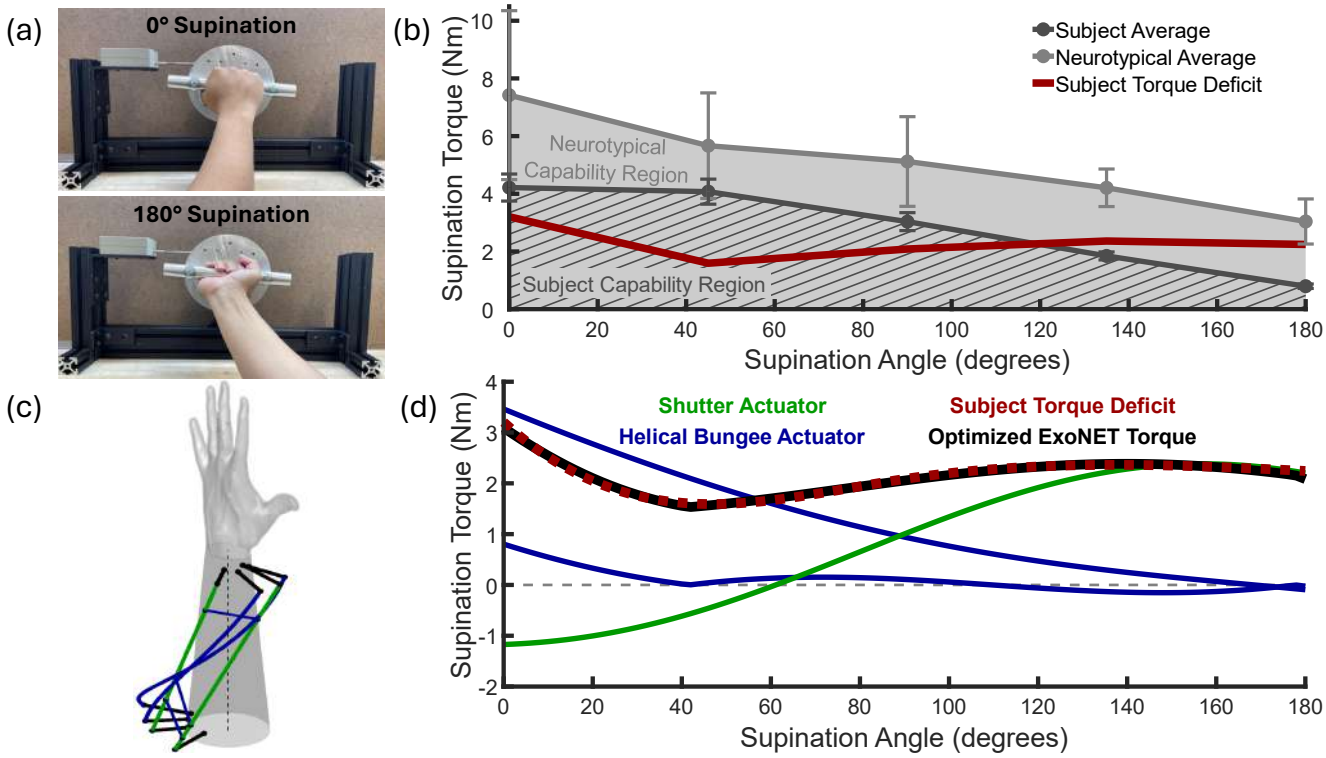

Fig. 5. Experimental results demonstrating the forearm ExoNET's personalized torque delivery. (a) Hand orientation during diagnostic testing at 0°and 180°of supination. (b) The subject's torque deficit profile (red) was correctly identified by comparing their torque ability curve (dark gray) with a neurotypical baseline (light gray). (c) Optimization results predicting actuator configurations tailored to the subject's specific torque needs. (d) Simulated torque output from the ExoNET (black), demonstrating targeted assistance in regions of limited strength and precise alignment with the subject's torque deficit profile (red), achieving a predictive accuracy of $R^2 = 0.987$ and a root mean square error (RMSE) of $0.039Nm$.

supination range of motion and maximum voluntary torque production at discrete angles across the forearm's range of motion (0°, 45°, 90°, 135°, 180°). Examples of hand orientation during testing are illustrated in Fig. 5(a).

All torque measurements were taken three times per individual, and each individual's three torque profiles were averaged to generate a single profile. At each discrete angle, both supination and pronation torque production were recorded to assess whether the subject exhibited total weakness in either motion. To establish a representative neurotypical baseline, supination torque profiles were collected from four neurotypical research team members (three female, one male), and then averaged. The subject's averaged torque profile was subsequently compared against the neurotypical baseline to quantify their torque deficit. This comparison was completed through direct subtraction of the subject's torque profile from the neurotypical average.

III. RESULTS

The subject exhibited sufficient strength in both pronation and supination, with no signs of total weakness, confirming the suitability of their data for optimization. Additionally, across three trials (n=3), the subject demonstrated an average active supination range of motion of 161°at 90°of elbow flexion and 147°at 0°of elbow flexion. The subject's supination torque measurements were compared with those of four neurotypical individuals to generate an individualized torque deficit profile. This deficit profile highlighted specific regions of weakness and asymmetry in the subject's supination torque generation, particularly around 90°of supination (Fig. 5(b)). This result directly guided the optimization of the forearm ExoNET configuration to address the subject's unique torque requirements.

The computational model successfully utilized the subject's individualized torque deficit profile to predict actuator configurations tailored to their specific needs (Fig. 5(c)). The optimization process involved 500 runs (4,595,065 function evaluations), during which an optimal solution was identified (Fig. 5(d), black). The resulting configuration combined the summed torque contributions of two helical bungee actuators (Fig. 5(d), blue) and three shutter springs connected to two shutter rods (Fig. 5(d), green), aligning with the subject's torque deficit profile to provide consistent assistance of varying magnitudes across all areas of weakness. Table I presents a representative subset of the 70 parameters optimized for the forearm ExoNET. These parameters were selected to illustrate the diversity of design variables involved in the optimization process, including actuator attachment points, stiffness values, and lengths. While these parameters contribute to defining the torque profile, no formal analysis was conducted to determine their relative influence compared to other optimized variables. As shown in Fig. 5, the ExoNET's simulated torque outputs closely aligned with the subject's torque deficit profile, achieving a predictive accuracy of $R^2 = 0.987$ and a root mean square

TABLE I
SUBSET OF OPTIMIZED PARAMETERS FOR THE FOREARM EXONET
(SUBSET OF 70 TOTAL PARAMETERS)

Parameter	Actuator Type	Value
Unstretched Length (m)	Helical Bungee	0.29, 0.22
Stiffness (N/m)	Helical Bungee	465, 352
Wrist Attachment (°)	Helical Bungee	235, 264
Forearm Attachment (°)	Helical Bungee	126, 96
Stiffness (N/m)	Shutter Spring	485, 212, 326
Spring Location Along Rod 1 (%)	Shutter Spring	15, 79, 7
Spring Location Along Rod 2 (%)	Shutter Spring	36, 82, 21
Wrist Attachment (°)	Shutter Rod	248, 198
Forearm Attachment (°)	Shutter Rod	174, 133

error (RMSE) of $0.039Nm$. This alignment ensures precise, targeted assistance to enhance functional supination while avoiding unnecessary torque in unaffected regions.

Preliminary testing was conducted to gain initial user insights into the comfort and perceived benefits of the forearm ExoNET. During this testing, the subject provided anecdotal feedback, noting that the device was comfortable and that they recognized its potential benefits. Additionally, they described an unexpected sensation of weightlessness at the elbow, suggesting a potential secondary effect of the device. This observation has prompted further investigation to determine its underlying cause and whether it may have therapeutic implications for users of the ExoNET.

IV. DISCUSSION

The results outlined in this study suggest that the diagnostic tool can effectively quantify supination deficits and that the computational model can generate user-specific actuator configurations for the forearm ExoNET in a single subject with chronic stroke. While findings from this single-subject study demonstrate the feasibility of using a structural optimization algorithm to design passive actuator configurations for targeted supination torque profiles, additional testing with a larger cohort is needed. Further validation is required to assess the diagnostic tool's reliability and evaluate the ExoNET's therapeutic impact in a clinical setting. This tailored approach demonstrates substantial promise for customizing rehabilitation strategies to address the unique needs of individual subjects, ultimately supporting improved upper-limb functionality post-stroke. To translate this technology into clinical application, the next step is to implement the optimized actuator configurations into the forearm ExoNET and test the device on a user. This will be critical for validating model predictions and refining device performance. Additionally, refining the computational model itself remains an essential step to ensure accurate optimization of actuator configurations for user-specific needs.

The computational model provides a promising initial framework for designing the forearm ExoNET, enabling a cost-effective, data-driven approach to creating personalized devices for individuals with supination torque deficits. By aligning the ExoNET's torque delivery with the user's torque deficit profile, the model aims to provide targeted support where it is most needed, integrating resistance and assistance within a single motion. These findings suggest that the forearm ExoNET has the potential to address the gap in accessible, user-specific supination-supporting devices. However, while preliminary results demonstrate feasibility in a single-subject study, further validation with a larger, more diverse cohort is necessary to determine the model's generalizability and clinical effectiveness.

While the model demonstrates strong predictive capabilities, physical validation of the forearm ExoNET remains a crucial next step. Future work will focus on constructing and testing the device based on the model's predictions to evaluate its real-world performance. Limitations in the current model will be addressed to improve its mathematical representation of the physical system. For example, incorporating contact forces and refining the helical bungee actuator's wrapping mechanics to account for variable spring/segment expansion could improve the model's accuracy and applicability. Although further validation is required, the approach used to model the helical bungee actuator in this study may offer insights for improving musculoskeletal modeling tools such as OpenSim [31], which currently rely on simplified geometric representations to approximate how muscles interact with bones and neighboring structures [32].

Similarly, modeling the shutter actuator rods as deformable beams rather than rigid components could enhance the accuracy of force and torque predictions, allowing for energy storage and transfer that facilitates supination or modifies spring torque contributions. Expanding the model to include pronation torque and additional upper-limb motions would further broaden its applicability to other impairments, such as those associated with C7 spinal cord injuries. Incorporating real-time feedback mechanisms and conducting longitudinal studies to evaluate motor learning, functional recovery, and quality of life will be essential to ensuring the device's long-term therapeutic benefits.

V. CONCLUSIONS

This study presents a novel framework for addressing supination deficits in individuals with motor impairments, leveraging user-specific diagnostic data and computational optimization to guide the design of the forearm ExoNET. The model demonstrates the ability to accurately approximate desired torque profiles, compensating for deficits and facilitating the full range of supination motion. This approach represents a shift from software-based control to hardware-encoded torque generation, emphasizing simplicity and accessibility without sacrificing functionality. While these results provide a promising foundation, future work will focus on implementing the optimized actuator configurations into the forearm ExoNET and evaluating its safety, usability, and therapeutic efficacy in clinical settings. If successful, the forearm ExoNET could significantly enhance the accessibility and effectiveness of stroke rehabilitation therapies.

ACKNOWLEDGMENT

A Novel Template-Matching Method for Extracting Gait Cycles from Underfoot Pressure Data

Grange M. Simpson, Kylee North, Sonny T. Jones, Ashley N. Dalrymple

***Abstract*— The isolation of gait cycles from underfoot pressure data is a critical step in human movement analysis, yet existing methods require either expensive equipment or substantial manual effort. We present a generalizable, low-resource algorithm for parsing gait cycles from wearable underfoot pressure sensor data across multiple walking terrains. Compared to a ground-truth dataset manually marked and verified by an expert, our algorithm achieved similar accuracy with significantly reduced processing time. For a dataset of 577 steps, our algorithm parsed gait cycles in 41 seconds with only one false negative, whereas three naïve manual parsers required an average of 29 minutes, with total errors ranging from 6 to 33 gait cycles. The algorithm also outperformed threshold-based parsing, which produced 49–362 false positives, depending on the threshold value. By improving computational efficiency with accuracy, this method enables scalable gait cycle detection in real-world applications, expanding the feasibility of automated gait analysis beyond controlled laboratory environments.**

***Index Terms*— Gait Analysis, Walking, Underfoot Pressure, Ground Reaction Force, Rehabilitation**

I. Introduction

Advances in gait analysis and rehabilitation technology, such as wireless sensors, motion capture, exoskeletons, and gait assistance devices, have created a growing demand for efficient, high-quality data analysis methods. A critical component of gait analysis is isolating complete individual gait cycles. Historically, gait analysis has relied on motion capture systems in controlled laboratory settings, but the field is rapidly shifting toward wearable sensors that enable data collection in real-world environments [1]–[3]. This shift presents new challenges, particularly the need for generalizable data reduction and analysis techniques to parse individual gait cycles effectively. The ability to automatically parse gait cycles is particularly challenging when gait data are collected in variable walking environments or with populations that have motor impairments [4].

Gait data from wearable underfoot pressure sensors exhibit substantial variability due to changing walking speeds, terrains, and patient footwear in both healthy individuals and those with motor deficits from musculoskeletal or neurological conditions [5], [6]. These factors complicate the development of standardized analysis pipelines to identify key events, such as the transition from swing to stance phase (i.e., heel strike, marked by the onset of loading), which is critical for parsing gait cycles. Existing pipelines to parse gait cycles, including manual labeling, thresholding, and neural networks [7]–[9], are resource-intensive and have notable limitations. Access to gait experts who can dedicate the time necessary to manually mark large datasets is often limited, leaving the task to naïve parsers. Manual labeling is prone to human bias, time-consuming, and difficult to generalize across datasets and applications [10]. Thresholding entails setting a minimum value to indicate the onset of limb loading [9]. It is prone to false positives with variable pressure, shuffling, or bumping of the foot, requiring the use of catch statements to exclude missteps. Neural networks require large pre-labeled training datasets, extensive computational power, and expertise in machine learning [7]. Previous work has applied a template-based approach to angular velocity signals, but the template was made for waveforms across the entire gait cycle, limiting its generalizability [4].

This work introduces a novel template-matching framework forefficient, generalizable, low-resource gait cycle parsing. A semi-automated approach allows users to mark the onset of limb loading in a subset of data via an intuitive graphical user interface (GUI). After the parser marks the onset of loading, a shape template is generated, capturing the characteristic pressure pattern at the transition from the swing to stance phase. This allows the algorithm to identify similar events across the dataset. This template-matching method was compared to standard methods of parsing gait cycles, including manual labeling by experts and naïve researchers, and thresholding. By overcoming the limitations of existing gait cycle parsing methods, this template-matching framework offers a simple yet scalable and transferable solution for isolating gait cycles, which supports the growing needs of locomotor and rehabilitation research and real-world gait applications.

II. Methods

A. Participants and Data Acquisition

Four male participants with no known neuromuscular deficits were recruited for this study after providing written informed consent following the University of Utah Institutional Review Board (IRB00171076). Participants were 31, 19, 27, and 25 years of age (mean weight = 182.25 ± 17.90 lbs).

A wireless pressure insole containing 235 embedded pressure sensors (XSensor High-Resolution Intelligent Insoles Pro, Calgary, AB, Canada) was placed in each shoe and

We thank the Departments of Biomedical Engineering and Physical Medicine and Rehabilitation for funding this study. We also thank our participants for volunteering their time.

G. M. Simpson (corresponding author e-mail grange.simpson @utah.edu), K. North, S.T. Jones are with the Department of Biomedical Engineering, University of Utah, Salt Lake City, UT, USA. A.N. Dalrymple (corresponding email ashley.dalrymple@utah.edu) is with the Departments of Biomedical Engineering and Physical Medicine and Rehabilitation, University of Utah, Salt Lake City, UT, USA.

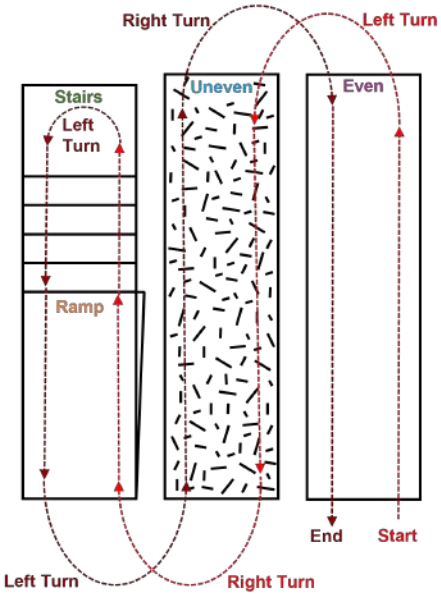

Fig. 1. Walking track containing different types of terrains (7.3m long).

sampled at 33 Hz. A custom GUI built in Python (version 3.8.1, Python Software Foundation, Wilmington, DE) and ran on a desktop computer with an Intel Core i7 CPU and 32 GB of RAM. The GUI controlled the hardware and data collection and data were saved for subsequent offline analysis.

B. Data Collection Experimental Protocol

To evaluate our framework on a dataset reflecting the complexity of real-world walking, participants navigated a mixed-terrain track at a self-selected pace. The mixed-terrain track consisted of even ground, uneven ground, up and down ramps, upstairs, downstairs, and left and right turns (Fig. 1). Each participant completed seven trials: four mixed-terrain trials traversing all types of terrain arranged in the track and three terrain-specific trials on stairs, ramps, and uneven ground to increase the number of steps for each of these terrains. Transitions between types of terrain were manually marked. A mixed-terrain dataset was constructed from all participant data. Manually marked terrain transitions were used to generate five datasets per participant: two datasets combining even ground, turns, and uneven ground; one combining even and uneven ground; one combining even ground and stairs; and one combining even ground and ramps. Of the 20 datasets (five datasets from each of the four participants), two were excluded from analysis due to technical issues, leaving 18 datasets for testing the manual and automatic parsing methods. Pressure values from each insole were normalized to the participant's weight and the area of the individual sensor cell.

C. Establishing the Ground Truth of Gait Cycle Parsing

Underfoot pressure data were upsampled by a factor of 60 from 33 Hz to 1980 Hz to increase the resolution for selecting the onset of limb loading and smoothed using a Savitzky-Golay filter (3rd order, window size = 93, derivative order = 1, rate = 1). This onset of limb loading is an inflection point in the pressure data and defined as the lowest point before a sharp positive increase in slope due to initial ground contact at the transition from swing to stance phase. Pressure profiles from each dataset were visualized for manual marking of the inflection points using a custom GUI (Python, PyQT5 library). At typical walking speeds, each gait cycle is approximately 60% stance phase and 40% swing phase [11]–[13]. The stance phase is characterized by a single or double peak, whereas during swing phase, the underfoot pressure is zero. Gait cycles with noisy or incomplete steps from shuffling, sharp turns, or tripping were excluded if they visually lacked: distinct single or double peaks, a roughly 60/40 stance-to-swing ratios, and/or near-zero pressure values during swing. All 18 datasets were manually marked, based on the above rules, by an individual with 3+ years of experience with underfoot pressure data. The experienced individual's work was validated by a gait researcher with over 6 years of experience analyzing underfoot pressure data. These cross-checked inflection points served as the ground truth for gait cycle parsing. The total number of complete gait cycles was 577.

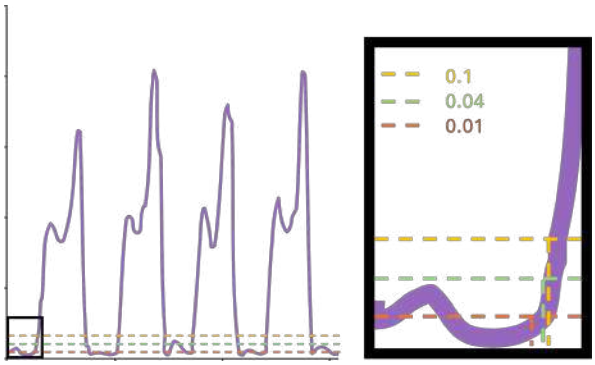

Fig. 2. Three different thresholds were applied to remove low-level noise between gait cycles. Higher thresholds removed more noise but also truncated the signal, affecting the accuracy of loading onset detection.

D. Naïve Manual Gait Cycle Parsing

To simulate naïve junior researchers manually parsing gait data, three independent researchers with no prior experience in gait analysis were recruited. Each naïve parser received instructions for using the GUI, the three criteria defining a complete gait cycle, and a reference of marked inflection points on a set of 10 gait cycles. Each researcher independently marked the same 18 datasets using the GUI. All marked points were saved in a Python dictionary and categorized by dataset for later analysis.

E. Thresholding Algorithm

Thresholding is a widely used automated method for identifying inflection points in gait data [4]. Thresholds are typically set as a multiple of the standard deviation of the background (noise) signal, or manually selected by leveraging knowledge of the particular data, making this method subjective. Thresholding often results in false positives and

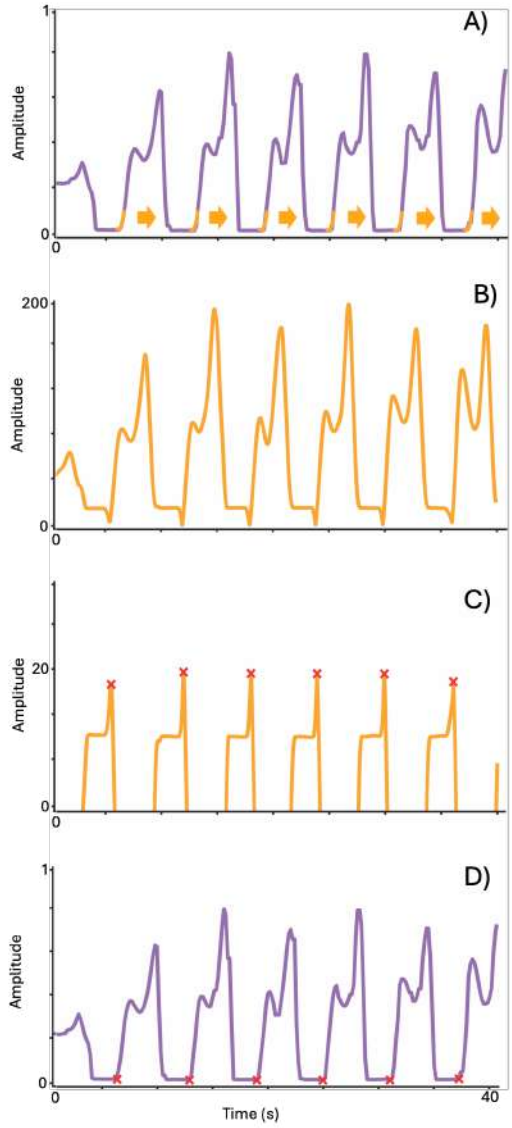

Fig. 3. Template matching algorithm flow chart. A) Iterating the template across the underfoot pressure signal to obtain the sum of the absolute difference between the raw signals and the template. B) The result of the sum of the absolute difference between the raw signals and the template. The sharp troughs indicate the point where the template best overlaps with the raw signal at the inflection point. C) Reflected signal from B about the horizontal axis, isolating the region near the peak overlap between the raw signal and the template, for each step. The peak represents the timepoint of maximum overlap (i.e., the inflection point) and is marked by a red X. D) Found inflection points mapped back onto the underfoot pressure signal, indicated by a red X.

inaccurate marking of the time of loading onset. To evaluate these limitations on parsing gait cycles, three different thresholds were tested. As gait data were normalized between 0 and 1, a low threshold of 0.01, a medium threshold of 0.04, and a high threshold of 0.1 [4] were used (Fig. 2). For each of the three thresholds, underfoot pressure values below the thresholds were set to zero, and time points where transitions from 0 to a value greater than zero were marked as inflection points. No additional programming statements were added to remove false positives or adjust positioning of the marked inflection points.

F. Template-Matching Algorithm

A total of 577 manually marked inflection points from ground truth parsing were grouped into their respective datasets (18 total). For each marked inflection point, a 200-point array was created by extracting 100 points before (including the inflection point) and 100 points after from the underfoot pressure data. These 200-point arrays were averaged within each dataset to generate a template representing the inflection point for that dataset. The final template was created by taking the average of all template arrays across all 18 datasets. The template was matched to the underfoot pressure signal by iterating the 200-point window across the signal (Fig. 3A). At each window position, the similarity between the template and the signal was quantified using the sum of absolute differences (Equation 1), producing a waveform of these differences (Fig. 3B).

$$\sum |(\textit{200 points underfoot pressure}) - \textit{template}| \quad (1)$$

Regions where the template best matched the signal appeared as pronounced troughs in the difference waveform, corresponding to the points of minimum difference (Fig. 3B). To identify these troughs, the difference signal was inverted and shifted upward by 10% of its maximum value (Fig. 3C). This transformation ensured that regions far from an inflection point remained below zero. As the transformed signal rose above zero, values were stored in a buffer until it returned below zero. The index of the maximum value within each buffer was identified as the location of the template match. Identified maxima were then mapped back onto the underfoot pressure signal to mark the inflection points (Fig. 3D). Access the full open-source pipeline on GitHub [14].

G. Template-Matching Algorithm Using Subsets of the Ground Truth Inflection Points

Given the impracticality of manually parsing all inflection points, we investigated whether fewer inflection points could still yield reliable template-based parsing. Templates using 50% (282) and 25% (112) of the total ground truth inflection points were created. A 10-fold validation was performed by randomly selecting a subset of inflections points from the full dataset, building a template from these subsets, and evaluating that template's performance relative to the 100% template for each of the 10 iterations.

H. Comparing Performance of the Template-Matching Algorithm, Thresholding, and Naïve Manual Parsers

The performance of the template-matching algorithm, thresholding, and naïve researcher manual parsing were evaluated by calculating their proximity of the marked inflection points to the ground truth, as well as the number of false positives and negatives in relation to the ground truth. Comparing the location of the inflection points relative to the expert gait data (ground truth) allows for the assessment of error related to the loss of loading data at the onset and the subsequent addition of that loading data to the end of the following step. A closest-pair algorithm was used to calculate the proximity of each method's inflection points to the ground truth. The closest-pair algorithm iterated through all ground

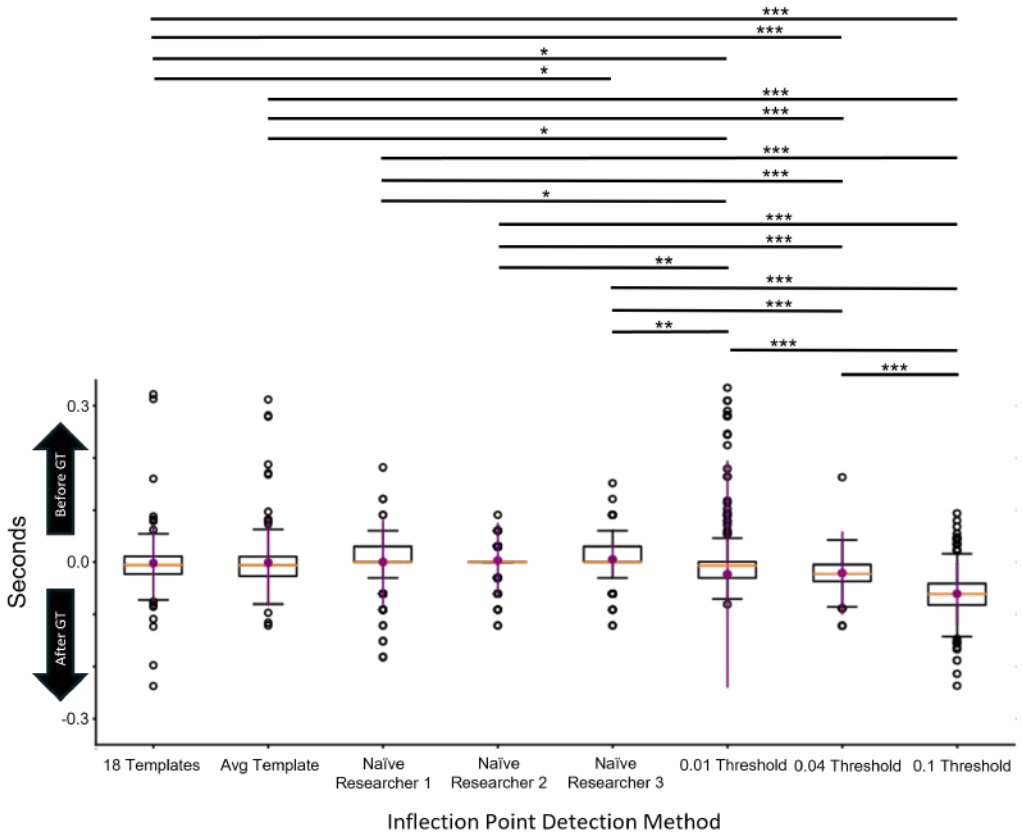

Fig. 4. Box and whisker plots of differences in inflection point location relative to the ground truth for all non-ground truth methods. Zero on the y-axis represents a perfect match with the location of the ground-truth dataset. A positive value indicates the detected inflection point occurred before the point in the ground truth. A negative value indicates the detected inflection point was after the point in the ground truth. The orange line represents the median, the box represents the first and third quartiles, and the whiskers represent the maximum and minimum for each. *p $<$ 0.05; **p $<$ 0.01; ***p $<$ 0.001.

truth inflections points, identifying the non-ground inflection point from either the template, thresholding, or naïve parsers. For each closest-pair value, the index difference between the ground truth and non-ground truth inflection point was determined. The closest-pair algorithm was also used to determine the number of false positives and false negatives of the non-ground truth methods. For example, if the naïve researcher identified 17 inflection points, and the ground truth parser identified 19, the closest pairs algorithm matched 17 points, indicating two false negatives. False positives were calculated as the total number of additional steps from the ground truth.

I. Performance of a Mean Template Built from 18 Different Templates

Building a separate template for each of the 18 datasets is not the most efficient way to parse the data. A more efficient method is to build a template that can capture the inflection points from all 18 datasets that have different cadences, step lengths, and types of terrains. To assess the performance of this mean template, all 577 inflection points were used to construct 577 templates which were then averaged to create one mean template. This mean template was then iterated across all 18 datasets identical to the methods described in section G.

J. Statistical Analysis

Normality was assessed using the Anderson-Darling test (Python's *anderson* function from the scipy.stats library). The data were nonparametric; therefore, a Kruskal-Wallis multi-group test was performed using the scipy.stats library's *kruskal* function to compare the time difference in the detection of the inflection point between all detection methods. Multiple comparisons with a Bonferroni correction were performed using Python's statsmodels.stats. *multicomp* function. The performance of the 50% and 25% templates were compared to the 100% template. For each iteration of the 10-fold validation, the Kruskal-Wallis test was performed to compare the difference in inflection point location from the ground truth for all templates. For all comparisons, a significance level less than or equal to 0.05 was considered significant.

III. Results

A. Number of Marked Inflection Points Compared to Ground Truth

Table I summarizes the total number of marked inflection points, false positives, false negatives, and the mean and standard deviation of the time between the marked inflection points and the ground truth.

TABLE I

PERFORMANCE STATISTICS FOR EACH NON-GROUND TRUTH DATASET IN RELATION TO THE GROUND TRUTH

	Marked Inflection Points #	False Positives	False Negatives	Mean Inflection Point Difference from Ground Truth (ms)	Std Inflection Point Difference from Ground Truth (ms)
18 Templates	606	28	1	-1.8	75
10x Random 50% Template	606	28	1	-1.8	73.6
10x Random 25% Template	606	28	1	0.4	76.2
Average Template	605	27	1	-1	81.2
Threshold = 0.01	939	362	0	-23	217.8
Threshold = 0.04	633	56	0	-20.8	80
Threshold = 0.1	626	49	0	-60.6	59.1
Naïve Researcher 1	544	0	33	0.4	81.3
Naïve Researcher 2	560	0	17	3.3	72
Naïve Researcher 3	571	0	6	5.3	34.5

B. Time of Marked Inflection Points Compared to Ground Truth

All methods differed significantly from the higher threshold ($p < 0.001$). The lower and medium thresholds were each different from all other methods ($p < 0.030$), except each other. Additionally, the template made of the 18 individual datasets differed from the naïve researcher 3 ($p = 0.040$). See Fig. 4. The naïve researchers marked inflection points approximately 5 ms or less before the actual onset from the ground truth (Fig. 4; Table I). For the thresholding method, all thresholds resulted in delayed detection of the inflection point, with the highest threshold resulting the largest delay (60.6 ms). The template-matching method detected the inflection point with a delay of less than 2 ms from the ground truth, accounting for less than 0.2% of a typical gait cycle duration (which is typically 1 second) [11]–[13]. The template-matching algorithm required on average 41 seconds to analyze all 18 datasets, the thresholding method required on average 22 seconds, and the manual parsers required 29 ± 2 minutes.

C. Performance of the Template-Matching Algorithm Built Using Subsets of Steps

Templates were built using a subset of steps: 50% and 25% of the total dataset containing 577 steps. The subsets of steps used for the reduced templates were randomly extracted from the full dataset 10 different times. For each 10-fold validation, the time difference of the detected inflection point between the reduced templates and the template from the full data set were compared.

The time differences ranged from -2.3 ms to 0.59 ms and -10.7 to 7.7 ms for the 50% and 25% templates, respectively. The p-values from the Kruskal-Wallis test ranged from 0.12 to 0.96, meaning that the difference in the detected time of the inflection points for the 50% template was not statistically different from the full template. However, the p-values for the 25% template ranged from 0.012 to 0.46, meaning that the time differences were sometimes statistically different.

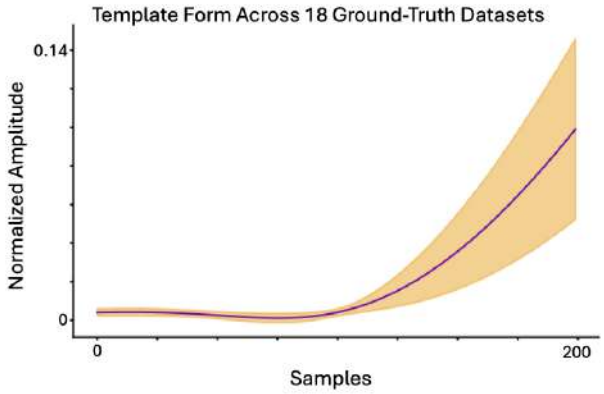

Fig. 5. Mean (± standard deviation) template shape of all templates across the 18 datasets.

IV. DISCUSSION

This work presents a novel template-matching framework that provides a low-resource, efficient, and accurate solution for gait cycle parsing across multiple terrains. Our approach is more efficient than manual parsing and more accurate than thresholding techniques, making it a practical tool for parsing large-scale gait datasets. By testing the algorithm on varying walking terrains, we demonstrated its potential for real-world applications, where traditional gait parsing methods struggle. This novel template-matching approach overcomes key limitations of existing methods and offers a transferable and accessible solution for parsing gait data in both controlled and uncontrolled settings.

Thresholding identifies the onset of loading when pressure surpasses a predefined minimum value. While computationally efficient, thresholding techniques inherently involve a trade-off between false positives and timing accuracy. This was evident in our study, as shown in Table I and Fig. 2. A lower threshold (0.01, or 1% of full scale) detected loading onset more accurately than higher thresholds (-23 ms mean difference from ground truth) but resulted in 362 false positives. In contrast, a higher threshold (0.1, or 10% of full scale) reduced false positives to 49 but introduced greater timing errors, delaying loading onset detection by -60.6 ms. This trade-off demonstrates that while increasing the threshold reduces false positives, it also shifts the detected inflection point later in the gait cycle, leading to loss of early loading pressure information. However, even at the lowest threshold, the timing of the onset of loading was significantly different compared to the template matching algorithm (Fig. 4). To mitigate false positives, researchers often implement dataset-specific catch statements to exclude misclassified steps. However, these custom rules limit generalizability across datasets which include shuffling, foot bumps, or other transient pressure fluctuations as steps. In contrast, the template-matching algorithm automatically differentiated true gait cycles from transient fluctuations, reducing false positives without custom rules.

In contrast to thresholding, which is prone to false positives, manual parsing effectively eliminates this issue but is more susceptible to false negatives. In our study, all three

naïve manual parsers exhibited fewer total errors (6–33) compared to thresholding (49–362 false positives; Table I, highlighting the relative accuracy of human annotation. The template-matching algorithm performed similarly to the naïve manual parsers, with total errors ranging from 27 to 28. Additionally, the timing of the marked inflection point, as measured by the mean difference from the ground truth in milliseconds, was statistically different between only 1 of the 3 naïve parsers when compared to the 18 template-matching algorithm and showed no statistical difference when compared to the average template algorithm (see Fig. 4). The inconsistencies among the naïve researchers highlight the limitations associated with human non-experts, which is problematic with these large-scale datasets.

The template-matching algorithm retains the strengths of manual parsing while maintaining speed (29 minutes for manual parsing compared to 41 seconds for the template-matching algorithm). With the template-matching approach, a user selects a subset of data to generate a template, which is then used to automatically identify the onset of gait cycles. This method also benefits from the low-resource nature of thresholding techniques but with improved accuracy. Additional fine-tuning of the template matching algorithm is possible using a shift parameter that enables adjustment of the height of the inverted sum absolute value signal (Fig. 3).

A limitation of the template-matching approach is the reliance on a high-quality and consistent dataset. Parsing the 577 steps with an average template constructed from all18 datasets was not significantly different in performance compared to the template made from the average of the 18 templates specific to each dataset. This demonstrates the feasibility of a generalizable template for parsing multiple datasets. There are key are some key considerations to keep in mind before using building a generalizable template. Fig. 5 displays the mean and standard deviation from the 18 different templates. There is little variability in the template values before the inflection point, and large variability in the template slope after the inflection point. Care should be taken during template construction to capture the variability in slope data after the inflection point. Cross validation, as performed here, helps to avoid biases from data sampling when constructing the template.

To further refine the template-matching algorithm, future work will involve performance testing on a larger and more diverse population, including variability in age and sex, and test its generalizability on data collected from people with gait impairments. We plan to investigate the feasibility of using the template matching algorithm for other applications and signals, specifically live or real-time parsing of data, angular velocity, reflex responses, or electrocardiography.

V. Conclusion

With this novel template-matching algorithm, large volumes of gait data can be efficiently and accurately parsed to meet the demand of modern gait analysis and rehabilitation technology development. This method successfully detected individual gait cycles from underfoot pressure data collected from participants walking across varying types of terrain. This will enable researchers to expand their gait analysis capabilities to a larger scale and beyond highly controlled laboratory settings to more variable real-world settings.

Robotic Assessment of Cognitive and Motor Impairment in Adults with Sickle Cell Disease

Joana Opong-Duah[1], Arushi Mittal[2], Erica Waters[3], Farzana Sayani[4], Suzanne Sall[5], Frances Shofer[6], Michelle J. Johnson[7]

***Abstract*— For decades, Sickle Cell Disease (SCD) research has explored the influence of the disease in many domains of functioning throughout childhood. As medical advancements have increased the lifespan of those living with SCD, it is crucial to also evaluate the effects of the disease in adulthood. This paper investigates the relationship between cognition and physical abilities in adults with and without Sickle Cell Disease. We present a preliminary analysis identifying the influence of one domain over the other, focusing on the way cognitive impairment may worsen motor function. To determine this, we employ the Haptic TheraDrive one-degree-of-freedom robot as an objective measure to assess performance, and we compare the results to a battery of clinical assessments. SCD participants were frequency matched to healthy controls to investigate the cognitive and motor functions affected by SCD. There were not many significant differences between groups across cognitive and motor domains, partly due to a small sample size. We did identify significant impairments in elements of working memory. We also found that motor performance could have been impacted by SCD-related pain and stiffness affecting robotic score.**

I. Introduction

Sickle Cell Disease (SCD) is considered one of the most prevalent monogenic disorders in the world. In the United States (US) alone, there are about 100,000 individuals living with SCD [1]. A critical protein in our red blood cells responsible for oxygen transport to our tissues is hemoglobin. Beta Hemoglobin or β-globin, a subunit of that protein, is where the mutation causing SCD occurs. In the β-globin, there is a substitution in the base nucleotides; this mutation causes a replacement of the amino acids, switching from glutamic acid to valine, thus producing HbS or sickle hemoglobin. This change in amino acids causes polymerization, which forms fibers that reshape the red blood cells. These fibers "sickle" the red blood cells, giving them the 'C' shape commonly associated with this disease, thus the name Sickle Cell [1,2]. SCD is a hereditary condition and can manifest in various subtypes, including the three most common: Sickle Cell Anemia (HbSS), Sickle Cell-Hemoglobin C (HbSC), and S-Beta Thalassemia ($HbS\beta^{+}$-Thalassemia/ $HbS\beta^{0}$-Thalassemia). Some people are carriers of the trait but do not suffer from complications of SCD itself, Sickle Cell Carrier (HbAS) [3]. HbSS occurs when both parents pass along the sickle gene to their child, as it is the homozygous inheritance of the gene mutation. This subtype represents the most severe cases of SCD and is the most prevalent, accounting for 70-75% of SCD cases globally [4]. In the US and the UK, HbSC accounts for about 30% of SCD cases and is the second most common disease variation [5].

Some studies have found past evidence of neurocognitive and motor impairments across the lifespan of the SCD population when compared to controls. Structural changes to the red blood cells can lead to many physical issues. These changes often cause repeated vessel occlusion, leading to a variety of impairments, including painful episodes and chronic anemia, which lead to organ and tissue damage, delayed growth, a compromised immune system, and, in many cases, stroke or infarction [6,7]. Approximately 11% of SCD patients have clinically apparent strokes before the age of 20; by the time they reach 45 years old, this number jumps to 24% [8]. These strokes have been thought to account for some impairments identified in domains of executive functioning, such as processing speed, visuospatial function, and attention, which in the past, has been measured by the Wechsler Adult Intelligence Scale-Third Edition (WAIS-III), symbol digit coding, and the Montreal Cognitive Assessment (MoCA) [1][9]. Physical assessments used in past literature have included the 6-minute walk test and Grip Strength, observing significantly lower performance in SCD participants than controls.

Due to a lack of research and understanding, SCD had once been considered a black pediatric disease, with many patients dying in childhood from disease complications [10]. Given the commonality of stroke in childhood, there was and still is a significant emphasis on providing consistent and extensive care for children living with SCD. However, this initiative has failed to follow patients once they age out of

pediatric care at 18, leaving a significant gap in the literature that explores the effects of SCD in adulthood. The lack of research about the effects of SCD on daily function and quality of life in adults also means there is little to no research on the possibility and usefulness of rehabilitation in this age group. As medicine has advanced and the lifespan expectancy of SCD patients has increased, there is a significant need for continued diagnostic and rehabilitation efforts in this population.

Assistive technologies have been used to objectively measure cognitive and motor impairment in adults with stroke and other brain injuries. The Haptic TheraDrive, a one-degree-of-freedom robot, was initially created to provide affordable therapy and assess upper arm function in stroke survivors. It can also be used to provide an affordable and objective measure of impairment in various populations. This robotic system utilizes multiple computerized assessments to identify impairments. This study explores the role of the Haptic Theradrive as an objective and accurate assessment tool for the cognitive and motor impairments of SCD in adults. Our efforts are aimed at identifying the cognitive and motor impairments associated with SCD and adding to the literature. This paper is also focused on understanding the relationship between clinical assessments and robotic tasks and identifying whether increasing the cognitive aspect of robotic tasks interferes with SCD participants' motor performance. To consider both objectives, we have matched SCD patients to healthy controls and compared their results across both clinical and robotic assessments.

II. Methods

A. Study Design/ Setting

This study was implemented at the Rehabilitation Robotics Lab located in Philadelphia, PA, at the Penn Medicine-Rittenhouse Rehabilitation and Acute-Care Facility. All SCD participants were recruited from the Penn Medicine Comprehensive SCD Program, while all healthy controls were recruited from the Penn Medicine iConnect database and the community. After determining eligibility, participants were invited to the lab and consented. The University of Pennsylvania Institutional Review Board (IRB) approved this study (#854019). After giving consent, participants performed a battery of four cognitive, four motor, and two robotic assessments. Assessments were split into two sections: the clinical and the robotic portion. These could all be performed in one day, or participants could choose to split the sections over two days, within 7 days of each other.

B. Participants

Inclusion criteria for this study detailed that all adults over the age of 18 with or without SCD, any race, gender, and education level were welcomed. Due to chronic pain commonly associated with this disease, participants were not excluded based on pain levels. Instead, pain for all participants was recorded before and throughout the trials. Exclusionary criteria for all subjects prevented adults with a history of stroke or silent infarct from participating. SCD participants were excluded from the study if they had experienced a vaso-occlusive pain crisis within the 7 days leading up to pre-screening or if they were experiencing a vaso-occlusive pain crisis at the time of the pre-screening as well. Other exclusionary criteria for both groups included a Montreal Cognitive Assessment (MoCA) score of less than 18, drug and/or alcohol abuse, or a depression score greater than nine as measured by the Patient Health Questionnaire-9 (PHQ-9).

A total of 19 adults were recruited and completed the study protocol. Ten participants were living with SCD, and 9 were healthy controls. Of the 19, one person was excluded due to an inability to focus on completing the tasks asked of them during the study protocol. Their matched pair was removed from this data set for the purpose of having paired data included in this paper. Another participant's clinical data was eligible to remain in the study but, due to extreme shoulder pain in one arm, was unable to complete the robot assessments in a standardized way. In this case, their data and the matched control's data were also removed from this paper for one arm. The last participant had not yet been placed into a matched pair, so their data was also removed. Table I outlines the demographics of the final groups discussed in this paper. Of the 16 participants, 12 were female, 14 were Black, and 15 had over a high school education. In this study, pairs were made based on age, gender, and education level. We had aimed for a total of 10 pairs and were able to present the data of eight matched pairs (Table I).

D. Assessments

Participants were contacted to complete the pre-screen forms with a study Research Assistant, which included the PHQ-9 and two of the Patient-Reported Outcomes Measurement Information System (PROMIS) Pain Intensity/ Pain Interference short forms. The PHQ-9 was used as a measurement of depression in this study population. This assessment is commonly used across many populations as a valid measure of depression, with nine questions that are based on the Diagnostic and Statistical Manual of Mental Disorders- Fourth Edition (DSM-IV) criteria [11]. The PROMIS Pain Interference and Pain Intensity Scales were used to assess pain details within the seven days before recruitment. These valid measures have previously been used in the adult SCD population alongside the Adult Sickle Cell Quality of Life Measurement Information System (ASCQ-Me) [12][13]. Due to consistent pain associated with

SCD, we monitored pain levels throughout the study. During the clinical and robotic trials, every participant was asked to rate any pain using the Visual Analog Scale (VAS). During the robot session, we also recorded the level of effort to complete the assessments using the BORG Rating of Perceived Exertion Scale (Table III).

Cognitive assessments included the MoCA, Color Trails I & II (CT), Hopkins Verbal Learning (HPVL), and Digit Symbol Coding (DS). The MoCA test was used to assess multiple domains of functioning, including visuospatial/executive function, naming, memory, attention, language, abstraction, delayed recall, and orientation. Scoring less than 18 out of 30 indicates moderate to severe cognitive impairment, while a score of 26 and above is indicative of normal functioning [14]. Color Trails I & II are a set of assessments used to test for visuospatial functioning, attention, motor speed, and mental flexibility. For these tests, a higher score indicates poorer performance [15]. Hopkins Verbal Learning is an assessment focused on immediate recall, delayed recall, recognition index, and retention, which means that the more words a participant can remember, the better their score [16]. Digit Symbol Coding is used primarily to test for processing speed alongside attention. The more symbols a participant can quickly and accurately match to its specified number, the higher their score and the better their performance [17].

Motor assessments for this study included Box & Blocks (BB), Grip Strength (GS), Grooved Pegboard (GP), and the 10m Walk. The box & blocks assessment is used primarily to determine the level of gross motor skills in participants; higher scores signify better gross motor function [18]. In the grooved pegboard assessment, participants were asked to complete this task as quickly as possible to assess fine motor skills and executive functioning. A lower time could demonstrate normal functioning in both domains, as defined in the literature [19]. The Grip strength test assesses upper body strength and has been used in past research as a measure of impaired development [20]. As for the 10m Walk, this test was used to determine lower limb ability across participants. A shorter time on this assessment demonstrates better lower limb usability [21].

All participants were placed in standardized seating next to the robotic arm (Fig. 1), where they then completed two computerized games using the Haptic TheraDrive robot [22]. The Trajectory Tracking (TT) motor task is mainly used to assess upper limb performance. However, it also holds a cognitive element as participants are expected to learn the assessment and improve accuracy as they complete all 15 trials. This assessment required participants to push and pull the Haptic Theradrive robot arm forward and backward, controlling a small cursor on the screen that moves left and right in correspondence. Participants saw a semi-opaque box on the screen that followed a vertical sinusoidal path. To score well in this task, one must stay within the moving box, controlling the cursor to remain as accurate as possible. Participants completed a total of 15 trials that were about 15 seconds each, not including the 1-3 practice trials every participant completed (Fig. 2- left).

For the Spatial Span (SS) Motor-cognitive task, participants were shown a 3x3 grid of squares (Fig. 2 right). They were asked to move the robotic arm back at the start of each of the 18 trials. Once they have moved into position, a pattern of squares on the screen will flash in green. When the green stops, they were to use the robotic arm to repeat the pattern exactly as they witnessed it, in order. If they matched the pattern correctly, the next trial would be one square longer; if they were incorrect, it would be one tile shorter. All participants started with a pattern of two squares and tried to work their way up to the maximum of seven squares in a trial. Participants were asked to complete 18 trials in total.

One assessment was completed only by the SCD participants, which was the ASCQ-Me. This test is specifically used to assess SCD's physical, emotional, and social impact on daily living. For this study, the survey was used to understand how SCD patients feel and function in their day-to-day lives. This questionnaire was created by the American Institutes for Research (AIR) and the National Heart, Lung, and Blood Institute (NHLBI) and can be compared to the generalized results of the PROMIS scales as a more SCD-focused survey [11][23].

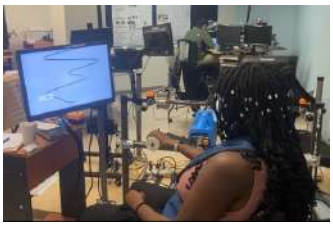

Figure 1. *Participant's position with the Haptic TheraDrive Arm*

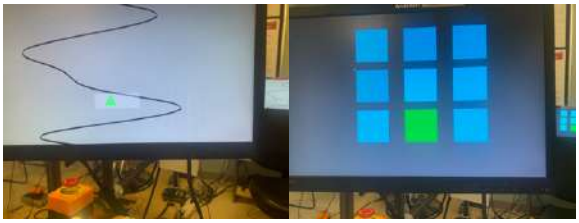

Figure 2. Robotic Assessments *(Left-TT, Right-SS)*

E. Statistical Methods

For the Trajectory Tracking task, we calculated four metrics: Root Mean Square Error (RMSE), Normalized Distance Traversed (ND), Mean Absolute Velocity (MAV), and Spectral Arc Length (SPARC) (Fig.5) for both groups. RMSE was defined as the root mean square error between the angular trajectory that the participant travels and the desired trajectory. A higher RMSE indicates greater error and worse performance. ND is defined as the total angular distance traveled by the participant divided by the distance required to travel the desired trajectory. An ND value close to 1 indicates that the participant moved as much as the task required. An ND value of less than 1 indicates that the participant did not move enough, and a value greater than 1

indicates that the participant moved more than the desired trajectory. MAV was calculated by finding the mean of the absolute value of angular velocity. A higher MAV indicates faster movements. Finally, we calculate smoothness using SPARC [24]. A more negative SPARC value indicates a less smooth movement. For the spatial span task, we calculate a task-specific metric, mean sequence length, and two kinematic metrics, MAV and SPARC. Mean Sequence Length is defined as the mean length of the displayed sequence across all trials. MAV and SPARC are defined for Spatial Span the same as for Trajectory Tracking. For the Spatial Span task, the mean sequence length is the primary metric reported (Fig.6).

To analyze and visualize the robotic assessment data, Python scripts were developed to process the raw data and generate meaningful charts. The graph in Fig. 3 was created to compare the position of the robot handle over time in TT, highlighting the differences between the actual and desired movement paths. All graphs were presented as participant pairs through the example of Participant 5 and Participant 13. To generate these plots, the time points for each trial were averaged across all trials for each participant, creating one averaged trial that was then compared to the desired path. The processed data was then visualized using Matplotlib, enabling a clear representation of movement performance. For the SS task, the data was processed to plot the sequence length distribution as a histogram, which displayed the frequency of different sequence lengths completed during the task (Fig. 4). This figure's analysis and visualization aided in the interpretation of performance patterns across the participant pairs.

In Table II, we were also able to run a Wilcoxon Signed-Rank Test to properly compare the SCD and Controls' Z-Scores on the Hopkins Verbal Learning assessment, Box & Blocks, Grooved Pegboard, and Grip Strength after calculating the raw means and standard deviations displayed.

In Fig. 5, an analysis of variance was used in repeated measures where the trial number was the repeated measure. Like many of the results in this study, these analyses did not display significant differences between groups. However, it does provide us with interesting and unexpected visuals about the similarities and differences in performance based on other factors.

*Statistically Significant p-value

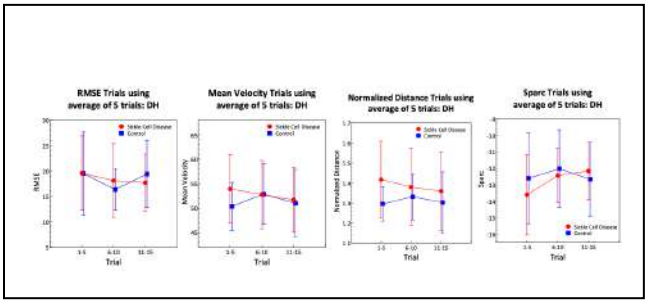

Figure 5. Trajectory Tracking Results of SCD Participants and Healthy Controls For Dominant Hand (DH)

A. Example Robotic Tasks

Figs. 3 and 4 display examples of paired Trajectory Tracking and Spatial Span results. Participant 5 was a 60-year-old female SCD volunteer. They scored in the normal cognitive function range with a MoCA score of 27 and a CT2 T-score above 60. Participant 13 was a 65-year-old female control displaying mild-normal cognitive impairment with a MoCA of 20 and a CT2 T-score of 59.

The dotted line in Fig. 3 represents the desired trajectory presented to all participants while completing the task. The example trajectories of the two participants indicate the average path taken by them across 15 trials. In this case, we see that the SCD participant averaged better along the desired trajectory as opposed to the healthy subject. The highlighted regions depict the standard deviations of each participant.

In Fig. 4, the Y-axis shows us the number of instances, and the X-axis shows us the number of squares in a pattern. For this pair, we can see that both participants were able to reach up to a pattern of five squares at some point during their 18 trials. However, the SCD participant was able to remember the pattern of five squares five times, compared to the healthy control, who only reached a pattern of five, twice. This could indicate that the SCD participant had better working memory function when compared to their healthy control, which was unexpected.

We identified three clinical assessments as comparable to the results of the robotic assessments. The MoCA for overall cognitive function and Color Trails 1 & 2 (CT1, CT2) served as different measures of executive function and were used in comparison to the Spatial Span Task. The box & blocks were used as a measure of gross motor function, which was necessary to adequately use the robotic arm for both TT and SS. Table II displays the raw clinical assessment data of all participants. The significant differences identified were between the groups in the HPVL- Delayed Recall and Retention with p-values of 0.016.

TABLE III. ROBOTIC ASSESSMENT DATA

Assessment	***SCD Participants n=8***	***Control Participants n=8***
Average Pain (Trajectory Tracking)	1.53 ± 2.6	0.63 ± 1.0
Average Pain (Spatial Span)	1.49 ± 2.4	0.13 ± 0.35

Average Exertion (Spatial Span)	2.1 ± 1.24	1.25 ± 0.82
Average RMSE	18.5 ± 8.8	18.0 ± 7.3
Average SPARC	-12.8 ± 3.18	-12.1 ± 2.9
Mean Absolute Velocity	52.0 ± 10.1	53.4 ± 8.6
Normalized Distance	1.36 ± 0.27	1.36 ± 0.2
Mean Sequence Length	4.17 ± 1.05	3.72 ± 0.90

IV. DISCUSSION

A. Key Results

Many of the clinical assessments did not present significant results, which was expected based on past literature. This is in part due to the small sample size of this study as well as the possibility that adults with SCD have lived with deficits for years and have learned to adapt to life with these impairments. The significant differences noticed in Delayed Recall and Retention were, however, an expected result, as memory is one of the domains often described as being impacted by SCD, [25]. In trials and our preliminary analyses, it was clear that as participants were completing the assessments, our results would be much closer than originally expected.

Based on the SPARC results (Fig. 5- right), our SCD participants seemed to have a mean smoothness that started lower but improved throughout the 15 trials, whereas the controls were higher throughout the first 10 trials and dropped at the last five. Based on past literature, we hypothesized that our SCD participants would indicate pain levels greater on average than the controls (Table III). The potential for pain was an expected risk factor of using the robot. However, if a subject already reports chronic pain, we were interested in seeing how additional pain would impact performance. For example, could chronic pain lead to a quicker onset of fatigue? We believed the additional pain could have prevented SCD participants from performing consistently or as well as their healthy counterparts. The presented MAV results could potentially support this belief. Fig. 5 depicts the SCD participants' steady decrease in their velocity, which was an expected result versus the controls who increased in velocity before tapering off in their dominant hand (DH). When looking at RMSE (Fig. 5- left), we expected to see a decrease in scores as participants completed the trajectory-tracking task. This would indicate improved learning of the task and a participant's ability to adjust to the robotic arm movement. In this study, we saw that both groups showed some learning, and the healthy controls seemed to learn faster in the first six trials. This result is somewhat mirrored in the ND scores, as, on average, the controls were able to move in a more consistent manner than the SCD subjects. If SCD participants were experiencing pain or fatigue, their accuracy would take a hit, as the speed of the task did not change during the 15 trials. In Fig. 6, we see how close the SCD group and controls were scoring in their average number of sequences. Fig.6 shows that the SCD participants were able to memorize more sequences of the pattern than the controls. Results such as this have been an interesting example of SCD participants outperforming their healthy control when, by all accounts, the result should be flipped. This brings to question what other factors may not have been considered in the assessment of the SCD group. One belief we had was that medications that SCD participants have been taking for years to reduce anemia symptoms, such as hydroxyurea and folic acid, could help SCD subjects live relatively symptom-free lives, therefore allowing for more freedom to perform as "healthy" participants themselves. Much of the literature explains that the subtype of SCD that someone has, or in other words the genotype they live with, determines the severity of the disease and, in turn, the level of impact in daily life. Our study suggests this may not always be the case. Instead, we hypothesize that based on our population and their recorded genotypes, sometimes those with even the HbSC type of the disease can experience symptoms as severe as those who are HbSS. We can infer from the results of this study that some motor impairment is apparent and has

affected participant performance in the Trajectory-Tracking task. Along with the SCD groups' individually reported pain levels at the end of the robotic trial, this was an expected result. What we have observed in the Spatial Span results shows that although there were significant impairments in long-term memory (Table II), the same may not be true for short-term memory. Based on the literature reviewed, while working memory has been identified as a common domain of impairment in SCD subjects, it has not been specified whether it's long or short-term memory that is impacted.

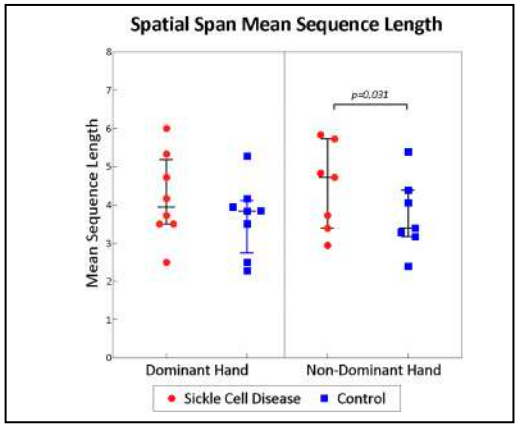

Figure 6. Mean Sequence Length Results of The Spatial Span Task Between Groups

B. Limitations

The major limitation of this study is the small sample size. With this sample size, we were unable to identify many significant differences between our SCD and control groups. Future directions for this research include growing our sample to create stronger arguments and supporting data.

Financial Conflicts of Interest

Dr. Michelle J Johnson, who is the PI and/or Co-I leading this study, has a patent that uses devices inspired by the device being evaluated through this research. The PI is a co-founder of Recupero Robotics LLC and should appear before the acknowledgment.

Acknowledgment

We would also like to acknowledge Dr. Laura Stubbs and the University of Pennsylvania School of Engineering Office of Diversity, Equity, and Inclusion for their continued support of this project, as well as the Penn Medicine Comprehensive Sickle Cell Disease Program and other members of the Rehabilitation Robotics Lab and Recupero, LLC.

Interactive Gait Rehabilitation Through Gamified Real-Time Biofeedback and Adaptive Hip Exoskeleton Assistance: A Preliminary Evaluation

Mariya Tohfafarosh, Neethan Ratnakumar, *Student Member, IEEE,* Lorenzo Zurzolo, Sergei Adamovich, *Member, IEEE,* Xianlian Zhou*, *Member, IEEE*

***Abstract*— This paper presents the design and functional evaluation of an interactive rehabilitation system that integrates a hip exoskeleton with a game-based environment for targeted gait rehabilitation. The system offers real-time visualization of full-body motion tracking and biofeedback, including electromyography (EMG) based muscle activation feedback. Users control an anatomical avatar within a task-based gameplay interface, where the avatar mirrors their motion and displays muscle activation through dynamic, red-shaded overlays corresponding to real-time EMG signals. To assess the system's functionality, a healthy subject participated in a study involving treadmill walking at 0.25 m/s slower than their self-selected speed. The subject navigated a forest environment to collect virtual apples while using two stiffness-based hip control modes: an in-phase assistive mode and an out-of-phase resistive mode. The assistive mode reduced muscle activation, while the resistive mode increased muscle activation for strength training. Additionally, the system supports post-processing of collected data for further analysis, enabling visualization of kinematics, exoskeleton torques, and EMG patterns. Users can customize rehabilitation parameters to tailor the experience to their needs. The results demonstrate the system's potential as an interactive, feedback-driven rehabilitation platform, showcasing its biofeedback capabilities and adaptability.**

Keywords—gamified rehabilitation, assistive technology, biomechanical feedback, myofeedback

I. Introduction

Movement disabilities, whether chronic or temporary, can arise from various medical conditions and injuries, including neurological events, motor impairments, congenital disorders, trauma affecting the lower body, or common post-operative conditions such as those following joint replacement surgery. Approximately, 12.2% of individuals in the United States experience significant challenges in walking or climbing stairs [1]. This limited mobility not only impacts their quality of life but also heightens their risk of secondary health complications [2]. As a result, effective rehabilitation strategies are critically needed. However, hospital-based physiotherapy is often costly and logistically challenging, which can lead to inconsistent patient participation and slower recovery.

Successful rehabilitation requires a highly personalized approach, with recovery plans tailored to each patient's specific condition, type of impairment, personal goals, and individual circumstances. This underscores the need to follow three main principles: first, rehabilitation exercises should be designed to sustain patient motivation; second, they must be adaptable to the patient's needs; and third, patient performance should be objectively evaluated, for instance, comparing movements against an ideal reference model [3]. Gamified approaches, with real-time biofeedback and customizable features, have emerged as valuable tools to engage patients and meet these principles. Specifically, incorporating motion and electromyographic (EMG) feedback into these programs provides additional benefits.

Real-time motion feedback is a critical component in rehabilitation gaming, offering patients immediate insights into their movements. This instantaneous feedback enables individuals to adjust their posture, refine motor skills, and improve task execution, thus fostering enhanced motor learning [4]. By guiding patients toward real-time corrections, motion feedback not only enhances therapy effectiveness but also accelerates recovery and contributes to sustained long-term improvements. Furthermore, such feedback increases patient motivation, making rehabilitation more engaging and impactful [5]. Integrating motion feedback allows clinicians to track and evaluate patient performance seamlessly, proving its value in both clinical and home-based therapy settings.

Combining motion feedback with biofeedback modalities like muscle EMG creates a more interactive and immersive rehabilitation experience, addressing both physical and psychological recovery dimensions. Studies, such as those by Giggins et al [6], emphasize the importance of virtual reality and real-time feedback in improving functional outcomes for post-stroke patients and Parkinson's patients by offering tailored, actionable insights during therapy sessions and helps the patients to preserve their motivation during the rehabilitation process.

EMG feedback offers real-time insights into muscle activity, motivating, and empowering patients to adjust their movements and enhance motor control. Studies have shown that EMG feedback training can be effective in improving muscle strength, pain reduction, functionality, and joint range of motion in the context of sports and orthopedic rehabilitation [7, 8]. Additionally, evidence suggests that EMG biofeedback therapy also significantly improves limb function after stroke, particularly in the short term [9, 10]. For example, Intiso et al. [11] show the effectiveness of EMG feedback in increasing muscle strength in the tibialis anterior which plays a critical role in avoiding foot drop during gait. By delivering personalized myofeedback, EMG complement gamified

strategies, boosting patient motivation and facilitating neuromuscular re-education. The same systems can also be applied to sports training [12].

Repetitive and targeted gait movements, on the other hand, also play a pivotal role in fostering neuroplasticity, enabling the brain to establish new neural connections critical for relearning walking patterns and achieving functional recovery [13]. Exoskeletons can assist in facilitating these repetitive movements, particularly when a patient's strength or coordination is insufficient to sustain the intensity needed for effective therapy. We believe that integrating gamified strategies, EMG biofeedback, and advanced technologies like lower-limb robotic exoskeletons will foster neuroplasticity through repetitive, targeted movements, making gait rehabilitation more effective and personalized for individuals regaining mobility. To advance this vision, we developed an interactive rehabilitation framework that combines a Unity-3D based gaming system with a backdrivable hip exoskeleton. This system incorporates real-time multimodal feedback, including inertial measurement unit (IMU) based motion tracking, visualization of muscle activation via surface electromyography (sEMG) sensors, and dynamically adapts gameplay based on patient performance, providing tailored visual and physical guidance.

By reducing physical strain and metabolic energy consumption, hip exoskeletons enable patients to participate in extended rehabilitation sessions, promoting consistent progress. Studies have shown that the metabolic cost of walking is significantly reduced while wearing a hip-only exoskeleton compared to unassisted walking [14], which could help improve endurance and overall participation in therapy. In addition to these assistive benefits, hip exoskeletons can provide resistive training by targeting key hip muscles, effectively aiding in muscle strengthening stability [15, 16]. Our framework integrates these features into a rehabilitation gaming system designed to explore its potential for clinical and home-based use. It aims to provide a cost-effective and accessible approach to support motor recovery and contribute to long-term rehabilitation outcomes.

II. Gaming System Framework

Over the past decade, gamification has advanced significantly in healthcare, showing positive impacts through engaging experiences, progress tracking, and accessible technology, while gaining widespread adoption across various fields [17]. Our approach builds on this progress by integrating a realistic Unity-3D game environment with a backdrivable, size-adjustable hip exoskeleton for targeted gait rehabilitation exercises. The following subsections provide a detailed overview of the system's components, including the game environment and the hip exoskeleton. The Unity game serves as the central component of the system, incorporating motion sensors to track movement and EMG sensors to monitor muscle activation, delivering real-time biofeedback to the user. The hip exoskeleton complements these elements by actively interacting with the user and providing self-tailored assistance or resistance during rehabilitation tasks. Together, these components form a cohesive framework for effective gait rehabilitation, as illustrated in Fig. 1.

A. Game Functionality and Sensor Integration

The game environment primarily features an avatar within a flexible setting, where tasks, surroundings, and gameplay elements can be adjusted as needed, to make rehabilitation both engaging and effective. Unlike traditional rehabilitation tools, the game integrates dynamic and immersive gameplay elements to captivate users while addressing specific therapeutic goals. The avatar is an anatomically accurate human model, composed of 3D meshes of skin, bones, muscles, and other anatomical structures. This high fidelity human anatomic avatar model provides superior realism

compared to typical skin avatars or stick figures employed in most games [18, 19] and offers in-depth exploration of its musculoskeletal behavior through visualization of muscle activation and 3D deformation with tracked motion.

The avatar's whole-body movements are dynamically tracked through synchronization with the Xsens MVN system, which employs 17 Xsens Awinda IMU sensors (Xsens Technologies B.V., Netherlands) [20]. Real-time movement data tracked by the sensors, including segment orientation and position, is transmitted to the Unity-Xsens MVN Live plug-in through UDP network protocol, allowing integration of the subject's real-time actions within the game environment. To measure muscle activation, wireless Delsys Trigno Avanti sEMG sensors (Delsys Inc., MA, USA) are placed on selected lower leg muscles of the subject, namely Rectus Femoris, Biceps Femoris (Long Head), Gluteus Maximus, and Semitendinosus. These sensors wirelessly transmit real-time sEMG signals to the Delsys API using a proprietary radio frequency protocol, and subsequently to Unity. In Unity, the signals are normalized in real time using a z-score method.

To establish a baseline, the subject first walks on a treadmill at their normal walking speed for 30 seconds. During this baseline period, sEMG data is recorded, and the mean and standard deviation of the signals are calculated. These baseline values are then used to continuously compute the z-score of the real-time EMG data during gameplay. To ensure precise synchronization across all components, the Xsens motion capture system and sEMG data acquisition are simultaneously triggered by the exoskeleton's graphical user interface (GUI). This synchronization mechanism is essential for preserving the temporal integrity of multimodal data streams, enabling accurate alignment of muscle activation (sEMG) and body motion (Xsens) data within the Unity environment.

The normalized EMG signals, representing muscle activation levels, are visualized on corresponding 3D muscle models in Unity. A gradient color map is used for rendering, with shades transitioning from lighter, more transparent red (indicating lower activation) to darker, more intense, and opaque red (indicating higher activation), as shown at the bottom of Fig. 2.

B. Hip Exoskeleton Integration

The hip exoskeleton utilized in this study is adapted from the open-source OpenExo design [21], with several key modifications to enhance performance. These include the use of a more powerful motor, the MyActuator RMD X8 Pro V2, with a nominal torque of 13 Nm. The original electronic components were replaced with a Raspberry Pi 4B (RPi), a USB-C to Controller Area Network (CAN) module to facilitate communication between the RPi and the motors, and a handheld emergency safety switch. The exoskeleton is powered by two 3300 mAh LiPo batteries for extended duration operations. Additionally, some structural components were replaced to accommodate the motor's increased torque. The total weight of the exoskeleton is approximately 7 kg. Fig. 3 illustrates multiple views of the exoskeleton device.

The hip exoskeleton currently operates in two distinct stiffness modes: an in-phase assistive and another out-of-phase resistive mode. The exoskeleton is controlled by a GUI that communicates with the RPi on the exoskeleton. The GUI

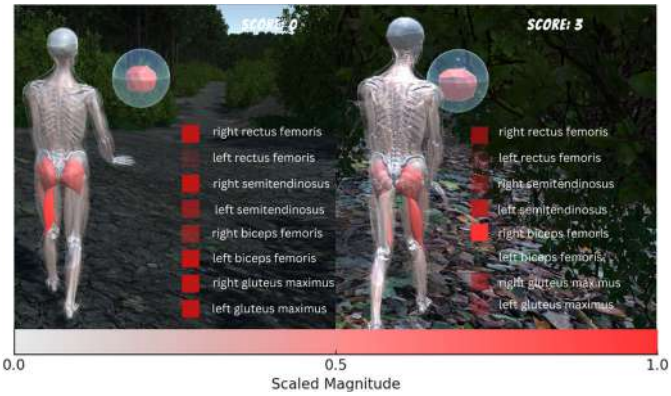

Fig. 2. Snapshots of the game scene show different time instants and viewing angles of the game when the subject approaches the apple. Muscle activations are shown with a list of color-coded boxes and shaded on the muscles of the avatar. The color bar at the bottom maps the normalized muscle EMG (between 0 and 1) to the rendering color of the 3D muscle mesh.

Fig. 3. Front, side, and back views of the hip exoskeleton CAD assembly and as worn by subjects.

allows users or researchers to adjust stiffness levels, control motor operation (start/stop), and trigger the recording of data, including encoder measured joint angles and velocities, commanded motor torques, sEMG, and Xsens motion capture data. Additionally, the GUI provides real-time visualization of trajectories for joint angles, velocities, and torques, enhancing user interaction and data monitoring, as illustrated in Fig. 1B.

1) Stiffness based assistive mode (in-phase)

Modulating hip exoskeleton stiffness has been extensively utilized in gait rehabilitation, as the inability to tune natural hip joint stiffness is believed to contribute to gait impairments. For example, the GEMS-H (Samsung Electronics, Suwon, South Korea) exoskeleton has been used in this mode to study the induced gait changes in healthy populations [22]. Additionally, it has demonstrated significant improvements in walking speed and endurance in older adults using a more complex delayed feedback approach [23].

In our work, we configured our exoskeleton to simulate a virtual torsional spring between the thighs, governed by the following control law [22, 24]:

$$\tau_R = -\tau_L = k\,\theta_{REL} \quad (1)$$

Here k is the stiffness and θ_{REL} is the relative angle between the encoder measured left and right hip angles (θ_L - θ_R). The torque was limited to 15 Nm for safety reasons and filtered by

a low pass filter to avoid sharp fluctuations caused by encoder noise. This control follows the trend of biological hip torques approximately and operates in phase with the relative hip angle to provide a naturalistic assistive force.

2) Stiffness based resistive mode (out-of-phase)

The resistive mode opposed the subject's gait movement by applying torque off-phase to the hip joints. The torque magnitude was calculated similarly to the stiffness-based assistance, but with a reversed direction. For safety reasons, the torque was also limited to 15 Nm.

III. Experimental Procedure & Data Processing

A set of preliminary experiments were carried out to demonstrate the feasibility of the gaming system. A healthy adult (male, weight 97 kg, height 180 cm, age 32 years-old) took part in the pilot test under the NJIT approved protocol (# 2305033091). Delsys Trigno Avanti EMG sensors were attached to four hip muscles per leg (Gluteus Maximus, Biceps Femoris (Long Head), Semitendinosus and Rectus Femoris). The maximum voluntary contraction (MVC) for each muscle was recorded by performing specific isometric exercises against resistance, ensuring maximal effort for each target muscle group. The subject was also equipped with the 17 IMU sensors required for the full body motion feedback.

The subject participated in the game while wearing the exoskeleton under an unassisted zero torque walking condition (No Torque), as well as the in-phase and out-of-phase hip exoskeleton conditions detailed in Section II. sEMG, IMU and exoskeleton data were continuously recorded during each trial, which lasted for two minutes each. The walking speed was set to 0.25 m/s lower than the self-selected speed (when not wearing the exoskeleton) to account for dual-tasking demands, as concurrent gameplay and treadmill walking may increase cognitive load and compromise gait stability.

A. Unity Game Setup

The game was designed to simulate an engaging forest environment where the subject's avatar collects scattered apples by navigating through varied terrains. A USB Joystick (Retro Games Ltd., UK) was used to allow the subject to turn the avatar to the left or right during gameplay, which was performed on a treadmill (AC5000, SCIFIT Systems, Inc., OK, USA).

This setup enables the game to be played in confined spaces, such as at home or in small rehabilitation facilities, while the subject explores a large, unconfined environment within the game. The game environment was displayed on a large screen in front of the subject, providing real-time feedback on their movements and interactions with the virtual world. Fig. 2 shows the game setup and game environment details. Fig. 4 depicts the data collection setup, including a screenshot of the subject walking on the treadmill and playing the game while wearing the exoskeleton.

B. Data Post-processing

The raw EMG signals were postprocessed using a multi-step filtering approach to obtain a clean and meaningful signal envelope for analysis. First, the signals underwent a fourth-order Butterworth bandpass filter with a passband of 50–450 Hz to isolate the EMG frequency range and remove low-

Fig. 4. Data collection setup showing the treadmill control, joystick, and screen (top) and a subject playing the game on the (bottom).

frequency motion artifacts and high-frequency noise. Following this, the processed signals were rectified, and a sixth-order Butterworth low-pass filter with a 6 Hz cutoff frequency was applied to extract the smoothed signal envelope. The signals were then finally normalized by the corresponding MVCs.

Virtual markers for each trial were exported in C3D format using Xsens Analyze Pro. Since a normal gait cycle is defined as beginning and ending with a heel strike [25], the trajectory of the virtual heel marker was used to segment the trials into individual gait cycles for further analysis. The mean trajectory and standard deviation (SD) across all cycles were calculated for muscle activations, hip joint angles, and exoskeleton torques, with the results plotted as mean ± SD for each variable.

IV. Results and Discussion

We conducted functionality tests on the gaming system integrated with the hip exoskeleton. This system provided real-time, semi-immersive feedback on the subject's gait and navigation, displaying dynamic, red-shaded overlays of muscle activation intensity and coordination which could enhance understanding of muscle engagement during training. In the game, the subject navigated a forest-based environment, to collect virtual apples while walking on a treadmill. The apple-picking task was scored based on the user's accuracy and efficiency in navigating the environment, creating an additional layer of motivation and challenge. The system also allowed the subject to adjust rehabilitation parameters in real time, such as switching between assistive and resistive modes and modifying stiffness levels to match their needs. The overall operational smoothness of the system was high, with minimal latency between user motion and avatar response. Beyond real-time feedback, the system also supports post-processing of collected data, enabling detailed analysis of the subject's gait adaptation and muscle coordination under various training modes and conditions.

To illustrate the muscle activation results, we present data from representative activations of two hip muscles per leg as depicted in Fig. 5: the Gluteus Maximus and Rectus Femoris on the left leg, and the Biceps Femoris and Semitendinosus on the right leg, under assistive, no torque, and resistive modes. The results reveal that the Gluteus Maximus (Left) displays relatively consistent activation across all modes. The Rectus Femoris (Left) shows smaller activation in the assistive mode compared to the no torque and resistive modes, suggesting reduced engagement when assistance is provided. For the Biceps Femoris (Right), the resistive mode leads to noticeably higher activation, highlighting increased muscle engagement with resisting torques. Similarly, the Semitendinosus (Right)

demonstrates significantly higher activation in the resistive mode, while assistive and no torque modes exhibit comparable and lower levels of activity.

Fig. 6 shows the right hip joint angle and torque trajectories under the no-torque, assistive, and resistive conditions. The results illustrate that, as expected, the hip torque in the assistive mode aligns in phase with the hip angle, providing support during flexion and reducing extension effort. In contrast, the resistive mode generates out-of-phase torque, opposing the natural motion to encourage muscle engagement, particularly during extension.

Notably, the resistive mode also led to a noticeable increase in the peak extension angle compared to the no-torque and assistive conditions, likely due to the subject compensating for the opposing force and a slight tilt of the waistbelt due to large torque (close to 15 Nm). Across all conditions, the trajectories of both the hip angle and torque are relatively smooth, demonstrating the system's ability to deliver consistent and controlled assistance or resistance during gait.

Moreover, walking in the resistive mode was perceived as noticeably harder compared to the no-torque condition by the subject. However, in the assistive mode, the subject did feel a notable reduced effort compared to the no-torque condition. The overall experience of the subject was positive, with him describing the gaming system as interactive and stimulating.

The gaming system could benefit from testing across a broader range of populations, including both healthy individuals and specific patient groups. Post-stroke patients are a promising focus, as the system may help normalize spastic muscle contractions [26] through EMG feedback, while also promoting neural plasticity and enhancing motor control. Similarly, children with cerebral palsy could experience enhanced gait performance and mobility. By functioning as a strengthening intervention, the system has the potential for widespread application across various age groups and medical conditions[27]. The present system utilizes proprietary Xsens software and IMUs for motion capture and data transfer. Alternatively, we can replace it with the real-time OpenSim inverse kinematics (IK) method, where kinematics may be tracked using inexpensive IMUs or other markerless mocap devices, such as depth cameras or video based systems, making it a cost-effective solution that can also be used in out-of-the-lab conditions [28]. While our system integrates biofeedback, gamification, and an exoskeleton to enhance gait rehabilitation, its holistic nature makes it challenging to determine the individual contribution of biofeedback. Understanding its specific role is essential not only for optimizing system effectiveness but also for ensuring the right balance between feedback complexity and user comprehension to prevent cognitive overload. Future studies could systematically remove certain components and evaluate their impact on rehabilitation outcomes, helping refine the system for better therapeutic benefits and usability. Moreover, future enhancements could further boost user immersion and system functionality. Based on internal user feedback, we identified that the exoskeleton's weight and design caused some discomfort. We plan to integrate a mixed- reality platform , such as Microsoft HoloLens, to create a more realistic and interactive environment. This would allow users

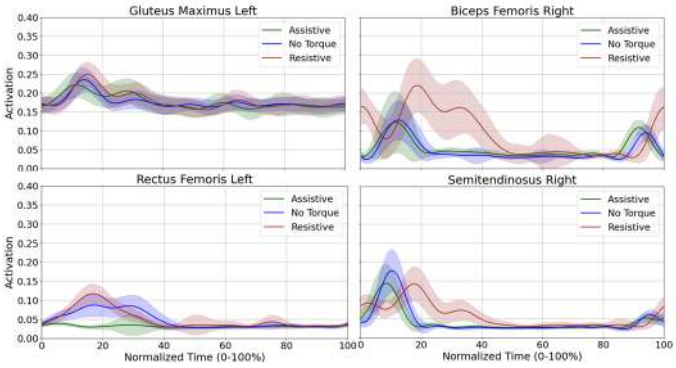

Fig. 5. Mean±SD muscle activations for left Gluteus Maximus and Rectus Femoris as well as right hamstrings.

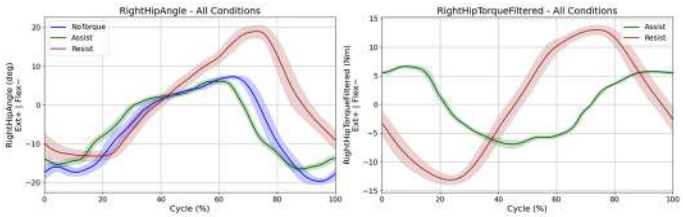

Fig. 6. Right hip joint angles and hip exoskeleton assistive torques for different exoskeleton conditions.

to move naturally and unrestrictedly without the need for a joystick, replacing it with head rotation to control movement. This approach will foster more lifelike interactions and enrich the therapeutic experience. Additionally, we plan to integrate instrumented pressure insoles such as OpenGo (Moticon GmbH, Munich, Germany) [29] or loadsol (novel GmbH, Munich, Germany) [30] in our rehabilitation gaming system. These insoles will provide real-time feedback on the estimated center of pressure (COP) position and vertical ground reaction force within the Unity game. This feedback will enable patients to monitor their walking, identify asymmetries or abnormal COP movements, and detect improper foot placement that could lead to imbalance or impede rehabilitation progress [31, 32].

V. Conclusion

We designed and conducted a preliminary evaluation of a gaming system integrated with a hip exoskeleton, intended as an interactive and adaptive tool for gait rehabilitation. The system incorporates motion feedback, with a high-fidelity avatar that mirrors the user's movements in real-time using IMU sensors, alongside EMG-based biofeedback to enhance engagement, muscle coordination, and gait improvement. Preliminary tests with a single user showed the system to be highly engaging, with the hip exoskeleton and effectively modulating activation levels in the major hip muscles. Activation was reduced in the assistive mode and increased in the resistive mode. We believe this system has significant potential to improve rehabilitation outcomes by providing personalized, motivating, and effective therapy for users.

Acknowledgment

The authors would like to thank Erick Nunez for their contributions to the prototype implementation and system setup.

Developing a methodology for quantifying infant interaction with a robotic toy*

McKenzie E. Davis[1], O. Francis Sowande[2], Julie Skorup[3], Melanie Segado[4], Frances Shofer[5], Laura A. Prosser[6], Michelle J. Johnson[7], *Member, IEEE*

***Abstract*— Preterm infants are at increased risk for developmental delays and disability such as cerebral palsy. When these delays are detected early, movement training can significantly improve patients' quality of life. Instrumented toys have the potential to solve the pressing need for easily accessible, inexpensive diagnostic tools for infant development. While many studies have focused on developing toys for sensor-based assessment, the body of work dedicated to developing quantitative measurements from this data is minimal and has several limitations. Using a consistent and novel video coding methodology, a case study of 18 preterm and full-term infants' videotaped interactions with the Play and Neuro Development Assessment (PANDA) Gym, an affordable, mechatronic, and sensor-based play environment, were analyzed. The coding methodology was able to quantify infant interactions with the PANDA toy and differences between preterm and full-term infants, but future analysis of involuntary interactions and a larger sample size are needed to determine whether results are consistent with expected developmental milestones.**

I. Introduction

Cerebral palsy (CP) is the main chronic condition causing disability in childhood [1]. CP results from perinatal brain lesions such as those seen following preterm birth [2], and risk of cerebral palsy increases with decreasing birthweight and gestational age [3, 4]. Cerebral palsy is non-curable, and no mechanisms are in place for healing or recovery [2], but movement training can significantly improve quality of life for individuals with CP. It is important for movement training to begin as early as possible, as the first year of life is a crucial period for the establishment of the key neural circuits that support the development of normal motor function in humans [2]. However, many children are not diagnosed with cerebral palsy until around 2 years of age [5]. Thus, there is a need for earlier detection of deviation from the typical course of development, as earlier interventions can leverage the greater neuroplasticity seen in younger infants and improve developmental outcomes for infants with CP [6].

Instrumented toys have demonstrated potential to solve the need for accessible, inexpensive diagnostic tools for infant development, and a significant amount of work has been done to improve these toys to the point of serving as tools for assessment. For example, a sensorized ball designed by Campolo et al. used quantum tunneling composites to detect grasping patterns during manipulation [7]. Tenzer et al. developed a versatile, low-cost, and sensitive tactile sensor using commercial off-the-shelf MEMS barometers [8] and Takada et al. used a waterproof mobile device's built-in barometer to measure touch force [9]. Additionally, Ramanathan et al. designed a set of 8 instrumented toys outfitted with Physilog 6 commercial off-the-shelf wearable motion sensors [10]. Further studies demonstrate potential for the use of these toy measurements as clinical indicators for infant development. For example, Serio et al. developed a soft, horseshoe-shaped sensorized, wireless toy, and found that typically developing infants could produce unimanual (one-handed) and bimanual (two-handed) grasps detectable by the sensors [11]. Udayagiri et al. have also worked toward developing a toy leveraging soft lossy force sensors from optical fibers to gather play interaction data and were able to identify distinct interaction types using machine learning analysis [12].

However, there have been minimal studies dedicated to evaluating interactions with toys and developing quantitative measurements. Kather et al. successfully used manual video coding to quantify the frequency and duration of toy interactions and found that preterm infants gazed at the toys with similar frequency as full-term infants, but infants born full-term physically engaged more frequently and for longer durations with the robotic toys than infants born preterm [13]. However, there are significant challenges with manual video coding – it is time-consuming, is prone to user bias and inconsistency, and it can be difficult to capture complex behaviors. Additionally, despite its ability to output quantitative measures of infant interaction, it is hard to relate

manual video coding outputs to clinical measures due to limited camera views and obstructions.

This study aims to address the issues with manual video coding by developing a consistent, novel methodology for coding interactions with toys that can be used on larger datasets and in the future, to train a machine learning algorithm. To address the issue of limited camera views and obstructions with manual coding, multiple camera angles were used. This paper reports the protocol for establishing the interaction labels and the coding methodology. Additionally, it outlines a preliminary study to verify the methodology is sensitive to babies' age, term status (preterm vs. full-term) and its impact on their motor performance and presents initial results using this system.

II. Development of Coding Protocol

To develop the interaction classifications (Table 1), a literature review was performed of previous manual video coding studies and clinical movement definitions for observed motor behaviors. Kather et al. used "touch" and "grasp" interactions for upper body classifications, "touch" and "kick" for lower body classifications, "mouth" if the infant placed a piece of the toy in their mouth, "gaze" if the infant's eyes locked on the toy, and "involuntary" interactions if the infant interacted with the toy unintentionally [13]. However, Kather's classifications neglected to mention reaching behavior [13]. Additionally, a literature review of infant motor milestones was conducted. The 14 classifications used in this study are more robust and specific than previous studies, and they are consistent with developmental milestones expected for babies aged 1-6 months – gazing, touching, kicking, reaching, and grasping [14]. Additionally, unimanual, bimanual, unilateral (one-legged) and bilateral (two-legged) interactions were coded separately, given that as infants get older, unimanual interactions increase while bimanual interactions decrease [15].

TABLE I. Parent Codes: High Level Interaction Descriptions

Movement Classification	Interaction Description
Involuntary	Any unintentional contact with toy with any body part; toy does not appear to be the direct target & the infant was not looking at the toy
Gaze	Direct eye contact with toy; determined by pupil direction and head angle
Voluntary Reach	Any intentional reach for the toy with one or both arms or legs without touch, kick, or grasp event
Voluntary Touch	Preceded by reach, any contact of the toy with one or both hands or feet
Voluntary Kick	Preceded by leg reach, one or both feet intentionally contact toy with greater force than a touch
Voluntary Grasp	Preceded by arm or leg reach, one or both hands or feet intentionally come into contact with the toy and at least three fingers cup/close around the toy
External Movement	Any movement of the toy caused by a non-infant entity (ex. parents moving the toy, toy movement caused by the baby rolling off the mat)
Baby Off Mat	Baby was off mat for any reason (i.e., rolled off mat, removed by parents)

A. Interaction Classification

A total of 7 parent codes were used (Table 1) and 14 voluntary interaction codes were used (Table 2), along with Involuntary Interaction and Gaze. Each video was also coded for emotion – positive, neutral, or negative (Table 3). The code "Pre/Post Trial" was used to indicate portions of the video where the cameras may have been recording, but the two-minute trial had either started or ended.

TABLE II. Voluntary Interaction Codes

Parent Code	Code
Voluntary Kick	Unilateral Kick
	Bilateral Kick
Voluntary Touch	Bilateral Leg Touch
	Unilateral Leg Touch
	Bimanual Arm Touch
	Unimanual Arm Touch
Voluntary Grasp	Bilateral Leg Grasp
	Unilateral Leg Grasp
	Bimanual Arm Grasp
	Unimanual Arm Grasp
Voluntary Reach	Bilateral Leg Reach
	Unilateral Leg Reach
	Bimanual Arm Reach
	Unimanual Arm Reach

TABLE III. Emotion Codes

Emotion	Description
Negative or Crying	Baby crying or otherwise visibly upset
Positive	Baby smiling or otherwise visibly happy
Neutral	Emotion not positive or negative

B. Coding of Interactions

MAXQDA (Verbi Software, 2024) was leveraged to assign codes to video segments. The videos were separated into two-second frames, and codes were manually assigned by the investigator if the interaction was observed at any point during the frame. Interactions were coded in two-second frames to reduce subjectivity by eliminating the need to determine an exact time point when the interaction began. If an interaction began in a previous frame but continued into the current frame (i.e. the infant touched the toy and sustained contact), the interaction was still coded in the current frame. If an interaction occurred twice in a frame (i.e., the infant touched the toy, removed their hand, and touched the toy again), the interaction was coded twice. This protocol was preliminarily implemented with 18 infants, a subset of the 90 enrolled in the study. The goal was to understand the sensitivity of some of the key metrics of age and motor delay and to identify challenges in applying this methodology to the rest of the infant population.

III. METHODS

A. Participants

This study was approved by the Institutional Review Boards (IRBs) of the University of Pennsylvania and the Children's Hospital of Philadelphia. Informed consent was obtained from parents of all infants. Infants born preterm and full-term (at least 36 completed weeks of gestation) between the ages of 1-6 months were eligible for participation. Infants born full-term were excluded if they had a history of any neurologic, orthopedic, cardiac, or genetic condition. Infants born preterm were born after 24–35 weeks of gestation. Ninety infants were enrolled in the study. Of the 18 infants analyzed in the case study, 12 were full-term and 6 were born preterm and had motor delay as determined by the AIMS and TIMP clinical assessment measures (Table 4). The ages of the preterm infants were corrected for prematurity by subtracting the number of weeks born before 40 weeks of gestation from their age to provide a more accurate assessment of developmental milestones.

B. The Play and Neuro Development Assessment (PANDA) Gym

The Play and Neuro Development Assessment (PANDA) gym (Figure 1) is a low-cost, portable instrumented play environment designed to measure infant interactions in high and low resource settings. The system uses a pressurized mat, a sensor-based panda-shaped toy, and 7 GoPro cameras positioned to give different views of the interaction. The toy contains a 9 DOF internal measurement unit (IMU), touch sensors on the face and the ears, and NeoPixel lights in the ears. The panda shape was chosen because for several months after birth, infants prefer toys with high black-and-white contrast, and the overall shape is symmetrical and circular, allowing for safe interaction [16].

TABLE IV. CASE STUDY DEMOGRAPHIC DATA

Infant #	***Full-term/Preterm***	***Corrected age (months)***	***Sex***
221	Full-term	1	Male
219	Full-term	1	Female

63	Preterm	6	Male

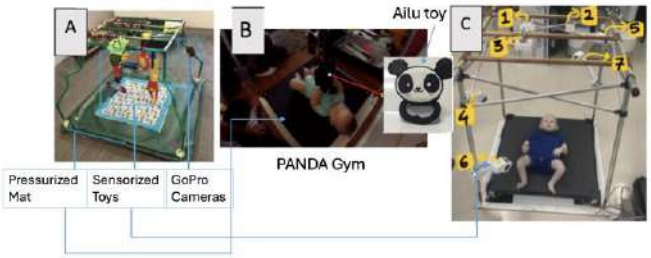

Figure 1: A: PANDA GYM version 1, B: Current set-up of PANDA gym, C: Seven GoPro camera set-up in current gym.

C. Data Acquisition

Static calibration, with an ArUco board placed lying down on the mat, and dynamic calibration, with the board moving around slowly within view of the cameras, were performed to collect the cameras' extrinsic and intrinsic parameters. Then, data was recorded of the gym with nothing inside to collect baseline data for the sensors. Infant data acquisition lasted a total of six minutes in two-minute intervals– infants were first placed supine on the mat with no toy. Next, the toy was placed near their arms (tilted so they could see the face) and at their feet (within kicking distance) in randomized order. Rest breaks were not given between trials unless the baby was upset, and trials resumed once the baby calmed down. Infants were encouraged to engage with the toy through the built-in sounds and lights. Most trials occurred at infants' homes; some trials on preterm infants were performed at the Children's Hospital of Philadelphia. Some preterm infants who were recruited from the NICU required supplemental oxygen at the time of testing. Equipment was arranged so that it did not disturb the infants' ability to engage with the toy. This analysis will focus only on the toy at arms and toy at feet conditions, totaling 4 minutes of interaction time.

D. Video Coding Protocol

MAXQDA (VERBI Software, 2024) was leveraged to assign interactions to the corresponding two-second frames of videos with the toy at arms and toy at feet. Videos from camera 7 were analyzed, and camera 4 videos were used to verify interactions with the back of the toy. Infants were coded in randomized order. Individual interactions were initially classified as involuntary, voluntary, or gaze—with voluntary interactions further classified by extremity and unimanual/bimanual or unilateral/bilateral nature. Interactions were classified as voluntary when the infant's interaction occurred with clear intent, often accompanied by a gaze interaction to confirm said intent. Simultaneous interactions were often observed, and the videos were coded accordingly. For example, if an infant were to intentionally grasp the toy with one arm while simultaneously touching it

with both feet and one hand (Figure 2), "Voluntary Unimanual Arm Grasp", "Voluntary Unimanual Arm Touch", "Voluntary Bilateral Leg Touch", and "Gaze" would be coded for the two-second interval. Frequency of each interaction was calculated for each trial.

Figure 2: In this image, Infant 28 (left) simultaneously performs a unimanual arm touch, bilateral leg touch, and unimanual arm grasp while gazing at the toy. The two-second coded segment is shown at right.

E. Data Analysis & Processing

Once each video was coded, the MAXQDA "Codes" output was generated (Table 5). For each video, the output included the parent code, code, how many video segments were coded the percentage of total interactions each code represents, and information about the coder(s). Emotion and Pre/Post Trial codes were removed from the frequency and percent of coded segments calculations. Then, the frequency of each interaction for each infant was compiled to analyze trends.

TABLE V. EXAMPLE MAXQDA OUTPUT: INFANT 28

Parent Code	*Code*	*# of Coded Segments*	*% Coded Segments*
Pre/Post Trial	Pre/Post Trial	1	0.99
Emotion: Neutral	Emotion: Neutral	1	0.99
Gaze	Gaze	58	38.41
Involuntary Interaction	Involuntary Interaction	2	1.32
Voluntary Grasp	Bimanual Arm Grasp	4	2.65
Voluntary Grasp	Unimanual Arm Grasp	17	11.26
Voluntary Grasp	Unilateral Leg Grasp	1	0.66
Voluntary Reach	Unimanual Arm Reach	3	1.99
Voluntary Reach	Bimanual Arm Reach	1	0.66
Voluntary Touch	Unimanual Arm Touch	37	24.50
Voluntary Touch	Unilateral Leg Touch	8	5.3
Voluntary Touch	Bilateral Leg Touch	5	3.31
Voluntary Touch	Bimanual Arm Touch	13	8.61

IV. RESULTS

Table 6 reports the combined MAXQDA output for each infant across both toy trials (toy at arms and at feet). Figure 3 shows how this total number of interactions varied by age and infant group (full-term versus preterm with motor delay).

Across the 18 infants, a total of 1,652 motor and gaze interactions were coded. 1,424 (86.2%) of these interactions were voluntary, while 228 were involuntary (Table 6). As full-term infants got older, the percentage of involuntary interactions decreased significantly while the percentage of voluntary interactions increased (Table 6). This trend was not seen in preterm infants – the percentage of involuntary interactions remained high (50-100%). A two-way ANOVA was done by age and term (preterm vs. full-term) on the percentage of voluntary movements, and a significant difference was found by age ($P=0.002$) and term ($P=<0.0001$). On average, full-term infants interacted with the toy more when the toy was at their arms (average = 75.33 interactions) compared to when the toy was at their legs (average = 52 interactions). Preterm infants interacted with the toy more when it was at their legs (average = 18.5 interactions) than at their arms (average = 2.16 interactions).

Additionally, as full-term infants got older, they interacted with the toy more frequently (Figure 3). This trend was not seen in preterm infants – frequency of interactions with the toy among preterm infants were similarly low regardless of age. Despite this, infants interacted with the toy frequently. Of the 18 infants, only 1 of preterm infant (Infant 64) did not voluntarily interact with the toy.

TABLE VI. TOTAL VOLUNTARY & INVOLUNTARY INTERACTIONS BY INFANT

Infant #	*Adjusted Age (mo)*	*Term*	*Tot. Voluntary Interactions (%)*	*Tot. Involuntary Interactions (%)*
221	1	Full-term	16 (59%)	11 (41%)
219		Full-term	3 (10%)	26 (90%)
52		Preterm	1 (13%)	7 (87%)
16	2	Full-term	3 (19%)	13 (81%)
61		Full-term	40 (83%)	8 (17%)
50		Preterm	2 (6%)	31 (94%)
13	3	Full-term	32 (52%)	30 (48%)
31		Full-term	70 (93%)	5 (7%)
64		Preterm	0 (0%)	17 (100%)
32	4	Full-term	104 (99%)	1 (1%)
45		Full-term	182 (98%)	4 (2%)
72		Preterm	4 (21%)	15 (79%)
23	5	Full-term	269 (99%)	4 (1%)
19		Full-term	248 (96%)	9 (4%)
55		Preterm	1 (3%)	34 (97%)
20	6	Full-term	190 (98%)	4 (2%)
28		Full-term	253 (99%)	2 (1%)
63		Preterm	6 (50%)	6 (50%)
Total			1,424 (86.2%)	228 (13.8%)

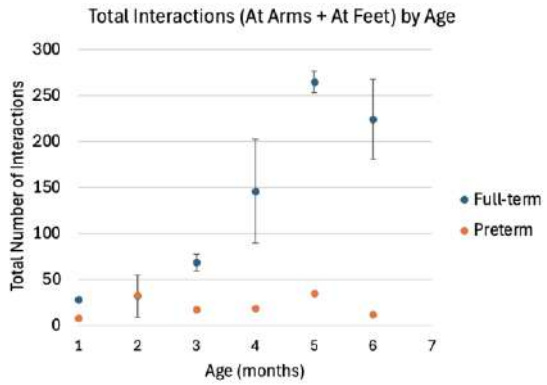

Figure 3: Total arm and leg interactions (voluntary and involuntary, with standard deviation bars) with PANDA toy by age. No standard deviation bars included for preterm infants, as only 1 preterm infant was analyzed per month.

Figure 4 shows the emergence of arm and leg interactions by age. The mean number of voluntary arm interactions across all ages was 30.4 for full-term infants and 0.16 for preterm motor delayed infants. Arm interactions increased with age for full-term infants, peaking at 5-months. The mean number of voluntary leg interactions across ages for full-term infants was 21.25 and 0.66 for preterm motor delayed infants. Leg interactions also increased with age for full-term infants, peaking at 5 months. In full-term infants, arm interactions emerged at two months and leg interactions emerged at three months. In preterm infants with motor delay, similar trends were not observed. Arm interactions emerged at 5 months in preterm infants, but the six-month-old infant did not interact with the toy with their arms. Leg interactions emerged at 1 month, but the 3,4-, and 5-month-old infants did not interact with the toy using their legs.

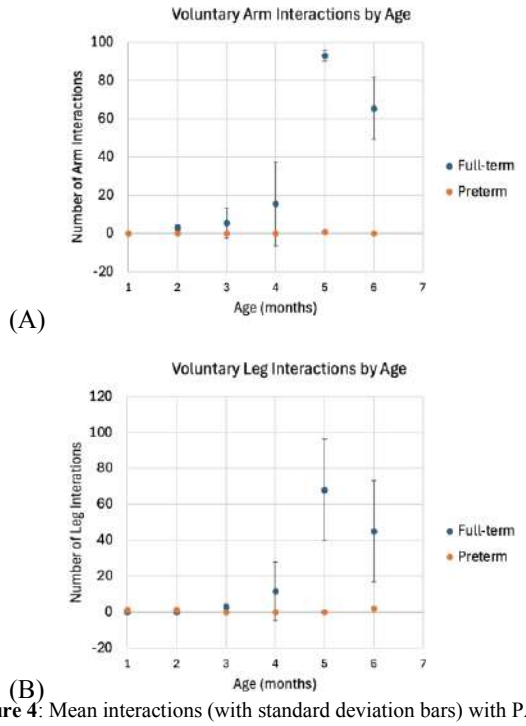

Figure 4: Mean interactions (with standard deviation bars) with PANDA toy by infant group and age: A) Total number of unimanual/bimanual arm touch and grasp interactions; B) Total number of unilateral/bilateral leg touch and kick interactions. No standard deviation bars included for preterm infants, as only 1 preterm infant was analyzed per month.

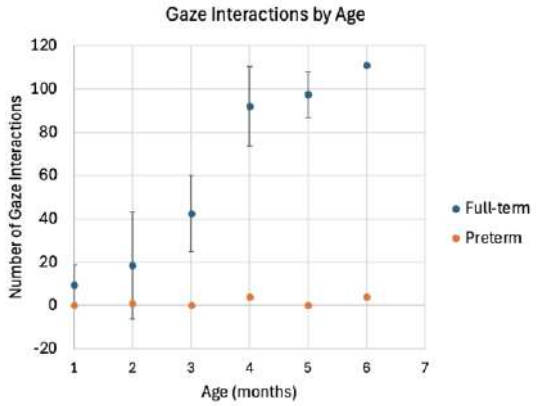

Figure 5: Mean gaze interactions (with standard deviation bars) with PANDA toy by infant group and age. No standard deviation bars included for preterm infants, as only 1 preterm infant was analyzed per month.

Figure 5 shows gaze interactions by infant group and age. Gaze interactions were coded regardless of whether the toy was engaged. The mean number of gaze interactions was 61.8 for full-term infants and 1.5 for preterm motor delayed infants. Out of arm, leg, and gaze interactions, gaze interactions emerged first in full-term infants - at one month. Gaze interactions increased with age for full-term infants, peaking at six months. The trend was not clear in the preterm infants with motor delay. Although gaze interactions emerged at two months, both the 3- and 5-month-old infants did not gaze at the toy.

V. Discussion

The PANDA gym successfully evoked motor and gaze interactions and the coding methodology successfully quantified differences between full-term and preterm infants – suggesting that it is sufficiently sensitive to metrics of age and motor delay. Building on the work of Kather et al. [13], infants in this study were correctly age-matched and differences were still seen among the two infant populations. The interaction codes were specific enough that all interactions seen in the videos were adequately described by one of the codes. Critically, coding in two-second intervals simplified the process of separating out interactions. However, the process of manual annotation is still time-consuming, and may benefit from the integration of automated object and gesture recognition tools from computer vision to scale to larger datasets.

Based on the literature on infant milestones, it was expected that as infants got older, their interactions with the toy would increase. In full-term infants, leg interactions emerged at three months. This is supported by the literature, which states that by three months old, infants should be able to touch toys with their feet [14]. Leg interactions peaked at five months, which was unexpected, given that the literature suggests interactions should continually increase as infants get older. However, this may be an artifact of the small sample size and high degree of inter-subject variability.

In full-term infants, arm interactions emerged at two months. This is about 1-2 months earlier than expected by the

literature, which expects infants to begin reaching for toys using their arms at around 3-4 months of age [14]. Additionally, "feet-reaching" typically precedes hand-reaching by a month or more [17], so the emergence of arm interactions before leg interactions was unexpected. However, typical infant milestones represent averages and the 50th percentile for age, so individual variation is expected. Additionally, involuntary interactions were not separated out into arm and leg interactions – if involuntary interactions were separated into upper and lower limb, it is expected that the high percentage of involuntary interactions seen at 1 and 2 months would be lower limb interactions. Similar to leg interactions, arm interactions peaked at five months, which was unexpected, as the literature expects interactions to continue increasing with age.

In full-term infants, gaze interactions emerged at one month. This is at least one month earlier than expected given the literature, which states that at two months old, typically developing infants should be able to follow large, highly contrasting objects such as toys with their eyes [14] and that purposeful gazing becomes more sophisticated around four to six months of age [18]. Preterm infants gazed at the toy with much less frequency than full-term infants.

Here we show that our coding methodology can yield insights into infant motor development using a small sample. However, due to the time-consuming nature of manual video coding, only 18 of the 90 infants were included in this case study. The limited sample size, and the use of only 1 preterm infant from each age group, limits a more robust analysis. Additionally, manual video coding is subject to an element of qualitative judgment and potential error, especially when quantifying gaze interactions. Despite the small sample size, the patterns observed are largely consistent with the literature, suggesting that the coding methods are suitable for quantifying infant/toy interactions if scalability is addressed.

VI. Conclusion

This study presents a novel methodology for coding infant interactions with a robotic toy. Going forward, the coding of involuntary interactions will be separated into upper and lower limb at a minimum, with the goal of eventually using the same 14 codes used for voluntary interactions for involuntary interactions. This revised coding methodology will be applied to the larger infant population in the study, and inter-rater reliability studies will be conducted to verify that the methodology is sufficiently standardized. Future work will focus on increasing scalability. State of the art approaches from computer vision, such as pre-trained vision transformers, are ideally suited to overcoming scalability limitations by automating the process of coding toy interactions. No direct comparison was made; however, we anticipate that manually coded labels could be used to train a supervised learning algorithm to automatically quantify infant interactions with the PANDA toy from video, thus providing a low-cost, efficient, and scalable method of evaluating infant motor development at home.

Acknowledgment

We would like to acknowledge study participants and their caregivers for their time and effort to participate in this research. We would also like to acknowledge the members of the Rehabilitation Robotics Lab PANDA Gym development team, the Children's Hospital of Philadelphia, and Dr. Prosser's clinical team including Noor Ruwaih for coordinating the data collection with infants. Additionally, we thank the University of Pennsylvania School of Engineering and Applied Science's First Year Exposure to Research in STEM program and Michaile Rainey for supporting undergraduate research.

***Abstract*— The goal of this study was to determine the feasibility of applying targeted force perturbations paired with spatiotemporal transcutaneous spinal cord stimulation during walking for improving balance in individuals post-stroke. Five individuals with chronic stroke (> 6 months) were recruited and completed 6 sessions (3 times/week) of balance training paired with spatiotemporal spinal cord stimulation. Balance was assessed pre, post 2 weeks of training, and follow-up, i.e., 2 weeks after the end of training. Results indicated that individuals post-stroke could tolerate the force perturbations applied to the pelvis paired with spatiotemporal spinal cord stimulation during walking. Further, individual post-stroke showed improvements in balance, assessed using the Dynamic Gait Index and Berg Balance Scale scores, after targeted force perturbation balance training paired with spatiotemporal spinal cord stimulation, although this was not significant due to the small sample size. Results from this study suggest that it was feasible to improve balance in individuals post-stroke using targeted pelvis force perturbations paired with spatiotemporal spinal cord stimulation during walking.**

Keywords*— *stroke, balance, spatiotemporal spinal cord stimulation, walking, lateral force perturbation.

I. INTRODUCTION

While clinical significance of falls in individuals post-stroke is widely acknowledged, current fall prevention programs are not very effective in preventing falls in many stroke survivors [1-3]. One of the possible reasons for this is that the motor skills obtained from current conventional balance interventions, such as voluntary stepping or perturbation-based standing balance training [4], may not be effectively transferred to most real-life fall circumstances, of which most occur during walking for community-dwelling stroke survivors [3]. The ability to execute a successful reactive protectivestepping is very crucial for balance recovery and avoiding falls [5], particularly when the magnitude of the perturbation is large [6]. However, many individuals post-stroke demonstrate impairments in reactive stepping, such as slow initiation, reduced step length and reduced foot clearance [7]. There is, therefore, a critical need to develop a new intervention approach to improve the ability of reactive stepping, particularly stepping of the paretic leg (as the majority of fallers landed sideways, toward the paretic side [8]), during dynamic activities, such as walking, which is expected to reduce falls in stroke survivors [9].

Perturbation-based balance training has been shown to reduce falls in healthy older adults [10], although the evidence of reducing falls in individuals post-stroke is still unclear [11, 12]. One of possible reasons may be due to the lack of focusing on improving key impairments of the paretic leg, e.g., the impairments in reactive stepping of the paretic leg during walking, particularly in the frontal plane. For instance, most current perturbation-based balance trainings are conducted during standing [13, 14] or focus on perturbations acting in the sagittal plane [15, 16], which may have limited transfers to balance control in the frontal plane [17].

On the other hand, neuromodulation, such as non-invasive direct current brain stimulation, has been used to improve the efficacy of gait training in individuals post-stroke, although there is still insufficient evidence to recommend this treatment [18]. Previous animal studies [19, 20] indicate that electrical epidural spinal cord stimulation may engage large myelinated fibers associated with proprioceptive and cutaneous feedback circuits, and the recruitment of these fibers may raise the excitability of spinal circuits [21] and activate central pattern generating networks [22, 23]. Clinical application of spinal epidural stimulation through continuous, non-modulated stimulation patterns has been used to improve walking in humans with spinal cord injury [22, 24, 25]. However, this continuous stimulation has two major limitations in the clinical application of spinal cord neuromodulation therapies [26]. First, the spatial location of electrical stimulation is confined to single spinal cord segments [22]. Second, the temporal structure of electrical stimulation is a non-modulated pattern that remains constant during locomotor execution regardless of the state of leg movement [22, 24]. Thus, while this continuous stimulation may increase the general excitability of the spinal circuits, it may

be less effective in addressing subject-specific deficits of gait through dynamic movement execution [27].

Results from previous studies suggest that the production of locomotion involves activation of spatiotemporal distributed motoneurons [28, 29], which are continuously adjusted through sensory feedback [30]. For individuals post-stroke, the disruption of descending pathways toward the paretic side may alter this task-dependent modulation of sensorimotor feedback circuits [31, 32]. Consequently, increasing the general excitability of the spinal cord through continuous stimulation may be insufficient to target the specific impairments of the paretic leg. Thus, electrical spinal neuromodulation that integrates spatial selectivity and temporal structure matching the natural dynamics of motoneuron activation may be more effective in improving motor performance of the paretic leg [26].

Clinical application of spatiotemporal epidural spinal electrical stimulation has shown improvements in walking function in people with spinal cord injury [33, 34]. Recent studies indicated that non-invasive transcutaneous spinal stimulation may activate the same neural structures as epidural spinal stimulation [35, 36]. In particular, results from previous studies suggested that multi-electrode configuration may improve muscle recruitment selectivity through non-invasive transcutaneous spinal cord stimulation [37]. Thus, there is a clear need to determine whether targeted force perturbations paired with spatiotemporal transcutaneous spinal cord stimulation during walking can improve reactive stepping of the paretic leg and result in improvements in balance in individuals post-stroke. The goal of this pilot study was to determine the feasibility of applying targeted force perturbations paired with spatiotemporal transcutaneous spinal cord stimulation during walking for improving balance in individuals post-stroke. We hypothesized that it would be feasible to apply controlled lateral perturbation forces to the pelvis during walking paired with spatiotemporal spinal cord stimulation to improve motor control of reactive paretic stepping, resulting in improvements in balance in individuals post-stroke.

II. Method

A. Participants

Five individuals post chronic stroke (> 6 months) were recruited in this pilot study (average age: 66.0 ± 7.0 years old; and average time post stroke: 11.2 ± 4.1 years, 1 female), see Table 1.

The inclusion criteria were: 1) 21-75 years old; 2) a single unilateral, supratentorial stroke of either ischemic or hemorrhagic etiology, confirmed by radiographic imaging; 3) weakness/paresis of the affected leg; and 4) ability to stand and walk (>10 m) without physical assistance and with the use of assistive devices or ankle-foot orthoses as needed.

Exclusion criteria were: 1) brainstem or cerebellar stroke; 2) a score of <24 on the Mini Mental State Examination [38]; 3) other neurological conditions, cardiorespiratory/metabolic disorders, or orthopedic conditions that affect ambulatory ability; 4) uncontrolled hypertension (systolic >200 mg Hg, diastolic >110 mm Hg); 5) botulinum toxin injection within the prior 6 months; 6) inability to tolerate 30 min of treadmill walking with sitting breaks. The Northwestern University Medical School Institutional Review Board approved all procedures and all participants signed an informed consent document before data collection.

B. Apparatus

A custom designed cable-driven robotic system, which was mounted over a treadmill (Woodway, Waukesha, WI, USA), was used to apply controlled lateral perturbations to the pelvis during treadmill walking (Figure 1), which has been reported previously [39]. In brief, the cable-driven robotic system was composed of 2 nylon-coated stainless-steel cables (in diameter 2mm) driven by 2 motors (AKM 43H, Kollmorgen, Radford, VA) through cable spools, which were mounted on an aluminum frame that was located at the two sides of the treadmill. In this study, we used only one pair of a motor and a cable spool at one side to apply controlled lateral perturbation forces to the pelvis toward the paretic side, depending on which side of each participant was affected.

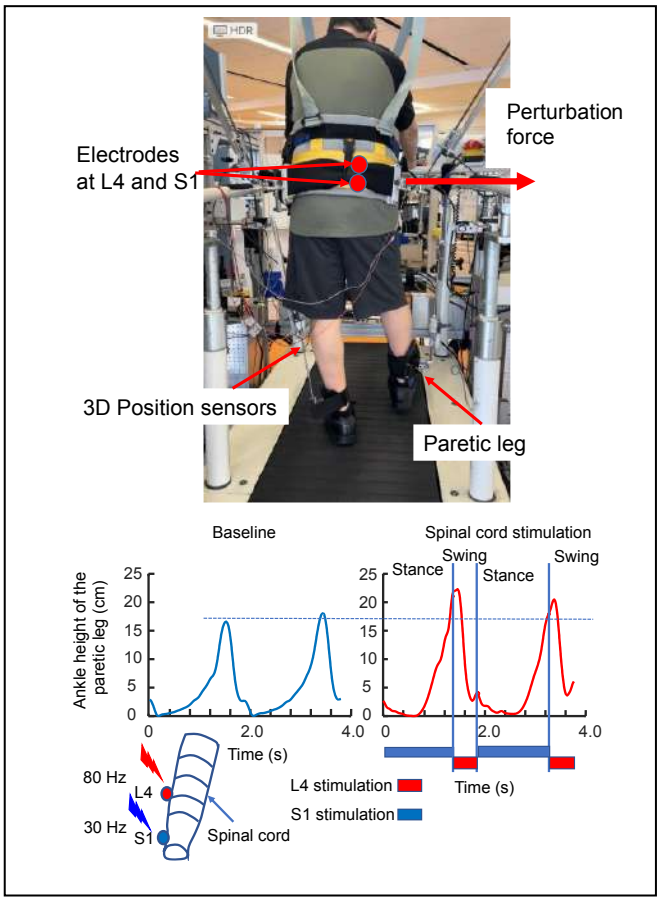

Fig. 1. Cable-driven robotic system paired with spatiotemporal transcutaneous spinal stimulation, which was applied to the L4 during swing phase of the paretic leg (80Hz) and to S1 during stance phase of the partic leg (30Hz). Ankle height of the paretic leg with spatiotemporal stimulation and without stimulation (baseline) during treadmill walking. Red curves indicate an increased step height of the paretic leg with the application of spatiotemporal spinal cord stimulation.

In addition, a set of customized 3-dimensional position sensors was attached to ankles through straps to collect ankle position signals, and another set of position sensors was attached

to the pelvis through a waist belt to measure pelvis position signals, see Fig 1. Specifically, each position sensor consisted of a detector rod and 3 potentiometers (one linear and two rotational potentiometers). One end of the rod was attached at the subject's ankle through a strap and the other end of the rod was attached to a fixed frame located at both sides of treadmill through a U joint. Two rotational potentiometers (P2201, Southborough, MA) were used to measure the angular displacement of the detector rod in the anterior-posterior and mediolateral directions. One linear potentiometer (SP-2, Celesco, Chatsworth, CA) was used to measure the length of telescopic detector rod. We used the positional signals from these 3 potentiometers to calculate the ankles and pelvis 3D trajectories. The robotic system was controlled by a custom-written program in LabVIEW (National Instrument, Austin, TX, USA) on a personal computer. The controller used ankle position signals to trigger the pelvis perturbations force at targeted phase of gait, i.e., starting at the early swing phase of the paretic leg for 300 ms.

Spatiotemporal transcutaneous spinal stimulation was delivered using a current stimulator (DS8R, Digitimer, UK), electrode selector, and a custom designed controller. The controller detected the gait events based on the ankle position signals, which were recorded using a set of custom designed 3D position sensors, and delivered the electrical currents to the electrodes at targeted phase of gait, which was controlled by a PC through a custom LabVIEW program. The ankle position signals were used to trigger electrical stimulations at targeted phase of gait (e.g., stance phase and swing phase of the paretic leg) through an electrode selector (D188, Digitimer, UK), which was controlled by a custom LabVIEW program. Two self-adhesive round electrodes (5cm in diameter, cathode) were placed ~2cm laterally from midline of spinal cord at the level of L4 and S1 spinous processes on the paretic leg side as active electrodes. In particular, we attached electrodes at ~2cm laterally toward the paretic side from the midline of the spinal cord in order to selectively target specific motoneurons pools [40]. Two round electrodes (5cm in diameter, anode) were placed on the anterior superior iliac spine on both sides as references.

TABLE I. PARTICIPANTS INFORMATION.

	Age	Sex	Time post stroke (y)	Weak side	Brace	AD
Sub 1	58	M	14	Right	AFO	RW
Sub 2	77	M	14	Left	None	None
Sub 3	66	M	12	Right	None	None
Sub 4	63	F	4	Left	AFO	Hemiwalker
Sub 5	66	M	12	Left	AFO	Tripod cane

AD: assistance device; RW: reverse Walker.

C. Experimental protocol

The participants trained 3 times/week for two weeks. They walked on a treadmill for 40 minutes excluding setup time although short sitting breaks were allowed during the training session in each visit. An overhead harness was used for protection only and no body weight support was provided. The treadmill speed was set at the subject's comfortable speed and was gradually increased during the course of training. Blood pressure and heart rate were monitored during training and were maintained below 220/110 mm Hg and 85% of age-predicated maximum heart rate, respectively.

The magnitude of the force was set at ~8% of body weight, which was adjusted depending on the tolerance of each subject and gradually increased during the course of training sessions. In order to make the perturbation force less predictable, the perturbation force was randomly applied in one step within every 5 steps of the paretic leg, which was determined based on our pilot study. The rating of perceived exertion (RPE) [41] was monitored during the course of training and the targeted RPE was 12 to 16.

We applied electrical stimulation on spinal cord at the level of L4 and S1 spinous processes during swing and stance phases of the paretic leg, respectively, to target leg flexor and extensor muscles, based on the results of previous epidural stimulation studies [34]. In particular, a higher frequency (e.g., 80 Hz) and a lower frequency (e.g., 30 Hz) of stimulation was applied during the swing phase and stance phase, targeting the paretic leg flexor and extensor muscles, respectively, as the motor neurons innervating these muscles exhibit distinct preferential activation frequencies, based on previous studies in animals [26] and in humans with spinal cord injury [34]. The electrical stimulations were filled with a carrier frequency of 9.5 kHz. The stimulation intensity was determined based on the tolerance of pain of each participant, with the average intensity of stimulation was 25.7±1.2 mA across participants. The stimulation intensity was reduced as needed if participant felt discomfortable.

Dynamic balance, the primary outcome measure, was assessed using Dynamic Gait Index (DGI) [42], Berg Balance Scale (BBS), and endurance (i.e., 6-minute walking distance), secondary outcome measures, were evaluated at pre and post 2 weeks of balance training, and follow up, i.e., 2 weeks after the end of training. DGI was used as the primary outcome measure because that scores have discrimination in the prediction of falls in stroke survivors and the probability that stroke survivors with a DGI score of $\leqslant$ 16.5 will experience a fall is 3.8 times higher than those with a DGI score of > 16.5.

D. Data analysis

The normality of outcome measures of interest was examined using Kolmogorov-Smirnov test. Given the data were not normally distributed, Kruskal-Wallis test was used to examine the changes of variables across three time points (pre, post and follow up) with significance noted at $p < 0.05$. Multiple comparisons were corrected for with Bonferroni correction, again with significance noted at $p < 0.05$. In addition, Cohen's d was used to calculate effect size, where 0.2 was considered a small effect, 0.5 a medium effect, and 0.8 a large effect [43].

III. RESULTS

Five participants completed all the training and assessment sessions with no dropout in this pilot study. All participants could tolerate the force perturbations applied to the pelvis and spinal cord electrical stimulation during walking. Further, as shown in Fig 2, the average DGI score increased from 12.6 ± 5.5, baseline, to 13.2 ± 5.3, post perturbations balance training

paired with spatiotemporal spinal cord stimulation, and further increased to 14.0 ± 4.7 at 2 weeks follow up test, the effect size d = 0.3, although this was not significant (Kruskal-Wallis ANOVA, $p > 0.05$, n = 5) due to small sample size. In addition, the average BBS score increased from 38.8 ± 12.7, baseline, to 40.8 ± 12.0, post balance training paired with spinal cord stimulation, and was 40.6 ± 11.7 at 2 weeks follow up test, the effect size d = 0.2, although this was not significant due to the small sample size (Kruskal-Wallis ANOVA, $p > 0.05$, n = 5). The 6 minutes walking distance increased from 187.1 ± 124.9 m, baseline, to 197.9 ± 130.9 m, post balance training, and was 193.7 ± 134.3 m at 2 weeks follow up test, the effect size was d = 0.1, and this was not significant ($p > 0.05$).

IV. Discussion

We have tested the feasibility of applying targeted lateral force perturbations paired with spatiotemporal spinal cord stimulation during walking for improving balance, particularly dynamic balance, in individuals post-stroke. We found that individuals post-stroke could tolerate the robotic perturbation force paired with spatiotemporal spinal cord electrical stimulation with the dropout rate of 0. We also found that individual post-stroke showed improvements in balance, which was assessed using the DGI and BBS scores, after force perturbation balance training paired with spatiotemporal spinal cord stimulation, although this was not significant due to the small sample size.

Given the impairments in motor control of the paretic leg and/or dyscoordination between the two legs often experienced by people with stroke, many individuals post-stroke show impairments in reactive stepping with the paretic leg [44]. Impairments in reactive stepping with the paretic leg may be one of key factors contributing to the falls in individuals post-stroke. In this study, the application of targeted perturbation forces might force individuals post-stroke to take a reactive stepping using the paretic leg during walking. Repetitive practice in this manner may lead to reinforcement of this stepping strategy, which is consistent with use-dependent synaptic plasticity [45].

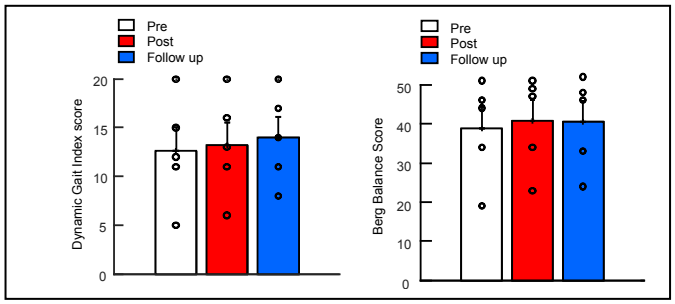

Fig. 2. Dynamic Gait Index (left column) scores and Berg Balance Scale (right column) per and post robotic balance training paired with non-invasive spatiotemporal spinal cord stimulation and follow up, i.e., 2 weeks after the end of training. Data shown are average of scores across participants (n = 5) and standard error.

In particular, the application of spatiotemporal spinal cord stimulation paired with targeted force perturbation balance training might facilitate the motor learning of reactive stepping with the paretic leg in individuals post-stroke. Specifically, in this study, electrical stimulation was applied at the L4 and S1 segments during swing phase and stance phase of the paretic leg, respectively, which might enhance afferents inputs of hip flexors and dorsiflexors during swing, and hip extensors and plantarflexors during stance, respectively. In particular, a higher stimulation frequency (i.e., 80 Hz) was applied during swing phase, and a lower stimulation frequency (i.e., 30 Hz) was applied during stance phase of the paretic leg, which may be more effective in recruiting flexors and extensors, respectively. The application of the spatiotemporal spinal cord stimulation, which may induce enhanced afferents inputs that are more consistent with the natural patterns of neural activity during walking, may have led to improved motor control of paretic leg in individuals post-stroke through use-dependent neural plasticity.

The results of this study need to be interpreted with caution due to the following limitations. First, while this study was a pilot feasibility study, the sample size was small. Further studies with a large cohort of participants are needed to obtain a confirmed conclusion. Second, we had no control group in this pilot study. We do not know whether this approach is more effective than the conventional balance training approaches in improving balance in individuals post-stroke. Further studies are needed to determine the effect of targeted pelvis force perturbations paired with spatiotemporal spinal cord stimulation through randomized controlled studies. Third, because the dosage of intervention was small, i.e., only 6 training sessions, the functional gains in balance were small. We expect to see greater functional gains in balance through a greater dosage of balance training. Fourth, the functional gains in balance in individuals post-stroke after the intervention might be due to the application of both repeated force perturbations and spatiotemporal spinal cord stimulation. Thus, further studies are needed to determine the functional gains in balance induced by the perturbation force and/or the spatiotemporal spinal cord stimulation during walking.

In conclusion, results from this study indicated that it was feasible to improve balance in individuals post-stroke using targeted force perturbations paired with spatiotemporal spinal cord stimulation during walking. Perturbation induced repeated practice of reactive stepping with paretic leg during walking when paired with spatiotemporal spinal cord stimulation might induce improvements in balance, particularly dynamic balance, in individuals post-stroke.

ACKNOWLEDGMENT

This was supported by NIH/NICHD, R01HD082216. We thank Mr. Jack Snodgrass' assistance in the development of the controller of spatiotemporal spinal cord electrical stimulation system.

***Abstract*—Each year, over 7 million stroke survivors experience upper limb dysfunction, often losing the ability to perform essential hand movements like finger extension and contraction for grasping. Exoskeletons offer a promising solution for rehabilitating gross hand function, providing controlled, repetitive movements and personalized exercises. However, existing models struggle with affordability, usability, and integration into daily life. This paper presents Recovr Glove, a cost-effective, user-friendly exoskeleton glove aimed at improving gross hand function recovery. Recovr features passive extension and active contraction mechanisms, adaptable to varying levels of spasticity. By capturing surface electromyography (sEMG) signals from the flexor digitorum profundus muscle, responsible for grasping, it enables cognitive control of hand movements. We evaluated the Recovr Glove across four parameters: grip strength, extension strength, contraction angle, and object grasping. In motor response testing, Recovr achieved 95% accuracy, with reliable rotation and an average delay of 0.49 seconds ± 0.41. During contraction tests, the grasp strength was an average of 55.21 ± 5.68 N. Extension testing, using a spring scale on each finger, showed an adjustable average force range of 0.1 to 5.5 N for the pinky and from 0.7 to 7.7 N for the thumb, depending on rubber band tension.**

***Index Terms*—Stroke Rehabilitation, Electromyography, Hand Spasticity**

I. Introduction

In the United States alone, there are over 7 million stroke survivors, and more than 80% experience significant loss of hand functionality [1]. This impairment often leads to a loss of independence, reduced quality of life, and increased financial strain on individuals and their families [2].

Early access to an effective rehabilitation regimen is crucial for maximizing the potential to regain hand function following a stroke [3]–[6]. Rehabilitation therapies, such as constraint-induced movement therapy, aim to restore motor skills through repetitive, targeted exercises. However, patients with moderate to severe impairments often face significant challenges in fully engaging with these therapies due to limited motor function [7]. These difficulties are further exacerbated by the high costs and time commitments associated with therapy. As a result, these barriers can lower adherence rates and hinder the overall effectiveness of rehabilitation [8].

Several devices on the market, including the SaeboGlove, SYREBO, Emovo Grasp, and Hand of Hope, have demonstrated efficacy in improving gross hand motor function [9]. In addition, academic innovations such as the FlexoGlove [10] and AirExGlove [11] focus on features like portability - allowing patients to move freely while wearing the device - and customizability - allowing users to modify glove features based on individual needs. Despite these advancements, current designs are often limited by a lack of tactile sensing, insufficient portability such as the inclusion of a tethered control system, high costs, and inadequate customizability (Table 1) [12]. These limitations hinder accessibility and reduce their effectiveness for daily living activities [13]. Additionally, many of the devices on the market, such as ExoFlex and AirExGlove do not aid in the reconstitution of the cognitive motor link due to the lack of direct muscle-controlled feedback and sensory input [14].

This paper introduces Recovr Glove, a customizable and cost-effective exoskeleton glove designed to address these deficiencies. Recovr integrates forearm surface electromyography (sEMG) signals to control hand grasping and releasing. By providing real-time sensory feedback to the user during movements, Recovr stimulates neural pathways that are crucial for motor control, promoting neuroplasticity. This process helps retrain the brain's motor-cognitive pathways, encouraging the re-establishment of functional connections and enabling the restoration of fine motor skills essential for activities of daily living [15] [16]. Concerns regarding the viability of sEMG signals in stroke survivors with limited muscle activity are addressed by studies demonstrating their effectiveness in rehabilitation and assistive technologies, even in cases of diminished muscle strength [17]–[19]. Our design leverages sensory-motor feedback loops to promote neuroplasticity and retrain motor-cognitive pathways, facilitating functional recovery and aiding activities of daily living (ADLs) [20].

II. Recovr Glove System Design

This section outlines the design architecture of the Recovr system, including customized mechanical features, sEMG signal acquisition and processing, software implementation, hardware integration, and attention to affordability in the overall design.

Recovr Glove only aids in gross grasping and extension motions of the hand and not individual finger control. The device is meant for patients who struggle with grasping motions where fine-tuned movements are typically only regained after the gross movements have been achieved [21]. The purpose

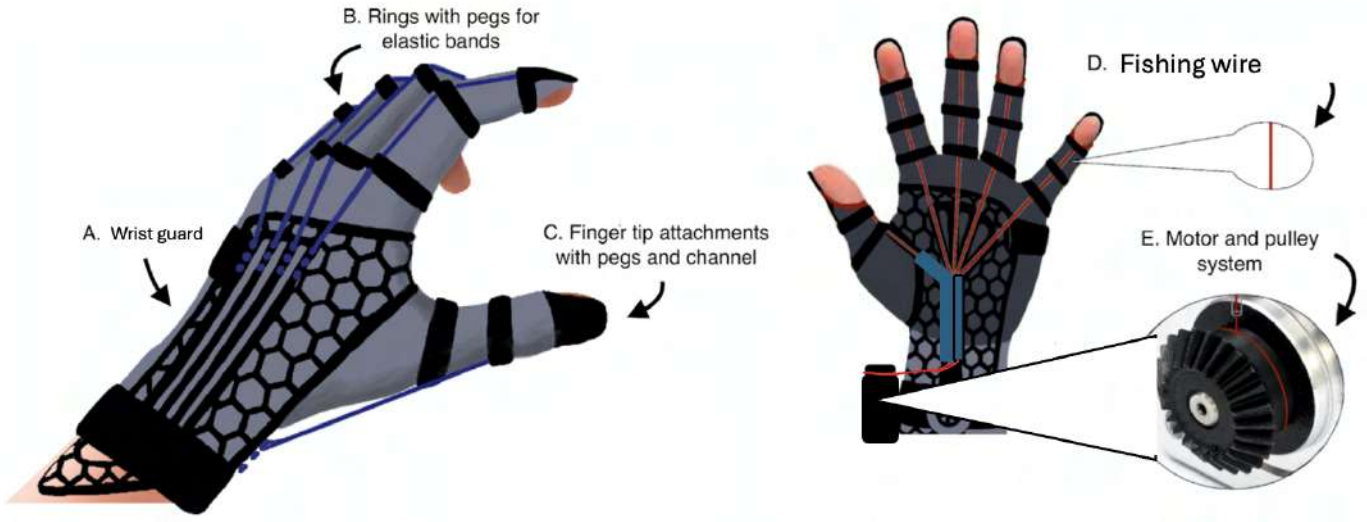

Figure 1: A) Removable wrist guard with adjustable straps, pegs for elastic band attachment, and channel for fishing wire. B) Rings with pegs sewn into gloves for reliable extension. Each ring has two components sewn together via elastic cords. C) Finger tip attachments with pegs for elastic bands. Contains a channel for fishing wire to loop through. D) Fishing wire for contraction. E) Pulley and motor system to control fishing wires for contraction or extension.

Table 1: Comparison of Hand Rehabilitation Solutions

Comparison of the prominent exoskeleton gloves on the market to Recovr Glove, evaluated across several key criteria.

*Price not listed.
**Utilizes MyoBand, which is priced at $199.99. This price does not include 3D printing and customization costs.

of the Recovr Glove is to both aid in rehabilitation through motor recovery and aid in everyday activities. Rehabilitation focuses on strengthening gross motor skills as a foundation for fine motor control, while the support function aims to assist individuals in performing routine tasks despite their motor impairments. Therefore, the Recovr Glove was designed for both comfort of use and sEMG integration for easy wear and effective retraining of the neuromotor connection [22]–[24].

A. Custom Mechanical Design

The mechanical design can be seen in Figure 1. It consists of a fabric glove with sewn-in rings, a 3D-printed PLA wrist guard, a pulley system, and a 3D-printed enclosure housing the electronics. The wrist guard is sized and molded to the user's hand during the manufacturing process. It utilizes a honeycomb structure to minimize weight while maintaining structural integrity. Adjustable elastic bands are secured to pegs on the back of the glove, allowing users to fine-tune resistance by looping the bands around the pegs. This supports gradual increases in resistance as hand extension improves. The fishing wire is threaded through the rings on the front of the glove and connected to an elastic band to create a dampening system, such that the elastic bands would snap before over-contraction. The fishing wires are actuated by a motor, actively controlling the contraction of all five phalanges.

A pulley cover is included to maintain a consistent fishing wire pathway and ensure user safety. The speed of the DC motor can be pre-configured to provide personalized contraction support. Additionally, two fabric straps were sewn onto the wrist guard design and hook-and-loop fasteners were attached to the straps. The electronics enclosure is approximately $6\times4\times4$ inches in size and incorporates a curved side to ensure comfort when belted around the user's hips (Figure 2). The entire product weighs approximately 2.13 pounds, making it lightweight and highly portable - ideal for supporting everyday tasks and facilitating rehabilitation.

B. sEMG Processing

We created our own sEMG filter circuit as it minimizes the cost significantly relative to commercially available sEMG

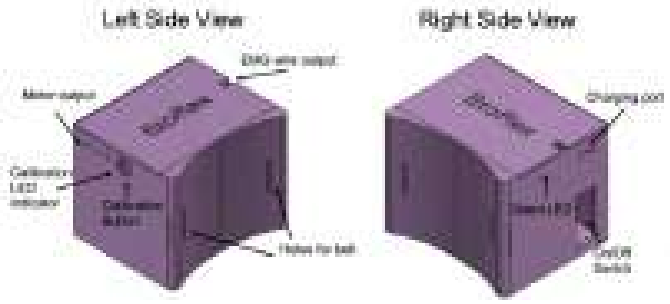

Figure 2: CAD of Electronics Enclosure

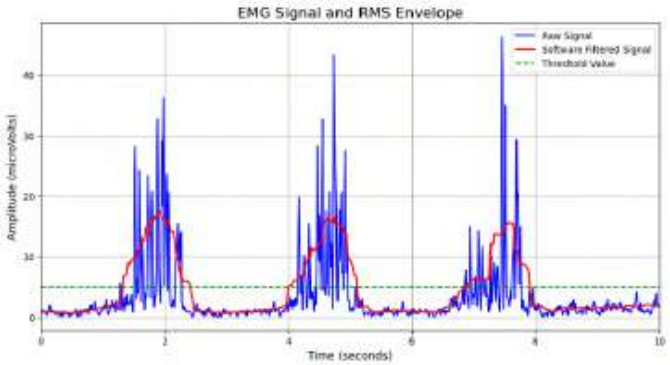

Figure 3: The hardware filtered sEMG signal (blue), recorded for 10 seconds, shows three distinct peaks, each representing a forearm flex. The red signal indicates post-software filtering with a 30-sample rolling average. When the red signal exceeds the green threshold, the motor triggers hand contraction; when it falls below, the motor releases the hand to its original position.

circuits. Raw sEMG signal was collected at a baud rate of 9600 and passed through a passive high-pass filter with a cutoff frequency of 0.16 Hz to eliminate any potential fluctuations caused by the DC component [25]. The signal then went through a differential amplifier, which both amplified the signal and converted the three-lead sEMG input into a two-lead output with respect to the ground signal. The signal was then passed through a buffer to prevent signal backflow, followed by a Sallen-Key bandpass filter designed to isolate frequencies between 50 Hz and 160 Hz [26]. Afterward, the signal was processed by a full-wave rectifier and finally passed through a non-inverting amplifier to further enhance its amplitude. Figure 3 showcases the unfiltered and filtered sEMG signal. The hardware and software processing did not create any noticeable delay in the signal response.

C. Software

The embedded software calculates a threshold by averaging sEMG data collected during the first five seconds of use, during which the forearm is slightly flexed. Therefore the threshold would be significantly above baseline for an individual but below the amplitude of an active flex. Subsequently, a rolling average of the EMG signal, computed over a window size of 30 samples (120ms), is continuously compared to this threshold. If the rolling average exceeds the threshold, the microcontroller drives the motor in one direction to initiate contraction; if it falls below the threshold, the motor is driven in the opposite direction to enable extension. If the encoder count exceeds a pre-configured value corresponding to a comfortable contraction or extension position, the motor halts to prevent over-contraction.

Table 2: Overall Recovr Glove Cost

Item	Cost ($)
Athletic Glove	4.53
Basic Electric Components	14.56
Basic Materials	1.80
EMG Electrode Leads + Stickers	30.99
ESP32C3 Microcontroller	8.00
Lipo Batteries	41.97
12V CB Motor + Encoder	38.90
3D Printed Components	7.97
Total Cost	**148.72**

D. Hardware

Recovr uses electrodes connected to the forearm to acquire sEMG signals, which are initially processed by passive and active filters before being sent to an ESP32C3 microcontroller. This microcontroller controls a brushed DC motor (12V, 5.5A stall current) with encoders that winds and unwinds fishing wire, actively regulating the contraction and passively allowing the rubber bands to control the extension of the hand. Zebco Omniflex Monofilament Fishing Line was used for its strength and flexibility.

E. Affordability

Recovr was designed with accessibility in mind, prioritizing both user comfort and affordability. A detailed cost breakdown of all the physical components of Recovr is provided in Table 2. Current gloves on the market typically exceed $300. To minimize costs, we incorporated a single motor, utilized 3D printing for cost-effective production, and minimized the use of expensive electronic components by employing software filtering. The bulk purchasing of many components could further reduce costs in mass production. However, it is important to note that this cost calculation does not include manufacturing expenses, which could significantly increase the final unit price.

III. Recovr Glove Performance Evaluation

This study focuses on evaluating the functionality and design of Recovr. As such, all experiments were conducted solely to assess the device's technical performance, usability, and effectiveness in simulated scenarios. The following methods were designed to validate its functionality and ensure its readiness for future clinical studies.

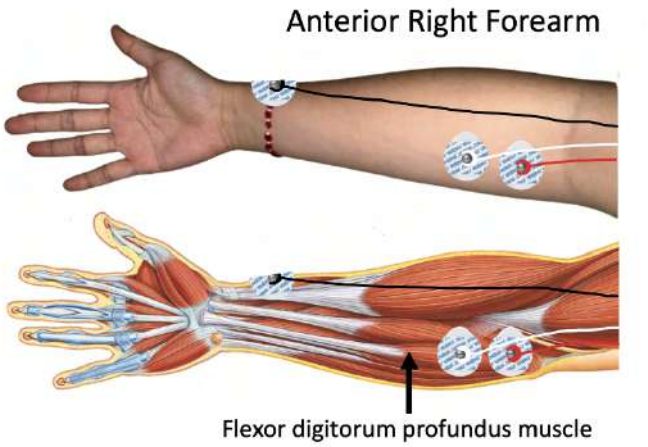

Figure 4: Positive and negative electrodes are placed on the flexor digitorum profundus muscle of the dominant arm to detect sEMG signals. Ground is placed towards the wrist for signal comparison.

Loops/Peg	Thumb	Index	Middle	Ring	Pinky
1	0.8	0.6	0.7	0.3	0.1
2	2.7	2.0	2.2	1.8	0.9
3	4.1	3.9	3.8	3.0	2.8
4	5.8	5.0	6.2	4.8	4.0
5	6.8	6.0	6.6	5.5	4.7
6	7.5	6.2	7.2	6.7	5.6

Table 3: Average Tensile Force Measurements (N) Per Phalange

A. Data Collection

Electrodes were placed on the dominant forearm (Figure 4) to read the sEMG signal and to control the motor. The Recovr glove was fitted to a wooden hand model for testing and evaluation. The device was turned on and the calibration was done by lightly flexing the forearm for approximately 5 seconds, indicated by a blinking LED easily visible to the user near the top of the box before testing began.

1) Grip Strength Testing: We evaluated Recovr's grip strength by contracting the glove around a pneumatic dynamometer squeeze bulb before using its surface area to convert from pressure to force. We conducted three contraction trials and measured an average grip force of approximately 55.21 ± 5.68 N, under full contraction. This makes sense as motor gearbox torque limit is 5 kg-cm with the pulley being a distance of 0.3 inches from the motor shaft.

2) Tensile Force Testing (N): We evaluated the tensile force exerted by the elastic bands wrapped around the hand to determine if they provide sufficient force to assist the fingers into an extended position. The evaluation involved measuring the force applied to a wooden finger as it was moved from a relaxed to a contracted position using a stationary spring scale.

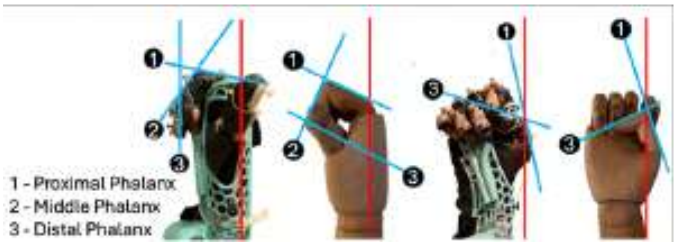

Figure 5: Side and front view of contraction angle of each finger comparing a hand model wearing Recovr to the model hand not wearing Recovr.

The tensile force of the elastic bands required to achieve finger contraction was recorded during testing.

Our measurements indicated that the elastic bands' applied forces ranged from approximately 0.1 N to 5.6 N for the pinky and 0.8 to 7.5 N for the thumb (Table 3).

3) Contraction Angle Analysis: We evaluated the constraints that Recovr may impose on hand movement by conducting an experiment where the wooden hand model was used to form a fist, both with and without wearing gloves. Images were taken from the front of the hand, and from the side (Figure 5). An online protractor was used to measure the angle of the index and thumb phalanx that dictate the shape of a fist relative to the back of the hand. It can be assumed that the other phalanges bend at similar angles as the index when forming a fist. These measurements were taken for both conditions—gloved and ungloved. The percentage difference between these measurements was then calculated. The thumb distal phalanx showed the most impairment, with a percent difference of 22.91%, whereas the index proximal phalanx showed the least at 8.45% (Table 4). This assessment shows that the glove does impair some joint contractions especially in the distal phalanx. Future iterations of the device therefore would need to be altered to allow for a higher range of motion. Although, it can be noted that the wooden glove model is not entirely accurate to a real hand's anatomy and therefore the results are only an indication of actual performance.

	Proximal Phalanx	Middle Phalanx	Distal Phalanx
Index			
With glove	74	144	180
Without glove	68	158	221
Percent Difference	8.45%	9.27%	20.45%
Thumb			
With glove	14	-	85
Without glove	17	-	107
Percent Difference	19.35%	-	22.91%

Table 4: Joint angles (in degrees) for index and thumb with and without glove using the wooden hand model.

4) Object Grasping: The glove with the wooden hand model was activated via sEMG to grasp and lift six distinct objects vertically: a can, a wire stripper, a multimeter, a

(a) Toothbrush (b) Canned Drink (c) Tennis Ball

(d) AirPods (e) Candy Container (f) Scissor

Figure 6: Object grasping assessment with a variety of objects that one may encounter in daily life.

toothbrush, a cube, and an AirPods case (Figure 6). These objects were deliberately selected to represent a diverse range of shapes from cylinders to spheres to irregular shapes as well as a range of sizes in order to reflect the variety of items individuals typically encounter in daily life. The model hand successfully grasped and lifted each object, maintaining a secure hold at various heights without the objects falling.

5) Motor Response Accuracy: The motor response accuracy was evaluated by instructing when to initiate and stop flexion. A total of 30 trials were conducted with the hand model. These sessions were recorded on camera to measure the latency between the onset of the sEMG signal and the activation of the motor for contraction through post analysis of the videos recorded at 30 fps and converted to seconds. The analysis indicated an average delay of 0.49 ± 0.41 seconds. Additionally, the motor reliably halts upon reaching the pre-configured contraction or extension position. However, in some instances, motor noise caused initial movement in the opposite direction before correcting itself, resulting in 95% accuracy for the motor moving in the intended direction initially.

IV. Discussion

The evaluation of Recovr demonstrates its potential as an effective assistive and rehabilitative device while identifying areas for refinement. The design incorporates key features that aim to balance adaptability, functionality, and user safety. This study provides a systematic assessment of Recovr's capabilities and limitations, offering insights into its current performance and areas for future development.

Recovr's ability to adjust the intensity of grip strength is a critical feature for user adaptability. In our grip strength testing, we observed that Recovr produced an average grip force of approximately 55.21 ± 5.68 N during full contraction. This is more than the maximum force of 20N to sufficiently grasp day-to-day objects for vertical lifting [27], [28].

Moreover, the tensile forces exerted by the elastic bands further highlight Recovr's customizability. By adjusting elastic tension, the device achieved a range of forces from 0.1 to 7.5 N per finger, with potential for higher forces through the use of high-tension elastic bands. This range is consistent with external research, which suggests that a total force between 3.4 N and 12.6 N may be necessary to extend the fingers, depending on the user's level of spasticity [29]. These results demonstrate that the elastic bands are capable of providing adequate assistance for finger extension. This adaptability enables the device to be tailored to individual user needs, including those with spastic clenched fist deformity, where increased resistance must be overcome to facilitate functional hand opening and movement [30].

Contraction angle analysis revealed minimal movement restrictions imposed by Recovr, where the overall limitation was less than 30% for all fingers when not wearing the glove vs. wearing the glove. Although the wooden hand model may have restrictions as previously mentioned, these restrictions did not impede basic grasping tasks, and thus indicates that the glove does not severely limit hand movement and is effective in gross function rehabilitation. Although the performance could be improved with thinner rings that still maintain structural integrity.

The ability to maintain functional grasping, despite minor

movement restrictions, suggests that Recovr's design can be adjusted to provide either increased support for users with severe hand impairments or greater flexibility for those with higher levels of hand mobility. Additionally, Recovr is capable of accommodating a variety of object shapes and sizes. This adaptability is particularly relevant in rehabilitation contexts, where patients often progress through different stages requiring varying levels of assistance.

Further developments may also include obtaining regulatory approval for clinical testing on stroke rehabilitation patients, addressing feedback from subjects and improving motor response. We believe these implementations would not increase costs significantly, if at all.

V. Conclusion

Recovr Glove offers a promising solution for stroke rehabilitation by integrating surface electromyography (sEMG) control with both passive extension and active contraction mechanisms. Our design allows for customization of both fit and support level, making it adaptable to varying degrees of spasticity. Recovr is portable, and user-friendly, ensuring comfort and ease of use during daily activities. Its affordability potential for personalized therapy make it a promising tool for improving hand function and quality of life in stroke survivors. In our preliminary characterization of Recovr, we found that the glove has the ability to effectively support both hand contraction and extension during gross grasping movements. The lack of testing on post-stroke individuals highlights the need for further evaluation, ideally through long-term use by stroke survivors, to draw more robust conclusions about the glove's rehabilitative effectiveness. We plan to conduct additional clinical testing with post-stroke individuals to refine its performance in real-world rehabilitation settings.

ACKNOWLEDGMENT

We want to thank the Bioengineering Department and the George H. Stephenson Foundation Educational Laboratory & Bio-MakerSpace at the University of Pennsylvania for funding this project and providing endless support.

Digital Design Workflow for Individualized 2-DOF Ankle Exoskeletons

Hunter M. Schmidt, Andy Li, Aytac Teker, Mariana H. Rocha, Biruk A. Gebre,
Karen J. Nolan, Kishore Pochiraju and Damiano Zanotto

***Abstract*— Gait rehabilitation programs aid individuals recovering from brain injury or severe lower-leg trauma. While robotic exoskeletons may offer advantages over traditional exercise-based interventions, their high cost and lack of personalized fit limit their clinical utility. In this paper, we present a new efficient design workflow for individualized 2-DOF ankle exoskeletons. The anatomical orientations of the talocrural and subtalar joints are estimated by utilizing a functional calibration procedure and then embedded and implemented into the ankle exoskeleton. The exoskeleton is fabricated using affordable additive manufacturing processes to conform to the user's leg morphology. This creates a personalized design that encapsulates the envelope of the ankle joint complex motion. By achieving this without the need for kinematic redundancy, we aim at maintaining a lightweight design with reduced mechanical complexity. Early tests with two healthy individuals indicate the feasibility of the proposed approach.**

***Index Terms*— Personalized Ankle Exoskeleton, Robot-Assisted Gait Training, Functional Calibration.**

I. Introduction

The ankle is capable of motion across all three planes (frontal, sagittal, transverse) of the body. On top of this triplanar motion, the joint axes of the ankle are very complex, spanning two non-orthogonal articulations (talocrural and subtalar) [1]. There is currently no consensus on how to identify the orientation of the talocrural and subtalar joints in a non-invasive manner. Additionally, the talocrural joint has been shown to have high interpersonal variability [2]. These characteristics of the ankle joint contribute to the difficulty of creating a robotic orthosis that does not inhibit the ankle's range of motion. Conventional "one-size-fits-all" powered ankle-foot orthoses (AFOs) and ankle exoskeletons can cause discomfort due to excessive rubbing against the wearer's skin. This excessive movement of the exoskeleton relative to the patient's body is caused by misalignment between the exoskeleton joint axis and the anatomical joint axis [3], [4]. One of the primary complaints documented with patient satisfactory surveys regarding AFOs is that they are not comfortable [5]. This may cause the patient to refrain from wearing their AFO. Therefore, it is critical to prioritize user comfort when wearing the AFO and to minimize the AFO's affect of altering the ankle's natural motion during walking tasks.

Two main approaches have been introduced in recent years for reducing misalignments: soft exosuits and multi-degree-of-freedom (DOF) exoskeletons. Soft exosuits are a relatively new addition to the robotic orthosis field. These devices assist two or more limbs without rigidly connecting to them. Hence, they do not introduce misalignment because movement is constrained solely by the anatomical joint. However, the anatomical joint must bear all the forces and torques applied by the device, which limits the magnitude of forces and torques that the exosuit can exert. Most existing ankle exosuits, such as the design by Awad, Bae, and colleagues, are single-DOF devices [6], [7]. Over a decade ago, Park and colleagues introduced the first two-DOF, pneumatically actuated ankle exosuit [8]. However, their innovative design was tethered and its use was limited to ankle mobilization exercises. More recently, Xia *et al.* developed a soft, lightweight ankle exosuit capable of actuating the ankle joint in both the sagittal and frontal planes [9]. This design consists solely of a foot and calf brace. While it demonstrated success in reducing drop foot and stabilizing ankle inversion and eversion, it was tested only at a slow walking speed of 0.7 m/s. Zhang *et al.* designed a two-DOF soft ankle exosuit that includes a foot brace, calf brace, and waist strap [10]. This device was tested primarily during seated ankle movements, with limited testing conducted during walking.

Multi-DOF ankle exoskeletons include two-DOF devices that use the additional joint to better accommodate the range of motion of the ankle, and three-DOF devices wherein kinematic redundancy is leveraged to compensate for joint misalignment between the orthosis axes and the human joints. Several two-DOF powered AFOs have been proposed in attempt to match the two anatomical joints of the ankle. Carberry *et al.* [11] created a symmetric powered exoskeleton with two-DOFs. Elery *et al.* [12] created a spring-powered, lateral, two-DOF AFO. Both designs involve two orthogonal joints for ankle rotation on the sagittal and frontal planes. This allows for an increased range of motion compared with traditional single-DOF AFOs, but prevents foot rotations on the transverse plane. Agrawal *et al.* [13] created a two-DOF AFO with the talocrural and subtalar joints oriented based on the average orientations of the anatomical joints [1]. While this subject-agnostic approach improved the ranges of motion about both joints, large inter-subject variability might restrict its applicability [3]. The design was also relatively bulky, which may negatively impact the wearer's natural gait [14].

H. M. Schmidt, A. Li, and D. Zanotto (dzanotto@stevens.edu) are with the WRS Lab., Stevens Inst. of Technology, Hoboken, NJ 07030, USA.

M. H. Rocha, A. Teker, B. A. Gebre, and K. Pochiraju are with the PROOF Lab., Stevens Inst. of Technology, Hoboken, NJ 07030, USA.

K. J. Nolan is with Human Performance and Engineering Research, Kessler Foundation, West Orange, NJ 07052, USA and Rutgers-NJMS, Newark, NJ 07103, USA.

Similarly, Lee *et al.* [15] created a two-DOF AFO with both joints aligned with the average anatomical joint orientation. Here, a poly-centric linkage joint was placed at the talocrural exoskeleton joint. This aligns the talocrural joint very well, but can make it difficult to actuate this joint due to its increased mechanical complexity. The subtalar joint is also still not aligned with the anatomical joint.

Dežman *et al.* [16] introduced a multi-DOF exoskeleton with three DOFs to accommodate the complex nature of the ankle joint. The redundant design effectively captures the full range of motion of the ankle joint, including compensation for the movement of the ankle joint center of rotation. Notably, it is one of the few designs validated for walking tasks beyond straight-line walking. This is critical for the final phases of rehabilitation to allow for a more seamless transition back into daily life. Although the redundant AFO is effective in mitigating misalignment between the human leg and the orthosis, it increases the mechanical complexity of the AFO, as well as its distal mass, thereby increasing the inertia reflected at the hip joint, which may hamper the wearer's natural gait patterns [14].

In this paper, we introduce an efficient design method for generating fully-constrained, two-DOF personalized ankle exoskeletons. The resulting design (Fig. 1) features two joints, with their alignment calibrated to the average orientations of the wearer's own talocrural and subtalar axes, estimated during functional movements. Compared to a traditional single-DOF design, we show that this approach substantially mitigates misalignment when performing in-place movements and ambulatory tasks, though slight residual misalignment persists due to the inherent movement of the ankle joint center of rotation. To develop this design, the orientation of the two joints on the exoskeleton must be personalized to the user. To this end, we modified the functional calibration technique first introduced by van den Bogert *et al.* [17] and enhanced by Leitch *et al.* [18], to find the orientation of the wearer's anatomical joint axes. The estimated joint axes are then fed into an automated design workflow recently introduced by our team at Stevens Institute of Technology, which generates a subject-tailored AFO model from 3D scans of the wearer's lower leg [19], [20]. The AFO is then fabricated using affordable additive manufacturing processes. To validate the proposed design method, we carried out preliminary tests with healthy individuals who performed several motor tasks using unpowered AFOs.

The remainder of this paper is organized as follows: Section II describes the functional calibration methods used to obtain the subject-specific joint orientations. Section III describes the design workflow that generates personalized Ankle Units. Section IV details the process of fabricating the AFO. Section V describe the experimental validation for preliminary testing of the non-actuated, personalized two-DOF AFO while Section VI summarizes the results from these tests. Lastly, the paper is concluded in Section VII.

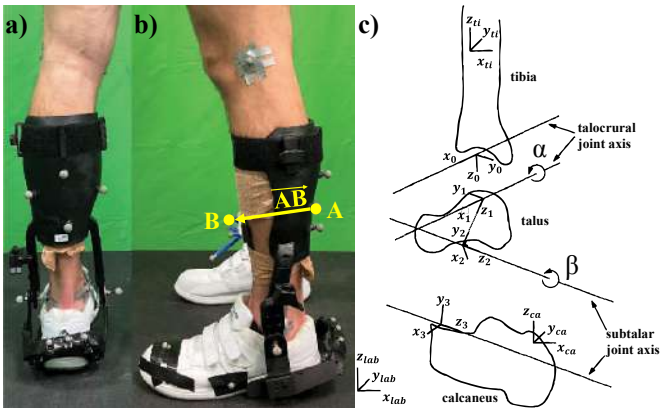

Fig. 1. **(a-b)** Posterior and lateral views of individualized 2-DOF ankle exoskeleton and the marker setup used for validation. **(c)** Twelve-parameter kinematic model of the ankle joint complex (adapted from [17]), with dorsiflexion-plantarflexion (D-P) and inversion-eversion (I-E) rotations labeled as α and β, respectively. This model was used for the functional calibration of the D-P and I-E axes.

II. Ankle Joint Functional Calibration

A. Anatomy of the Ankle Joint Complex

The ankle joint can be modeled by three rigid bodies connected by two non-orthogonal hinge joints (Fig. 1-c). The tibia (shank) is connected to the talus by the talocrural joint. This joint is primarily responsible for the dorsiflexion-plantarflexion (D-P) movement. Due to the orientation of the talocrural joint, it also enables motion across the other biological planes, however this motion is deemed to be negligible compared to the D-P motion [1]. The subtalar joint connects the talus and the calcaneus and is responsible for the coupled motion of inversion-eversion (I-E) and abduction-adduction of the foot. Similarly, this has a small component of D-P motion, but it is also deemed negligible [1].

B. Related Work on Functional Calibration

Functional calibration techniques enable the accurate localization of anatomical joints through sequences of single-axis motions [21], [22]. The functional calibration technique utilized in this work builds upon the method introduced by van den Bogert *et al.* [17]. This method utilizes the ankle joint complex model described in Sec. II-A, wherein the distances and orientations between the shank, the two joints, and the foot are described by a twelve-parameter kinematic model using the Denavit-Hartenberg (DH) convention. For calibration, subjects were instructed to raise their foot while keeping their leg straight, and performed several motions across the range of the D-P and I-E joints [17]. A least-squares optimization was used to find the model parameters, with the initial guess based on the location of the malleoli [17]. While this method produced repeatable results for a single subject, the estimated orientations of the D-P and I-E axes did not match across subjects, highlighting the need for subject-specific models.

Leitch *et al.* expanded upon van den Bogert's method by incorporating additional functional movements into the model, beyond the foot-raised motions, and by performing

walking tasks to validate the model [18]. The additional functional movements included tasks where the subject stood with their foot "planted" on the floor [18]. They also determined the optimal locations for the reflective markers on the shank and the shoe that resulted in the best model fit. While their results confirmed high inter-subject variability in the D-P and I-E axes, emphasizing the need for subject-specific calibration, they also showed that the difference in model fit between the foot-raised and foot-planted calibrations, as evaluated on the walking dataset, were minimal, concluding that both could be used.

C. Modified Functional Calibration Method

The functional calibration method summarized in Sec. II-B was adapted to align with the goal of developing a new personalized two-DOF AFO prototype. Data was collected using an optical motion capture system (Vero 2.2, Vicon Motion Systems, Oxford, U.K.) with 9 cameras, and a split-belt instrumented treadmill (Bertec, Columbus, OH). Four reflective markers on the shank and four on the shoe were placed as in [18] (Fig. 1-a,b). Additionally, two markers were placed at the knee (lateral and medial femoral condyles) and two were placed at the ankle (medial and lateral malleoli) to enable the integration of the results from the functional calibration procedure with the automated AFO design workflow described in Sec. III. Subjects performed nine *foot-raised* and seven *foot-planted* ankle motions, similar to [18], with each motion being repeated three times. The foot-raised motions were dorsiflexion and plantarflexion with the foot in neutral, inverted, and everted positions followed by inversion and eversion with the foot in neutral, dorsiflexed, half-plantarflexed, and full-plantarflexed positions and lastly circular motion in the clockwise and counter-clockwise directions. The foot-planted motions were calf raises with the foot neutral, inverted, and everted followed by quarter squats with the foot neutral, inverted, and everted and lastly swaying side to side. Subsequently, subjects walked for 90 seconds on the treadmill at 1 m/s.

A genetic algorithm (GA) was utilized in place of the least-squares method used in [17], [18] to find the optimal set of twelve DH model parameters (Fig. 1-c) based on the data collected from the foot-raised and foot-planted motions. GA is an evolutionary algorithm that employs heuristic search strategies to solve complex global optimization problems, even in the presence of multiple local minima, without requiring gradient information. The optimization procedure was conducted on a 4.5 GHz AMD Ryzen Threadripper PRO 5975WX with 32 cores, using the `ga` function from MATLAB (The Mathworks Inc., Natick, MA). Appropriate upper and lower bounds were set on each of the twelve DH parameters to constrain the search range to anatomically meaningful values. Additionally, the following GA settings were used, based on preliminary tests: max generations - 3000, population size - 800, function tolerance - 10^{-6}, max stall generations - 60, elite count 40, cross over fraction - 0.9. In line with [17], [18], the difference between the measured coordinates of each foot marker and the corresponding coordinates estimated by the DH model was computed for each foot marker, at each timestamp. The root-mean-square (RMS) difference between measured and predicted coordinates was then selected as the cost function for GA.

III. Personalized Design Workflow

The personalized AFO design workflow is based on shape/size information obtained from a 3D scan of the wearer's leg. It builds upon our previous work in [20], but integrates calibrated D-P and I-E axes derived from the procedure described in Sec. II-C. After the user completes the functional calibration movements, the shank and shoe markers are removed, so that a 3D scan can be captured of the lower leg in neutral pose, with only two markers on the femoral condyles and two on the malleoli. Those four markers serve as reference points for the AFO design, and to locate the calibrated D-P and I-E axes in the coordinate frame of the AFO model.

Similar to [20], the workflow uses five tools implemented in Python and Open3D to derive the AFO design directly from the 3D scan, with minimal manual input (Fig. 2). First, the calibrated D-P axis is imported into Open3D, and virtual markers are added onto the medial and lateral intersections between the calibrated D-P axis and the surface of the user's leg as determined from the point cloud. The *marker detector* identifies the position of the femoral condyles markers and defines anatomical axes based on those two markers and the virtual D-P markers. The *mapper* extracts from the point cloud the portion of the calf surface that is relevant to the design of the AFO shank bracket. The *mesher* tool uses the Poisson Reconstruction Algorithm to produce a triangle mesh from the point cloud. The *slicer* computes a set of closed curves by slicing the mesh with a set of planes orthogonal to the longitudinal axis of the shank and applying a desired thickness determined by strength and kinematic constraints. Next, the *solid generator* creates a 3D object by connecting the contour curves with triangles. This procedure creates a personalized shank bracket that fits the user's calf precisely and aligns with the calibrated D-P axis. More details about the five tools can be found in [20].

The shoe bracket assembly, which includes a gimbal and a main shoe bracket anchored on the user's shoe (Fig. 2), is created following a similar approach. First, the calibrated I-E axis is imported into the model, Next, medial and lateral dropdown links are added to connect the shank bracket to the shoe bracket assembly. These dropdown links allow the shoe bracket assembly to rotate with respect to the shank link about the calibrated D-P axis. The distal ends of the dropdown links are rigidly connected to the gimbal. A curved rail-slider mechanism connects the gimbal to the main shoe bracket, allowing for rotations of the latter about the I-E axis. This mechanism was chosen to avoid a physical joint lying directly on the I-E axis, i.e., above the dorsal foot or posterior to the calcaneous. The posterior location is undesirable due to potential interferences with the ground at initial contacts (heel strikes). The dorsal location results

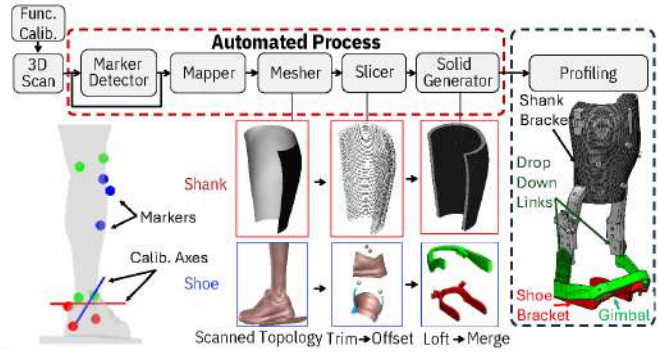

Fig. 2. Digital design workflow to generate personalized shank and shoe brackets for the two-DOF AFO, from a 3D point cloud augmented with the D-P and I-E axes extimated via functional calibration.

Fig. 3. Personalized two-DOF AFO prototype: sagittal plane (top) and frontal plane (bottom) motions.

in cumbersome designs and makes it harder to don/doff the AFO [13]. Conversely, the gimbal-like design allows most AFO components to be located medially and laterally to the hindfoot, enabling rotation about the I-E axis without compromising the ease of donning and doffing the AFO.

IV. AFO Fabrication

Two passive (non-actuated) AFOs were fabricated to evaluate the feasibility of the calibration method and the personalized design workflow (Fig. 3). The two test subjects were healthy male adults in their early-to-mid twenties. The study was approved by the U.S. Army Office of Human Research Oversight (OHRO) under protocol E03214.1a-1, and both participants provided written informed consent. Personalized shank and shoe bracket assemblies were produced using carbon fiber-PLA (CF-PLA) with fused deposition modeling (FDM) 3D printing technology, resulting in a total weight of 0.7 kg for the entire two-DOF AFO structure. In a prior study [23], we demonstrated that the AFO components have a substantial safety factor against anticipated compressive loads. A torque wrench was used to apply simulated D-P assistive torques to the assembly, while the AFO shank was secured to a 3D printed model of the subject's leg. The AFO assembly failed above 60 Nm [23], significantly exceeding the maximum assistive torque of 18 Nm [20]. A 3-mm soft foam layer, contoured to match the inner curvature of the shank via laser-cutting technology, was positioned as a cushioning interface between the shank module and the wearer's skin. The shank was secured to the wearer's shinbone with a wide Velcro strap to ensure comfort.

The shoe bracket assembly, entirely fabricated from CF-PLA, connects the gimbal to the main shoe bracket through a curved rail-slider mechanism. The rail piece comprises two curved sub-rails with identical circular cross-sections, offset from each other to enhance stiffness. The slider piece features two hooks designed with tolerances to snap into place on the rail and slide smoothly over the circular sub-rails during use. Silicone-based lubricant was applied between the hooks and the rails to minimize friction. This specific lubricant was selected for its effectiveness and its non-irritating properties on the skin. For evaluation purposes, a locking mechanism was incorporated into each slider-rail sub-assembly. This mechanism allows a bolt to be inserted into both components, creating a rigid connection between the gimbal and the main shoe bracket and thereby preventing relative I-E rotations between the two pieces.

V. Experimental Validation

For both study participants, the accuracy of the functional calibration method was quantified as the RMS difference between the measured and predicted coordinates of the foot markers during the 90-second walking task collected during the functional calibration procedure (but not used for calibration).

Additional tests were conducted to evaluate the personalized two-DOF AFO design. To this end, each participant was asked to perform two types of motion tasks: a set of 9 foot-raised ankle motions (two repetitions each), identical to the functional calibration movements described in [17], followed by a 90-second treadmill walking bout at 1 m/s. These tasks were repeated under two conditions: with the AFO having a locked I-E axis (1DOF-AFO), and with the AFO having both D-P and I-E axes enabled (2DOF-AFO). During these tests, reflective markers were placed on the AFO and on the participant's lower leg and shoe, as shown in Fig. 1-a,b. These markers were used to evaluate the ranges of motion about the D-P and I-E axes, as well as the relative displacements between the AFO structure and the wearer's leg. D-P and I-E ranges of motions were quantified using the calibrated axes for each subject. Relative displacements between the AFO structure and the human leg were evaluated in terms of maximum percent changes in the distance between markers attached to the AFO shank bracket and the human lower leg (i.e., markers A and B in Fig. 1-b), as described by Langlois *et al.* [24]. Compared to the 1DOF-AFO condition, we hypothesized that the 2DOF-AFO would enable extended D-P and I-E ranges of motion. Additionally, we hypothesize that the 1DOF-AFO condition would result in larger relative displacements, indicative of misalignment between AFO joints and human articulation [24].

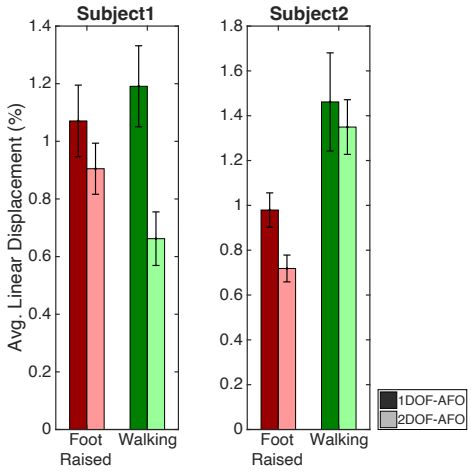

Fig. 4. Relative displacements between the AFO structure and the human leg during foot-raised tasks and treadmill walking task, under the 1DOF-AFO and 2DOF-AFO conditions, averaged across all repetitions/gait cycles. Error bars indicate ±1SE.

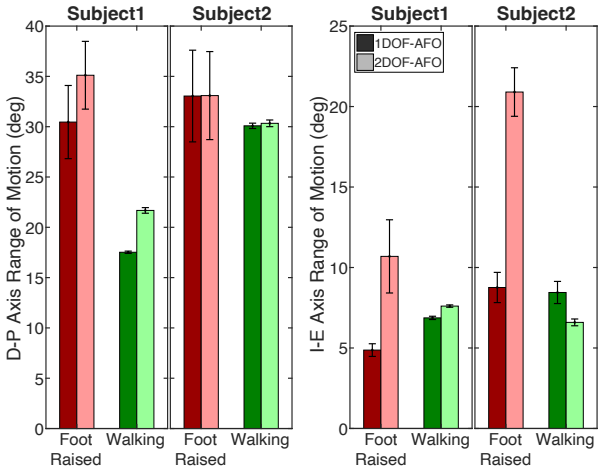

Fig. 5. Ranges of motion about D-P (left) and I-E (right) axes during foot-raised tasks and treadmill walking task, under the 1DOF-AFO and 2DOF-AFO conditions, averaged across all repetitions/gait cycles. Error bars indicate ±1SE.

VI. Results

A. Evaluation of Functional Calibration Method

To confirm convergence of the GA to a global optimum, the optimization procedure was run three times for each study participant. It took approximately 45 minutes for the optimization procedure to converge. Variations in each of the estimated DH parameters across all repetitions never exceeded ±0.25 rad and ±7.5 mm for angular and linear parameters, respectively, with over half remaining within ±0.15 rad and ±2.5 mm. These relatively small variations indicated that the method can converge in a single run – an evident advantage of the proposed GA-based approach over previous implementations that relied on non-linear least-squares optimization [17], [18], which is prone to falling into local minima and thus requires careful trial-and-error tuning [18]. Residuals (evaluated on the calibration dataset) were within ±0.3 mm for all 12 DH parameters, in line with previous works [17], [18]. The RMS difference between measured and predicted coordinates was 2.77 mm and 3.23 mm for the two participants, again aligned with previous works [18].

Figure 4 indicates the relative displacements between the AFO structure and the human leg during foot-raised tasks and treadmill walking tasks. For both participants, there was a noticeable reduction in these relative displacements when both DOFs were enabled (2DOF-AFO condition), indicating better fit.

Figures 5 illustrates the range of motion (ROM) of the ankle measured about the D-P and I-E axes during foot-raised tasks and treadmill walking tasks. The 2DOF-AFO configuration consistently enabled larger ROM during foot-raising tasks across individuals, though differences in D-P ROM between the two configurations were minimal for the second subject. The discrepancies in the I-E ROM was likely due to anatomical inter-subject variability. This finding suggests that the personalized two-DOF AFO design effectively encapsulates more of the range of motion of the ankle joint complex compared to the single-DOF configuration. For the treadmill walking task, the 2DOF-AFO condition resulted in increased D-P and I-E ROM for subject 1, while subject 2 exhibited a slight increase in D-P ROM and a noticeable decrease in I-E ROM. This discrepancy might be attributed to the nature of the walking task, which does not require significant ankle motion in the frontal plane.

VII. Discussion and Conclusion

In this paper, we introduced a novel design workflow for a personalized two-DOF AFO with both joints aligned with the anatomical D-P and I-E joints of the user. By building off of previous functional calibration algorithms, we developed an efficient GA-based optimization procedure capable of accurately estimating the twelve parameters modeling the wearer's ankle joint complex. Additionally, by leveraging the personalized shank and shoe bracket design workflow from our previous work [20], we integrated the calibrated joint axes into an AFO structure that conforms to the morphology of the wearer's leg. Unlike recently proposed multi-DOF AFO designs [16], [25], the proposed AFO encompasses a considerable portion of the range of motion of the ankle joint complex without relying on kinematic redundancy. This approach enables efficient fabrication while maintaining a lightweight, simple, and affordable design. However, it requires additional lead time—approximately 30 minutes for functional calibration and 15 minutes for leg scans—to generate personalized shank and shoe brackets.

When unlocked, the AFO I-E axis was successful in reducing relative displacements between the wearer's shank and the AFO structure during in-place foot-raised tasks and walking, indicating that the two-DOF version of our AFO more accurately aligns with the anatomical joints and may reduce user discomfort [24]. Similarly, the increased range of motion for foot-raised tasks with both DOFs unlocked demonstrates that the design encapsulates the ankle complex

motion well. The mixed results obtained during treadmill walking warrant further investigation, but can be contributed to the fact that treadmill walking does not require significant ankle motion in the frontal plane.

The preliminary validation of the AFO design was conducted with a small number of able-bodied subjects and a limited set of motion tasks. Expanding the scope to include a broader range of ambulatory tasks and testing the prototype on a larger sample will be essential to confirm the findings. Collecting data from ambulatory tasks performed without the AFO will also provide valuable insights for comparing the ROM of the D-P and I-E axes to baseline values. The single-DOF configuration still permitted some movement about the I-E axis, even when that axis was mechanically locked, suggesting that the current locking mechanism should be improved before future tests. Additionally, the AFO was non-actuated in this study. Given the serial configuration of the D-P and I-E axes in the design, we do not anticipate significant spurious forces or moments along the I-E axis resulting from the application of assistive torques about the D-P axis. However, further testing with an actuation unit [20] will be necessary to validate this hypothesis.

An Offline Reinforcement Learning-Based Auto-Tuning Framework for Continuous Impedance Control in Powered Prostheses

Woolim Hong[1], Abbas Alili[2], and He (Helen) Huang[1]

***Abstract*— A continuous impedance control framework has recently gained attention in powered prosthesis control for its ability to mimic human behavior by smoothly and continuously modulating joint impedance. While recent advancements in tuning this framework have enabled more personalized control for walking, the manual tuning process remains time-intensive and empirical, limiting its scalability and adaptability. To address this challenge, we propose a reinforcement learning (RL)-driven framework for offline tuning, focusing on stiffness parameters that play a critical role in shaping knee kinematics during walking. A Gaussian Process Regression (GPR)-based Continuous Stiffness-Kinematics (CSK) model was developed to predict knee kinematics based on stiffness parameters, trained and validated using experimental data from four participants. Leveraging the Deep Deterministic Policy Gradient (DDPG) algorithm, we optimized stiffness parameters in offline, significantly reducing the need for manual adjustments. Validation results confirmed the reliability of the CSK model in capturing the relationship between stiffness parameters and knee kinematics, as well as the feasibility of the RL framework for offline tuning. This study demonstrates the potential of RL-driven tuning to enhance prosthesis control for walking within a continuous impedance control framework. Future work will focus on integrating offline-trained policies into an online human-in-the-loop framework, enabling adaptive and personalized real-time control while extending functionality to a broader range of ambulation tasks.**

I. Introduction

A recent study estimated that over 2 million individuals in the United States are living with limb loss, with this number projected to increase by 145% by 2060 due to the rising prevalence of vascular diseases and diabetes [1]. Lower-limb amputation profoundly impacts individuals both physically and psychologically, increasing the risk of falls and injuries while also restricting their ability to participate in daily activities and engage with their communities [2], [3]. For decades, powered prostheses (i.e., robotic prostheses) have been studied to restore a more natural gait and enable enhanced mobility in dynamic scenarios such as navigating ramps [4], [5] and stairs [6], [7]. These advanced devices have demonstrated significant potential, offering improved functionality alongside clinical benefits such as enhanced symmetry [8], [9], reduced metabolic energy expenditure [10], and greater overall mobility [11].

Impedance control is a widely used approach for controlling powered prostheses due to its compliant behavior, which allows adaptation to varied terrains and facilitates safe locomotion [12]–[14]. Traditional impedance control frameworks typically feature 4–5 discrete states, each governed by specific impedance parameters, including stiffness, damping, and equilibrium angle. These parameters are fine-tuned based on user feedback, clinical observations, or the requirements of specific tasks such as ramps or stair navigation [15]–[17]. However, the piecewise nature of these frameworks often results in reduced accuracy and mechanical jerkiness in prosthesis control [18], [19]. In contrast, humans control their movements by continuously modulating joint impedance during locomotion [20]–[22], making continuous impedance control a promising alternative for powered prosthesis control. This approach offers a more human-like control strategy, enabling smoother and more natural movements [5], [23]. A key challenge, however, lies in estimating human joint impedance in a continuous manner. Previous studies using perturbation systems have empirically estimated human ankle joint impedance, identifying a certain trend throughout the gait cycle [24], [25]. Building on these findings, researchers introduced linearly varying joint impedance parameters for prosthesis control, including stiffness and damping [23], [26]. More recently, data-driven methods have been developed to derive joint impedance and directly apply it to powered prosthesis control [5], [19]. For example, Best et al. used constrained convex optimization to generate a continuously varying impedance model—encompassing stiffness, damping, and equilibrium angle—achieving global optimality across various slopes and walking speeds [5]. This method has been further extended to accommodate sit/stand [9] and stair ascent/descent [7], demonstrating its versatility and effectiveness in enhancing prosthesis functionality.

Although generalized models are versatile, they lack the adaptability required for personalization, as their parameters are predetermined through offline optimization and fail to account for individual differences in physiological traits and preferences [27]. Specifically, these models are often derived from data collected from able-bodied (AB) individuals, which may not adequately represent the physiological differences between AB and amputee populations. As a result, adjustments are necessary to address the unique needs of amputees more effectively. Personalization is crucial for delivering tailored assistance to individuals when controlling powered prostheses [14], [28], particularly considering that

approximately 68% of amputees use a prosthesis for at least seven hours per day [2]. Despite its importance, the personalization of continuous impedance control remains largely unexplored. A key challenge lies in effectively characterizing continuous impedance curves with a reasonable number of adjustable parameters. Reducing the dimensionality of these parameters is crucial, as higher-dimensional parameter spaces demand significant tuning effort, making manual or automatic adjustments impractical [29]. This challenge is further amplified when accounting for multiple joints (e.g., knee-ankle prostheses) or diverse ambulation modes (e.g., slope and stair walking), where the tuning burden and computational cost become overwhelming. To address this, our previous work introduced the use of Principal Component Analysis (PCA) to parameterize continuous impedance functions, streamlining the personalization process for powered prostheses [30], [31]. Despite inherent individual variability, human locomotion shares common physiological traits [32], [33], making PCA an effective tool for capturing these shared characteristics in joint impedance functions. Through PCA, we identified six principal components (PCs)—two each for stiffness, damping, and equilibrium angle—and used their weights as tuning parameters. This approach enabled the personalization of impedance functions for powered prosthesis control by tuning the given parameters to achieve the target knee kinematics [31]. However, while this significantly simplified the tuning dimension, manual adjustments remain inefficient, and automated tuning processes are becoming increasingly necessary. Reinforcement learning (RL) presents a promising approach for automatic prosthesis tuning. RL-based methods can dynamically learn and adjust tuning policies in real time, optimizing performance by adapting parameters as needed. These methods have demonstrated both feasibility and robustness, effectively fine-tuning prosthesis control as the wearer-prosthesis system evolves [34]–[36].

To the best of our knowledge, auto-tuning within the continuous impedance control framework has yet to be explored. This study aims to address this gap by implementing RL to automate the tuning process for continuous impedance control. Specifically, we focus on offline training and validating the trained RL policy to achieve a target knee profile. The main contributions of this work are (1) developing an RL-based auto-tuning scheme for a continuous impedance control framework, (2) conducting offline training to establish an initial policy, and (3) validating the performance of the offline-trained RL policy.

II. Methods

A. Continuous Impedance Control Framework

Knee joint impedance was determined through convex optimization by aligning the generated torque $\hat{\tau}$ from the impedance controller (1) with the human knee joint torque τ obtained from Camargo et al., which was based on data from 20 AB individuals [37].

$$\hat{\tau} = f_K(\phi) \cdot (\theta - f_{EQ}(\phi)) + f_D(\phi) \cdot \dot{\theta} \tag{1}$$

where $f_K(\phi)$, $f_D(\phi)$, and $f_{EQ}(\phi)$ represent the knee stiffness, damping, and equilibrium angle functions, respectively. The phase variable $\phi \in [0, 1]$ denotes the user's gait phase within the gait cycle, while θ and $\dot{\theta}$ correspond to the measured human knee angle and velocity. The stiffness and damping functions were modeled as fourth-order polynomials, while the equilibrium angle function was defined as a sixth-order polynomial, as given in (2). The polynomial coefficients for stiffness, damping, and equilibrium angle–denoted as k_i, d_i, and e_i, respectively–were estimated via convex optimization [30].

$$f_K(\phi) = \sum_{i=0}^{4} k_i \phi^i,\ f_D(\phi) = \sum_{i=0}^{4} d_i \phi^i,\ f_{EQ}(\phi) = \sum_{i=0}^{6} e_i \phi^i \tag{2}$$

Each individual's stiffness ($f_K(\phi)$), damping ($f_D(\phi)$), and equilibrium angle ($f_{EQ}(\phi)$) functions can be obtained through offline optimization. While gait patterns vary across individuals, there are shared characteristics due to fundamental human gait traits [32], [33]. To capture these shared gait features from 20 AB individuals, we employed PCA to reduce the dimensionality of the impedance functions by identifying key components that account for most of the variance [4], [38]. These PCs were extracted during the offline process, and their corresponding weights are used as tuning parameters for fine-tuning of the impedance functions. We selected the first two PCs for each impedance function (PC_1, PC_2), as they capture the majority of variance. The impedance functions can then be reconstructed using these two PCs and their associated coefficients, as shown in (3).

$$\begin{aligned} f_K(\phi) &= K_1 \cdot PC_1^k(\phi) + K_2 \cdot PC_2^k(\phi) \\ f_D(\phi) &= D_1 \cdot PC_1^d(\phi) + D_2 \cdot PC_2^d(\phi) \\ f_{EQ}(\phi) &= E_1 \cdot PC_1^{eq}(\phi) + E_2 \cdot PC_2^{eq}(\phi) \end{aligned} \tag{3}$$

Our earlier findings revealed that stiffness parameters play a more significant role than damping parameters in influencing knee kinematics [31]. Building on this insight, this study focuses on implementing an RL-driven offline tuning framework exclusively for stiffness parameters K_1 and K_2.

B. Data-Driven Continuous Stiffness-Kinematics Model

To develop an offline RL training model for the continuous impedance control framework, it is crucial to establish the relationship between stiffness parameters (inputs) and knee kinematics from the prosthesis (outputs). To achieve this, we employed Gaussian Process Regression (GPR) to construct the Continuous Stiffness-Kinematics (CSK) model, enabling dynamic prediction of knee kinematics based on the stiffness parameters K_1 and K_2, as illustrated in Fig. 1. GPR was chosen for its ability to adapt flexibly to complex, nonlinear relationships between stiffness parameters and knee kinematics while providing a robust solution with high predictive accuracy, even with relatively limited data.

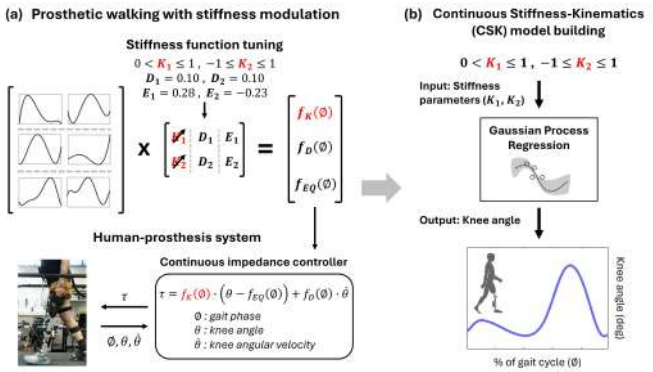

Fig. 1. Building the Continuous Stiffness-Kinematics (CSK) model using Gaussian Process Regression (GPR): (a) Data collection from prosthetic walking: During walking, the stiffness parameters (K_1 and K_2) were modulated, and the resulting knee kinematics were recorded from four participants. (b) Model construction: Using the collected prosthetic walking data, the CSK model was developed via GPR, with stiffness parameters as inputs and knee kinematics as outputs.

1) Data collection: As shown in Fig. 1a, the CSK model was trained using walking experiment data collected from four participants: three AB individuals and one transfemoral amputee (all male, 31.5±3.35 years, 171.4±2.82 cm, 72.6±5.90 kg). A powered knee prosthesis prototype, controlled by the continuous impedance controller, was used for the experiments [31]. All participants were given sufficient training time to ensure they could walk comfortably with the prosthesis. Safety measures included handrails on both sides of the treadmill and a ceiling-mounted harness for fall prevention. Written informed consent was obtained from all participants, and the study protocol was reviewed and approved by the Institutional Review Board (IRB) of North Carolina State University (#24356). Each participant walked for over 30 combinations of K_1 and K_2, with each trial lasting 30 seconds, during which knee kinematics were recorded; the AB participants used an adapter to walk with the prosthesis, while the amputee participant used his daily-use socket to connect to the prosthesis. The stiffness parameters were varied within the range of $0< K_1 \leq 1$ and $-1\leq K_2 <1$, while the damping and equilibrium parameters were held constant at (D_1, D_2) = (0.10, 0.10) and (E_1, E_2) = (0.28, -0.23), respectively.

2) CSK model training: To prevent overfitting to specific participants or experimental conditions, we trained the GPR model on experimental data from four participants and performed 3-fold cross-validation. Using sets of stiffness parameters (K_1, K_2) and PCs, the knee stiffness functions (3) were calculated to serve as the input dataset for the CSK model and the corresponding measured knee kinematics served as the output dataset (see Fig. 1b). A sparse Gaussian Process model was implemented using MATLAB's $fitrgp$ function (R2024b, MathWorks, Natick, MA, USA) to ensure computational efficiency for real-time applications and minimize training and prediction times [39]. Additionally, automatic hyperparameter optimization was performed during training to enhance the CSK model's predictive accuracy and performance.

C. RL Framework for Offline Tuning

In our previous work, we demonstrated that tuning stiffness parameters in continuous impedance control effectively achieves the desired knee profile. [31]. However, manual tuning is inherently empirical and time-intensive, making the process challenging. To overcome this limitation, we propose an RL-based approach for tuning the stiffness parameters of a continuous impedance controller. This study focuses specifically on offline training, leveraging the CSK model to identify an optimal policy adaptable to different participants, as depicted in Fig. 2.

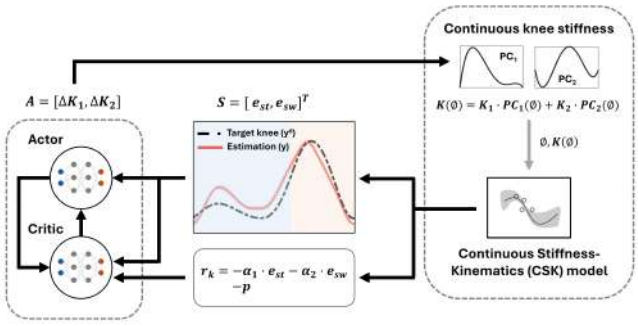

Fig. 2. Offline training process of the RL agent. The RL agent is trained offline to tune the stiffness parameters (K_1 and K_2) using the state variable (S), action variable (A), and reward (r_k). Knee kinematics are predicted using the CSK model based on the given stiffness parameters.

1) RL framework design: The RL framework optimizes two stiffness parameters (K_1 and K_2) by updating them every four gait cycles within each episode. To encourage exploration, these parameters are randomized at the start of each episode within a predefined range. The state variables, $S \in R^2$, are derived from the root-mean-square errors (RMSEs) between the predicted knee kinematics (y) and the desired knee kinematics (y^d) during the stance (e_{st}) and swing (e_{sw}) phases. The action variables, $A \in R^2$, represent updates to the stiffness parameters, defined as (4):

$$S = [e_{st}, e_{sw}], \quad A = [\Delta K_1, \Delta K_2] \tag{4}$$

where $e_{st} = \sqrt{\sum_{i=1}^{N_{st}} \frac{(y_i - y_i^d)^2}{N_{st}}}$ and $e_{sw} = \sqrt{\sum_{j=1}^{N_{sw}} \frac{(y_j - y_j^d)^2}{N_{sw}}}$, with N_{st} and N_{sw} representing the number of data points in the stance and swing phases, respectively.

2) Reward function design: The reward function, r_k, for each update step k, is designed to penalize errors and prevent undesirable conditions:

$$r_k = -\alpha_1 \cdot e_{st} - \alpha_2 \cdot e_{sw} - p \tag{5}$$

where p, the penalty term, is defined as:

$$p = \begin{cases} 100, & \text{if } K < 0 \text{ or y} < \text{-}10^\circ \\ 0, & \text{otherwise.} \end{cases} \tag{6}$$

The coefficients α_1 and α_2 are set to 0.6 and 0.4, respectively, to prioritize minimizing stance phase errors, which are more critical and perceptible than swing phase errors [27]. In the reward function, the first two terms penalize stance and swing errors, while the penalty term prevents negative stiffness values and excessive knee hyperextension; a penalty is applied when the knee angle exceeds -10° to ensure a safety margin of 2°, considering the prosthesis hardware constraint of -12° for hyperextension.

3) Actor-Critic network design: The RL model was trained using the Deep Deterministic Policy Gradient (DDPG) algorithm, including two neural networks [40]:

- Actor network – Maps the input state vector S to an action vector $A(\mu(S))$.
- Critic network – Estimates the long-term discounted reward $Q(S, A)$ using the Bellman equation.

Both networks were implemented and trained using MATLAB's Reinforcement Learning Toolbox (R2024b, MathWorks, Natick, MA, USA). In the actor network, the state input is passed through two fully connected layers, each with 250 neurons, followed by ReLU activation and batch normalization layers to enable nonlinear transformations. The final action output layer applies a $tanh$ activation to constrain actions to the range $[-1, 1]$, followed by a scaling layer to match the stiffness parameter range. The critic network takes two inputs: the state vector (S) and the action vector (A). Each input is processed separately through fully connected layers with 250 neurons, followed by batch normalization and ReLU activation. These processed inputs are combined and passed through an additional fully connected layer with batch normalization, ReLU activation, and a final output layer.

4) RL training workflow: At the start of training, the weights of the actor (μ) and critic (Q) networks were randomly initialized. Target networks (μ' and Q') were also created with identical structures and initialized weights: $\theta^{\mu'}$ and $\theta^{Q'}$. Training was conducted up to 1,000 episodes, with stiffness parameter sets randomized at the start of each episode. During each update step k, the knee kinematics were predicted using the CSK model based on the current stiffness parameters. The state vector S_k and reward r_k were computed as defined in (5). The actor network generated the action vector A_k, augmented with a noise vector N_m from an Ornstein-Uhlenbeck process to promote exploration [40]:

$$A_k = \mu(S_k) + N_m. \tag{7}$$

A minibatch of N transitions was sampled randomly from a replay buffer for network weight updates:

- Critic update: The critic weights were updated by minimizing the loss function (8):

$$L_Q = \frac{1}{N}\sum_i (y_i - Q(S_i, A_i|\theta^Q))^2. \tag{8}$$

where y_i, derived from the Bellman equation (9), represents the target value, and γ is the discount factor:

$$y_i = r_i + \gamma Q'(S_{i+1}, \mu'(S_{i+1})). \tag{9}$$

- Actor update: The actor weights were updated to maximize the long-term discounted reward using the policy gradient optimization (10):

$$\nabla_{\theta^\mu} J = \frac{1}{N}\sum_i \nabla_A Q(S_i, \mu(S_i)) \nabla_{\theta^\mu} \mu(S_i). \tag{10}$$

- Target network update: The target actor ($\theta^{Q'}$) and critic ($\theta^{\mu'}$) weights were updated using a soft update rule (11):

$$\theta^{Q'} = \tau \cdot \theta^{Q} + (1-\tau)\cdot\theta^{Q'}, \;\; \theta^{\mu'} = \tau \cdot \theta^{\mu} + (1-\tau)\cdot\theta^{\mu'}. \tag{11}$$

III. Results and Discussion

A. CSK Model Validation

To validate the trained CSK model, we computed the RMSE for both the training and testing datasets to assess potential overfitting and evaluate the model's generalization ability. Figure 3a presents the RMSE results for the training and testing sets across three folds: 3.4193±1.4224 for training and 3.5348±0.9372 for testing. The model exhibited consistent predictive performance across folds, with training and testing RMSE values remaining within a similar range, suggesting less likely overfitting. The error bars represent the standard deviation across the three folds, reflecting the variability in prediction accuracy. Figure 3b illustrates the predicted knee kinematics over the gait cycle for each fold. The solid lines represent the mean predicted trajectory, while the shaded regions indicate the standard deviation, capturing variability in predictions across different participants and stiffness conditions. The results confirm that the CSK model generalizes well across different participants and varying stiffness parameters, capturing the variations in knee kinematics. These findings demonstrate the robustness and flexibility of the CSK model, indicating its suitability for offline RL tuning in continuous impedance control for powered prostheses.

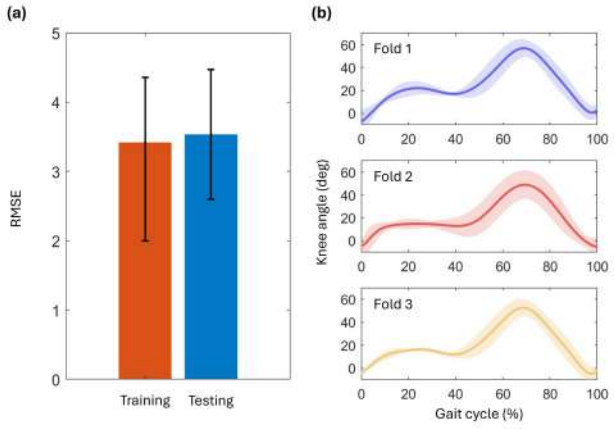

Fig. 3. Validation of the CSK model. (a) RMSE comparison between the training and testing datasets. (b) Predicted knee kinematics over the gait cycle for each fold. The solid lines represent the mean trajectory, while the shaded regions denote the standard deviation.

B. Offline RL Framework Validation

The RL training phase converged after 421 episodes during offline learning, requiring approximately 21 minutes on an NVIDIA Quadro P620 GPU, as shown in Fig. 4a. The training process automatically stopped upon meeting the convergence criterion, defined as the average reward stabilizing within the range [-7,0] over 15 consecutive steps. This stopping criterion was heuristically determined, balancing fast convergence and minimizing the error between the target and predicted knee kinematics. As further shown in Fig. 4a, after 48 episodes, the average reward began staying between -13 and -10, nearing the stopping threshold but not meeting it. If a lower threshold (e.g., -10) had been set, convergence would have been faster, but this study prioritized minimizing the error with respect to the target kinematics. The stiffness variations in the final episode are given in Fig. 4b, resulting in the optimized stiffness parameters: $K_1 = 0.235$ and $K_2 = 0.190$, with a final average reward of -6.9755.

Figure 4c presents the RMSE (vs. target knee) across different tuned parameters, including (1) the offline RL-tuned stiffness parameter set, (2) the initial parameter setting (from optimization [31]), (3) RMSE results from previous studies [31]. The offline RL-tuned parameter set achieved an RMSE of 6.7569, showing a notable improvement over the initial condition (8.2179 RMSE). This demonstrates that RL effectively optimized the stiffness parameters, generating knee kinematics that closely match the target profile. The offline RL-tuned model was also compared with RMSE values reported for a transfemoral amputee (TF01) and AB participants (AB01, AB02) in [31]. Notably, the offline RL-tuned model (6.7569 RMSE) performed better than AB01 (6.808±0.667 RMSE) but the error was slightly higher than AB02 (5.857±0.710 RMSE); TF01 showed the lowest RMSE (5.580±1.021). Compared to both AB individuals and the transfemoral amputee, the RL-tuned model achieved a competitive performance range, indicating that it can generalize well without requiring manual tuning.

C. Limitations and Future Directions

While the data-driven CSK model exhibited reasonable accuracy in predicting knee kinematics based on continuous knee stiffness, it does not fully capture the complex dynamics of the human-prosthesis system. Further improvements could be achieved by collecting additional experimental data or incorporating a digital twin environment to simulate prosthetic walking. Additionally, although the offline-trained policy provides safety boundaries and facilitates faster convergence, the RL policy might shift when a human interacts with the powered prosthesis in real-world scenarios. To address these limitations, we plan to integrate an online RL-tuning phase using a human-in-the-loop framework, complementing the offline tuning presented in this study. The RL formulation and stopping criteria will be further refined to balance convergence speed and tuning performance for real-time online learning. Furthermore, we aim to extend the proposed framework to optimize damping and equilibrium angle parameters, enabling the system to support a broader range of ambulation

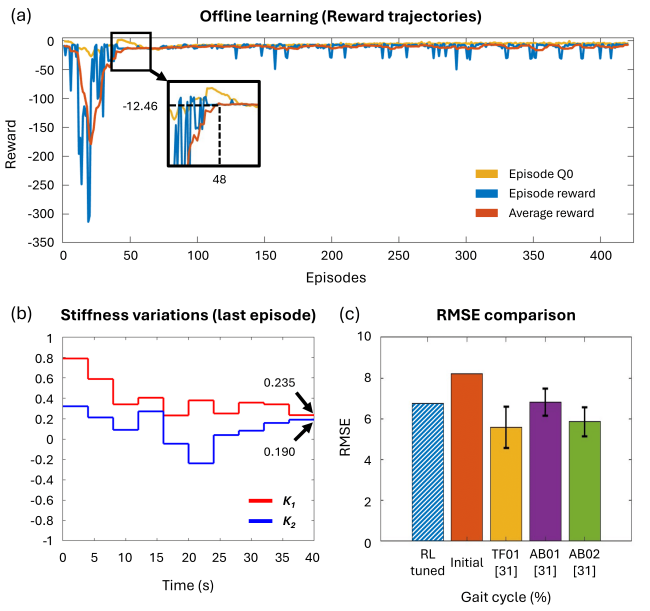

Fig. 4. Offline RL tuning result. (a) Reward trajectories during training until convergence. (b) Stiffness variations in the last episode, resulting in the optimized stiffness parameters: $K_1 = 0.235$ and $K_2 = 0.190$. (c) RMSE comparison between the target and the knee profiles across different tuned parameters, including the offline RL-tuned stiffness parameters, the initial parameter setting, and previously reported results from one amputee and two AB individuals in [31].

tasks, such as slope and stair navigation. The proposed framework has the potential to scale to multi-joint prostheses (e.g., knee-ankle prostheses) by utilizing multi-agent RL to personalize the controller, enhancing coordination between the prosthesis and the user.

IV. Conclusion

This study introduced an RL-driven framework for offline tuning of continuous impedance control in powered knee prostheses, with a specific focus on stiffness parameters, which were identified as significant in our previous work. Using the GPR-based CSK model, we successfully established a predictive relationship between stiffness parameters and knee kinematics, validated with experimental data from both able-bodied and amputee participants. The RL framework, built on the DDPG algorithm, demonstrated the feasibility of optimizing stiffness parameters in an offline setting, reducing reliance on the time-intensive manual tuning process. The results highlight the potential of this approach to effectively personalize powered prostheses within a continuous impedance control framework while providing a foundation for future studies. Future efforts will integrate the offline-trained policies into a real-time human-in-the-loop framework, enabling adaptive and personalized prosthesis control for a wide range of ambulation tasks.

UP-CARE: An Upper Limb Portable Cable Assistive Recovery Exoskeleton for Elbow Movement Assistance

Jarren Bachiller Berdal, Ryan Jason Hartnett, and David Quintero

***Abstract*— Each year, many stroke survivors experience upper limb paralysis, negatively affecting their ability to perform activities of daily living. Powered assistive exoskeletons can help restore these abilities, promoting independence and improving their quality of life. While upper limb assistive devices show promise, challenges still remain in developing a lightweight and portable system for broad patient use. This paper presents the Upper limb Portable Cable Assistive Recovery Exoskeleton (UP-CARE) a lightweight, portable robotic exoskeleton designed to assist elbow movement. UP-CARE features a brushless DC motor whose torque is amplified through a two stage planetary gearbox and dual-pulley cable system made with high strength additive manufacturing materials. By leveraging 3D printing, the actuator design achieved a 52% weight reduction as compared to conventional off-the-shelf gear transmissions, while promoting design modularity and an increase in accessibility. UP-CARE has a total mass of 4.75 kg, with only 0.62 kg resting directly on the user's arm. Its high torque to weight ratio makes it suitable for portable assistive rehabilitation. Preliminary subject testing demonstrated accurate elbow position tracking up to 90°, while producing an average elbow joint torque of 18.9 Nm. The performance indicate that UP-CARE can support the assistive needs of elbow flexion/extension, helping stroke survivors regain independent living.**

I. INTRODUCTION

Nearly 800,000 people in the United States experience a stroke each year due to traumatic brain injury or cardiovascular disease [1]. Recent studies show that 70% of stroke survivors develop arm muscle weakness, preventing them from articulating solely, or a combination of, their shoulder, elbow, wrist, or hand, under their own physical power [2]. This impairment leads to both mental and physical hardships, significantly reducing their quality of life [3]. Elbow augmentation in particular is critical for performing activities of daily living (ADLs), such as drinking water or picking up objects [4]. To regain a sense of independence and improve their quality of life, stroke survivors may turn to robot-assistive devices, such as exoskeletons, in order to perform ADLs [5], [6].

Exoskeleton advancements over the past few decades have demonstrated that upper limb devices can enhance a patient's independence and quality of life [7], [8]. Various prime mover approaches have been developed to assist upper limb impairments and support ADLs movements. Pneumatic actuators use compressed air to drive an exoskeleton joint movement, offering a high force-to-weight ratio, low-cost implementation, and inherent system compliance for user safety [9]. However, their delayed response time and reliance on an air reservoir limit their suitability for portable exoskeletons. Hydraulic actuators provide high power density by compressing fluid but suffer from bulky designs and complex hydraulic plumbing, hinders portability [10], [11]. Electric motors are commonly used to actuate upper limb exoskeletons due to their precise control. When paired with a transmission system, they can generate the high torque required for various ADLs. Further, cable-driven systems powered by high-torque motors and pulley systems, can elevate a user's impaired arm. [12].

An emerging area of research focuses on integrating additive manufacturing, or 3D printing, into medical robotics technologies [13]. Fused Deposition Modeling (FDM) and Stereolithography Apparatus (SLA) 3D printers have become industry standards due to their affordability and accessibility, driven by a growing consumer market. These technologies enable rapid prototyping of medical devices [14]. 3D printing has facilitated the creation of strong structural components for exoskeletons, such as rigid links, and allowed the development of complex geometries for pneumatic actuators [13], [15]. Lopez Garcia et al. (2019) showcased the potential of 3D printed components in gearbox transmissions, while Urs et al. (2022) demonstrated the durability and performance of 3D printed transmissions, rivaling those of metal gearboxes [16], [17].

This paper introduces the Upper limb Portable Cable Assistive Recovery Exoskeleton (UP-CARE), a mobile, modular actuation system designed to assist elbow movement in stroke patients. UP-CARE emphasizes lightweight portability and customization by leveraging 3D printing with off-the-shelf (OTS) components, facilitating rapid fabrication and easy accessibility. The system targets elbow impairment and incorporates a brushless DC motor (BLDC), coupled with a custom 3D printed two stage planetary gearbox (TSPG) with a 19:1 gear reduction to deliver an average torque of 18.9 Nm during preliminary tests, exceeding the healthy human elbow joint torque requirement of 17 Nm [18]. The use of 3D printing reduced the TSPG's weight by 52% compared to traditional metal 19:1 planetary gear transmissions. The complete UP-CARE system, including the actuator, backpack, mounting platform, and dual-pulley system has a totals 4.75 kg, promoting portability and ease of transport. Preliminary subject tests consist of position tracking and frequency response evaluation, demonstrated

the system's ability to control the user's elbow joint while delivering the necessary torque. These results validate UP-CARE as a proof-of-concept and showcase the potential of 3D printing in developing a lightweight, portable exoskeleton for patients with arm muscle weakness.

II. METHODS

The UP-CARE portable assistive exoskeleton is designed for both clinical and home care setting, focusing on lightweight construction and user accessibility. The design leverages 3D printing to fabricate key components of the actuator and backpack platform, reducing weight while maintaining structural integrity. The combination of 3D printed elements with OTS components facilitates rapid manufacturing, easy accessibility, and cost-effective assembly. The system consists of two primary sub-assemblies: the backpack mounting platform and the UP-CARE actuator, as shown in Figure 1. The backpack mounting platform houses the motor control driver and mechanical actuator. The UP-CARE actuator includes the BLDC motor, custom multistage transmission, and dual-pulley system. The complete UP-CARE exoskeleton weighs 4.75 kg, ensuring portability without compromising performance.

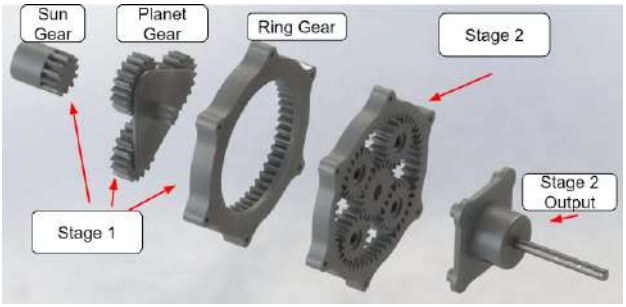

Fig. 2. Image of UP-CARE's 3D printed two stage planetary 19:1 reduction gearbox

A. UP-CARE Actuator

1) Transmission and DC Motor: The UP-CARE's actuator uses a Maxon EC 90 400W BLDC motor, delivering continuous torque of 1.29 Nm when supplied with 9.5 A. Previous studies from Vrije Universiteit Brussel highlight the viability of 3D printed gearbox transmissions [16]. In addition, researchers from the University of Michigan further analyze the use of 3D printed transmissions in quasi-direct actuators for legged robot (8-15 kg), revealing that moderate ratio gearboxes (1:1 to 30:1) that can handle intensive use over extended periods of time (420,000 strides) and perform comparable to metal gearboxes [17]. These findings support the integration of 3D-printed elements in UP-CARE to achieve a lightweight, high-torque transmission without sacrificing durability [19].

The custom TSPG features a 19:1 reduction ratio, selected to meet the torque demands of 8 to 17 Nm for ADLs involving motions close to and away from the body [18]. Additionally, 3D printing allows rapid development of custom gear ratios, allowing adaptations tailored to individual user needs. The theoretical torque produced by our BLDC amplified by a 19:1 TSPG, neglecting efficiency losses, would output a continuous torque of 24.5 Nm. However, based on efficiencies of 95% and 77% for similar TSPG [20] and cable driven exoskeleton systems [21], respectively, the UP-CARE system should achieve a continuous joint torque of 18 Nm. This validates our choice to meet the minimum joint torque requirement for elbow actuation, while accounting for an approximate efficiency of 73%, consistent with reported literature.

The sun gear, planet gears, planet carrier, and ring gear of the TSPG (Figure 2) were fabricated using SLA due to its high dimensional accuracy and superior layer bonding strength [22]. Formlabs Tough 2000 resin was selected for its ductile characteristic under tensile, compressive, and rotational loads [23]. Components were printed with a five-degree offset from the X-Y plane to reduce shear between print layers, followed by a post-curing to enhance mechanical strength. [23]. The sun gear connects to the BLDC motor via a knurled brass threaded insert, pressure-fitted with epoxy. This allows a set screw to secure the motor's D-profile output shaft. The second stage carrier outputs torque through a high carbon steel D-profile shaft, chosen for its rigidity and durability to withstand the joint torque demands of ADLs. The resulting 3D printed TSPG achieves a 52% reduction in weight at 301 g in comparison to an OTS metal 19:1 TSPG transmission (Maxon Group, Model: 223085) at 620 g.

2) Dual-pulley System and Elbow Brace: The UP-CARE device employs a close cable configuration for its dual-pulley system, enabling bidirectional push-pull cable movements to transmit torque efficiently [24]. Similar to the TSPG, the dual-pulley system is 3D printed, allowing torque transfer from the actuator to the user's elbow. Each push and pull cable runs through separate channels around the pulley without interference. The cables wrap in opposite directions and are anchored into precision grooves on the pulley's sides,

180° apart, using cable crimps for secure fastening. The driving pulley mounts directly onto the TSPG's output shaft via set screws, while steel cables connect it to the driven pulley, which integrates with a commercial arm brace. To introduce compliance and maintain pretension, a 19 Nm spring is incorporated as a series elastic element with each cable on the driven pulley [25]. This setup enhances safety and smoothens force transmission during elbow actuation.

Slack is inherent in the configuration of the close cable dual-pulley system, requiring proper tensioning to ensure effective torque transfer. To address this, the UP-CARE device integrates a custom 3D printed idler tensioner system, created using FDM (see Figure 1). The idler tensioner body is printed from polylactic acid (PLA) material, chosen for its ease of printing and rigidity. The adjustable idlers are made from polyethylene terephthalate glycol (PETG), selected for its superior mechanical strength and durability. Idlers were printed in the same orientation as the TSPG gears with a 60% infill gyroid pattern [26], [27], to balance strength and weight. Tension is adjusted by rotating a bolt located on top of the tensioner body, which presses the idler against the steel cable, increasing tension and eliminating slack.

UP-CARE includes a hard form factor elbow brace from Orthomen for its accessibility and cost-effectiveness [28]. The elbow brace provides a range of motion (ROM) from $0°$ to $110°$, meeting the minimum 80° ROM required for common ADLs involving elbow flexion and extension [29]. Total weight on the user's arm is 0.62 kg.

3) Backpack and Actuator Mounting Platform: An OTS harness from EGO Electronics (see Figure 1), allows the mounting platform and attached actuation system to be transported by a user [29]. The lightweight, adjustable harness is chosen for its durability and capability to carry heavy loads comfortably. UP-CARE's mounting platform was fabricated in two pieces with PLA filament, chosen for high strength property, connects the actuator to the EGO harness. To reduce weight, a 20% gyroid pattern infill is applied and two metal rods are inserted in the platform for added rigidity between the two pieces. One side of the platform contains mounting brackets designed to interface with the EGO harness. The other side is modeled after an optical board, allowing for easy attachment of the full actuator system. The optical board-like mounting platform enhances system modularity, enabling the attachment of multiple actuators to expand UP-CARE's functionality for future integration to assist additional arm joints (e.g., shoulder).

B. Electronics

UP-CARE uses Samesky (formerly CUI) AMT10 series rotary incremental encoders for position sensing feedback with resolution of 2048 counts per revolution. They are attached to the output of the TSPG driving pulley and the elbow brace driven pulley at the elbow joint (Figure 1). To monitor and measure cable pretension, 10-kΩ sliding potentiometers mounted at the elbow joint pulley track changes in spring compression. Using the measured displacement and the known spring constant, the system calculates the corresponding cable pretension force. A dSPACE MicroLabBox provided the real-time control development programmed in MATLAB/Simulink and provide data acquisition at 1 kHz to send analog control commands to the Copley Nano NPS-180-30-D motor driver (Figure 3). UP-CARE operates while tethered to an DC power supply (Keysight, N5766A/861) set at 35 V/28 A during each experiment. A 20.4 mF capacitor is connected in parallel with a Copley motor driver from the power supply for a low noise voltage/current draw to the driver.

III. PRELIMINARY EXPERIMENTATION AND RESULTS

A. Experimental Setup and Protocol

Preliminary experimental tests to assess the performance of UP-CARE consists of two experiments to the quantify system's accuracy and determine the device's controller bandwidth. A single-patient and a single test run methodology have been seen in literature [30], [31], allows for analyzing the mechanical system response before scaling to a larger sample of trials. Given the need for user-specific tuning, a case study approach provides meaningful feedback while reducing ethical and logistical constraints. UP-CARE uses a position-based proportional-derivative (PD) controller, custom-tuned for each wearer. Elbow joint position and velocity serve as feedback inputs to operate the system during experiments. The experimentation was approved by the Institutional Review Board (IRB) at San Francisco State University.

- Experiment I involves six tests tracking $90°$ positive and negative minimum jerk trajectory command with a maximum velocity of $35°$ per second which is 27% the velocity needed during ADLs [32]. A 5'7" male subject, weighing 89.6 kg (197 lbs), with no prior injuries, volunteered for the experiment. Before each test, the subject's arm is positioned perpendicular to the level floor and initialized at $0°$. Subject was allowed to rest shoulder vertically in their natural position. Experiment I employs a single-patient study to provide preliminary validation of UP-CARE's design and supply insight of its initial performance. The subject wore UP-CARE system and stood beside the power supply. A solid-state relay is placed in series for an emergency stop button and is positioned near the user's free hand.
- Experiment II evaluated a $15°$ magnitude position with frequency response sweep up to 100 Hz. UP-CARE was mounted on a table with a table fixture without a human subject. The arm brace was placed on a mount at a $45°$ offset from vertical and initialized at $0°$ (Figure 3).

B. Results

The UP-CARE system utilization of a position PD controller in Experiment I yield an average root mean square error (RMSE) of $8.29 \pm 2.11°$ across six trials as seen in Figure 4. During the user trajectory tracking, the average current draw is 10 A, peaking at 28 A. Using the BLDC motor torque constant of 0.136 Nm/A with an estimated

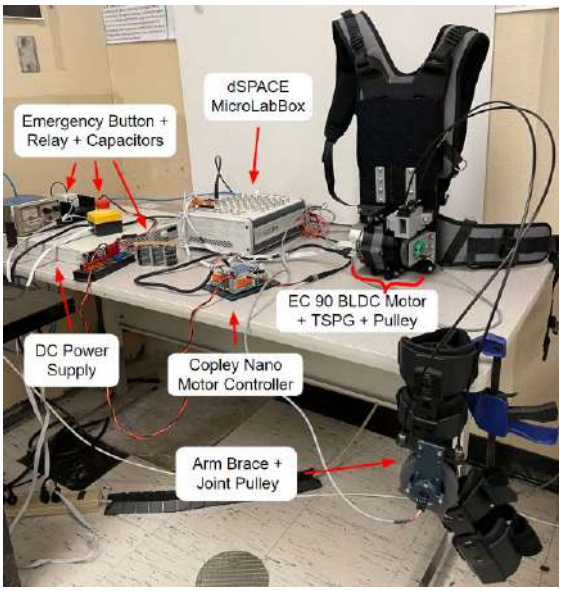

Fig. 3. Photo of experimental test setup for Experiment I & Experiment II frequency response test.

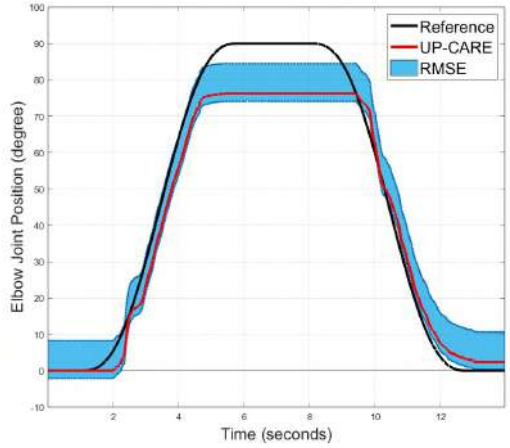

Fig. 4. Six trial average of system response of a bidirectional 90° minimum jerk trajectory command while lifting user's arm.

73.2% efficiency for the system based on similar actuators [20], [21], the derived average and peak torque throughout the six trials was 19 Nm and 53 Nm, respectively.

Experiment II consisting of a position chirp frequency response commands the elbow joint to actuate between 0° and 15° while varying frequency from 0 to 100 Hz. Figure 5 shows the results from Experiment II of a bode magnitude and phase plots, producing a closed-loop bandwidth (magnitude at -3 dB) at 2 Hz.

IV. Discussion

The UP-CARE system's RMSE position tracking performance is comparable to other cable assistive devices as shown in [33], [34]. Results from Experiment I demonstrate the UP-CARE system is able to achieve the ADLs torque

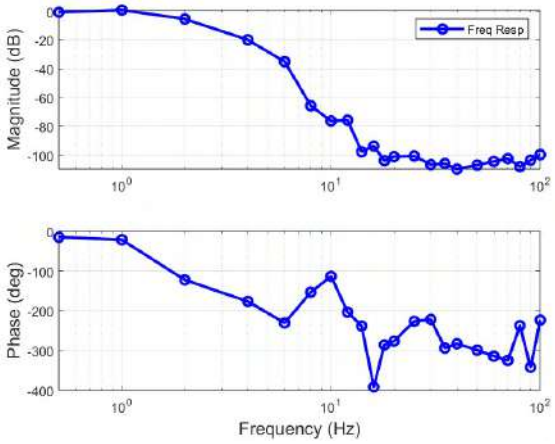

Fig. 5. Response of a 15° 100 Hz chirp frequency sweep with a 45° offset from vertical

performance requirement of 17 Nm for elbow flexion and extension [18]. With an estimated peak torque of 52.96 Nm, UP-CARE is able to output higher torque, exceeding commensurate systems such as [11], [34], [35]. In addition, UP-CARE's actuator can achieve a higher force output per weight of a nominal torque of 3.97 Nm/kg compared to other portable devices at 1.78 Nm/kg and 3.59 Nm/kg [36], [33]. From Experiment II, UP-CARE system's control scheme is able to perform while peaking at a bandwidth of 2 Hz, meeting the ADLs minimum bandwidth metric for therapeutic and assistive operation [33], [34]. Further more, UP-CARE's control bandwidth is higher than portable cable driven systems such as those seen in [34] and [36] using traditional controllers.

A. Limitations and Future Works

Though 3D printed transmissions are expected to be less durable when compared to metal gearboxes, a new study sheds light on the potential of 3D printed transmissions to perform similarly to metal gearboxes [17]. Urs et al. 2022 characterizes 3D printed gearboxes for legged robots. Their study observed a 3D printed actuator perform 420,000 cycles with minimal wear and backlash [17]. Power efficiency of the 3D printed transmission is elevated during high speeds and low torque applications, similar to other actuators in the literature [37]. Urs et al. concludes 3D printed actuator transmissions can deliver high torques and have properties that allow for impact mitigation, such as low output mechanical impedance and low resistance to external loads applied by the user. Thus, they are suitable for wearable robotic applications. 3D printing allows cost savings for rapid manufacturing of customizable actuators tailored to meet the performance requirements for each use case [17], [15]. To further increase durability of UP-CARE TSPG and other components, higher grade materials such as Nylon can replace the Formlabs Tough 2000 resin.

Incorporating the idler tensioner system has advantages and disadvantages. This system can easily apply tension

needed for a close cable pulley configuration and reduce slack [24]. Disadvantages to the idler tensioner is the added inertia and friction the system has to overcome to operate in conjunction with nonlinearities, such as convergent, bifurcation, and bistable states which may occur during operation. To solve these nonlinearities, a torque controller may need to be derived and implemented into the system [24]. Some approaches to minimize error include model based advance control schemes such as feed-forward to achieve greater precision in trajectory response trials [35]. Investigating frictional backlash in the TSPG and accounting for hysteresis effects in the steel cabling can also provide better performance [38].

UP-CARE's modular portable platform can support multiple UP-CARE actuators to address other areas of impairments such as the shoulder, hand, or wrist as seen in [35]. The next iteration of the system will include an embedded system controller on the backpack, a smaller motor driver, and an optimized battery pack to allow the user to roam without being tethered to a power source. In addition, UP-CARE will develop various assistance modes and controllers to allow more user control. Intuitive control operation for user could be improved by employing a deep machine learning algorithm to control the elbow using surface electromyography signals, force transducers, and an inertial measurement unit [39], [40], [41].

V. CONCLUSIONS

This paper delivers a proof of concept of UP-CARE as a functional elbow impairment assistive device for clinical and in-home care. The UP-CARE actuator, consisting of a TSPG and a dual-pulley system, is manufactured using 3D printed and OTS parts. The use of 3D printed and OTS components allows for ease of accessibility, enabling rapid production, and adaptability for UP-CARE to be tailored to meet each patient's own assistance needs. The proposed exoskeleton meets the minimum requirements to deliver 17 Nm of torque to assist elbow flexion and extension ADLs and operates within the therapeutic and assistive movements bandwidth of 2 Hz. The device's light-weight and modular features with the UP-CARE actuator and backpack platform place it among the higher torque output to weight ratio portable exoskeletons, suitable for stroke patient's various needs for in home assistance.
